   Practice exclusive breastfeeding from birth to 6 months of age, and introduce complementary foods at 6 months of age (180 days) while continuing to breastfeed.
2. *Maintenance of breastfeeding*
   Continue frequent on-demand breastfeeding until 2 years of age or beyond.
3. *Responsive feeding*
   Practice responsive feeding, applying the principles of psychosocial care. Specifically: (a) feed infants directly and assist older children when they feed themselves, being sensitive to their hunger and satiety cues; (b) feed slowly and patiently, and encourage children to eat, but do not force them; (c) if children refuse many foods, experiment with different food combinations, tastes, textures, and methods of encouragement; (d) minimize distractions during meals if the child loses interest easily; (e) remember that feeding times are periods of learning and love – talk to children during feeding, with eye-to-eye contact.
4. *Safe preparation and storage of complementary foods*
   Practice good hygiene and proper food handling by (a) washing caregivers' and children's hands before food preparation and eating, (b) storing foods safely and serving foods immediately after preparation, (c) using clean utensils to prepare and serve food, (d) using clean cups and bowls when feeding children, and (e) avoiding the use of feeding bottles, which are difficult to keep clean.
5. *Amount of complementary food needed*
   Start at 6 months of age with small amounts of food and increase the quantity as the child gets older, while maintaining frequent breastfeeding. The energy needs from complementary foods for infants with 'average' breast-milk intake in developing countries are approximately 200 kcal day^{-1} at 6–8 months of age, 300 kcal day^{-1} at 9–11 months of age, and 550 kcal day^{-1} at 12–23 months of age. In industrialized countries these estimates differ somewhat (130, 310, and 580 kcal day^{-1} at 6–8, 9–11, and 12–23 months, respectively) because of differences in average breast-milk intake.
6. *Food consistency*
   Gradually increase food consistency and variety as the infant gets older, adapting to the infant's requirements and abilities. Infants can eat puréed, mashed, and semi-solid foods from the age of 6 months. By 8 months most infants can also eat 'finger foods' (snacks that can be eaten by children alone). By 12 months, most children can eat the types of foods consumed by the rest of the family (keeping in mind the need for nutrient-dense foods, as explained in #8 below). Avoid foods that may cause choking (i.e., items that have a shape and/or consistency that may cause them to become lodged in the trachea, such as nuts, grapes, and raw carrots).
7. *Meal frequency and energy density*
   Increase the number of times that the child is fed complementary foods as he/she gets older. The appropriate number of feedings depends on the energy density of the local foods and the usual amounts consumed at each feeding. For the average healthy breastfed infant, meals of complementary foods should be provided two or three times per day at 6–8 months of age and three or four times per day at 9–11 and 12–24 months of age. Additional nutritious snacks (such as a piece of fruit or bread or chapatti with nut paste) may be offered once or twice per day, as desired. Snacks are defined as foods eaten between meals – usually self-fed, convenient, and easy to prepare. If energy density or amount of food per meal is low, or the child is no longer breastfed, more frequent meals may be required.
8. *Nutrient content of complementary foods*
   Feed a variety of foods to ensure that nutrient needs are met. Meat, poultry, fish, or eggs should be eaten daily, or as often as possible. Vegetarian diets cannot meet nutrient needs at this age unless nutrient supplements or fortified products are used (see #9 below). Fruits and vegetables rich in vitamin A should be eaten daily. Provide diets with adequate fat content. Avoid giving drinks with low nutrient value, such as tea, coffee, and sugary drinks such as soda. Limit the amount of juice offered to avoid displacing more nutrient-rich foods.
9. *Use of vitamin–mineral supplements or fortified products for infant and mother*
   Use fortified complementary foods or vitamin–mineral supplements for the infant, as needed. In some populations, breastfeeding mothers may also need vitamin–mineral supplements or fortified products, both for their own health and to ensure normal concentrations of certain nutrients (particularly vitamins) in their breast milk. (Such products may also be beneficial for pre-pregnant and pregnant women.)
10. *Feeding during and after illness*
    Increase fluid intake during illness, including more frequent breastfeeding, and encourage the child to eat soft, varied, appetizing, favorite foods. After illness, give food more often than usual and encourage the child to eat more.

Reproduced from Pan American Health Organization/World Health Organization (2003) *Guiding Principles for Complementary Feeding of the Breastfed Child*. Washington, DC: Pan American Health Organization.

introduce complementary foods until 6 months, and the risk of micronutrient deficiencies is very low among full-term infants of normal birth weight whose mothers are well-nourished. Although iron deficiency may occur prior to the age of 6 months in infants whose iron reserves at birth are low (e.g., low-birth-weight infants and those whose mothers were iron deficient during pregnancy), the recommended approach is to provide medicinal iron drops from 2–3 months of age to such infants, rather than introducing complementary foods. Zinc status may also be marginal in low-birth-weight infants, and deficiency can be prevented by using zinc supplements. When the mother's diet is poor, the concentrations of certain vitamins (e.g., vitamin A and many of the B vitamins) and trace elements (e.g., iodine and

selenium) in breast milk may be lower than desirable. In such situations, improving the mother's diet or giving her micronutrient supplements are the preferred approaches, rather than providing complementary foods to the infant before the age of 6 months.

At 6 months of age, infants are developmentally ready to consume complementary foods and can benefit from the additional nutrients that they provide. Continued breastfeeding is recommended because breast milk remains an important source of energy, fat, protein, and several micronutrients. In addition, continued frequent breastfeeding beyond 6 months protects child health by reducing the risk of diarrhea and other infections in disadvantaged populations and by delaying maternal fertility (thereby increasing the interval before the next pregnancy among women who do not use other forms of contraception).

Nutrient Needs from Complementary Foods

The amounts of nutrients provided by breast milk can be estimated by multiplying average breast-milk intake by the concentration of each nutrient in human milk. By subtracting these values from the total recommended nutrient intakes (RNIs) one can derive estimates of the amounts of nutrients needed from complementary foods after 6 months of age. Using this approach, **Table 2** lists these estimates for three age ranges: 6–8 months, 9–11 months, and 12–23 months. In this table, the RNIs for energy and protein are taken from the update report on complementary feeding published in 2003, and the RNIs for micronutrients are taken from the most recent FAO/WHO estimates or the US dietary reference intakes. The estimated amount of each nutrient provided by breast milk is based on the average milk intake during each of the age intervals, calculated separately for infants in developing countries and in industrialized countries, using data from the studies compiled in the 1998 WHO/UNICEF document. Because of differences between developing and industrialized countries in average milk intake and in the assumed breast-milk concentration of vitamin A, the estimated amount of each nutrient provided by breast milk may vary. Within each column of **Table 2**, the first value listed refers to developing countries, and the second value refers to industrialized countries.

The first row of **Table 2** shows the total energy requirements and the estimated amounts of energy obtained from breast milk and required from complementary foods at each age. In developing countries, the average expected energy intake from complementary foods is approximately 200 kcal (837 kJ) at 6–8 months, 300 kcal (1256 kJ) at 9–11 months, and 550 kcal (2302 kJ) at 12–23 months. These values represent 33%, 45%, and 61% of total energy needs, respectively. In industrialized countries, the corresponding values are approximately 130 kcal (544 kJ) at 6–8 months, 310 kcal (1298 kJ) at 9–11 months, and 580 kcal (2428 kJ) at 12–23 months (21%, 45%, and 65% of total energy needs, respectively). Of course, these values will differ if the child is consuming more or less breast milk than the average.

The second row of **Table 2** shows the same estimates for protein. Assuming average breast-milk intake, the amount of protein needed from complementary foods increases from about $2\,g\,day^{-1}$ at 6–8 months to $5–6\,g\,day^{-1}$ at 12–23 months, with the percentage from complementary foods increasing from 21% to about 50%. The remaining rows show the estimates for the key vitamins and minerals. For vitamin B_{12} and selenium, the amounts needed from complementary foods prior to 12 months are zero because human milk contains generous amounts of these nutrients if the mother is adequately nourished. For the other micronutrients, the percentage of the RNI needed from complementary foods varies widely. At 6–8 months, for example, complementary foods need to provide less than 30% of the RNI for vitamin A, folate, vitamin C, copper, and iodine but more than 70% of the RNI for niacin, vitamin B_6, vitamin D, iron, and zinc. The values for the amount of niacin needed from complementary foods are high in all age intervals (75–88% of the RNI), but, because niacin needs can also be met by the contribution of tryptophan in the diet, niacin is not likely to be a limiting nutrient among infants who receive adequate protein. Similarly, the percentage of vitamin D needed from other sources is very high (more than 92%) because there is relatively little vitamin D in human milk; however, it should be noted that adequate exposure to sunlight can meet the child's needs for vitamin D even if complementary foods are not rich in this nutrient.

Complementary foods need to provide relatively large amounts (at least 80% of the RNI in all age intervals) of iron, zinc, and vitamin B_6. Because the amount of iron in human milk is very low (even though what is present is well absorbed), it is likely to be one of the first limiting nutrients in the diets of infants who rely predominantly on breast milk.

Fat is not listed in **Table 2** because there is uncertainty about the optimal intake of fat during the first 2 years of life. Dietary lipids are important not only as a source of essential fatty acids but also because they influence dietary energy density and sensory qualities. Breast milk is generally rich in fat (approximately 30–50% of energy) relative to most complementary foods, so as breast-milk intake

[d]Assuming medium bioavailability of iron.

declines with age, total fat intake is also likely to decline. If one assumes that the percentage of energy from fat in the total diet should be at least 30% and that the concentration of fat in breast milk averages $38\,g\,l^{-1}$, the amount of fat needed from complementary foods (assuming average breast-milk intake) is zero at 6–8 months, approximately $3\,g\,d^{-1}$ at 9–11 months, and $9–13\,g\,d^{-1}$ at 12–23 months, or 0%, 5–8%, and 15–20% of the energy from complementary foods, respectively. As infants decrease their intake of breast milk they also need other good sources of essential fatty acids, such as fish, egg, liver, nut pastes, and most vegetable oils.

Meal Frequency, Energy Density, and Consistency of Complementary Foods

The frequency with which complementary foods need to be fed (i.e., the number of meals per day) depends on the total amount of food required and the amount of food that a child can consume at a single meal (gastric capacity). The total amount of food required is a function of the amount of energy needed from complementary foods (which varies with age and breast-milk intake) and the energy density of the foods (i.e., kcal g^{-1}). The functional gastric capacity of infants and young children is assumed to be $30\,g\,kg^{-1}$ reference body weight. Thus, for a given age interval and level of breast-milk intake, calculating the recommended number of meals requires information about the energy density of the foods. To cover the needs of nearly all children, these calculations use as a starting point the average total energy requirement plus two standard deviations (25%). For children with average breast-milk intake who consume complementary foods with an energy density of at least $0.8\,kcal\,g^{-1}$, the number of meals required is two at 6–8 months and three thereafter. Children who consume less breast milk or who consume complementary foods with a lower energy density would need a greater number of meals. These calculations assume that children are fed to their gastric capacity at each meal, which may not be the case. For this reason, the guidelines recommend that additional nutritious snacks be offered once or twice per day, as desired (see guiding principle 7, **Table 1**).

A meal frequency greater than necessary may lead to excessive displacement of breast milk and may also require more time and effort by caregivers. Thus, it is useful to adapt meal-frequency guidelines to the characteristics of the target population.

The consistency of complementary foods needs to be appropriate for the child's stage of neuromuscular development. Semi-solid or puréed foods are needed at first because young infants do not have the ability to chew and swallow food of thick or solid consistency. By the age of 8 months most infants can also eat 'finger foods,' and by 12 months they can generally consume 'family foods' of a solid consistency. Thus, there should be a gradual change in the consistency of foods offered between 6 and 12 months, to match the infant's developmental progression (see guiding principle 6, **Table 1**).

Meeting Nutrient Needs During the Period of Complementary Feeding

As described above and shown in **Table 2**, breastfed infants need considerable amounts of certain nutrients from complementary foods after 6 months of age. It is a challenge to meet nutrient needs at this age because the amount of food consumed is relatively small, yet nutrient requirements during infancy (per unit of body weight) are very high because of the rapid rate of growth. Thus, nutrient-dense complementary foods are needed. The desired nutrient density (e.g., the amount of nutrient per 100 kcal of food) can be calculated by dividing the amount of each nutrient needed from complementary foods by the amount of energy expected to come from complementary foods (as shown in **Table 2**). When the desired nutrient densities are compared with the actual nutrient densities of the typical complementary foods consumed in various populations, protein density is generally seen to be adequate but several micronutrients are 'problem nutrients.' In most developing countries, iron, zinc, and vitamin B_6 are problem nutrients, and even in industrialized countries these nutrients may be limiting. Intake of iron is likely to be marginal in all populations unless iron-fortified products or substantial amounts of meat are consumed. Riboflavin, niacin, thiamin, folate, calcium, vitamin A, and vitamin C may also be problem nutrients, depending on the local mix of complementary foods. At present there is insufficient information to determine the extent to which some of the other micronutrients, such as vitamin E, iodine, and selenium, may be problem nutrients. Guiding principles 8 and 9 (**Table 1**) provide general recommendations to help ensure that the nutrient density of complementary foods will be adequate. It is difficult to develop more specific dietary 'prescriptions' to be used globally because of the great variability across populations in the types of complementary foods available. However, it is clear that predominantly vegetarian diets cannot meet the nutrient needs of breastfed infants unless nutrient supplements or fortified

products are used. Part of the reason for this is that plant-based diets are often high in phytate, which greatly reduces the bioavailability of iron and zinc. Therefore, it is recommended that meat, fish, poultry, or egg be offered daily, if possible. Iron-fortified infant cereals are a good source of iron, but meats can also provide adequate iron if consumed in large enough quantities, and they have the added advantage of being rich in zinc. When the amount of animal-source food available locally is limited, the amounts of iron and zinc absorbed from the diet can be enhanced by, first, reducing the phytate concentrations of the staple complementary food through germination, fermentation, and/or soaking, second, reducing the intake of polyphenols (e.g., from coffee and tea), which are known to inhibit iron absorption, and, third, increasing the intake of enhancers of iron and zinc absorption, such as vitamin C (for iron) and other organic acids (for iron and zinc). Adequate calcium can be obtained from cheese, yoghurt, and other dairy products, but feeding fresh unheated cow's milk is not recommended before 12 months because it is associated with fecal blood loss and lower iron status. Some vegetables can also provide modest amounts of calcium, but the bioavailability of calcium from foods with high amounts of oxalate (such as spinach) is very low. Fruits and vegetables rich in vitamin A are recommended daily because of the importance of preventing vitamin A deficiency, which has been linked with excess child mortality and other adverse outcomes. The bioavailability of pro-vitamin A carotenoids can be enhanced by finely chopping or puréeing the food and serving it with a source of fat to facilitate absorption. Beverages with low nutrient density (e.g., sugary drinks) should be avoided and the amount of juice should be limited because such beverages can displace more nutrient-dense foods and potentially contribute to child obesity.

In most populations, designing a diet that satisfies the requirements for all the 'problem nutrients' without the use of fortified foods is difficult, because, even when animal-source foods are available, infants typically eat very small quantities. One option that is currently being investigated is the addition of micronutrients, in the form of 'sprinkles' or fat-based products, to home-prepared foods.

Preparation and Feeding of Complementary Foods

Complementary feeding involves not only what to feed but also how to feed infants and young children. The first issue is the safe preparation and storage of complementary foods (see guiding principle 4, **Table 1**). Attention to hygienic practices during food preparation and feeding is essential for preventing gastrointestinal illness. In developing countries, the age range of 6–24 months is when diarrhoea is most prevalent, largely because of microbial contamination of complementary foods. Feeding bottles can be a major source of contamination because they are difficult to keep clean, and thus in resource-poor populations it is recommended that they be avoided. The other recommendations in guiding principle 4 stress the importance of washing hands and feeding utensils carefully, serving food immediately, and storing leftovers safely.

The second issue involves the interaction between caregiver and infant during feeding (see guiding principle 3, **Table 1**). Appropriate feeding behavior is termed responsive feeding and is more sensitive to the child's hunger and satiety cues than either a laissez-faire style of feeding (the caregiver rarely encourages the child to eat) or, at the opposite extreme, a controlling style of feeding (the caregiver determines when and how much the child will eat, even to the point of force feeding). Responsive feeding also involves feeding slowly and patiently, minimizing distractions during meals, and positive interactions with the child while feeding. Although there is little evidence to date regarding the impact of promoting responsive feeding, it is hypothesized that it will enhance dietary intake, child growth, and possibly behavioral development.

The third issue regarding behavioral aspects of complementary feeding involves feeding during and after illness (see guiding principle 10, **Table 1**). The need for fluids is often greater during illness, and for this reason it is recommended that breastfeeding frequency be increased and other fluids be offered as needed. During illness, children prefer breast milk over other foods, so frequent breastfeeding is critical for maintaining nutrient intake. Although appetite may be reduced, continued consumption of complementary foods is recommended to enhance recovery. After illness, the child needs more food than usual to make up for nutrient losses during illness and to allow for catch-up growth.

Introduction

Transition metals occupy a special niche in aerobic physiology: as facile electron donors and acceptors, they are essential participants in oxidation/reduction reactions throughout the cell. These unique properties of transition metals are largely dependent on the electronic configuration of the electrons in the outer shell and in the penultimate outer shell. These metals can exist in different oxidation states, which is critical for their usefulness as catalysts. However, it is during these same committed reactions essential for aerobic metabolism that toxic reactive oxygen species can be generated. As such the transition metals are chaperoned as they traffic through the body and are regulated tightly. Subtle disruptions of metal homeostasis culminate in disease and death. Iron, copper, and zinc are the most abundant and well-studied transition metals. Copper is the oldest metal in use: copper artifacts dating back to 8700BC have been found. The physiology, requirements, and dietary sources of copper are described here with an emphasis on the role of copper in human health and disease.

Copper, as a trace metal, can be found in all living cells in either the oxidized Cu(II) or reduced Cu(I) state. Copper is an essential cofactor for many enzymes critical for cellular oxidation. These include: cytochrome *c*-oxidase, which is essential for mitochondrial respiration as the terminal enzyme in the electron transport chain; superoxide dismutase, a potent antioxidant defense mechanism; tyrosinase, which is critical for melanin production; dopamine B-hydroxylase, a prerequisite for catecholamine production; lysyl oxidase, which is responsible for collagen and elastin cross-linking; ceruloplasmin, a ferroxidase/metallo-oxidase; hephaestin, a ferroxidase/metallo-oxidase; and peptidylglycine α-amidating monooxygenase, a peptide processor (**Table 1**). Mice that lack the copper transport protein Ctr1 are embryonic lethal, which confirms the importance of copper in enzyme function and normal cellular homeostasis.

Copper Homeostasis

Dietary intake of copper is approximately $5\,\mathrm{mg\,day^{-1}}$ with an equivalent amount being excreted by bile in stool. Approximately $2\,\mathrm{mg\,day^{-1}}$ are directly absorbed across the gastrointestinal tract daily and incorporated into blood, serum, liver,

Hephaestin	Ferroxidase/metallo-oxidase
PAM	Peptide processing

brain, muscle, and kidney. An equal amount is excreted and maintains the sensitive copper balance (**Figure 1**). The main sources of copper are seeds, grains, nuts, beans, shellfish, and liver (**Table 2**). Drinking water no longer contributes significantly. When copper pipes were commonly used for plumbing, copper toxicity was a more recognized phenomenon.

It is difficult to define specific dietary copper requirements because of the lack of suitable indices to assess copper status. As such, knowledge of factors affecting the bioavailability of dietary copper is limited. Ceruloplasmin contains 95% of the copper found in serum and is frequently used as a marker of copper status. However, ceruloplasmin levels vary with pregnancy and inflammation and ceruloplasmin mRNA is regulated by estrogen, infection, and hypoxia among other factors. Currently, investigators are searching for genetic biomarkers in intestinal, liver, and lymphocyte cells that respond to copper levels and may serve as better markers of copper status. Whole-body copper metabolism is difficult to study in human subjects. However, isotopic tracers and kinetic modeling have added a dimension to what can be learned in humans by direct measurement. These studies suggest that the efficiency of copper absorption varies greatly, depending on dietary intake. Mechanisms regulating total body copper seem to be strong, given the relatively small and constant body pool, but they are not yet well understood. Changes in efficiency of absorption help to regulate the amount of copper retained by the body. In addition, endogenous excretion of copper into the gastrointestinal tract depends heavily on the amount of copper absorbed. When dietary copper is high and an excess is absorbed, endogenous excretion increases, protecting against toxic accumulation of copper in the body. When intake is low, little endogenous copper is excreted, protecting against copper depletion. Regulation is not sufficient with very low amounts of dietary copper ($0.38\,mg\,day^{-1}$) and appears to be delayed when copper intake is high.

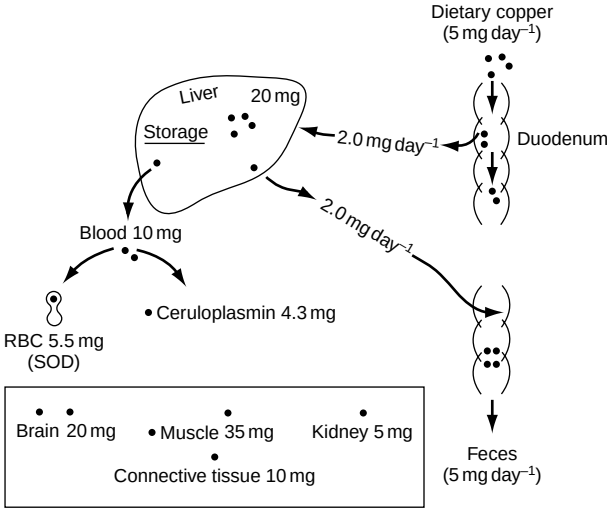

Figure 1 Mammalian copper metabolism: daily copper cycle including oral absorption, tissue distribution, and excretion. Values are for adult men ($mg\,day^{-1}$). An equal amount of copper is absorbed and excreted to maintain copper balance.

Table 2 Copper content of various foods

Food	*Copper concentration (μg wet wt)*	*Size of typical serving (g)*	*Copper/ serving ($mg\,g^{-1}$)*
Fish	0.61	120	0.070
Turkey	0.71	120	0.090
Chicken	0.34	120	0.040
Hamburger	0.95	120	0.110
Roast beef	0.82	120	0.100
Steak	1.2	120	0.140
Sheep liver	157.05	120	18.850
Pork liver	141.14	120	16.940
Egg	0.8	40	0.030
Single sliced cheese	0.43	120	0.050
Whole wheat	1.07	30	0.030
Scallops	6.08	120	0.030
Clams	7.39	120	0.730
Crab	1.75	120	0.890
Shrimp	1.75	120	0.210
Oysters	2.89	120	0.350
Smoked oysters	15	120	1.800
Mussels	4.75	120	0.570
Lobster	36.6	120	4.390
Candy bar	1.18	15	0.020
Milk	0.33	120	0.040
Peas	2.38	120	0.290
Soy beans	109	120	0.130
Applesauce (can)	0.2	120	0.020
Avocado	1.68	120	0.200
Raisins	1.68	30	0.050
Peanut butter	8.53	30	0.260

Recommended Intakes

The Tolerable Upper Intake Limit (UL) for adults is 10 mg daily, based on degree of liver damage associated with intake. UL for children vary with age: 1–3 years/1 mg daily, 4–8 years/3 mg daily, 9–13 years/5 mg daily, 14–18 years/8 mg daily (irrespective of pregnancy or lactation status). UL for children under the age of 1 year are not possible to establish. There are no official recommended daily allowances (RDAs) for copper in children. The RDA for adult males and females is a daily intake of 0.9 mg. Measurements of the dietary requirements for copper in adult men have shown the requirement to range from about 1.0 to 1.6 mg daily. A review of nutrient intakes in the US from 1909 to 1994 confirms that intake varied between 1.5 mg day^{-1} (1965) to 2.1 mg day^{-1} (1909). These trends reflect a diet higher in copper-rich potatoes and grain predominating in 1909 versus a decline in potato popularity in 1965. Daily intake recommendations for children vary with age (see **Table 3**). Persons who consume diets high in zinc and low in protein are at risk of copper deficiency. High intakes of dietary fiber apparently increase the dietary requirement for copper. Diets in Western countries provide copper below or in the low range of the estimated safe and adequate daily dietary intake. Copper deficiency is usually a consequence of low copper stores at birth, inadequate dietary copper intake, poor absorption, elevated requirements induced by rapid growth, or increased copper losses.

Bioavailability

The issue of bioavailability from food sources and the interactions between food groups and copper availability remains a critical question. Lonnerdal *et al.* demonstrated that heat treatment of cows' milk formula decreases the copper bioavailability. Transitional complexes form in the milk upon heating that have a similar configuration to copper and thereby directly inhibit copper absorption. High doses of zinc also reduce copper bioavailability, as does combined iron and zinc supplementation. The dilemma is how to prepare an infant formula containing adequate copper, iron, and zinc that will meet the RDA for copper. Other nutrients dramatically affect copper absorption from foods. Soy protein-based diets promote less copper retention in tissues than lactalbumin-based diets. However, it is unclear if this effect is solely due to the soy protein composition or to the higher zinc in these soy-based formulas. In animals, phytate causes a drop in serum copper but human stable isotope studies reveal no effect on copper absorption in adult men. Patients with low copper indices need to be evaluated for the copper content of their diets, other foods ingested at the same time, and other mineral supplements that may be given.

Table 3 Recommended dietary allowances for copper (mg day^{-1})

Age	*RDA (daily)*
Infants	
<6 months	0.2 (30 mcg/kg)
6–12 months	0.2–0.3 (24 mcg/kg)
Children	
1–3 years	0.34
4–8 years	0.44
9–13 years	0.7
14–18 years	0.89
Adult	
19+ years	0.9
Pregnant women	1
Nursing women	1.3

Absorption and Excretion

Dietary copper is absorbed across the small intestine. It diffuses through the mucous layer that covers the wall of the bowel via the divalent metal transporter DMT1. Copper is thus released into the serum and presumably is transported bound to either albumin or histidine to the multiple sites that require copper or to storage tissues. The liver is the primary storage organ for copper followed by muscle and bone. Not all of the copper ingested is absorbed and gastrointestinal cells that hold on to the excess copper are 'sloughed' when the lining of the gut is turned over every 24–48 hs. Copper bound to albumin or histidine enters the hepatocyte via the high-affinity mammalian copper transporter, hCtr1. Initially identified in yeast by functional complementation studies, this protein has subsequently been cloned in mice and humans. Human Ctr1 has a high homology to the yeast proteins Ctr1 and Ctr3 involved in high-affinity copper uptake. The N-terminus of the protein is rich in histidine and methionine residues, which presumably bind the copper and move it into the cell. Characterization of hCtr1 confirms its localization on the plasma membrane consistent with its role as a copper transporter. *In vitro* work has also identified a vesicular perinuclear distribution for hCtr1 that is copper concentration dependent. Redistribution of the hCtr1 suggests that under different copper states, copper moves through the membrane transporter and into a vesicular compartment for further 'assignment' within the cell.

hCtr2, a low-affinity copper uptake transporter, has also been identified. This low-affinity copper transporter is unable to complement the respiratory defect seen in yeast strains lacking copper transport capabilities. Once inside the cell, copper has one of four fates: (1) bind to and be stored within a glutathione/metallothionein pool; (2) bind to CCS, the copper chaperone for Cu, Zn - SOD; (3) bind to cox 17 for delivery to mitochondrial cytochrome *c*-oxidase; or (4) bind to HAH1 (human Atox1 homolog) for subsequent copper delivery to either the Wilson disease P-type ATPase or the Menkes' P-type ATPase. Copper from HAH1 is incorporated into ceruloplasmin, the most abundant serum cuproprotein, within the trans golgi network (TGN). How the protein unfolds within the TGN to accept copper and how the copper is incorporated into ceruloplasmin is still under study. Ceruloplasmin is then secreted into the serum, and any excess copper not incorporated into ceruloplasmin is recycled in vesicles containing either the Wilson disease P-type ATPase or Menkes' P-type ATPase, and excreted into bile or stored in the liver. Recent characterization of a new protein, Murr1, suggests that this protein regulates copper excretion into bile such that mutations in the Murr1 gene are associated with normal copper uptake but severe defects in exporting copper from hepatocytes.

Approximately 15% of the total copper absorbed is actually transported to tissues while the remaining 85% is excreted. Of that copper pool, 98% is excreted in bile with the remaining 2% eliminated in the urine. The liver is the predominant organ responsible for regulating copper homeostasis at the level of excretion. Whereas copper import is highly conserved between yeast and humans, copper export in vertebrates involves a complex vesicular system that culminates in a lysosomal excretion pathway 'dumping' copper into the bile for elimination. At steady state, the amount of copper excreted into the biliary system is directly proportional to the hepatic copper load. In response to an increasing copper concentration within the hepatocyte, biliary copper excretion increases. There is no enterohepatic recirculation of copper and once the unabsorbable copper complex is in bile it is excreted in stool. Localization studies reveal redistribution of the ATP7b from the TGN to a vesicular compartment that migrates out to the biliary epithelium in response to increasing copper concentrations. Alternatively, under conditions of copper deficiency, the ATP7b remains tightly incorporated with the TGN for maximal copper incorporation into ceruloplasmin.

The highly homologous Wilson disease P-type ATPase (ATP7b) and the Menkes's P-type ATPase (ATP7a) differ only in their tissue expression and both function to move copper from one intracellular compartment to another. The ATP7a is predominantly located in the placenta, blood–brain barrier, and gastrointestinal tract and hence any mutation in the Menkes's P-type ATPase results in a copper deficiency in the fetus, brain, and tissues. In contrast, the Wilson's disease P-type ATPase is expressed in the liver and mutations in this culminate in profound copper overload of the liver because of the inability to shuttle copper into the trans golgi network for incorporation into ceruloplasmin. The excess copper is stored in the liver and eventually leaks out in the serum where it is deposited within sensitive tissues: the eye and brain. The psychiatric illnesses ascribed to Wilson's disease are a result of hepatocyte-derived copper 'leaking' out of the liver and accumulating within the basal ganglia. Similarly, Kayser-Fleischer rings arise from copper deposition in the cornea. The toxic copper in the liver eventually results in cirrhosis and hepatic fibrosis as a result of oxyradical damage. Menkes's syndrome has an incidence of 1:300 000 while Wilson's disease has an incidence of 1:30 000. Expression of these diseases may differ considerably among affected family members.

The recognition of a novel disorder of iron metabolism associated with mutations in the copper-containing protein ceruloplasmin revealed an essential role for ceruloplasmin as a ferroxidase and regulator of iron homeostasis. Patients and mice lacking the serum protein ceruloplasmin have normal copper kinetics: normal absorption, distribution, and copper-dependent activity. These data suggest that although under experimental conditions ceruloplasmin may donate copper, ceruloplasmin is not a copper transport protein. The six atoms of copper are incorporated into three type 1 coppers, one type 2 copper, and a type 3 copper. The type 1 coppers provide the electron shuttle necessary for the concomitant reduction of oxygen to water that occurs within the trinuclear copper cluster comprised of the type 2 and type 3 copper. This reaction is coupled with the oxidation of a variety of substrates: amines, peroxidases, iron, NO, and possibly copper. The recent observation that Fet3, the yeast ceruloplasmin homolog, also has critical cuprous oxidase activity in addition to ferroxidase activity has prompted renaming some of the multicopper oxidases (ceruloplasmin, Fet3, hephaestin) as 'metallo-oxidases' rather than ferroxidases.

Copper Deficiency

Reports of human copper deficiency are limited and suggest that severe nutrient deficiency coupled with

malabsorption is required for this disease state to occur. Infants fed an exclusive cows' milk diet are at risk for copper deficiency. Cows' milk not only has substantially less copper than human milk but the bioavailability is also reduced. High oral intake of iron or zinc decrease copper absorption and may predispose an individual to copper deficiency. Other infants at risk include those with: (1) prematurity secondary to a lack of hepatic copper stores; (2) prolonged diarrhea; and (3) intestinal malabsorption syndromes. Even the premature liver is capable of impressive copper storage. By 26 weeks' gestational age the liver already has 3 mg of copper stored. By 40 weeks' gestational age, the hepatic liver has 10–12 mg copper stored with the majority being deposited in the third trimester. Iron and zinc have been shown to interfere with copper absorption and further complicate the picture of copper deficiency. The most frequent clinical manifestations of copper deficiency are anemia refractory to iron treatment, neutropenia, and bone demineralization presenting as fractures.

The anemia is characterized as hypochromic and normocytic with a reduced reticulocyte count, hypoferremia, and thrombocytopenia. Bone marrow aspirate reveals megaloblastic changes and vacuolization of both erythroid and myeloid progenitor lineages. It is believed that a profound copper deficiency results in a multicopper oxidase deficient state and as such bone marrow demands are unmet by the lack of ferroxidase activity. Bone abnormalities are common and manifest as osteoporosis, fractures, and epiphyseal separation. Other manifestations of copper deficiency include hypopigmentation, hypotonia, growth arrest, abnormal cholesterol and glucose metabolism, and increased rate of infections.

Multiple factors associated with copper deficiency are responsible for the increased rate of infection seen. Most copper-deficient patients are malnourished and suffer from impaired weight gain. The immune system requires copper to perform several functions. Recent research showed that interleukin 2 is reduced in copper deficiency and is probably the mechanism by which T-cell proliferation is reduced. These results were extended to show that even in marginal deficiency, when common indexes of copper are not affected by the diet, the proliferative response and interleukin concentrations are reduced. The number of neutrophils in human peripheral blood is reduced in cases of severe copper deficiency. Not only are they reduced in number, but their ability to generate superoxide anion and kill ingested microorganisms is also reduced in both overt and marginal copper deficiency. This mechanism is not yet understood.

Copper Excess

Excess copper is the result of either excessive copper absorption or ineffective copper excretion. The most common diseases associated with copper excess are: (1) Wilson's disease, a genetic disease resulting in mutations in the Wilson's disease P-type ATPase and excessive hepatocyte copper accumulation; (2) renal disease, in patients on hemodialysis due to kidney failure when dialysate solutions become contaminated with excess copper; and (3) biliary obstruction. Excessive use of copper supplements may also contribute to copper toxicity and is clinically manifested by severe anemia, nausea and vomiting, abdominal pain, and diarrhea. Copper toxicosis can rapidly progress to coma and death if not recognized. Current management of most diseases associated with copper toxicity includes a low-copper diet, a high-zinc diet (competitively interferes with copper absorption), and use of copper chelators such as penicillamine and trientine. Affected individuals should have their tap water analyzed for copper content and drink demineralized water if their water contains more than 100 μg/liter. Given that the liver is the most significant copper storage organ, any activity that can affect hepatic cellular metabolism needs to be monitored. Hence, alcohol consumption is strongly discouraged.

There are reports of chronic copper exposure resulting in toxic accumulation. Fortunately, these events appear to be geographically restricted. Indian childhood cirrhosis (ICC), also known as Indian infantile cirrhosis or idiopathic copper toxicosis, has been associated with increased copper intake from contaminated pots used to heat up infant milk. The milk is stored and warmed in brass (a copper alloy) or copper containers. It is interesting to note that the increased copper absorption alone is not critical for disease formation but rather this occurs in infants that already have prenatal liver copper stores in excess of adult values. How the neonatal liver is able to compartmentalize this toxic metal so effectively is unknown. Perhaps in ICC, this delicate balance is disrupted. Tyrolean liver disease, occurring in the Austrian Tyrol, despite having a Mendelian pattern of inheritance suggestive of an autosomal recessive trait, appears related to use of copper cooking utensils. However, recent reports describe how a persistent percentage of the German population remains susceptible to copper toxicosis despite adjustments in cooking utensils. Perhaps a genetic susceptibility exists in this population that has yet to be determined.

Conclusion

Adult copper homeostasis rests on the foundation of an adequate copper balance in early life. Copper deficiency, either due to inadequate intake or abnormal absorption, may result. While the clinical stigmata of severe copper deficiency are easy to identify, the subtle changes in neurobehavioral development associated with mild copper deficiency are unknown. Given the high copper concentration in the brain, one could postulate that critical copper deficiency during development could lead to significant central nervous system deficits. Recent evidence suggesting that copper metabolism may be involved as an epigenetic factor in the development of Alzheimer's disease (AD) highlights the importance of balance. In this scenario, elevated central nervous system copper, as seen in AD, may initiate increased oxyradical formation and hasten damage. In fact, some are advocating that serum copper might be a good biomarker for AD. Copper is an essential trace metal critical for normal development. The goal of future studies will be to develop sensitive biomarkers for copper status. Only with these tools can we adequately assess copper status and treat copper-deficient and copper excess states appropriately.

CORONARY HEART DISEASE

Contents

Hemostatic Factors

W Gilmore, University of Ulster, Coleraine, UK

Introduction

The two major processes that contribute to the pathogenesis of coronary heart disease (CHD) and stroke are atherosclerosis and thrombosis. These, in turn, involve inflammation and hemostasis; two pathways that are linked both at the molecular and cellular levels. In addition to stimulating the inflammatory response, the proinflammatory cytokines, chiefly interleukin-1beta (IL-1β) and tumor necrosis factor alpha (TNFα), may promote the initiation of hemostasis by upregulating tissue factor (TF) on endothelial cells and the blood monocytes. The explosion of interest in the role of cholesterol in vascular diseases in the latter half of the twentieth century led to a decrease in interest in the role of hemostatic factors in this group of diseases. However, the efficacy of thrombolytic drugs in the treatment of acute myocardial

infarction together with the demonstration that clots were involved in sudden ischemic death renewed interest in the role of the blood clotting pathways in these disorders. Hemostasis is part of the body's normal defense system and response to injury. The advancement, by Russell Ross, of the response to injury hypothesis of vascular disease has directed attention towards hemostasis again. Hemostasis involves the interaction between cells of the immune system, blood platelets, smooth muscle cells, endothelial cells, and the blood clotting proteins. The blood clot is eventually broken down by the fibrinolytic mechanism and the normal tissue repair processes promote wound healing. A balance between the processes of hemostasis and fibrinolysis has always been thought necessary to prevent blood loss, on the one hand, and thrombosis, on the other. Many of the components of the hemostatic mechanism have been identified as risk factors for vascular disease and these include: increased plasma levels of the blood clotting proteins fibrinogen and factor VII, increased platelet aggregation, and elevated plasma levels of the inhibitor of plasmin activation, plasminogen activator inhibitor-1 (PAI-1).

Nutrition plays a central role in the activity of the blood coagulation factors with the requirement of vitamin K in the posttranslational carboxylation of glutamic acid residues on key blood clotting proteins and some of their physiological inhibitors. In addition to this involvement of vitamin K in the biosynthesis of biologically active blood clotting proteins other nutrients may modify components of the blood coagulation pathway. However, results from many intervention studies still often yield conflicting results. This article will concentrate on a description of hemostasis, as we currently understand it, rather than an exhaustive account of the studies on dietary factors and hemostasis. This may enable the reader to discern the most appropriate aspects of hemostasis for study by nutrition scientists.

Hemostasis

Platelets

When trauma occurs platelets can form a small primary hemostatic plug that is sufficient to stop bleeding from a small nick in the skin. Platelets are very easily activated and, therefore, difficult to study. They are formed from megakaryocytes in the bone marrow and, to a lesser extent, in the peripheral blood and lungs. Platelets are small (0.2–3.5 μm in diameter) buds off these large megakaryocytes. They have a volume of about 10 fl and number $100-400 \times 10^9\,l^{-1}$ in peripheral blood. When viewed under light microscopy, they have little structure; however, electron microscopy reveals abundant subcellular organelles. Platelets contain large quantities of lipids; their plasma membrane is highly involuted and their cytoplasm contains numerous membrane-bound granules. These granules are of two types: electron-dense granules that contain, *inter alia*, ADP, Ca^{2+} and serotonin, and the so-called specific alpha-granules that contain some blood coagulation proteins and growth factors such as platelet-derived growth factor (PDGF) and transforming growth factor-beta (TGF-β), which promote wound healing.

When activated, platelets express the adhesion molecule P-selectin (CD62P), which, in unactivated platelets, is present in the alpha-granules. Activated platelets stick to damaged endothelium, a process known as platelet adhesion, and then stick to each other, a process known as platelet aggregation. Adhesion molecules form important molecular components of this process. Platelet aggregation can be measured in the laboratory by simple photometric techniques. This *in vitro* aggregation is stimulated by adrenaline, collagen, ADP, and the toxic antibiotic risocetin and has been widely applied in studies of the effect of nutrients on platelet function. However, adhesion and aggregation may only be minor biological functions of platelets. The main function of these tiny fragments seems to be in their ability to release a vast array of biologically active substances. In particular, they release phospholipid from their membranes to participate in the coagulation cascade. Platelets release serotonin, a powerful vasoconstrictant. They also release PDGF and TGF-β both of which are growth factors intimately involved in wound healing and tissue regeneration. Low platelet numbers will lead to an increased bleeding tendency and, interestingly, to a decrease in the integrity of the blood vessel walls. Therefore, platelets have two main functions in the body: they participate in hemostasis, and are responsible for the repair and maintenance of the blood vessel walls.

The products of cyclooxygenases play a crucial role in the action of blood platelets. The substrates of these enzymes are the *n*-6 and *n*-3 long-chain polyunsaturated fatty acids. Platelets cannot synthesize these from the short-chain precursors and so must rely on direct incorporation of the long-chain polyunsaturated fatty acids into their cellular membranes. In platelets, cyclooxygenases and other enzymes convert arachidonic acid (C20:4*n*-6) to thromboxane A_2, which potentiates platelet aggregation, whereas the less potent thromboxane A_3 is

generated when eicosapentaenoic acid (C20:5*n*-3) is the substrate. The endothelial cells constitutively synthesize the arachidonic acid (C20:4*n*-6)-derived eicosinoid, prostaglandin I_2 (PGI_2) which is antiaggregatory in its action and thus the normal endothelium provides a surface that prevents blood clotting.

The Coagulation Cascade

Blood coagulation factors are proteins, most of which were discovered when a genetically inherited bleeding disorder was discovered in patients. A newly discovered coagulation factor was often named after the patient in whom it was first recognized, but nowadays the Roman numerals I through to XIII are designated and accepted names of these proteins. A suffix, 'a' indicates an activated coagulation factor. The components of the blood coagulation pathways are mostly serine proteases that sequentially activate each other in turn, giving rise to a fibrin clot. Some, however, act as cofactors in some of the reactions, e.g., factors Va and VIIIa. There are two different mechanisms whereby blood clotting may be initiated (**Figure 1**). The principal mechanism, known as the tissue factor (TF) pathway or the extrinsic coagulation cascade, involves the expression of TF (thromboplastin or factor III) on the cells of the intima of the damaged blood vessel. TF is only expressed on the cells that are not in contact with the peripheral blood. The exposure of blood to TF, in turn, leads to the sequential activation of the blood clotting factors, and the generation of the fibrin clot. The only cells in day-to-day contact with blood that can be stimulated to produce TF are endothelial cells and monocytes when the proinflammatory cytokines and bacterial endotoxins stimulate these cells to express this cell membrane-bound protein. The presence of a NFκB binding site in the promoter region of the tissue factor gene on chromosome 1 further indicates involvement of hemostasis in inflammatory processes.

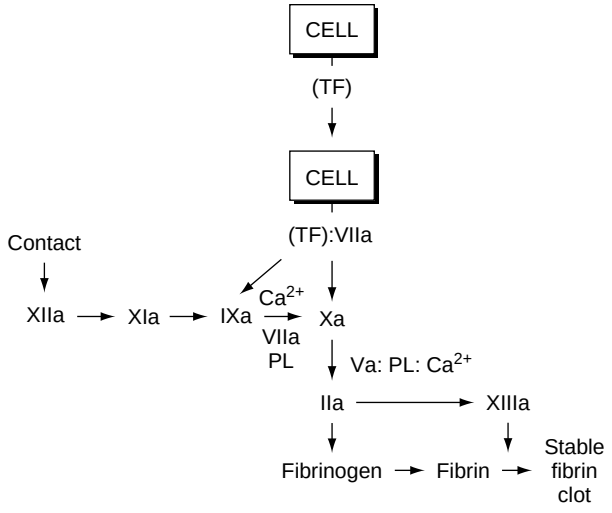

Figure 1 The tissue factor pathway and contact activation pathways of blood coagulation. PL, platelet phospholipids; TF, tissue factor.

TF is an integral membrane protein of 263 amino acids and molecular weight 47 000. It has been assigned CD142 by the VIth International Workshop and Conference on Human Leukocyte Differentiation Antigens held in Kobe, Japan, in 1996. The ligand for this cell surface protein is factor VII or factor VIIa. There are relatively small amounts of factor VIIa constantly present in normal blood. However, only when factor VIIa binds to TF does it become significantly potent as an activator of blood coagulation. A TF:Ca^{2+}:factor VIIa complex is formed and this activates both factor X to factor Xa and factor IX to factor IXa, which forms a complex with factor VIIa, Ca^{2+}, and platelet phospholipids to activate further molecules of factor X. The activated factor X forms a factor Xa:Ca^{2+}:factor Va complex, which converts prothrombin to thrombin. Thrombin acts on fibrinogen molecules to convert them to fibrin monomers. These monomers form an instantaneous clot by associating via noncovalent bonds. The clot is then stabilized in a reaction catalyzed by factor XIIIa by crosslinking the fibrin molecule by covalent bonds between glutamic acid and lysine residues of adjacent fibrin monomers. Thrombin plays a central role in hemostasis in that it not only converts fibrinogen to fibrin but also activates other key players in the pathways; in particular, factor VII, factor XI, and the copper-dependent factors V and VIII. The major physiological activator of factor VII remains unidentified but, in addition to thrombin; factor Xa, factor XIa, and factor XIIa are capable of converting factor VII to factor VIIa.

TF is inhibited by a specific inhibitor of the TF:Ca^{2+}:factor VIIa complex (**Figure 3**). This inhibitor, designated tissue factor pathway inhibitor (TFPI), is a 276 amino acid polypeptide that has three Kunitz-like regions. Therefore, this belongs to the Kunitz-type protease inhibitors whilst most other inhibitors of blood coagulation are serpins. In peripheral blood this inhibitor is associated with the lipid fractions and is, like tissue factor, synthesized by activated endothelial cells and monocytes. The TFPI remains inactive until sufficient amounts of activated factor X (i.e., factor Xa) can bind. The TFPI:factor Xa complex then inactivates the TF:Ca^{2+}:factor VIIa complex.

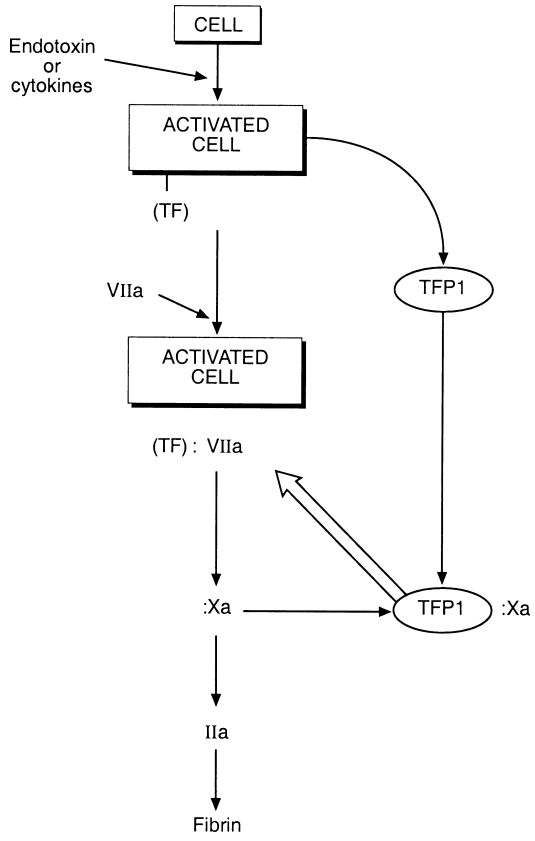

Figure 2 The action of tissue factor pathway inhibitor (TFPI). TF, tissue factor.

In the second mechanism of initiation, the contact activation pathway (**Figure 1** and **Figure 2**), blood coagulation may be triggered by activation upon contact with collagen and other highly charged surfaces, including glass or plastic test tubes. Contact with collagen leads to activation of factor XII and, in turn, factor XIIa activates factor XI. Factor XIa activates factor IX, which together with Ca^{2+}, platelet phospholipid, and factor VIIIa activates factor X to factor Xa. The contact activation pathway merges with the tissue factor pathway at this point and, as before, the factor Xa, together with Ca^{2+}, platelet phospholipid, and factor Va activates prothrombin to thrombin, which converts fibrinogen to fibrin. The existence of this second pathway means that fibrin production remains switched on as long as the blood remains in contact with external surfaces despite the fact that the tissue factor pathway may, at this point, be closed down by the action of TFPI and factor Xa. The formation of factor XIIa has important consequences for other processes involved in the response of the body to injury. For example; high-molecular-weight kininogen and prekallikrein are activated to the kinins and to kallikrein, mediators of inflammation that can activate the contact pathway (**Figure 3**). In addition, fibrinolysis and the complement pathway are both activated by factor XIIa. It is probable that the physiological role of factor XIIa is to act as a mediator in many of the processes involved in the defense of the body during trauma and its role in the activation of blood coagulation may be of minor importance.

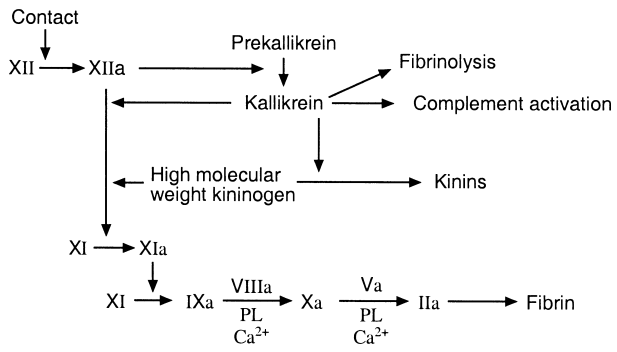

Figure 3 Contact activation pathway. PL, platelet phospholipids.

The coagulation process is inhibited by nonspecific mechanisms such as blood flow and by the presence in plasma of general serine protease inhibitors such as alpha2-macroglobulin. In addition, unique molecular systems will specifically inhibit blood coagulation and one of these involves heparin, a sulfated glycosaminoglycan. Heparin combines with antithrombin III in a one to one molar ratio and the resultant complex inhibits factor Xa and thrombin. Another specific control mechanism involves the vitamin K-dependent proteins, protein S and protein C, which combine with each other in molar ratios to form a complex with cellular membranes that inhibits the activity of factors Va and VIIIa. The complex also inhibits the action of PAI-1 thereby promoting fibrinolysis. Interestingly, a normal factor V molecule is essential for the inhibitory properties of this complex since mutation of factor V will cause a malfunction of the complex and result in a tendency to form clots (thrombophilia). This is the basis of the action of factor V Leiden, a mutant of factor V that causes familial thrombophilia.

Fibrinolysis, Fibrinogen, and the Acute Phase Response

The breakdown of the fibrin clot is initiated by activators of plasminogen, mainly tissue plasminogen activator (tPA) (**Figure 4**). This protein is produced by endothelial cells and activates plasminogen by converting it to plasmin. The plasmin then acts on fibrin to form the fibrin split

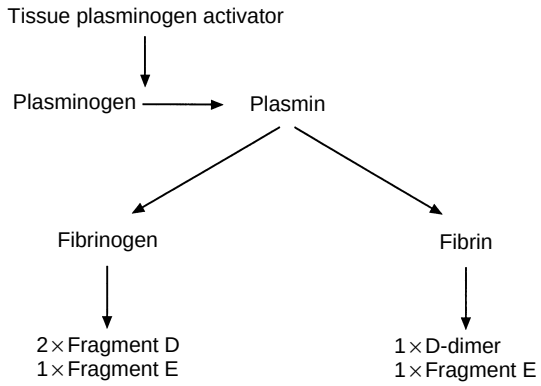

Figure 4 Fibrinolysis and fibrinogenolysis.

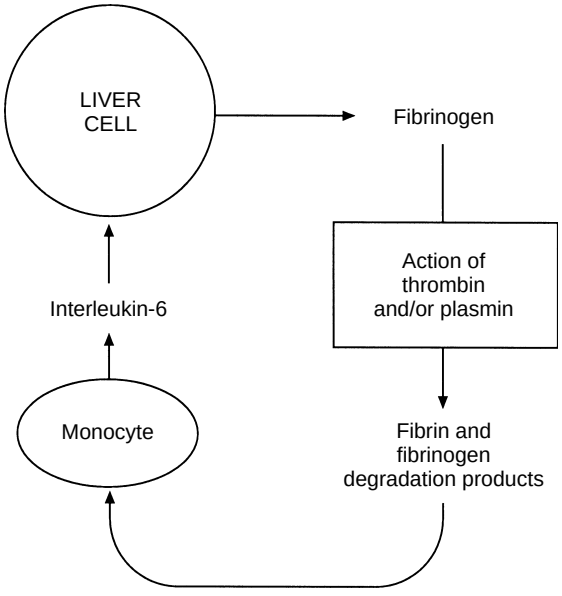

Figure 5 The role of interleukin-6 in fibrinogen synthesis.

products, a D-dimer and a fragment E from each fibrin monomer, and on fibrinogen to form the fibrinogen degradation products, two molecules of fragment D and one of fragment E. These breakdown products act as inhibitors of thrombin. They also stimulate the release of interleukin-6 (IL-6) from blood monocytes; the IL-6 then acts on the liver parenchymal cell to stimulate the synthesis of fibrinogen. The presence of this regulatory loop demonstrates the direct link between a proinflammatory cytokine, interleukin-6, and the production of a protein (fibrinogen) of the so-called acute phase response (**Figure 5**). Fibrinolysis is inhibited by PAI-1 and alpha2-antiplasmin.

Thrombosis

Thrombosis is a major cause of mortality and morbidity in Western societies. Deep venous thrombosis, myocardial infarction, pulmonary embolism, and acute thromboembolic stroke are, probably, all consequences of inappropriate blood coagulation or fibrinolysis. Fibrin formation is instantaneous and therefore clots can quickly occlude an artery and thereby precipitate an acute cardiac or cerebral event. This usually, but not exclusively, occurs in atherosclerotic blood vessels where plaques may rupture and cause thrombus formation.

The expression of tissue factor on cells and their subsequent exposure to blood is probably the major initiator of thrombus formation *in vivo*. It has been demonstrated that the blood monocytes from unstable angina and myocardial infarction patients express increased amounts of tissue factor when compared to healthy controls. Furthermore, it has been shown that monocytes from atherosclerotic plaques from unstable angina patients express increased amounts of tissue factor when compared to controls, thereby further implicating plaque rupture in the pathology of heart disease.

Hemostatic Factors and Risk of Coronary Heart Disease

Elevated plasma coagulation factor levels are risk factors for coronary heart disease. Fibrinogen synthesis in the liver is stimulated by the proinflammatory cytokine interleukin-6 and, therefore, elevated levels are found during the acute phase response. It has been argued that it may be difficult to assign elevated plasma fibrinogen as a definitive risk factor since the pathology of CHD involves inflammation and the acute phase response, which will lead to increased fibrinogen anyway. The same argument has been used in the case of elevated white cell counts, which is also a risk factor for coronary events. However, it has been demonstrated that if fibrinogen and/or white blood cell count remain high after a vascular event then there is greater risk of subsequent events. Therefore, increased plasma fibrinogen and elevated white cell count are now considered a major risk factor for CHD.

Further studies have indicated that other blood clotting factors may act as risk factors for CHD. For example, a prospective study, The Northwick Park Heart Study, identified factor VII as a risk factor for CHD and showed that plasma levels of factor VII were predictive of CHD in a dose-dependent manner. Another study has shown

that factor VIII may be a risk factor for cardiovascular disease. Increased levels of PAI-1 and decreased plasma levels of plasminogen activators have also been identified as risk factors for coronary heart disease.

Dietary Effects on Hemostatic Function

Dietary vitamin K profoundly affects the activity of the blood clotting factors II, VII, IX, and X and the inhibitory molecules, protein C and protein S. These proteins are synthesized in the liver and contain a region or module of the protein that contains modified glutamic acid residues (gamma carboxy glutamic acid) (Gla). Gla formation requires vitamin K and so a deficiency state will cause abnormal bleeding. A dietary deficiency of vitamin K is rare and nearly always occurs in the neonate leading to hemorrhagic disease of the newborn. However, the oral anticoagulant drugs based on warfarin are vitamin K analogs and thus prevent the synthesis of a biologically active coagulation protein.

Fibrinogen levels are elevated in obese individuals although many studies have failed to demonstrate any relationship between plasma fibrinogen levels and dietary fat. Active men have lower fibrinogen levels and a number of studies have demonstrated an inverse relationship between alcohol consumption and plasma fibrinogen. A high-fiber diet was also shown to correlate negatively with plasma fibrinogen. A few studies on the effects of antioxidant vitamins show that they may lower fibrinogen. For example, the Swedish MONItoring CArdiovascular disease (MONICA) study found that high levels of plasma retinol were associated with lower fibrinogen levels. However, plasma tPA levels were also lowered indicating that the fibrinolytic pathway was compromised in these subjects. Fish oil was shown to lower fibrinogen levels when the oil contained vitamin E.

Dietary fat profoundly affects the activity of factor VII. A high fat intake is associated with increased amounts of factor VIIa. Indeed, the postprandial levels of this active blood coagulation factor have been shown to be elevated after a high-fat meal. If exposed to tissue factor, these increased levels of factor VIIa would have major consequences for thrombogenesis. Platelet aggregation is often affected by diet and fish oils can reduce platelet aggregation.

The influence of diet on the components of the coagulation pathway is well recognized by the requirement of vitamin K. However, the role that diet plays in modulating the levels of coagulation factors that are, or may be, risk factors for coronary heart disease is unclear and the results are often conflicting. For example, in intervention studies examining the effects of fish oils on monocyte TF production, one study reported a decrease in expression whilst other studies showed no effect. The study where the positive effects were reported was carried out in Italy and it has been suggested that the Mediterranean diet of the Italians was a contributory factor in these findings. Obviously, more work is required to establish the effects of fish oils on TF expression.

Hemostasis is an exciting and important area of medicine and our knowledge of the molecular and cellular interactions that bring about clot formation is now at an advanced stage. Many of the studies on diet and hemostasis may have used inappropriate laboratory techniques. For example, blood platelets are easily activated making aggregation data difficult to interpret. The advent of automated coagulometers means that the clotting factors may be easily measured. There are commercially available immunoassays for many of the components of hemostasis described in this article. Using flow cytometry, TF can be measured on monocytes and P-selectin may be detected on activated platelets. Since thrombosis is a major cause of acute coronary events the rewards of studies on diet and hemostasis may be great.

Lipid Theory

D Kritchevsky, Wistar Institute, Philadelphia, PA, USA

Introduction

Arteriosclerosis is a group of conditions characterized by thickening and stiffening of the arterial wall. Atherosclerosis is characterized by the formation of atheromas (lipid-laden plaques) in medium to large arteries. These are associated with calcifications of the arterial wall along with other changes. Eventually, the arterial lumen is reduced and the restricted blood flow due to these changes leads to clinical symptoms. Over the years there have been varying theories about the development of arterial lesions and these theories become more complex as our biochemical and molecular biological skills and knowledge increase.

Arterial fatty streaks are ubiquitous in humans and appear early in life. The fatty streak is comprised of lipid-rich macrophages and smooth muscle cells. Macrophages that accumulate lipid and are transformed into foam cells may be involved in the transformation of the fatty streak to an atherosclerotic lesion. In susceptible persons the fatty streaks may progress to fibrous plaques. Fibrous plaques, at their core, consist of a mixture of cholesterol-rich smooth muscle and foam cells. This core may contain cellular debris, cholesteryl esters, cholesterol crystals, and calcium. The fibrous cap consists of smooth muscle and foam cells, collagen, and lipid. The final stage in this process is the complicated plaque, which can obstruct the arterial lumen. Rupture of the cap may lead to clot formation and occlusion of the artery.

There are several theories of atherogenesis and these may eventually be shown to be interactive. The lipid hypothesis suggests that persistent hyperlipidemia leads to cholesterol accumulation in the arterial endothelium. Hypercholesterolemia may activate protein growth factors, which stimulate smooth muscle cell proliferation.

The lipid infiltration hypothesis proposes that elevated LDL levels increase LDL infiltration which, in turn, increases uptake of epithelial cells, smooth muscle cells, and macrophages. This cascade leads to cholesterol accumulation and, eventually, atheroma formation. The endothelial injury may arise from the action of oxidized lipid.

The endothelial injury hypothesis may help to explain the focal distribution of atheromas, which is not adequately accounted for by the lipid hypothesis. The endothelial injury hypothesis asserts that plaque formation begins when the endothelial cells that cover fatty streaks separate thus exposing the underlying lesion to the circulation. This may lead to smooth muscle proliferation, stimulated by circulating mitogens, or may cause platelet aggregation leading to mural thrombosis.

Another hypothesis relating to atherogenesis is the response-to-injury hypothesis. In this hypothesis the injury may be due to mechanical factors, chronic hypercholesterolemia, toxins, viruses, or immune reactions: these increase endothelial permeability, and lead to monocyte adherence to the epithelium or infiltration and platelet aggregation or adherence at the site of the injury. Injury releases growth factors that stimulate proliferation of fibrous elements in the intima. These growth factors may arise from the endothelial cell, monocyte, macrophages, platelet, smooth muscle cell, and T cell. They include epidermal growth factor, insulin-like growth factors, interleukins 1 and 2, platelet-derived growth factors, transforming growth factors α and β, and tumor necrosis factors α and β, among others. Monocytes and smooth muscle cells carry the 'scavenger' receptor, which binds oxidized but not native low-density lipoprotein (LDL) in a nonsaturable fashion. Uptake of oxidized LDL converts macrophages and smooth muscle cells into foam cells. Another theory of atherogenesis suggests that it begins as an immunological disease, which starts by an autoimmune reaction against the heat stress protein, hsp60. There have been suggestions that oxidized LDL may be an underlying cause of arterial injury.

The term 'atherosclerosis' is derived from the Greek words *athere*, meaning gruel, and *skleros*, meaning hardening. The term was coined by Marchand in 1904 to describe the ongoing process beginning with the early lipid deposits in the arteries to the eventual hardening. The World Health Organization (WHO) definition describes atherosclerosis as a 'variable combination of changes in the intima of the arteries involving focal accumulation of lipids and complex carbohydrates with blood and its constituents accompanied by fibrous tissue formation, calcification, and associated changes in the media' – a decidedly more complex concept than attributing it all to the dietary cholesterol.

Discussions of the etiology of heart disease always describe it as a life-style disease and list a number of risk factors, which include family history, hypercholesterolemia, hypertension, obesity, and cigarette smoking. Having listed these factors, discussion generally reverts to blood cholesterol and its control.

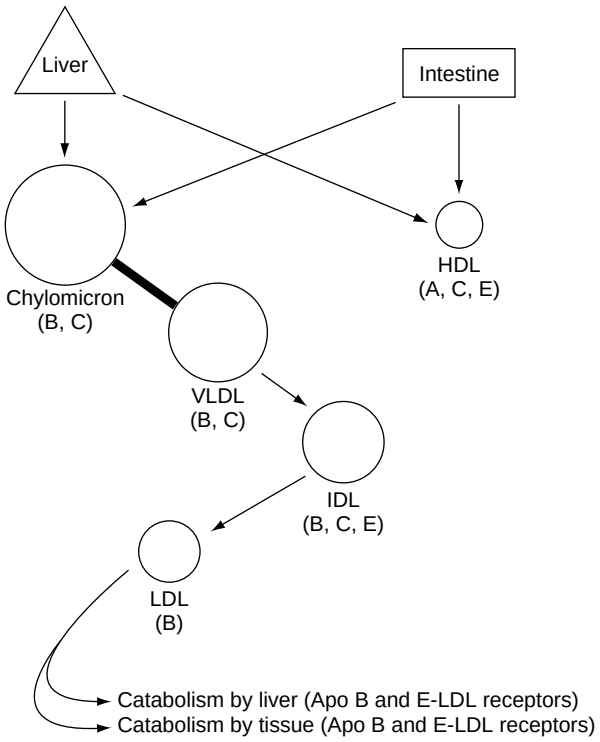

Figure 1 Outline of lipid metabolism. Letters in parentheses refer to apolipoproteins (apo). HDL, high-density lipoprotein; VLDL, very-low-density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein.

The fasting blood plasma of a healthy individual is a clear, straw-colored liquid, which may contain 400–800 mg of lipids per 100 ml. This clear solution, which is high in lipids, is made possible by the water-soluble complex of lipids with protein, the lipoproteins. A generalized view of lipoprotein metabolism is provided in **Figure 1**. The existence of soluble lipid–protein complexes in serum was suggested about a century ago. Precipitation of a lipoprotein from horse serum was achieved in 1929 and classes of lipoproteins were adduced from studies using moving boundary electrophoresis. The critical experiments were carried out by Gofman and his group in the 1950s. They demonstrated that classes of lipoprotein complexes could be identified by their flotation characteristics in the analytical ultracentrifuge. These complexes were separable because they possessed different hydrated densities and they were defined initially by Svedberg units of flotation (S_f). The lipoproteins vary in chemical composition and although it is common to provide tables describing lipoprotein composition, the values are generally average values. This is so since the lipoproteins exist in a dynamic state exchanging their lipid components with those of tissues or other lipoproteins. Since identification is made according to a physical property, i.e., hydrated density, it is evident that different agglomerates of lipid and protein may have similar hydrated densities. In general, the lipoproteins are a series of macromolecules that, as they progress from low to high density, display decreasing triacylglycerol content and increasing cholesteryl ester, phospholipid, and protein.

Table 1 describes the major lipoproteins. Their chemical composition is described in **Table 2**.

As research continues and as analytical methodology becomes more precise we find a higher resolution of some lipoprotein classes and better definition of their roles. One example is lipoprotein (a) (lp(a)), first described in 1963. Lipoprotein (a) is an LDL whose normal apoprotein (apo B) is linked to an additional protein, apoprotein a, via a disulfide bridge. Lipoprotein (a) interferes with normal fibrinolysis leading to an increased prevalence of blood clots, and is thought to present an especially high risk for myocardial infarction. Characteristics and functions of lipoproteins are described in **Table 3**.

Molecular size influences the ease with which LDL particles can enter the arterial wall. Diabetic rabbits have greatly elevated plasma lipid levels but display surprisingly little atherosclerosis. The reason

Table 1 Major plasma lipoproteins

Lipoprotein class	*Size (nm)*	*Mol. wt*	*Density (g ml^{-1})*	*Electrophoretic mobility*	*Origin*	*Major apoproteins*
Chylomicron	100–400	10^6–10^7	<0.95	Origin	Intestine	A-I, B-48, C-II, C-III, E
VLDL	40–70	5×10^3	0.95–1.006	Prebeta	Liver	B-100, C-II, C-III, E
IDL	30–40	4.5×10^3	1.006–1.019	Between prebeta and beta	Catabolism of VLDL	B-100, C-II, C-III, E
LDL	22.5–27.5	2×10^3	1.019–1.063	Beta	Catabolism of VLDL and IDL	B-100
HDL	7.5–10	0.4×10^3	1.063–1.210	Alpha	Liver, intestine	A-I, A-II, C-II, C-III, E

VLDL, very-low-density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; HDL, high-density lipoprotein.

Table 2 Plasma lipoprotein composition

Lipoprotein	*Composition (wt%)*				
	FC	*CE*	*TAG*	*PL*	*PROT*
Chylomicron	1	3	90	4	2
VLDL	7	14	55	16	8
IDL	6	22	30	24	18
LDL	7	48	5	20	20
HDL	4	15	4	27	50

FC, free cholesterol; CE, cholesteryl ester; TAG, triacylglycerol; PL, phospholipid; PROT, protein; VLDL, very-low-density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; HDL, high-density lipoprotein.

for this apparent discrepancy is that the lipoproteins of diabetic rabbits are rather large in size and do not penetrate the artery. Since 1982 we have known of an array of LDL particles ranging from small and dense to large and comparatively light. An LDL pattern characterized by an excess of small, dense particles is associated with a threefold increased risk of myocardial infarction, independent of age, sex, or body weight. Commonly, LDL is known as the 'bad' cholesterol and high-density lipoprotein (HDL) as the 'good' cholesterol. These recent findings indicate the presence of 'good, bad' cholesterol and 'bad, good' cholesterol.

Among the apolipoproteins, polymorphism of apoprotein E apparently dictates a subject's chances for successful treatment of lipidemia. The apoE alleles are designated as E2, E3, and E4. The most common pattern (55%) is homozygosity for E3, which gives rise to the E3/E3 phenotype. The next most common phenotype is E3/E4 (26%). The least frequently observed phenotype is E2/E (1%), which is often associated with type III hyperlipoproteinemia. There is some evidence suggesting that subjects bearing the E4 allele have higher levels of LDL than those with the E3/E3 pattern; they may also be more prone to Alzheimer's disease. **Tables 4** and **5** list primary and secondary dyslipoproteinemias.

Cholesterol and Cholesterolemia

In 1913 Anitschkow showed that it was possible to establish atherosclerosis in rabbits by feeding cholesterol. Since then virtually all research on atherosclerosis has centered on cholesterol – circulating cholesterol and dietary cholesterol. The epidemiological data suggest a role for

Table 3 Characteristics and functions of major apolipoproteins

Apolipoprotein	*Lipoprotein*	*(Approximate molecular weight (kD))*	*Source*	*(Average plasma) concentration (mg dL^{-1})*	*(Physiologic) function*
A-1	HDL, chylomicrons	28	Liver, intestine	100–120	Structural apoprotein of HDL, cofactor for LCAT
A-II	HDL, chylomicrons	17	Intestine, liver	35–45	Structural apoprotein of HDL, cofactor for hepatic lipase
A-IV	HDL, chylomicrons	46	Liver, intestine	10–20	Unknown
Apo (a)	Lp(a)	600	Liver	1–10	Unknown
B-48	Chylomicrons	264	Intestine	Trace	Major structural apoprotein, secretion and clearance of chlylomicrons
B-100	VLDL, LDL	550	Liver	100–125	Ligand for LDL receptor, structural apoprotein of VLDL and LDL
C-I	Chylomicrons, VLDL, HDL	5.80	Liver	6–8	Cofactor for LCAT
C-II	Chylomicrons, VLDL, HDL	9.10	Liver	3–5	Cofactor for LCAT
C-III	Chylomicrons, VLDL, HDL	8.75	Liver	12–15	Inhibitor of LPL, involved in lipoprotein remnant uptake
E-2	Chylomicrons, VLDL, HDL	35	Liver, peripheral tissues	4–5	Ligand for cell receptor
E-3	Chylomicrons, VLDL, HDL	35	Liver, peripheral tissues	4–5	Ligand for cell receptor
E-4	Chylomicrons, VLDL, HDL	35	Liver, peripheral tissues	4–5	Ligand for cell receptor

HDL, LDL, VLDL, high-, low-, and very-low-density lipoprotein; LCAT, lecithin-cholesterol acyltransferase; LPL, lipoprotein lipase.

Table 4 The primary dyslipoproteinemias

Type	*Changes in plasma*		*Apparent genetic disorder*	*Biochemical defect*
	Lipids	*Lipoproteins*		
I	TAG ↑	CM ↑	Familial LPL deficiency	Loss of LPL activity
II-a	C ↑	LDL ↑	Familial hypercholesterolemia	Deficiency of LDL receptor and activity
II-b	C ↑, TAG ↑	LDL, VLDL ↑	Familial combined hyperlipidemia	Unknown
III	C ↑, TAG ↑	β-VLDL ↑	Familial type III hyperlipidemia	Defect in TAG-rich remnant clearance
IV	TAG ↑	VLDL ↑	Familial hypertriacylglycerolemia	VLDL synthesis ↑, catabolism ↓
V	TAG ↑, C ↑	VLDL ↑, CM ↑	Familial type V hyperlipoproteinemia	Lipolysis of TGA-rich LP ↓, Production of VLDL TAG ↑
Hyper Lp(a)	C ↑	Lp(a) ↑	Familial hyper apo(a) lipoproteinemia	Inhibits fibrinolysis
Hyperapobeta-lipoproteinemia	TAG ↑	VLDL, LDL ↑	Familial type V hyperlipoproteinemia	CETP deficiency
Familial hypobeta-lipoproteinemia	C ↓, TAG ↓	CM ↓, VLDL ↑, LDL ↓	?	Inability to synthesize apo B-48 and apo B-100
A-beta-lipoproteinemia	C ↓, TAG ↓	CM ↓, VLDL ↓, LDL ↓	?	Apo B-48 and apo B-100 not secreted into plasma
Hypo-alphalipoproteinemia	C ↓, TAG ↓	HDL ↓	?	LCAT deficiency
Tangier disease				Apo A-I ↓, apo C-III ↓
Fish eye disease				Abnormal apo A-I, and apo A-II metabolism

C, cholesterol; CM, chylomicrons; CETP, cholesteryl ester transfer protein; HDL, LDL, VLDL, high-, low-, and very-low-density lipoprotein; LCAT, lecithin-cholesterol acyltransferase; LPL, lipoprotein lipase; TAG, triacylglycerol.

dietary fat, and hypercholesterolemia has been established as a principal risk factor for atherosclerosis. The lipid hypothesis was developed from the data obtained in the Framingham study, which suggested a curvilinear relationship between risk of atherosclerosis and plasma or serum cholesterol levels. However, studies of actual cholesterol intake as it affects cholesterol levels have yielded equivocal results.

Several studies have shown that the addition of one or two eggs to their daily diet did not influence serum cholesterol levels of free-living subjects. Data from the Framingham study show no correlation between cholesterol intake and cholesterol level. So we are left with the anomalous situation that blood cholesterol is an indicator of susceptibility to coronary disease but it is relatively unaffected by dietary cholesterol. It is of interest to point out that we are also seeing a correlation between low plasma or serum cholesterol levels and noncoronary death.

The type of fat in the diet has a strong influence on serum or plasma cholesterol levels. Rabbits fed saturated fat develop more severe atherosclerosis

Table 5 Secondary dyslipoproteinemias

Type	*Associated disease*	*Lipoproteins elevated*	*Apparent underlying defect*
I	Lupus erythematosis	Chylomicrons	Circulating LPL inhibitor
II	Nephrotic syndrome, Cushing's syndrome	VLDL and LDL	Overproduction of VLDL particles, defective lipolysis of VLDL triglycerides
III	Hypothyroidism, dysglobulinemia	VLDL and LDL	Suppression of LDL receptor activity, overproduction of VLDL triglycerides
IV	Renal failure, diabetes mellitus, acute hepatitis	VLDL	Defective lipolysis of triglyceride-rich VLDL due to inhibition of LPL and HL
V	Noninsulin dependent diabetes	VLDL	Overproduction and defective lipolysis of VLDL triglycerides

HDL, LDL, VLDL, high-, low, and very-low-density lipoprotein; HL, hepatic lipase; LPL, lipoprotein lipase.

than do rabbits fed unsaturated fat. In 1965 the groups of Keys and Hegsted independently developed formulae for predicting changes in cholesterol levels based on changes in the diet. Their formulae were based upon changes in quantity of saturated and unsaturated fat and in dietary cholesterol, but the last value makes a very small contribution to the overall number. The Keys formula is:

$$\Delta C = 1.35(2\Delta S - \Delta P) + 1.5\Delta Z$$

where ΔC represents the change in cholesterol level, ΔS and ΔP represent changes in levels of saturated and unsaturated fat, and Z is the square root of dietary cholesterol in mg per 1000 kcal of diet. The Hegsted formula is:

$$\Delta C_P = 2.16\Delta S - 1.65\Delta P + 0.168\Delta C_D + 85$$

where ΔC_P is change in plasma cholesterol and ΔC_D is change in dietary cholesterol in mg per 1000 kcal.

Both studies found that changes in dietary stearic acid did not fit the formula. Since those formulae were introduced a number of newer formulae have appeared, which provide a coefficient for every individual fatty acid, but the original formulae are still used most frequently. Under metabolic ward conditions it has been shown that lauric ($C_{12:0}$), myristic ($C_{14:0}$), and palmitic ($C_{16:0}$) acids raise both LDL and HDL cholesterol levels, and that oleic ($C_{18:1}$) and linoleic ($C_{18:2}$) acids raise HDL and lower LDL levels slightly. Thus, the type of fat is the determining factor in considering dietary fat effects on serum cholesterol. Experiments in which subjects were fed low or high levels of cholesterol in diets containing high or low ratios of saturated to polyunsaturated fat have been reported. When the fat was homologous, changing from low to high dietary cholesterol raised serum cholesterol concentration by 2%. However, even under conditions in which low levels of cholesterol were fed, changing from saturated to unsaturated fat raised serum cholesterol levels by 10% or more.

In nature most, but not all, unsaturated fatty acids are in the *cis* configuration. The major source of fats containing *trans* unsaturated fatty acids (*trans* fats) in the diet of developed nations is hydrogenated fat, such as is present in commercial margarines and cooking fats. Interest in *trans* fat effects on atherosclerosis and cholesterolemia was first evinced in the 1960s. In general, *trans* fats behave like saturated fats and raise serum cholesterol levels, but have not been found to be more atherogenic than saturated fats in studies carried out in rabbits, monkeys, and swine. Studies have also shown that *trans* fat effects may be relatively small if the diet contains sufficient quantities of essential fatty acids.

Studies, clinical and epidemiological, on the influence of *trans* unsaturated fats on the risk of coronary heart disease have continued. The evidence is that *trans* fats may influence the chemical indicators of heart disease risk but final proof must rest on verification by clinical trial. The concerns relative to *trans* fat effects have led to recommendations that the levels of *trans* fats present in the diet be reduced as much as possible. The availability of *trans*-free margarines and other fats may render the entire argument obsolete.

Protein

The type of protein in the diet also influences cholesterolemia and atherosclerosis. In animal studies in which the sole source of protein is of animal or plant origin, the former is more cholesterolemic than atherogenic. However, a 1:1 mix of animal and plant protein provides the higher-grade protein of animal protein and the normocholesterolemic effects of plant protein. The results underline the need for a balanced diet.

Fiber

Dietary fiber may influence lipidemia and atherosclerosis. Substances designated as insoluble fibers (wheat bran, for instance) possess laxative properties but have little effect on serum lipid levels. Soluble fibers (gel-forming fibers such as pectin or guar gum) influence lipidemia and glycemia. Oat bran, which contains β-glucans, which are soluble fibers, will lower cholesterol levels despite its designation.

Variations in Cholesterol Levels

Ignoring the differences of technique involved in cholesterol measurement in the laboratory – variations that are amenable to resolution – there are physiological considerations that should be recognized. Age, gender, genetics, adiposity, and personality traits can affect cholesterol levels, as can diseases unrelated to coronary disease. Stress (job stress, deadlines, examinations) can lead to increased cholesterol levels.

A definite seasonal variation in cholesterol levels (usually higher in winter months) has been seen in a number of studies. Scientists from the National Institutes of Health in the US carried out one of

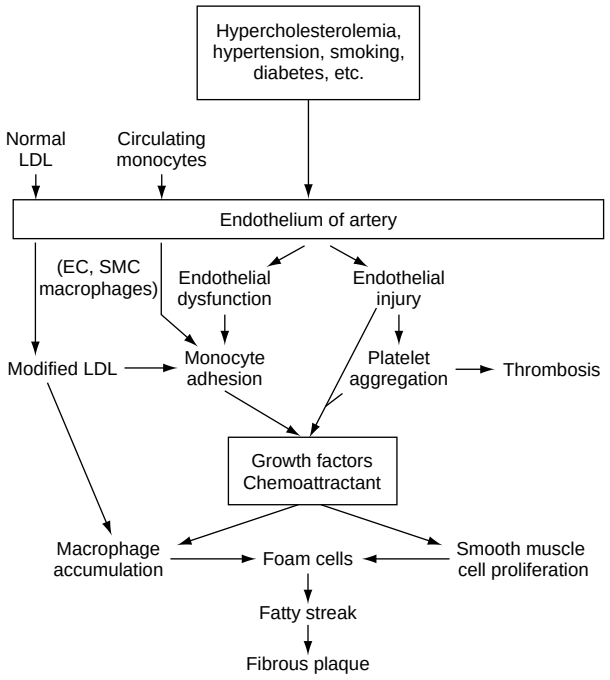

Figure 2 Factors involved in formation of the atherosclerotic plaque.

the finest studies in this area. They examined carefully the data from the 10 American Lipid Research Clinics. They observed that the etiology of their findings was unknown but they found the total and LDL cholesterol levels varied inversely with length of day. The level of HDL cholesterol varied much less, but its variation was correlated directly with ambient temperature. The foregoing does not reduce the importance of measuring cholesterol levels but makes it important to take into consideration the subjects' physical and mental state as well as time of year.

Figure 2 attempts to summarize the many factors now considered to play a role in the formation of the atherosclerotic plaque.

Prevention

K Srinath Reddy, All India Institute of Medical Sciences, New Delhi, India

Introduction

Coronary heart disease (CHD) is the leading cause of death in the world. While it is well established as the foremost contributor to mortality in most developed countries, it is also a major and rapidly rising cause of death in many developing countries. Global health transitions, which have seen substantial changes in age-specific coronary mortality rates across the world, in the past half a century, have also been associated with changes in nutrition, which explain a large part of the rise or fall of CHD-related death rates.

Diet and nutrition have been extensively investigated as risk factors for CHD. Many dietary factors have been linked directly to an increased or decreased risk of CHD or to major established risk factors of CHD like high blood pressure, disordered blood fats (dyslipidemia), diabetes and metabolic syndrome, overweight and obesity, and also to emerging risk factors like inflammatory markers and homocysteine. Nutrition influences atherogenesis, thrombosis, and inflammation – all of which are interconnected pathways that lead to CHD.

Observational epidemiological studies and clinical trials have contributed to a wide body of knowledge of the role that some nutrients (like saturated and *trans* fats, salt, and refined carbohydrates) play in

increasing the risk of CHD and of the protective effect of other nutrients (such as fruit and vegetables, polyunsaturated fats, nuts, and fish) against CHD. This knowledge has been successfully applied both in public health and in clinical practice to reduce the risk of CHD in populations as well as in individuals. The present state of that knowledge, as relevant to prevention of CHD, is summarized below.

Global Trends in CHD as a Reflection of Nutrition Transition

Coronary heart disease accounted for 7.2 million deaths in 2002, which forms a large fraction of not only the total number of deaths worldwide due to cardiovascular diseases (16.6 million) but also of the global total number of deaths from any cause (57 million). While age-specific coronary mortality rates have declined in the industrial countries over the past three decades, the absolute burdens of CHD continue to be high. CHD death rates are rising in the developing countries, where about half of these deaths occur below the age of 70 years. In Eastern and Central Europe CHD mortality rates rose sharply in the 1980s and 1990s and have only recently shown signs of stabilization, albeit at high levels.

These changes in CHD mortality rates have accompanied well-documented or clearly discernible shifts in the nutritional state of the populations. The decline of CHD mortality in Western and Northern Europe was linked to a reduction in the consumption of unhealthy fats (saturated fats and *trans* fats) and salt as well as an increased consumption of fruits and vegetables. This is best documented in The Netherlands and Finland. Similarly, the recent decline of CHD mortality in Poland was explained by the increase in fruit and vegetable consumption and growing substitution of vegetable fats for animal fats. Similar evidence of a favorable nutrition transition preceding the decline in CHD mortality rates is available from other developed countries like the US, Canada, Australia, and New Zealand.

The developing countries have, however, witnessed a recent transition in the opposite direction. China, for example, has experienced a large increase in fat consumption over the past two decades, accompanied by a progressive rise in the mean plasma cholesterol levels of the population as well as in the CHD mortality rates. Other developing countries are also increasingly adopting unhealthy dietary patterns that augment the risk of CHD.

Understanding the Links between Nutrition and CHD

The pathogenesis of CHD is mediated through the interconnected pathways of atherogenesis (fat deposition in the walls of the coronary arteries to form plaques), thrombosis (blood clotting over disrupted plaques) and inflammation (which initially damages the blood vessel walls and continues to destabilize the plaques). Nutrition has a major role in influencing each of these pathways and often provides the connecting link between them.

Major coronary risk factors include an abnormal blood lipid profile (especially plasma cholesterol and its subfractions), high blood pressure, and diabetes. Overweight and obesity (both the general and central patterns) are also associated with an increased risk of CHD. Nutrition has a powerful influence on all of these risk factors, with an unhealthy diet pattern tending to elevate them and a healthy diet pattern reducing the levels of risk. Diet becomes especially important in the context of the metabolic syndrome (a complex of central obesity, high blood pressure, dyslipidemia, and glucose intolerance), an entity which is being increasingly identified as a major risk factor for CHD. Nutrition is also linked to the propensity to develop cardiac arrhythmias, in the setting of CHD, and is an important predictor of sudden cardiac death. These links between dietary patterns and several specific nutrients not only manifest as fat deposition in the arteries, plaque growth, plaque instability, and thrombosis but are evident much earlier in the natural history of CHD, as endothelial dysfunction (inability of the arteries to dilate normally), elevated levels of inflammatory markers (such as C reactive protein), and increased intimal medial thickness of arterial walls. These precede and predict the clinical manifestation of CHD.

Nutrients and CHD

Dietary Fats: Cholesterol

The relationship between dietary fats and cardiovascular disease (CVD), especially CHD, has been extensively investigated, with strong and consistent associations emerging from a wide body of evidence accrued from animal experiments, as well as observational studies, clinical trials, and metabolic studies conducted in diverse human populations. This relationship was initially considered to be mediated mainly through the atherogenic effects of plasma lipids (total cholesterol, lipoprotein fractions, and triglycerides). The effects of dietary fats on

thrombosis and endothelial function as well as the relationship of plasma and tissue lipids to the pathways of inflammation have been more recently understood. Similarly, the effects of dietary fats on blood pressure have also become more evident through observational and experimental research.

Cholesterol in the blood and tissues is derived from two sources: diet and endogenous synthesis. Dairy fat and meat are major dietary sources. Dietary cholesterol raises plasma cholesterol levels. Although both high-density lipoprotein (HDL) and low-density lipoprotein (LDL) fractions increase, the effect on the total/HDL ratio is still unfavorable, but small. The upper limit for dietary cholesterol intake has been prescribed, in most guidelines, to be $300\,mg\,day^{-1}$. However, as endogenous synthesis is sufficient to meet the physiological needs, there is no requirement for dietary cholesterol and it is advisable to keep the intake as low as possible. If intake of dairy fat and meat are controlled, then there is no need for severe restriction of egg yolk intake, although some limitation remains prudent.

Saturated Fatty Acids (SFAs)

The relationship of dietary saturated fat to plasma cholesterol levels and to CHD was graphically demonstrated by the Seven Countries Study involving 16 cohorts, in which saturated fat intake explained up to 73% of the total variance in CHD across these cohorts. In the Nurses' Health Study, the effect of saturated fatty acids was much more modest, especially if saturates were replaced by carbohydrates. The most effective replacement for saturated fatty acids in terms of CHD prevention is by polyunsaturated fatty acids (PUFAs). This agrees with the outcome of large randomized clinical trials, in which replacement of saturated and *trans* fats by polyunsaturated vegetable oils effectively lowered CHD risk.

Trans-Fatty Acids (*t*-FAs)

t-FAs (*Trans*-Fatty Acids) are geometrical isomers of unsaturated fatty acids that assume a saturated fatty acid-like configuration. Partial hydrogenation, the process used to create *t*-FAs, also removes essential fatty acids such as LA (Linoleic Acid) and ALNA (Alpha Linolenic Acid). Metabolic studies have demonstrated that *t*-FAs render the plasma lipid profile even more atherogenic than SFAs, by not only elevating LDL cholesterol to similar levels but also decreasing HDL cholesterol. As a result, the ratio of LDL cholesterol to HDL cholesterol is significantly higher with a *t*-FA diet (2.58) than with a SFA diet (2.34) or an oleic acid diet (2.02). This greatly enhances the risk of CHD. Evidence that intake of *t*-FAs increases the risk of CHD initially became available from large population-based cohort studies in the US and in an elderly Dutch population. Eliminating *t*-FAs from the diet would be an important public health strategy to prevent CHD. Since these are commercially introduced agents into the diet, policy measures related to the food industry practices would be required along with public education. *t*-FAs have been eliminated from retail fats and spreads in many parts of the world, but deep-fat fried fast foods and baked goods are a major and increasing source.

Monounsaturated Fatty Acids (MUFAs)

The only nutritionally important MUFA is oleic acid, which is abundant in olive and canola oils and also in nuts. The epidemiological evidence related to MUFAs and CHD is derived from studies on the Mediterranean diet (see below), as well as from the Nurses' Health Study and other similar studies in the US.

Polyunsaturated Fatty Acids (PUFAs)

PUFAs are categorized as *n*-6 PUFAs (mainly derived from linoleic acid) and *n*-3 PUFAs (mainly present in fatty fish and also derived from alpha-linoleic acid). Clinical trials, in which *n*-6 PUFAs (containing linoleic acid) were substituted for SFAs showed a greater impact on reduction of both plasma cholesterol and CHD risk, in contrast to trials where low-fat diets were employed.

Much of the epidemiological evidence related to *n*-3 PUFAs is derived from the study of fish consumption in populations or interventions involving fish diets in clinical trials. Fish oils were, however, used in a large clinical trial of 11 300 survivors of myocardial infarction. After 3.5 years of follow-up, the fish oil group ($1\,g\,day^{-1}$) had a statistically significant 20% reduction in total mortality, 30% reduction in cardiovascular death, and 45% decrease in sudden death.

The Lyon Heart Study in France incorporated an *n*-3 fatty acid (alpha-linolenic acid) into a diet that was altered to develop a 'Mediterranean diet' intervention. In the experimental group, plasma ALNA and EPA (Eicosapentenoic Acid) increased significantly and the trial reported a 70% reduction in cardiovascular mortality at 5 years. Total and LDL cholesterol were identical in the experimental and control groups, suggesting that thrombotic and perhaps arrhythmic events may have been favorably influenced by *n*-3 PUFAs. Since the diet altered many other variables, such as fiber and antioxidants

(by increasing fruit and vegetable consumption), direct attribution of benefits to *n*-3 PUFAs becomes difficult to establish.

The proportions of SFAs, MUFAs, and PUFAs as constituents of total fat intake and total energy consumption have engaged active attention, in view of the strong relationship of these fatty acids to the risk of CHD. The reduction of SFAs in the diet has been widely recommended, but its replacement has been an area of debate, as to whether the place of reduced SFAs should be taken by MUFAs, PUFAs, or carbohydrate. Both MUFAs and PUFAs improve the lipoprotein profile, although PUFAs are somewhat more effective. In view of this, several recent dietary recommendations suggested that SFAs should be kept below 10% of daily energy intake (preferably reduced to 7–8%), MUFAs should be increased to 13–15%, and PUFAs raised to 7–10% of daily energy, with the total fat contributing to less than 30% of all calories consumed. These may need to be adjusted for populations who consume less quantities of total fat, so as to ensure an adequate intake of MUFAs and PUFAs even under those circumstances. The emphasis is now shifting from the quantity of fat to the quality of fat, with growing evidence that even diets with 30–35% fat intake may be protective if the type of fats consumed are mostly from the MUFA and PUFA categories. Enhancing the nutritional quality of dietary fat consumption, to provide greater cardiovascular protection, may be attempted by decreasing the sources of saturated fats and eliminating *t*-FAs in the diet, increasing the consumption of foods containing unsaturated fatty acids (both MUFAs and PUFAs), and decreasing dietary cholesterol consumption.

Carbohydrates

Diets which are high in refined carbohydrates appear to reduce HDL cholesterol levels and increase the fraction of small dense LDL, both of which may impact adversely on vascular disease. This dyslipidemic pattern is consistent with the elevation of plasma triglycerides and is typical of the 'metabolic syndrome.' Carbohydrate diets with high glycemic index might adversely impact on glucose control, with associated changes in plasma lipids, and have been linked to an increased risk of CHD.

Fiber

Most soluble fibers reduce plasma total and LDL cholesterol concentrations, as reported by several trials. Fiber consumption strongly predicts insulin levels, weight gain, and cardiovascular risk factors like blood pressure, plasma triglycerides, LDL and HDL cholesterol, and fibrinogen. Several large cohort studies in the US, Finland, and Norway have reported that subjects consuming relatively large amounts of whole-grain cereals have significantly lower rates of CHD.

Antioxidants

Though several cohort studies showed significant reductions in the incidence of cardiac events in men and women taking high-dose vitamin E supplements, large clinical trials failed to demonstrate a cardioprotective effect of vitamin E supplements. Beta-carotene supplements also did not provide protection against CHD and, in some trials, appeared to increase the risk.

Folate

The relationship of folate to CVD has been mostly explored through its effect on homocysteine, which has been put forward as an independent risk factor for CHD. Reduced plasma folate has been strongly associated with elevated plasma homocysteine levels and folate supplementation has been demonstrated to decrease those levels. Data from the Nurses' Health Study in the US showed that folate and vitamin B_6, from diet and supplements, conferred protection against CHD (fatal and nonfatal events combined) and suggested a role for their increased intake as an intervention for primary prevention of CHD. Recommendations related to folate supplementation must, however, await the results of ongoing clinical trials. Dietary intake of folate through natural food sources may be encouraged in the meanwhile, especially in individuals at a high risk of arterial or venous thrombosis and elevated plasma homocysteine levels.

Flavonoids and Other Phytochemicals

Flavonoids are polyphenolic antioxidants, which occur in a variety of foods of vegetable origin, such as tea, onions, and apples. Data from several prospective studies indicate an inverse association of dietary flavonoids with CHD. The role of these and other phytochemicals (such as plant stanols and sterols) in relation to CHD needs to be elucidated further.

Sodium and Potassium

High blood pressure (HBP) is a major risk factor for CHD. The relative risk of CHD, for both systolic and diastolic blood pressures, operates in a continuum of increasing risk for rising pressure but the absolute risk of CHD is considerably modified by coexisting risk factors (such as blood lipids and diabetes), many of which are also influenced by diet. A cohort study in Finland observed a 51%

greater risk of CHD mortality with a 100 mmol increase in 24-h urinary sodium excretion. Several clinical trials have convincingly demonstrated the ability of reduced sodium diets to lower blood pressure. A meta-analysis of long-term trials suggests that reducing daily salt intake from 12 g day^{-1} to 3 g day^{-1} is likely to reduce CHD by 25% (and strokes by 33%). Even more modest reductions would have substantial benefits (10% lower CHD for a 3-g salt reduction). The benefits of dietary potassium in lowering blood pressure have been well demonstrated but specific effects on CHD risk have not been well studied. Keeping the dietary sodium:potassium ratio at a low level is essential to avoid hypertension.

Food Items

Fruits and Vegetables

A systematic review reported that nine of ten ecological studies, two of three case–control studies, and six of sixteen cohort studies found a significant protective association for CHD with consumption of fruits and vegetables or surrogate nutrients. In a 12-year follow-up of 15 220 male physicians in the US, men who consumed at least 2.5 servings of vegetables per day were observed to have a 33% lower risk for CHD, compared with men in the lowest category (<1 serving per day). A follow-up study of NHANES (National Health and Nutrition Examination Survey), a large national survey in the US, also reported a coronary protective effect of regular fruit and vegetable intake. Persons who consumed fruits and vegetables 3 or more times a day were at 24% lower risk than those who consumed less than one portion a day. A global study of risk factors of CHD in 52 countries (INTERHEART) also reported low consumption of fruit and vegetables to be a major risk factor, across all regions.

Fish

In the UK diet and reinfarction trial, 2-year mortality was reduced by 29% in survivors of a first myocardial infarction in those receiving advice to consume fatty fish at least twice a week. A meta-analysis of 13 large cohort studies suggests a protective effect of fish intake against CHD. Compared with those who never consumed fish or did so less than once a month, persons who ate fish had a lower risk of CHD (38% lower for 5 or more times a week, 23% lower for 2–4 times a week, 15% lower for once a week, and 11% lower for 1–3 times a month). Each 20 g day^{-1} increase in fish consumption was related to a 7% lower risk of CHD.

Nuts

Several large epidemiological studies, the best known among them being the Adventist Health Study, demonstrated that frequent consumption of nuts was associated with decreased risk of CHD. The extent of risk reduction ranged from 18% to 57% for subjects who consumed nuts more than 5 times a week compared to those who never consumed nuts. An inverse dose–response relationship was demonstrated between the frequency of nut consumption and the risk of CHD, in men as well as in women. Most of these studies considered nuts as a group, combining many types of nuts (walnuts, almonds, pistachio, pecans, macadamia nuts, and legume peanuts).

Soy

Soy is rich in isoflavones, compounds that are structurally and functionally similar to estrogen. Several animal experiments suggest that intake of these isoflavones may provide protection against CHD, but human data on efficacy and safety are still awaited. Naturally occurring isoflavones, isolated with soy protein, reduced the plasma concentrations of total and LDL cholesterol without affecting the concentrations of triglycerides or HDL cholesterol in hypercholesterolemic individuals.

Dairy Products

Dairy consumption has been correlated positively, in ecological studies, with blood cholesterol as well as coronary mortality. Milk consumption correlated positively with coronary mortality rates in 43 countries and with myocardial infarction in 19 regions of Europe.

Alcohol

The relationship of alcohol to overall mortality and cardiovascular mortality has generally been J-shaped, when studied in Western populations in whom the rates of atherothrombotic vascular disorders are high. The protective effect of moderate ethanol consumption is primarily mediated through its effect on the risk of CHD, as supported by more than 60 prospective studies. A consistent coronary protective effect has been observed for consumption of 1–2 drinks per day of an alcohol-containing beverage but heavy drinkers have higher total mortality than moderate drinkers or abstainers, as do binge drinkers.

Composite Diets and CHD

The Mediterranean diet

The traditional Mediterranean diet has been described to have eight components:

1. high monounsaturated-to-saturated fat ratio;
2. moderate ethanol consumption;
3. high consumption of legumes;
4. high consumption of cereals (including bread);
5. high consumption of fruits;
6. high consumption of vegetables;
7. low consumption of meat and meat products; and
8. moderate consumption of milk and dairy products.

Most of these features are found in many diets in that region. The characteristic component is olive oil, and many equate a Mediterranean diet with consumption of olive oil.

A secondary prevention trial of dietary intervention in survivors of a first recent myocardial infarction (the Lyon Heart study), which aimed to study the cardioprotective effects of a 'Mediterranean type' of diet, actually left out its most characteristic component, olive oil. The main fat source was rapeseed oil. Vegetables and fruits were also increased in the diet. On a 4-year follow-up, the study reported a 72% reduction in cardiac death and nonfatal myocardial infarction. The risk of overall mortality was lowered by 56%. Large cohort studies in Greece and in several elderly European population groups have also recently reported a protective effect against CHD and better over all survival in persons consuming a Mediterranean type of diet. The protection was afforded by the composite diet rather than by any single component. Improvement in metabolic syndrome and reduction of inflammatory markers has also been observed with this diet, which may explain part of the protection against CHD.

DASH Diets

A composite diet, employed in the Dietary Approaches to Stop Hypertension (DASH) trials, has been found to be very effective in reducing blood pressure in persons with clinical hypertension as well as in people with blood pressure levels below that threshold. This diet combines fruits and vegetables with food products that are low in saturated fats. The blood pressure lowering effect is even greater when the DASH diet is modified to reduce the sodium content. Though the effects on CHD prevention have not been directly studied, the blood pressure and lipid-lowering effects of the low salt-DASH diet are likely to have a substantial impact on CHD risk.

Vegetarian Diets

A reduced risk of CVD has been reported in populations of vegetarians living in affluent countries and in case–control comparisons in developing countries. Reduced consumption of animal fat and increased consumption of fruit, vegetables, nuts, and cereals may underlie such a protective effect. However, 'vegetarian diets' *per se* need not be healthful. If not well planned, they can contain a large amount of refined carbohydrates and t-FAs, while being deficient in the levels of vegetable and fruit consumption. The composition of the vegetarian diet should, therefore, be defined in terms of its cardioprotective constituents.

Prudent versus Western Patterns

In the Health professionals follow-up study in the US, a prudent diet pattern was characterized by higher intake of vegetables, fruits, legumes, whole grains, fish, and poultry, whereas the Western pattern was defined by higher intake of red meat, processed meat, refined grains, sweets and dessert, French fries, and high-fat dairy products. After adjustment for age and other coronary risk factors, relative risks, from the lowest to the highest quintiles of the prudent pattern score, were 1.0, 0.87, 0.79, 0.75, and 0.70, indicating a high level of protection. In contrast, the relative risks, across increasing quintiles of the western pattern, were 1.0, 1.21, 1.36, 1.40, and 1.64, indicating a mounting level of excess risk. These associations persisted in subgroup analyses according to cigarette smoking, body mass index, and parental history of myocardial infarction.

Japanese Diet

The traditional Japanese diet has attracted much attention because of the high life expectancy and low CHD mortality rates among the Japanese. This diet is low in fat and sugar and includes soy, seaweeds, raw fish, and a predominant use of rice. It has been high in salt, but salt consumption has recently been declining in response to Japanese Health Ministry guidelines.

Prevention Pathways

The powerful relationship of specific nutrients, food items and dietary patterns to CHD has been persuasively demonstrated by observational epidemiological studies (which indicate the potential for primary

prevention in populations) and by clinical trials (which demonstrate the impact on secondary prevention in individuals).

Atherosclerotic vascular diseases (especially CHD) are multifactorial in origin. Each of the risk factors operates in a continuous manner, rather than across an arbitrary threshold. When multiple risk factors coexist, the overall risk becomes multiplicative. As a result of these two phenomena, the majority of CHD events occurring in any population arise from any individuals with modest elevations of multiple risk factors rather than from the few individuals with marked elevation of a single risk factor.

These phenomena have two major implications for CHD prevention. First, it must be recognized that a successful prevention strategy must combine population-wide interventions (through policy measures and public education) with individual risk reduction approaches (usually involving counseling and clinical interventions). Second, diet is a major pathway for CHD prevention, as it influences many of the risk factors for CHD, and can have a widespread impact on populations and substantially reduce the risk in high-risk individuals. Even small changes in blood pressure, blood lipids, body weight, central obesity, blood sugar, inflammatory markers, etc., can significantly alter the CHD rates, if the changes are widespread across the population. Modest population-wide dietary changes can accomplish this, as demonstrated in Finland and Poland. At the same time, diet remains a powerful intervention to substantially reduce the risk of a CHD-related event in individuals who are at high risk due to multiple risk factors, prior vascular disease, or diabetes.

A diet that is protective against CHD should integrate: plenty of fruits and vegetables (400–600 g day^{-1}); a moderate amount of fish (2–3 times a week); a small quantity of nuts; adequate amounts of PUFAs and MUFAs (together constituting about 75% of the daily fat intake); low levels of SFAs (less than 25% of the daily fat intake); limited salt intake (preferably less than 5 day^{-1}); and restricted use of sugar. Such diets should be culturally appropriate, economically affordable, and based on locally available foods.

National policies and international trade practices must be shaped to facilitate the wide availability and uptake of such diets. Nutrition counseling of individuals at high risk must also adopt these principles while customizing dietary advice to specific needs of the person. CHD is eminently preventable, as evident from research and demonstrated in practice across the world. Appropriate nutrition is a major pathway for CHD prevention and must be used more widely to make CHD prevention even more effective at the global level.

CYSTIC FIBROSIS

J Dowsett and O Tully, St Vincent's University Hospital, Dublin, Ireland

Definition and Etiology

Cystic fibrosis (CF) is a multisystem autosomal recessive disorder caused by the mutation of a single gene on the long arm of chromosome 7 that codes for the cystic fibrosis transmembrane regulator (CFTR). This protein regulates the passage of chloride through the membrane of secretory epithelia; the dysfunction of which results in an altered composition of epithelial secretions. Clinically, CF is characterized by chronic pulmonary infection with periods of acute exacerbation, pancreatic insufficiency and excessive losses of sweat electrolytes. The latter forms the basis for the diagnostic test. The mutated gene was identified in 1989 and since then over 800 CFTR mutations have been reported, the most common of these being △ F508.

Prevalence

Approximately 5% of the Caucasian North European and North American populations are carriers of the gene defect causing CF, leading to an approximate incidence of 1 in 2500 live births. This inheritance is illustrated in **Figure 1**. The incidence of CF in non-Caucasians is much lower and estimated to be around 1 in 100 000 in Oriental populations.

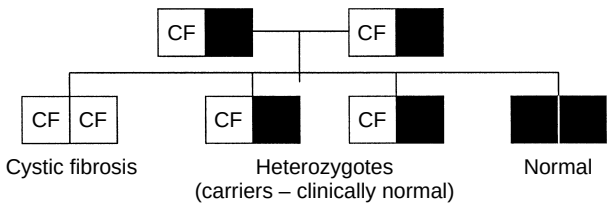

Figure 1 Mode of inheritance of CF: a Mendelian inherited recessive characteristic.

Prognosis

The median age of survival has dramatically risen from approximately 2 years in the 1940s to around 30 years in the 1990s. A current survival estimation following diagnosis is approximately 40 years. This improved prognosis can be attributed to a combination of factors including aggressive management of infections, effective antibiotics, improved nutritional management, modern physiotherapy techniques, and the centralization of treatment in specialist centers. The survival age for females with CF would appear to be less than that for males. This may be related to poorer nutritional status amongst female CF patients. Expert management started immediately after an early diagnosis of CF by neonatal screening results in an important beneficial effect on outcome and may be critical to the clinical course of the condition and long-term prognosis. Even though optimized nutrition, antibiotics, and chest physiotherapy remain the mainstay of CF management, new approaches to treatment are being developed that may add to the traditional medical therapy for CF. As prognosis and survival improves nutritional related issues become more prevalent including the effective management of pregnancy, diabetes, osteoporosis, and transplantation.

Clinical Features

The clinical features of CF are listed in **Table 1**.

Pathogenesis of Lung Disease

Pulmonary disease can be demonstrated within the first few months of life. Bacterial infection is characterized by high levels of neutrophils and mediators of infection in the form of interleukin 1, 8 and elastases. Mucous glands become dilated leading to obstruction, secondary infection, and progressive lung damage. Frequent periods of respiratory infection and exacerbation are common in CF with increased cough, increased sputum production, and shortness of breath. The immune response appears

Table 1 Clinical features of CF

Respiratory features of cystic fibrosis	
Atelectasis	Incomplete expansion of a lung or part of a lung due to airlessness or collapse
Bronchiectasis	Chronic dilatation of the bronchi associated with coughing and expectoration of purulent mucus
Bronchitis	Inflammation of one or more bronchi
Pneumonia	Inflammation of the lungs with air spaces becoming filled with exudates
Pneumothorax	An accumulation of air in the pleural space
Gastrointestinal features of cystic fibrosis	
Cholelithiasis	The presence or formation of gallstones
Cirrhosis	Liver disease characterized by loss of normal liver tissue and fibrosis
Distal intestinal obstruction syndrome	Blockage of the bowel with feces, mucus, and undigested food
Gastroparesis	Paralysis of the stomach or delayed gastric emptying
Malabsorption	Impaired intestinal absorption of nutrients
Maldigestion	Impaired intestinal digestion of nutrients
Meconium ileus	Blockage of the bowel with meconium
Osteoporosis/ Osteopenia	Reduction in bone mass
Pancreatic insufficiency	Reduction of enzyme production from the pancreas
Portal hypertension	High pressure in the portahepatic artery
Rectal prolapse	Protrusion of the rectal mucous membrane through the anus
Splenomegaly	Enlargement of the spleen

to be of great significance. Chronic inflammation has been cited as the cause of so much of the lung damage seen in CF. Steroidal anti-inflammatory drugs have been shown to be beneficial but have nutritional side effects such as hyperglycemia and osteoporosis. Nonsteroidal anti-inflammatory drugs such as ibuprofen have been used in some centers with positive results but their long-term effect on renal function is not yet known. The impact of malnutrition on lung disease and respiratory muscle function has been extensively studied in patients with CF. Malnutrition and deterioration of lung function are interdependent. Prevention of malnutrition from the time of diagnosis is associated with better lung function and improved survival.

Gastrointestinal Complications

Individuals with CF can develop a variety of gastrointestinal (GI) disorders related to the pathophysiological changes associated with CF. Pancreatic insufficiency, which is present in the majority of CF patients leads to many of the GI manifestations of CF including steatorrhea, abdominal pain, distal intestinal obstruction syndrome (DIOS), and rectal prolapse. Gastroesophageal reflux (GOR) occurs frequently in CF due to decreased lower esophageal sphincter pressure and is usually treated by proton pump inhibitors. In patients with advanced lung disease vomiting is common after strenuous bouts of coughing and this over time may lead to decline in nutritional status. Peptic ulcer disease, pancreatitis, and intussusception also occur to varying degrees in patients with CF. Crohn's disease and celiac disease occur more frequently in the CF population than in controls and gastrointestinal tumors, although rare, have an increased incidence in CF.

Meconium ileus is the presenting complaint in up to 15% of infants with CF. This is a condition in which the small intestine is blocked with tenacious meconium and surgical intervention is required to correct it. Excessive mucus in the small bowel of patients with CF can provide a physical barrier to the absorptive surface. Undigested or unabsorbed food in association with this mucus, and possibly a reduced gut motility, can lead to a partial or complete obstruction of the GI tract in older children and adults known as meconium ileus equivalent, or more accurately distal intestinal obstruction syndrome (DIOS). This is a condition specific to CF. The usual clinical presentation is one of abdominal pain, abdominal distension, and constipation. It can be precipitated by dehydration, change in eating habits, change in enzyme brand or dose, or immobility. DIOS is treated with a laxative regime and should have a diet and enzyme review.

CF-Related Diabetes Mellitus (CFRD)

Diabetes requiring insulin is the most common comorbidity in CF. The islets of Langerhan are the last cells to be damaged in the process of fibrosis of the pancreas. The incidence of diabetes in CF has been reported to be 8–15% but this may be underestimated due to lack of screening. It is estimated that 50% of patients over 30 years will have some degree of glucose intolerance. The primary cause of CFRD is insulin deficiency secondary to pancreatic fibrosis. Diagnostic criteria for CFRD are the same as for non-CF-related diabetes. Glucose metabolism is also affected by many factors including infection, malabsorption, abnormal intestinal transit time, and steroid use, all features of CF. While CFRD shares many of the characteristics of both type 1 and type 2

diabetes, it is itself a distinct clinical condition. Hyperglycemia may adversely influence weight and pulmonary function and as the age of survival increases may lead to the development of microvascular complications. Retrospective studies have shown in those presenting with overt diabetes mellitus, deterioration in weight and respiratory status for 2 years before diagnosis are reversed once insulin therapy is instituted. A program of multiple daily insulin injections and self-monitoring of blood glucose with the aim of normoglycemia is the preferred treatment with regular follow-up with the Endocrinology team. All patients with CF should be screened annually for CFRD using the oral glucose tolerance test. Minimal dietary restrictions are imposed on this group of patients in an attempt to maximize nutritional intake. See section on dietary management of CF.

Liver Disease

Another complication associated with increased longevity in CF is liver disease, which affects between 2 and 37% of adults with CF. The development of liver disease in CF has been attributed to the blockage of small bile ductules with thick secretions, and the subsequent development of progressive cholestasis, biliary fibrosis, and eventually biliary cirrhosis and portal hypertension. The persisting acidic conditions in the upper small bowel lead to bile salt precipitation and defective lipid emulsification. Unhydrolyzed fat and other products of maldigestion may interfere with bile acid reabsorption in the terminal ileum, thereby reducing the total bile salt pool. Fecal losses of primary and secondary bile acids leads to an imbalance of bile salts, which further increases the viscosity of the already tenacious bile. Treatment with ursodeoxycholic acid has led to an improvement in bile excretion and liver function tests. Complications of liver disease including ascites, gastro and esophageal varices may further exacerbate a patient's nutritional status. In a small number of patients liver failure may require liver transplantation. See section on dietary management of CF.

Nutritional Management

Aggressive nutritional management of patients with CF is key in their overall management. Nutritional management of CF involves maximizing dietary intake, minimizing malabsorption and maldigestion, monitoring vitamin intakes and serum levels, and adapting eating patterns in the event of diabetes, osteoporosis, DIOS, or liver disease. Nutritional support in the form of nocturnal gastrostomy feeding may be necessary if nutritional failure persists ($BMI < 18.5\,kg/m^2$). It is well recognized that the malnutrition seen in CF is due to an energy imbalance caused by three main factors: decreased dietary intake, increased energy requirements, and increased energy losses. There appears to be a direct association between the degree of malnutrition and the severity of pulmonary disease, affecting overall prognosis. Many patients are capable of balancing these factors effectively and have a normal growth velocity and good nutritional status. However, as lung function deteriorates, energy requirement increases and appetite decreases leading to a loss of energy stores and lean tissue further contributing to progressive deterioration of lung function (see **Figure 2**).

Decreased Dietary Intake

People with CF are advised to consume a diet high in energy with no fat restriction. Prior to the development of enteric-coated enzymes in the mid 1980s, patients with CF were advised to follow a low-fat diet in an attempt to minimize fat malabsorption and steatorrhea. Unfortunately, older patients continue this practice as they have developed an aversion to fatty foods after many years of avoiding them. Decreased dietary intake secondary to anorexia is common in CF and can become more of a problem during recurrent chest infections. There have also been an increased number of reports of eating disorders and abnormal eating behavior in the CF population. In addition polypharmacy, repeated exacerbations of CF, organomegaly, gastrointestinal problems, food intolerance, and poor social circumstances can reduce oral intake.

Increased Energy Requirements

Energy requirements are increased during periods of infection by catabolism and fever and continue to increase with advanced pulmonary disease. It has been estimated that CF patients require 120–150% of the estimated average requirement for energy. As pulmonary function deteriorates, mobility also decreases and overall energy expenditure is reduced as a result. Owing to the heterogenicity of CF the energy requirements of individuals will vary and should be assessed on an individual basis. Energy losses through sputum may also be significant in a patient with a marginal energy intake. Salbutamol, often used as a bronchodilator in CF, can increase basal metabolic rate.

Increased Energy Losses

Pancreatic changes are caused by the obstruction of small ducts with thick secretions and cell debris.

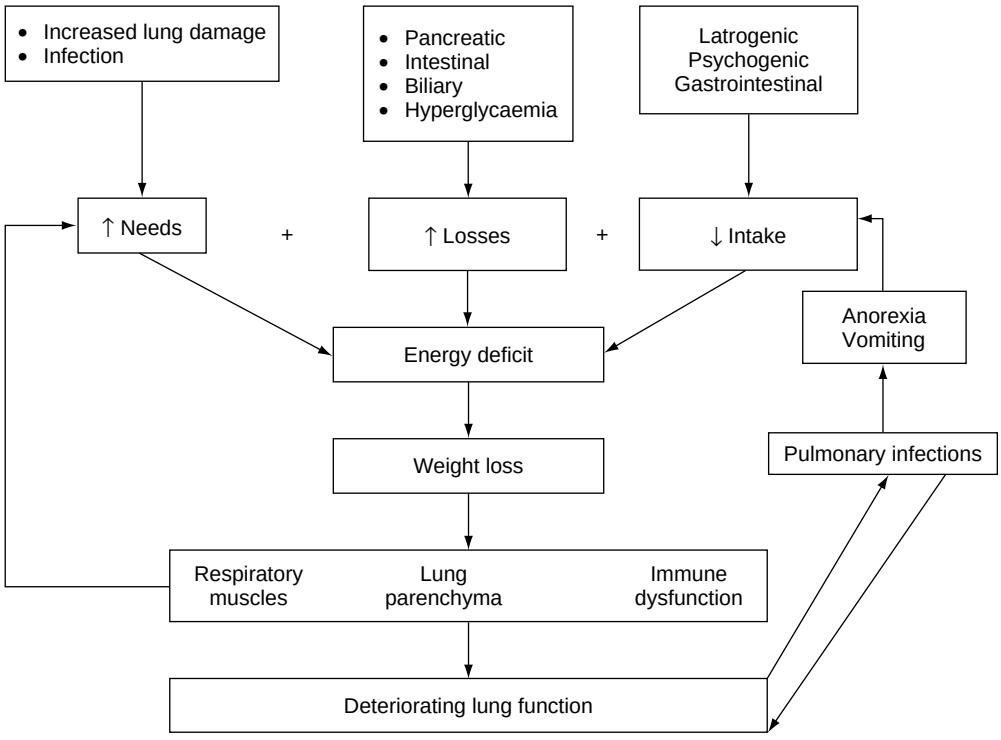

Figure 2 Interdependent factors that may give rise to progressive energy deficit as lung function deteriorates.

Functional tissue becomes replaced with fibrotic tissue leading to pancreatic exocrine insufficiency when more than 90% of the normal structure of the pancreas is lost. Pancreatic insufficiency is the most common gastrointestinal manifestation in CF, occurring in at least 95% of patients. The production of pancreatic secretions including enzymes and bicarbonate is reduced, necessitating pancreatic enzyme replacement therapy (PERT). PERT is supplied in the form of gelatin capsules containing microspheres, which are swallowed whole with food. The capsule dissolves within the stomach and releases the microspheres, which are protected from the gastric acid by an enteric coating. Enzymes should be taken immediately before or during a meal to maximize their efficacy. The microspheres mix with the stomach contents and pass through the pylorus into the duodenum where they become activated. Microspheres should be less than 1.5 mm in diameter to ensure they leave the stomach with food. Fibrosis of the pancreas tends to be a progressive process so increasing amounts of oral enzyme supplements are often required as patients get older. All people with CF have some level of pancreatic dysfunction but requirements of enzymes are variable and must be assessed individually. Clinically, the aim of PERT is to correct symptomatic steatorrhea, relieve any abdominal pain, reduce the mass and frequency of stool passed, and achieve weight gain within normal limits.

The enteric coating on enzyme supplements is designed to dissolve at a pH of 6, the optimal pH for pancreatic enzymatic action. Owing to the reduced production of bicarbonate and the resulting lower pH of the duodenum in patients with CF, the enteric coating of the enzyme may fail to dissolve so that the enzyme does not become activated at the absorptive surface of the small bowel. Increasing the duodenal pH by taking proton pump inhibitors may improve absorption. Changing the brand of enzyme may also improve absorption as dissolution characteristics of the enteric coating and proportions of enzymes contained within the microspheres vary. Patients should be dissuaded from chewing enzymes as this breaks the enteric coating and leads to deactivation in the acid medium of the stomach. Even with maximal PERT it has been estimated that between 10 and 20% of ingested fat will be malabsorbed. Colonic strictures known as fibrosing colonopathy (FC) in CF populations receiving high-potency enzymes with a more concentrated dose of lipase and protease per capsule have been reported The etiology of this FC remains unclear. Recently, it has been suggested that FC may be related to the presence of methacrylic acid copolymer (MAC) coating present in some preparations rather than

actual enzyme strength. Some adult patients continue to take high-dose enzymes and are advised to do so within recommended levels. The working group on PERT use recommends that no more than 10 000 units of lipase per kilogram body weight be taken per day.

Dietary Management of CF

Patients with CF are encouraged to consume a diet providing 150% of the recommended intake for age and sex. However, this is only a guideline, since in practice the energy requirement for a patient with CF is that which maintains their ideal body weight when malabsorption has been controlled. Maximizing energy intake from everyday foods should be the initial step in the promotion of a high-energy diet. As fat is the most concentrated source of energy in the diet, liberal use of fat should be encouraged; this can best be achieved by recommending frequent consumption of high-fat meals and snacks including confectionery, desserts, and cakes. PERT should be dosed accordingly.

Dietary Supplements

The energy intake of many patients with CF is commonly suboptimal. Many patients find it difficult to eat sufficient food daily to attain or maintain their ideal body weight. During a respiratory exacerbation of CF, energy requirements are at a maximum, but appetite is often reduced. Dietary supplements in the form of sip feeds can be a useful adjunct to a high-energy diet. Care should be taken to ensure that supplements are used in addition to a diet and not as a substitute for normal foods.

Enteral Feeding

When diet and oral dietary supplements are undesirable or ineffective and nutritional failure persists, i.e., BMI $<18.5\ kg/m^2$, enteral feeding should be considered. Research has demonstrated a sustained weight gain and a slowing decline in respiratory function associated with supplemental enteral feeding. Artificial nutritional support can be provided via nasogastric or gastrostomy tube depending on patient preference. Gastrostomy feeding is becoming more popular, whether passed endoscopically or under fluoroscopic guidance. The introduction of low-profile gastrostomy feeding tubes or 'button' tubes have made this method of nutritional support more acceptable of patients. The type of feed used and the PERT given with it, varies between centers. Feeds are usually administered overnight in an attempt to provide 30–50% of energy requirements and to allow for maximal oral intake during the day. Gastrostomy feeds can be used over longer periods during periods of acute pulmonary infection, loss of appetite, or in the severely malnourished patient. Patients with a previous poor intake should be monitored for refeeding syndrome.

Specific Dietary Considerations

There are some medical complications of CF that warrant particular nutritional attention.

Liver Disease

Patients with liver disease as a complication of their CF may have ascites, gastric, or esophageal varices, all of which may affect nutritional status and options for nutritional support. Dietary management of the patient with CF and liver disease centers on maximizing energy intake and is best achieved by encouraging small, frequent, energy-dense meals, snacks, and drinks. Suboptimal oral intake can arise in patients with hepatomegaly or splenomegaly, who often have a feeling of fullness after eating referred to as the 'small stomach syndrome.' The benefits of gastrostomy insertion should be carefully weighed in the patient with gastric varices or splenomegaly due to risk of bleeding. A moderate sodium restriction may alleviate ascites. If coagulation is impaired, supplementation with vitamin K may be indicated.

Treatment of liver disease in CF is with ursodeoxycholic acid, which has a positive effect on liver enzymes. Whether this improvement is associated with improvement in nutritional status is unknown.

Cystic Fibrosis-Related Diabetes (CFRD)

The dietary treatment of CF-related diabetes varies from standard diabetic dietary advice. The principle of the diet centers on maintaining caloric intake whilst ensuring glycemic control. The treatment of CFRD should enhance rather than impair a patient's nutritional status. This is done by encouraging a high-fat diet and confining the intake of refined carbohydrate to mealtimes. Insulin doses should be increased so as to maximize the flexibility of the diet, particularly in those patients who are already nutritionally compromised Patients taking oral nutritional supplements and/or overnight gastrostomy feeds need to have their insulin doses carefully monitored and adjusted accordingly.

Bone Disease in CF

Osteopenia and osteoporosis are now widely recognized in the CF population. There are a number of contributing factors to this early development of bone disease including steroid usage, malabsorption of calcium and, more importantly, vitamin D, poor nutritional status, decreased levels of physical activity, and a reduced peak bone mass in CF patients compared to healthy individuals. Assessment of bone health is by dual energy X-ray absorptiometry (DXA) scanning and there are a variety of treatment options available depending on the severity of disease ranging from dietary calcium and vitamin D supplementation to the use of bisphosphonate drugs, which aim to halt the progression of bone loss and promote bone formation.

Fertility Issues

As the number of people with CF of a reproductive age increases, so does the incidence of pregnancy in this group. Although almost all males with CF are infertile owing to the absence of the vas deferens, most females are fertile. Pregnancy in women with CF requires special nutritional attention with regular monitoring, particularly with respect to adequate weight gain, and vitamin and mineral status.

Body Composition Studies in CF

Studies of body composition in CF patients have shown deficits in total body mass, lean body mass, and body fat, which affect body density. As skinfold thickness percentiles are derived from body density, it has been suggested that the assessment of the body fat content of children with CF using, or derived from, body density such as skinfold thickness is invalid. Muscle function indices have been shown to respond to refeeding in malnourished patients with CF before body composition or biochemical indices of protein status improved, and so appear to be sensitive markers of nutritional status.

Assessment of Nutritional Status

Malnutrition in CF remains a major clinical problem. Growth and nutritional status should be monitored at each clinic visit to ensure early detection of any deterioration, and to prompt appropriate nutritional intervention. The many factors that complicate nutritional status in CF are shown in **Table 2**.

When weight falls to a BMI of less than 18.5 kg/m^2 nocturnal enteral feeding should be considered. At diagnosis and when the patient shows clinical deterioration the following should be determined:

Table 2 Factors affecting nutritional status

- Variation in gene mutation
- Frequency of pulmonary exacerbations
- Gastroesophageal reflux
- Distal intestinal obstruction syndrome
- Pancreatitis
- Liver disease
- Diabetes mellitus
- Drug therapy
- Dietary dislikes and misconceptions
- Psychological problems/eating disorders
- Pregnancy
- Transplantation

electrolytes, serum albumin and other liver function tests, oral glucose tolerance test, full blood count, serum retinol, and alpha tocopherol. If there is any evidence of iron deficiency, iron status should be assessed. Other medical disorders should be considered in the evaluation of nutritional failure. These include diabetes mellitus, liver disease, Crohn's disease, celiac disease, chronic abdominal pain, DIOS, and esophagitis.

Vitamin Status in CF

At least 85% of CF patients have some level of pancreatic insufficiency leading to a degree of fat malabsorption. For this reason, unless supplemented, most patients are at risk of developing either clinical or subclinical deficiencies of the fat-soluble vitamins, vitamin A, D, E, and K. Those most at risk appear to be individuals with poorly controlled malabsorption, poor adherence to treatment, liver disease, bowel resection, or following a late diagnosis.

Vitamin A

Vitamin A should be supplemented at a dose of 4000–10 000 IU per day. However, low serum levels of retinol have been noted even at this dose. If retinol levels are persistently low despite adequate supplementation, an assessment of compliance, retinol-binding protein (RBP), and zinc levels should be checked. Special care should be given to vitamin A supplementation during pregnancy as high levels are reported to be teratogenic.

It is important to consider hepatotoxicity with large supplemental doses of vitamin A in a patient who may store vitamin A in the liver, yet shows low serum levels of retinol, and who may display ocular signs of deficiency. The free alcohol retinol is almost entirely attached to RBP, which is synthesized in the liver. Decreased levels of RBP, which may occur in up to 25% of patients with CF, may be due to an

abnormality in its production by the liver, zinc deficiency, or protein energy malnutrition. Even with adequate vitamin supplementation and pancreatic enzyme replacement treatment, up to 20% of patients may have ocular signs of deficiency of retinol. Xerosis may improve by increasing the dose of vitamin A alone, or combined with zinc. It has been suggested that there may exist a specific defect in the handling of retinol in the GI tract of people with CF unrelated to the level of fat malabsorption. A correlation has been demonstrated between low levels of vitamin A and poor lung function.

Beta-Carotene

Beta-carotene is one of the carotinoids present in plasma and a precursor of vitamin A. It is effective as an antioxidant at lower oxygen saturation states than vitamin E. It has a biological role as a lipid-soluble chain-breaking antioxidant in biomembranes. Routine supplementation with beta-carotene could diminish lipid peroxidation and improve essential fatty acid status.

Vitamin D

Vitamin D deficiency may be caused by malabsorption, underexposure to sunlight or defects in metabolism due to liver disease. Even though skin exposure to sunlight is the major source of vitamin D, serum concentrations will vary between individuals depending on endogenous production in the skin. Rickets as a result of vitamin D deficiency is rare but has been described in CF. Osteopenia and retarded bone maturation have been reported in a number of CF patients, even with supplementation to recommended levels. Bone density has been shown to be significantly decreased in all sites compared with that of normal young adults. Other variables such as activity levels and nutritional status have not been adequately researched, although the incidence of osteoporosis was found to be higher in those patients with severe respiratory disease. To attain and maintain normal serum levels a daily dose of 400–2000 IU is generally required in adults.

Vitamin E

Cholestasis and a reduced enterohepatic circulation of bile acids contribute to the malabsorption of fat-soluble vitamins from the small intestine. Vitamin E is highly lipophilic and deficiency correlates with degree of fat malabsorption. Subclinical neuroelectrophysiological abnormalities are already present in about 40% of patients by 2 months of age. Neurological signs of vitamin E deficiency are responsive to supplementation if initiated early but are irreversible if treatment starts after the neurological lesions are present. As circulating alpha tocopherol is transported in the blood attached to lipid it is should be expressed as a ratio to total lipid to be correctly interpreted. Current recommendations are to monitor serum vitamin E levels annually and adjust supplementation accordingly. A daily dose of 400 IU per day should achieve normal serum levels in adults.

Vitamin K

A review of the literature provides conflicting opinions in the area of routine supplementation of vitamin K as the prevalence of vitamin K deficiency has not been established. Theoretically, the risk factors for patients developing vitamin K deficiency are pancreatic insufficiency, severe liver disease, extensive small bowel resection, and chronic broad-spectrum antibiotic use. Monitoring the coagulation system is advised, as vitamin K estimations are not generally routinely available. It seems prudent to prescribe vitamin K supplements to patients with the above risk factors. Vitamin K has recently been shown to play an important role in bone health. There are no specific guidelines on supplementation, but doses of 5–10 mg appear to be a prudent guide. Annual monitoring of fat-soluble vitamin levels should be carried out and doses of vitamins altered as appropriate.

Water-Soluble Vitamins

Supplementation with water-soluble vitamins is, in general, thought to be unnecessary in CF. In cases where dietary intake is poor or unbalanced, supplementation of vitamin C is advised. Supplementation with other water soluble vitamins is not routinely recommended.

Mineral Status in CF

Fat malabsorption can lead to the formation of insoluble fatty acid complexes with minerals in the gut, leading to a reduction in their absorption. CF may also be associated with intestinal mucosal defects, which may further retard the absorption of nutrients. Suboptimal levels of zinc, selenium, manganese, and iron have all been described in CF. Routine iron supplementation is not recommended as it has been suggested that *Pseudomonas aeruginosa* grows in tissues with a high concentration of iron. In addition, levels of iron may be suppressed as a normal body response in times of infection, and attempting to correct this is potentially harmful. Sodium and chloride do not need to be

supplemented unless in very hot climates or during excessive exercise.

The Oxidant/Antioxidant Imbalance in CF

Patients with CF frequently exhibit increased oxygen free radical generation from activated neutrophils due to chronic lung inflammation. This, coupled with antioxidant deficiencies due to exocrine pancreatic insufficiency, results in an oxidant/antioxidant imbalance. Consequently, free radical attack on unsaturated fatty acids of lipid structures occurs leading to lipid peroxidation. An efficient antioxidant supply is suggested to control tissue damage by restoring the oxidant/antioxidant balance.

Conclusions

There is a complex relationship between physiological, environmental, and genetic variables leading to a great variability in energy requirements among individuals with CF. Despite advances in the treatment of CF the need for good nutritional strategies in CF will continue. Individually tailored nutritional advice for each patient with CF by a dietitian experienced in the area of CF is essential.

CYTOKINES

R F Grimble, University of Southampton, Southampton, UK

Chemistry and Classification

Cytokines comprise a wide range of proteins that are released mainly from cells of the immune system in response to invasion of animals by pathogens or severe injury. Cytokines induce a state of inflammation in the body and modulation in the activity of the immune system. Research shows that cytokine production is not restricted to cells in the immune system, but that fibroblasts, endothelial cells, adipocytes, and specialized tissues, such as the ovary, produce cytokines. Although largely influencing immune function, a number of cytokines act as growth factors and lead to the proliferation and differentiation of a wide range of cell populations in the body. Cytokines are proteins of low molecular weight. They act generally in an autocrine or paracrine fashion and are active in the subnanomolar range. Cytokines are subclassified as interleukins (ILs), tumor necrosis factors (TNFs), interferons, and colony-stimulating factors. Examples from the family of cytokines are detailed in **Table 1**. All influence cells of the immune system; however,

Table 1 Main properties of the pro-inflammatory cytokines

Cytokine	*Mol. wt*	*Cell sources*	*Main cell targets*	*Main actions*
Interleukin-1α Interleukin-1β	33 000 17 500	Monocytes, macrophages, astrocytes, epithelial cells, endothelium, fibroblasts, dendritic cells	Thymocytes, neutrophils, T and B cells, skeletal muscle, hepatocytes	Immunoregulation, inflammation, fever, anorexia, acute-phase protein synthesis, muscle proteolysis, enhanced gluconeogenesis
Interleukin-6	20 000	Macrophages, T cells, fibroblasts, some B cells	T and B cells, thymocytes, hepatocytes	Acute-phase protein synthesis, immune cell differentiation
Tumor necrosis factor-α	50 000 (trimer)	Macrophages, lymphocytes	Fibroblasts, endothelium, skeletal muscle hepatocytes	As for IL-1

only three exert metabolic effects upon the host. These are denoted as pro-inflammatory cytokines IL-1, IL-6, and TNF-α. A summary of the cell sources, main cell targets, and actions of the proinflammatory cytokines is shown in **Table 1**.

Metabolism and Metabolic Functions

Widespread metabolic changes occur as a result of cytokine production (**Figure 1**). These responses are powerful, focused, and dangerous to both host and pathogens. A hostile environment for pathogens is created within the body by the release of oxidant molecules (superoxide, hydrogen peroxide, perchlorous acid, and nitric oxide) from phagocytes.

Nutrients are provided for the immune system as a result of wasting of peripheral tissues. Amino acids released as a consequence of increased proteolysis in muscle, skin, and bone provide substrate for the synthesis of cells in the system. Glutamine, released from muscle, and glucose, derived from increased hepatic gluconeogenesis of amino acids, are major sources of nutrition for the immune system. Likewise, increased lipolysis in adipose tissue provides fatty acids as metabolic fuel for the body. Zinc, an important cofactor in DNA synthesis, is released from peripheral tissues, incorporated into the zinc transporting protein metallothionein in liver and kidney, and subsequently utilised by the immune system. A loss of appetite often occurs. This may be purposeful in permitting a situation in which substrate is more closely tailored to the requirements of the immune system than would occur from the vagaries of habitual dietary intake. This concept, however, is a matter of debate. Nonetheless, it is important that the immune system receives a guaranteed source of nutrition immediately after the body is infected or damaged because bacterial cells

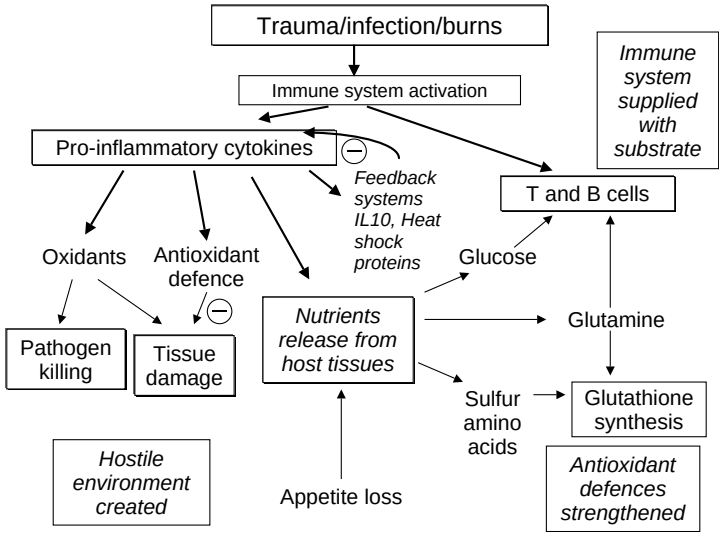

Figure 1 The coordinated actions of cytokines upon metabolism designed to defeat pathogens and protect the host. The resultant effects are shown in italics.

multiply at least 50 times more rapidly than T cells under favorable conditions. Under the actions of cytokines, the metabolic activity of the liver is greatly enhanced and modified. Large increases in the rates of gluconeogenesis, glycogen breakdown, and urea and fat synthesis occur. Blood glucose, urea, and triacylglycerol concentrations may rise. The increase in triacylglycerol levels may have functional importance due to the ability of these molecules to bind and neutralize endotoxin, thereby reducing the impact of this toxic bacterial product upon the host. Paradoxically, however, metabolism of xenobiotics is decreased due to a reduction in the activity of cytochrome P450. The profile of export proteins synthesized by the liver is changed, synthesis of albumin is reduced, and the synthesis of a group of proteins closely associated with inflammation (acute-phase proteins) is increased. Acute-phase proteins are multifunctional and include caeruloplasmin (an antioxidant and copper transport protein), C-reactive protein (to improve macrophage activity), fibrinogen (for blood clotting), complement proteins (for enhanced phagocytosis and pathogen destruction), and metallothionein (a zinc transport protein).

The antioxidant defences of the body are strengthened by increases in the activities of superoxide dismutase, catalase, glutathione peroxidase, and reductase and by increases in the hepatic synthesis of the reduced form of glutathione (GSH). The liver thus becomes the main focus for the synthesis of molecules for the nutrition, support, and direction of the immune system and for the protection of the body from the adverse effects of cytokine action. Indeed, when the ability of the liver of patients with sepsis (a severe clinical form of inflammation induced by infection) to extract amino acids from the circulation was assessed, it was found that the livers of patients who subsequently died had only half of that of livers of patients who survived.

A number of molecules synthesized in enhanced amounts when cytokines are produced are part of complex feedback systems that limit cytokine production and effects (**Figure 2**). These include GSH and some acute-phase proteins that suppress cytokine production and also cytokine receptor antagonist molecules for IL-1 and TNF. The first two types of molecule are derived from liver and the last two from lymphocytes and the cellular targets for TNF, respectively. Other molecules also moderate cytokine actions. Anti-inflammatory cytokines such as IL-10 and heat shock proteins exert an anti-inflammatory influence in the latter stages of the inflammatory response. This downregulation of inflammation, once the infectious agent has been defeated, is important for survival since the inflammatory process has a large capacity to deplete the body. The balance between the pro- and anti-inflammatory process is of key importance for survival since excessive production of IL-10 has been associated with increased mortality.

Role in Disease and Disease Processes

Despite the importance of cytokines in protecting the host from pathogens, the molecules may have damaging and even lethal effects on the host. Thus, the response of the host to a pathogen may play as significant a part in the demise of the host as the effects of the pathogen. Cytokines may also play a major role in tissue damage in chronic inflammatory disease, in which no infective agent is operating. Excessive or inappropriate cytokine production has been associated with increased morbidity and mortality in a wide range of diseases and conditions in which inflammation plays a role. These include

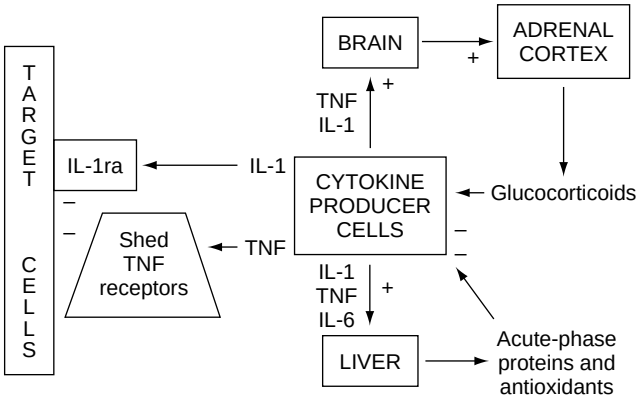

Figure 2 Innate systems for controlling the production and actions of pro-inflammatory cytokines. Stimulatory actions are indicated by plus signs and inhibitory actions by minus signs.

diseases where the immune system is clearly interacting with invading pathogens, such as malaria, meningitis, sepsis, and AIDS, and conditions such as asthma, inflammatory bowel disease, rheumatoid arthritis, and cancer, in which inflammatory disease develops without obvious involvement of pathogens. Furthermore, pro-inflammatory cytokines may be involved in the progression of disease processes such as plaque development in atherosclerosis and demylination in multiple sclerosis and Alzheimer's disease (**Figure 3**).

Damage may also be exerted on the host by release of free radicals and other oxidant molecules that are also released from phagocytic cells in response to the inflammatory stimulus and IL-1 and TNF. Furthermore, oxidant molecules upregulate production of IL-1, TNF, and IL-8 by activation of the transcription factor, nuclear factor-kappa B (NF-κB). The factor is normally held quiescent in the cytoplasm due to attachment of an inhibitory component (IκB) to it. In the presence of oxidants, IκB dissociates from NF-κB, migrates to the nucleus, and brings about the transcription of a large range of genes associated with the inflammatory process (**Figure 4**). Unfortunately, the human immunodeficiency virus (HIV) has an NF-κB response element on its genome. Thus, a by-product of the inflammatory response is increased replication of this virus and progression toward AIDS.

The fact that insulin resistance and disordering of lipid metabolism occur in obesity, diabetes mellitus, and during the inflammatory response has led to investigation of the possibility that obesity exerts an inflammatory influence on individuals. Large population studies show a strong association between indices of inflammation, abnormal lipid and carbohydrate metabolism, obesity, and atherosclerosis. This association is particularly strong in populations with a high incidence of obesity, diabetes, and cardiovascular disease (e.g., Pima Indians and Southeast Asians). TNF-α is produced not only by cells of the immune system but also by adipocytes and may provide the link between inflammation, insulin sensitivity, and the diseases associated therewith (**Figure 5**). TNF-α results in insulin insensitivity indirectly by stimulating stress hormone production and directly by down-regulating insulin receptor substrate-1 and by negative regulation of PPAR-γ, an important insulin-sensitising nuclear receptor. Adipose tissue produces both TNF-α and leptin. Production of the latter relates positively to adipose tissue mass and through its actions on immune function exerts a pro-inflammatory influence. It is unclear whether chronic inflammation is a trigger for chronic insulin insensitivity and conditions associated therewith or whether the reverse is the case. Evidence favours the former interpretation of the data.

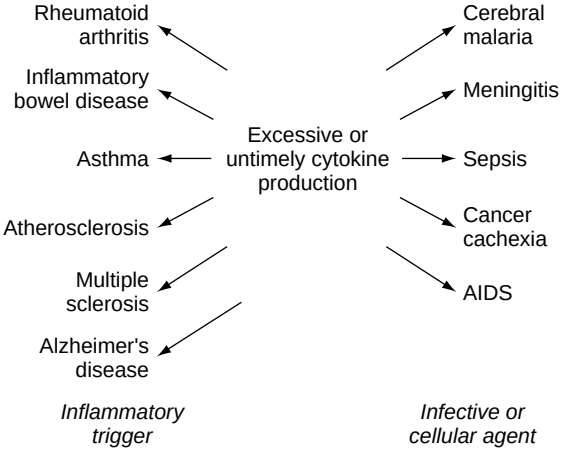

Figure 3 Diseases and conditions in which cytokines play a role.

Genetic factors play a role in the propensity of individuals to produce damaging or life-threatening amounts of cytokines during inflammation. Males and postmenopausal females possess a genetically determined propensity to produce high, medium, or low levels of cytokines in response to stimuli. Single base changes in the promoter regions of cytokine genes (single nucleotide polymorphisms (SNP)) result in these different levels of production. In the case of TNF-α, production of the cytokine is influenced by SNP in the TNF-α (*TNF2*) and TNF-β (*TNFB2*) genes. Individuals with the *TNF2* or *TNFB2* alleles produce higher amounts of TNF. In premenopausal women, the capacity to produce cytokines is influenced by the hormones of the oestrous cycle. Although the capacity for genetically determined levels of cytokines produces no apparent harm in healthy subjects, in disease, genetics has an impact on mortality. Studies in The Gambia showed that subjects who were homozygous for *TNF2* had a seven times higher rate of death or serious neural symptoms than subjects with one or no copies of the allele. Likewise, in patients with severe sepsis, possession of a *TNFB22* genotype resulted in 72% mortality in men compared with 42% mortality in men with a *TNFB11* genotype. Women were less severely affected by this genotypic influence. There is controversy about the reason for the retention of this lethal characteristic within the gene pool of the population. It is possible that in heterozygotes the presence of the genetic characteristic gives an immunological advantage. Homozygotes, who are less numerous than

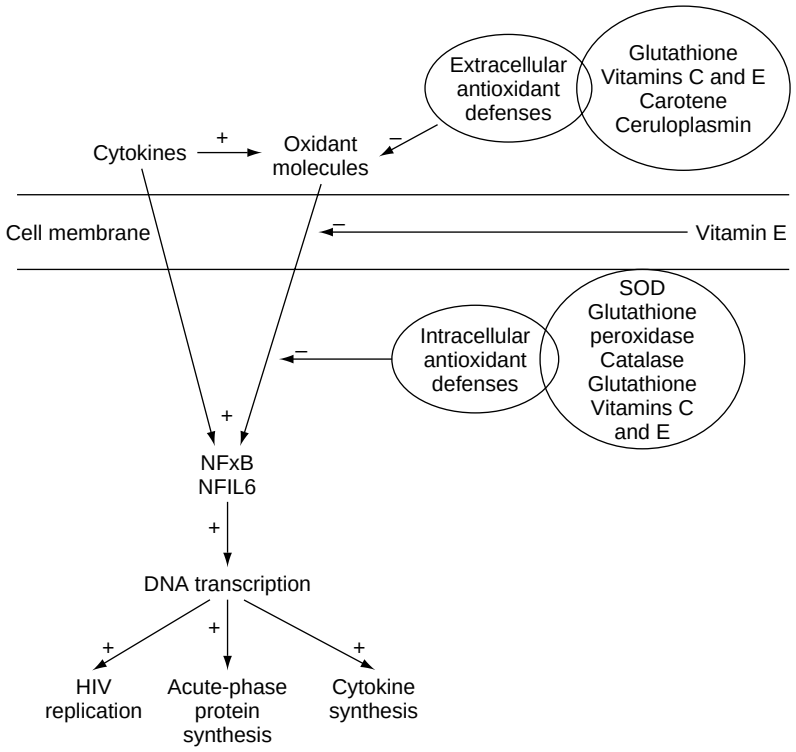

Figure 4 The interactions among oxidants, cytokines, and antioxidant defenses during inflammation. Minus signs indicate an inhibitory effect, and plus signs indicate a stimulatory effect. NF, nuclear factor; SOD, superoxide dismutase.

heterozygotes might pay the price for the advantageous retention of the genetic characteristic within the population. It is also interesting to note that in longevity studies a SNP that results in raised IL-10 production is more common in nonagenarians than in younger subjects, and conversely a SNP that results in raised production of IL-6 is rarer in the older than younger subjects. Thus, although it is an essential component of the ability of the body to combat pathogens, inflammation is inimical with longevity.

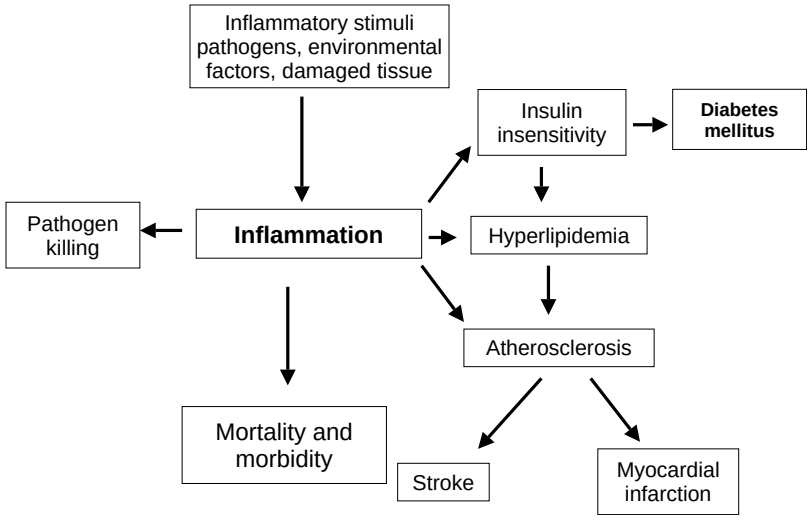

Figure 5 Linkage between inflammation as part of the defense against infection and as a factor in insulin insensitivity and disease processes.

Influence of Nutrients on Cytokine Biology

Proinflammatory cytokines exert widespread effects on metabolism, involving alterations in lipid, carbohydrate, and protein metabolism. In addition, there are substantial changes in micronutrient metabolism. A number of intracellular signaling pathways are activated by the actions of cytokines on target cells, including prostaglandins and leukotrienes, cyclic AMP, and protein kinase C. There are thus many levels at which nutrient intake can modify the intensity and characteristics of the response to inflammatory stimuli. The ability of nutrients to modify inflammation has been used in the treatment of diseases with an inflammatory basis. The interaction between nutritional status and inflammation is also important in public health because it determines the effects of infection on growth and well-being of populations with a poor nutrient intake.

The earliest indications that nutritional status could affect cytokine biology came from studies on malnourished hospital patients. White blood cells from patients had a reduced capacity to produce cytokines. The high mortality rates in these patients highlighted the importance of cytokines in the process of recovery from injury and infection. Protein supplements improved cytokine production and decreased the mortality rate. Since these observations were made, a large number of studies have been conducted in animals and human volunteers that show that fats, amino acids, and micronutrients change the ability of mammals to produce and respond to IL-1, IL-6, and TNF (**Figure 6**). **Figure 6** indicates whether a change in the intake of a nutrient, or nutrient status, alters cytokine production or the response of target tissues to the actions of cytokines.

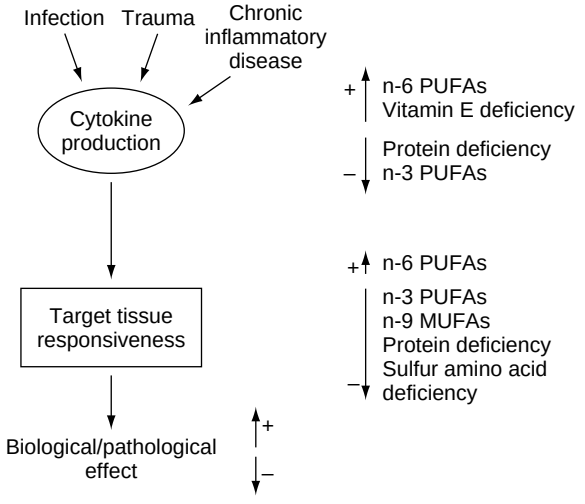

Figure 6 Summary of the effects of nutrients and nutritional conditions on cytokine biology. A stimulatory effect is indicated by a plus sign and an inhibitory influence by a minus sign.

Influence of Fats on Cytokine Production and Effects

Dietary fats can be divided into four main types. Some are rich in n-6 polyunsaturated fatty acids (PUFAs); fats in this group include corn, sunflower, and safflower oils. Some are rich in n-3 PUFAs; these include fats from marine sources. Some are rich in monounsaturated fatty acids; these include olive oil and butter. Some fats are characterized by a high content of saturated fatty acids, usually accompanied by low concentrations of PUFAs; coconut oil, butter, suet, and lard are in this category.

The production and actions of pro-inflammatory cytokines are profoundly influenced by dietary fat intake. There are a number of levels at which fats may modify cytokine biology. Most relate to the ability of fats to change the fatty acid composition of membrane phospholipids. Subsequently, membrane fluidity may be changed, the types and amounts of prostaglandins and leukotrienes produced during inflammation may be altered, and the synthesis of a number of cellular mediators that arise from phospholipids (platelet activating factor, diacylglycerol, and ceramide) may also be changed. As a result of these changes, the binding of cytokines to target tissues and the intensity of the inflammatory response may be altered.

Phospholipids contain two fatty acid chains attached to the remainder of the molecule at positions designated sn1 and sn2. Normally, arachidonic acid (AA C20:4 n-60) is released from this position and provides the parent compound for prostaglandins and leukotrienes. However, the long-chain PUFA eicosapentaenoic acid (EPA C20:5 n-3) may compete with AA for insertion at sn2. Prostaglandins and leukotrienes with a much lower bioactivity may result. This biological effect may account in part for the anti-inflammatory effects of fish oil. Many animal studies indicate that fats rich in n-6 PUFAs exert a pro-inflammatory influence, whereas fats rich in monounsaturated fatty acids or n-3 PUFA have the opposite influence. In human studies, however, evidence for the influence of n-6 PUFA or monounsaturated fatty acids is not so clear-cut. It has been postulated that the major increase in inflammatory disease that has occurred in the past 40 years in industrialized countries is due to a major

increase in the intake of n-6 PUFAs during this time (from approximately 5 to 7% of dietary energy). It has also been postulated that the lower levels of inflammatory disease associated with the habitual consumption of a 'Mediterranean diet' are due in part to high intakes of monounsaturated fatty acids. The evidence for n-3 PUFAs producing an anti-inflammatory effect in humans is much stronger, however. Also, n-3 PUFAs have been shown to produce beneficial effects in inflammatory disease. In many double-blind, randomised controlled clinical trials, fish oil produced significant clinical benefit in patients with rheumatoid arthritis. A number of trials also report beneficial effects of fish oil in the treatment of Crohn's disease. The precise mechanisms for these effects is unclear. A number of studies have demonstrated the ability of fish oil to reduce pro-inflammatory cytokine production and to alter the production of eicosanoids. However, recent studies have indicated a genomic influence on the ability of fish oil to reduce TNF production, thus indicating that fish oil may not be universally effective as an anti-inflammatory agent. A fish oil and vitamin E intervention trial (GISSI) was carried out on 11,324 survivors of a myocardial infarct in Italy. Patients were given 1 g of n-3 PUFA and/or 300 mg vitamin E/d. In the GISSI trial, fish oil supplements were shown to reduce the chance of stroke or a second myocardial infarct by 15%. Because inflammation plays a role in atherosclerosis, it is interesting to note that a trial of fish oil in patients with severe atherosclerosis showed that a supplement of 6 g/day of fish oil for 7 weeks significantly reduced macrophage activity in plaques.

Modulation of Cytokine Biology by Amino Acid and Protein Intake

Substantial increases occur in protein synthesis as the result of infection. It has been estimated that approximately 45 g of protein is required to produce and maintain the increased quantities of white blood cells and acute phase proteins in an infected individual. This demand will have a considerable impact on the availability of amino acids for other processes in the body that involve protein synthesis. The inhibitory effect of infection on growth, pregnancy, and lactation is well recognized. Output of amino acids from skeletal muscle, skin, and bone provides substrate for the synthesis of cells and proteins associated with the response to infection and trauma, as indicated previously. However, the supply may not always match demand, as is evident from the decrease in plasma concentrations of a number of amino acids. In particular, reductions occur in the concentrations of a metabolically related group of amino acids, including glycine, serine, and taurine. All three are metabolically related with the sulfur amino acids. Glycine and serine, together with the sulfur amino acids, are found in high concentrations in many compounds associated with the immune and inflammatory response, most notably comprising 66% of glutathione, 56% of metallothionein, and up to 25% of many acute-phase proteins. Experimental studies have shown that the production of cytokines, acute-phase proteins, and glutathione is influenced by the adequacy of both protein and sulfur amino acid intake. The partitioning of cysteine into glutathione and proteins in the liver may change if dietary sulfur amino acid intake becomes inadequate. This phenomenon is due to the biochemical properties of rate-limiting enzymes in both pathways. Whereas the K_m for γ-glutamyl cysteine synthetase (rate limiting for GSH synthesis) is 0.35 mM, that for amino acid activating enzymes (rate limiting for protein synthesis) is only 0.003 mM. This biochemical characteristic means that the GSH synthesis will fall below maximal rates at much higher intracellular cysteine concentrations than protein synthesis. Thus, at low sulfur amino acid intakes antioxidant defenses will become compromised. Low concentrations of GSH in tissues may have implications for the extent of inflammatory processes in the individual. In animal studies, decreased lung GSH concentrations are associated with the accumulation of inflammatory cells in tissues. In studies on HIV patients given *N*-acetyl cysteine, to improve GSH status, a decrease in plasma IL-6 concentrations has been noted indicating a reduction in inflammation. In view of the effects of NF-κB activation on HIV replication, it is interesting to note that the drug also brought about a reduction in HIV mRNA levels.

Modulation of Cytokine Biology by Micronutrients

Micronutrients play varied and complex roles in the response to infection and trauma. They are incorporated into substances that are synthesized in increased amounts during the response and into components of antioxidant defence, and they also modulate immune function. Trace elements are present in several acute-phase proteins and enzymes associated with antioxidant defense (**Figure 4**). These proteins include metallothionein (Zn), caeruloplasmin (Cu), superoxide dismutases (Mn, Cu, and Zn), and glutathione peroxidase (Se). Deficiencies

in copper impair the ability of rats to increase superoxide dismutase and caeruloplasmin activities in response to inflammatory agents. Deficiencies in zinc impair the ability to increase metallothionein synthesis; furthermore, zinc deficiency has potent suppressive effects on lymphocyte proliferation. Iron status may influence inflammation and immune function in a number of ways. Normally, iron is tightly bound to transport proteins such as transferrin and ferritin. However, following tissue damage and infections such as malaria, which may destroy red blood cells, free iron may be released and exert a proinflammatory effect by catalyzing free radical production. The latter effect may activate NF-κB and upregulate cytokine production. Indeed, iron dextran infusion has been shown to exacerbate inflammatory symptoms in rheumatoid arthritis. Desferrioximine, an iron chelator, suppresses TNF and IL-1 production by rodent macrophages. Iron deficiency also decreases the ability of such cells to produce cytokines. Impairment of immunological defence is commonly found in iron-deficient animals and human populations. Defects occur in T cell proliferation and in the ability of macrophages to engulf and kill bacteria. The latter may relate to the role of iron as part of the NADPH oxidase complex that is responsible for the respiratory burst and generation of hydroxyl radicals that kill bacteria. Myeloperoxidase activity generates hypochlorous acid for bacterial killing, and myeloperoxidase is also a hemoprotein whose activity is decreased by iron deficiency.

Vitamins also exert a number of effects on cytokine biology. These effects may relate to the roles that some of these nutrients play as antioxidants and growth factors (**Figure 4**). Rats deficient in vitamin E exhibit an enhanced inflammatory response to endotoxin; addition of the vitamin to the diet will suppress this effect. In healthy subjects and smokers, a daily dose of 600 IU of vitamin E for 4 weeks reduces the ability of white blood cells to produce TNF and IL-1. Cigarette smoking enhances cytokine production and raises acute-phase protein concentrations. The extent of the elevation is inversely related to vitamin E. Strenuous exercise results in a small increase in plasma concentrations of IL-1 and IL-6; vitamin E supplementation will prevent this effect.

Vitamin A status also influences cytokine production, although the mechanism underlying the effect is unclear. Macrophages taken from Indian children who received a supplement of 100 000 IU of retinol produced seven times the quantity of IL-1 produced by cells of children who had not received supplementation. The effect may be more pharmacological than nutritional in nature. Mice given vitamin A at a dose that was 16 times their requirement had macrophages that produced twice as much IL-1 upon stimulation than cells from unsupplemented animals.

Hormone-like properties have been attributed to vitamin D in relation to its effects on calcium. It is apparent that endocrine effects of the vitamin extend to immune function. Macrophages treated with 1,25-dihydroxyvitamin D_3 produce increased amounts of TNF and were more effective at killing *Mycobacterium avium* than untreated cells.

Vitamin B_6 supplementation has been found to increase lymphocyte proliferation and production of IL-2 in elderly subjects. The effect of the vitamin on pro-inflammatory cytokine production is unknown. Little is known about the effects of other water-soluble vitamins on cytokine biology. Although no effects of vitamin C status on pro-inflammatory cytokine production have been reported, doses of the vitamin reduce the incidence of respiratory infections in long-distance marathon runners.

Conclusions

The objective of the response of the body to infection and trauma is to disadvantage and destroy invading organisms while simultaneously protecting healthy tissues from the damaging influence of compounds produced during the response. Cytokines play a central role in the protection of the animal from damage during the response. The close interrelationship between pro-inflammatory cytokines, oxidant molecules, and antioxidant defenses gives a biological advantage to the host (**Figure 7**).

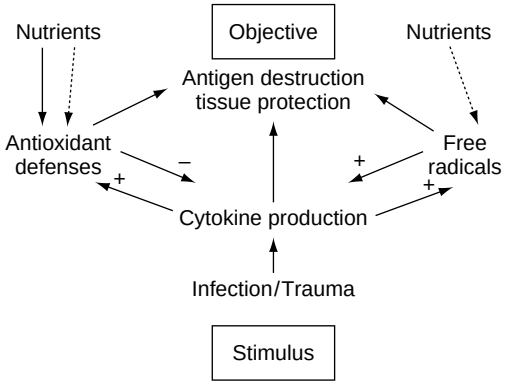

Figure 7 Influence of nutrients on the coordinated inflammatory events for destroying pathogens and protecting the host. Direct and indirect effects of nutrients are shown as solid and broken lines, respectively.

The essence of survival of an individual or species lies in the ability to prioritize physiological processes, particularly those processes that exert a large metabolic demand. Thus, at various times throughout the life cycle mammals will focus metabolic processes on achieving growth, the construction of placenta and fetus, the synthesis of milk components, or the repulsion of invasion by pathogens. For the infected individual, the marshalling of resources to combat the invading pathogen must assume a priority over all other physiological events. These other physiological processes can continue once the invasion has been repulsed and the damage done by the invader has been repaired.

The production of cytokines and other molecules associated with the inflammatory process carries risks of damage to the host as well as a survival advantage. The risk to the host is minimized by a sophisticated range of feedback control systems and synthesis of substances that protect the host. As discussed previously, nutrient intake modulates cytokine biology and the control and protective systems. A wide range of nutrients modulate cytokine biology at the level of production and sensitivity of target tissues (**Figure 6**). As a consequence of the modulation, the extent of depletion of nutrient stores and the risk of damage during the inflammatory response will be changed. The extent of tissue depletion and risk to the host will thus range from mild and transient in nature to severe, chronic, or lethal in effect.

DAIRY PRODUCTS

J Buttriss, British Nutrition Foundation, London, UK

Introduction

Dairy products are traditional dietary items in many parts of the world, in particular regions such as northern Europe where the cooler climate is especially suited to dairying. The history of milk as a food has been documented over the centuries and examples of early dairying are depicted in Egyptian friezes such as that from the sarcophagus of Queen Kawit from Der-al-Bahri, between Luxor and Karnak, dating back 4000 years. There is an even earlier Mesopotamian frieze from the temple of Ninkhasarg, near Ur, which is thought to be 1000 years older.

The popularity of milk as a staple food over the centuries must partly be due to its versatility. Early humans discovered that milk could be churned to make butter and fermented with bacterial cultures to produce cheese and yogurt, all of which were methods of preserving some or all of the nutrients in milk for consumption at a later date.

Variety

The range of dairy products on the market is immense. In most countries, a range of milks with differing fat contents is available. For example, in the UK consumers can choose between Channel Islands milk, with 4.9 g per 100 g fat, whole milk (3.9 g per 100 g), semiskimmed (1.6 g per 100 g fat), and skimmed milk, which has virtually no fat. Similarly, a wide range of cheeses exists with varying fat contents: at one end of the spectrum are soft fresh cheeses, made with skimmed milk, and at the other, hard cheeses such as Cheddar. Also available is cheese made with nonanimal rennet, suitable for vegetarians. In the UK alone, about two hundred different cheeses are produced, and cheese is particularly popular in countries such as France, where an even greater variety is available.

Fermented milk products such as yogurt, smetana, and kefir have always been popular in Middle Eastern countries, but their popularity, particularly that of yogurt, is increasing dramatically in Europe. Again, a wide range of yogurts exists, from very low-fat varieties to the creamier, whole milk or Greek-style product. Today, the range includes set yogurts, stirred yogurts, fruit yogurts, frozen yogurts, drinking yogurts, fromage frais, and the newer 'bio' yogurts with their milder flavor.

Traditional products such as cream and butter are still in demand, in spite of their high fat content, and are being joined by other 'luxury' products such as real dairy ice creams, fresh cream desserts, and luxury mousses. To meet the demand for a spread with a buttery flavor, products have been developed which incorporate butterfat for taste but often have a lower fat and energy content than butter.

A number of products also exist to which nutrients have been added, such as calcium-enriched milks and yogurts fortified with additional vitamins.

Nutrient Composition of Milk and its Products

Milk can be described as one of the most nutritionally complete foods. It provides a wide range of essential nutrients, in particular protein, and a range of vitamins and minerals (**Table 1**). It is, however, a poor source of iron and vitamin D, and contains no starch or dietary fiber. By volume, water is the major constituent of milk, comprising just over 87%. The remainder consists of milk fat and solids-not-fat (SNF)–principally comprising protein, lactose and minerals.

Protein

The principal proteins found in milk and its products are casein, lactalbumin, and lactoglobulin. Milk protein has a high biological value since it contains all of the eight essential amino acids, which cannot be synthesized in the body and so need to be provided by diet. In addition, milk can

improve the overall protein quality of a meal when consumed with foods of lower protein quality such as cereals and pulses.

Carbohydrate

The carbohydrate in milk is in the form of lactose, a disaccharide comprising a molecule of glucose and a molecule of galactose. This sugar is found naturally only in milk and is much less sweet than sucrose (packet sugar).

In the small intestine, lactose is digested by the enzyme lactase to its two component monosaccharides, in readiness for absorption. This enzyme is present in babies, young children, and most European adults. However, in some adults enzymatic activity can decrease, making milk in quantity less well tolerated. Such individuals are described as being lactose intolerant. Most can tolerate small quantities of milk, and fermented milk products appear to be better tolerated. Cheese is also usually well tolerated as it contains only trace amounts of lactose. In the UK, lactose intolerance is relatively rare in people of European descent but is more common in those of Asian, Far Eastern, and African descent, particularly first-generation members of these ethnic groups.

Fat

The fat in milk is in the form of minute droplets, which rise to the top when milk is left to stand. The principal component of milk fat is triacylglycerol, three fatty acids joined to a glycerol backbone. All triacylglycerols contain mixtures of three families of fatty acids: saturated, monounsaturated, and polyunsaturated. The contribution of these three types of fatty acid to milk fat in the UK is 61% saturated, 28% monounsaturated, and 3% polyunsaturated. The percentages do not add up to 100% because milk fat is not composed totally of fatty

acids. When milk is skimmed, it is the amount rather than the type of fat that changes, and so the fatty acid profile remains the same. Milk fat contains small amounts of the two essential fatty acids, linoleic acid (1.4 g per 100 g fatty acids) and linolenic acid (1.5 g per 100 g fatty acids).

Vitamins

All of the known vitamins are to be found in whole milk (**Table 1**), although some are present in small quantities. Milk and milk products make a significant contribution to intakes of a number of these (**Table 2**). The fat-soluble vitamins – A, D, E and K – are removed with the fat when milk is skimmed. Consequently, they are present in only trace amounts in skimmed milk and in reduced amounts in semiskimmed milk. Whole milk is a good source of vitamin A, a pint (568 ml) providing 47% of the adult male and 55% of the adult female UK reference nutrient intake (RNI).

All of the three major types of cows' milk (whole, semiskimmed, and skimmed) are good sources of riboflavin (vitamin B_2) and vitamin B_{12}. Milk can also make an important contribution to intakes of thiamin (vitamin B_1), niacin, and ascorbic acid (vitamin C), particularly where the overall diet is poor.

Some vitamins are sensitive to heat and light. Over 90% of milk for liquid consumption is pasteurized, a mild heat treatment that causes little loss of vitamins other than vitamin C. In general vitamin losses are less than 10%. Milk that has undergone the ultra heat treatment (UHT) process keeps for longer, but the higher temperature used in the processing results in slightly greater losses (10–20%) of some vitamins, particularly vitamins B_6 and B_{12}, vitamin C, and folate. The sterilization process used for milk has a somewhat greater effect: about one-third of the thiamin and half the vitamin C, folate, and B_{12} are destroyed.

Some loss of vitamins is inevitable when milk is stored. The extent of these losses is dependent on the translucency and permeability to light of the container, and the length and conditions of exposure. Milk exposed to bright sunlight on the doorstep will readily lose its vitamin C. Loss of riboflavin is slower but after 4 h, half will be lost and only a third remains after 6 h. Therefore, measures should be taken to limit such exposure. There will also be gradual losses of some vitamins from UHT and sterilized milks, even under ideal storage conditions, because of reactions with small amounts of oxygen remaining in the pack or bottle. Boiling milk also reduces its vitamin content, ranging from a 5% reduction in vitamin B_{12} to a 50% reduction in vitamin C.

Minerals

Milk makes a contribution to human needs for virtually all the minerals and trace elements known to be essential for health. These are often present in a form that is well absorbed and utilized by the body (high bioavailability), e.g., calcium and zinc. For most people in the Western world, milk and milk products are a major source of calcium. Almost 60% of the calcium in the typical British diet is contributed by milk and milk products (**Table 2**). Milk alone contributes about 40% of the total. Although the contribution to zinc requirements made by milk is relatively low compared with meat (the major contributor), the zinc in milk is in a highly bioavailable form and there is evidence that the combination of milk (or meat) with vegetable foods, in which the zinc is less bioavailable, can enhance the bioavailability of zinc from the whole meal.

Cultural Significance of Milk and Milk Products

In countries where dairying has traditionally been a strong industry, milk and milk product consumption tends to be widespread and makes a significant contribution to nutrient needs. **Table 2** shows the contribution in Great Britain. The average daily intake of milk in the UK is a little under half a pint per person (271 ml). **Table 3** shows the contribution half a pint of whole milk makes to the nutrient and energy needs of a 4-year-old girl and a man. Skimmed or semiskimmed milk would make smaller contributions to intakes of energy and fat-soluble vitamins.

In Scandinavian countries, where dairying is also traditional, liquid milk consumption is typically higher than in the UK. However, in warmer climates, in particular the Indian subcontinent, Africa and South America, climatic conditions lend themselves less readily to cows' needs, so that the development of dairying and, hence, milk-drinking habits has been far more patchy. Exceptions exist, such as the Masai in East Africa, whose culture is dominated by the cow. Similarly, in parts of India, cows have religious significance but have not, until recently, been intensively managed for their milk.

Being rich in calcium needed for skeletal development and maintenance, milk has traditionally been seen as an important food during childhood, pregnancy and lactation, when calcium requirements are particularly high. This view is still supported today. The Departments of Health in the UK advises milk (and water) to be the most suitable drinks for children, both from a nutritional standpoint and in terms of dental health.

Table 3 Contribution of 285 ml (half pint) of whole milk to nutrient needs

Availability of Subsidized and Free Milk in the UK

Under the school milk subsidy scheme, funded by the European Community (EC), primary school pupils are eligible to receive 250 ml of milk (whole or semiskimmed) each school day at a subsidized price. Until the spring of 1996, secondary school pupils were also eligible for this benefit and a subsidy was available for milk used in school catering (all age groups). Children under the age of 5 years, attending nursery schools or looked after by

registered child minders, are eligible to a third of a pint of milk, free of charge, on each day they attend.

For families on income support, pregnant women, breast-feeding mothers, and children under the age of 5 years are entitled to a pint of milk a day, free of charge. For bottle-fed babies, tokens can be exchanged for infant formula. Others entitled to free milk (a third of a pint per school day) include children attending special schools.

Nutritional Significance of Milk and its Products in the Diets of Children

The benefits of milk fall into three main areas: general provision of a range of nutrients and energy; provision of calcium for bone health; and dental health benefits.

General Benefits

Dairy products such as yogurt, fromage frais, grated cheese, and small amounts of whole milk, e.g., in custard, can be given to babies as they begin to experience a wide range of foods (4–6 months onwards). As the child becomes established on 'solids,' quantities can be increased, e.g., cows' milk may be used to mix infants' cereals. However, cows' milk should not be introduced as a main drink until a child is 1 year old. This is because, unlike infant formulas, cows' milk is relatively low in iron and vitamin D, and there is growing concern about the iron status of older infants and preschool children.

Amounts consumed by babies may be small, but for preschool and school-age children, milk and products such as cheese and yogurt can make a significant contribution to nutrient needs (**Table 3**). In summary, as well as providing energy, milk is a good source of protein, calcium, zinc, and vitamins A (whole milk only), B_2 (riboflavin), and B_{12}. Milk also makes a valuable contribution to intakes of iodine, niacin (a B vitamin), and vitamin B_6.

Given its nutritional credentials, it is not surprising that milk has been made available free of charge or at a subsidized price to children (see above). A study in Scotland of children aged 7–8 years found generally adequate intakes of most vitamins and minerals, although intakes of sugar and fat were high compared with the adult guidelines (no specific guidelines exist for schoolchildren). However, they noted that the nutrient provision of the diet as a whole improved with the amount of milk consumed. There was no significant difference in the proportion of energy provided by fat when the high milk consumers (at least 3 L a week) were compared with the low milk consumers.

Calcium and Bone Health

There is abundant evidence that calcium plays a major role in the development and maintenance of skeletal strength. Achieving adequate intakes of calcium during growth is important to optimizes peak bone density in early adulthood, thus protecting against osteoporosis in later life.

Approximately 45% of the mineral in the adult skeleton is laid down during adolescence. By the age of about 17 years (earlier in girls), over 90% of the maximum amount of bone mineral (e.g., calcium) that will ever be present in the skeleton is already there. Calcium requirements are, therefore, particularly high during adolescence. Yet it is at this age that milk consumption often falls, frequently resulting in dramatic reductions in calcium intake. There is evidence from national UK surveys among schoolchildren and adults that 1 in 4 teenage girls and young women have wholly inadequate calcium intakes, i.e., below the lower reference nutrient intake (LRNI).

Dairy Products and Oral Health

Milk is kind to teeth and dental experts recommend that milk or water are the most suitable drinks for children. A recent national dental health survey in Britain among preschool children revealed that among those aged between $1\frac{1}{2}$ and $3\frac{1}{2}$ years, the main dietary measure differentiating children with and without dental decay was taking a drink containing non-milk sugars (e.g., fruit juice or squash) to bed, as opposed to not drinking in bed or having other kinds of drink (milk or water). A significantly higher proportion of children who consumed drinks containing non-milk sugars in bed had tooth decay (26%) than did children who drank water (11%) or milk (12%).

Cheese is also considered to be important. A number of studies have shown that chewing (not just swallowing) a small cube of cheese (5–10 g) can revert the reduction in pH in the mouth brought about by the acid produced during the fermentation of sugars by bacteria in the mouth. It is this production of acid that is associated with tooth decay. It is thought that this effect is achieved via cheese's ability to stimulate saliva flow. However, other mechanisms may also be important, including cheese's high concentration of calcium and other minerals needed by teeth, and the ability of the protein in cheese (and milk) to buffer acid.

Nutritional Significance of Milk and its Products for Adults

During pregnancy, especially the final months, requirements for a number of nutrients increase. Although the mother's efficiency at absorbing nutrients rises to help meet this need, dietary supply remains important. Milk is seen to have a major part to play here, given the broad range of nutrients it contains (see **Table 1**).

The needs for some nutrients, for example calcium, rise dramatically after the baby is born in women who choose to breast-feed. Dietary requirements for calcium almost double and consumption of several servings of dairy products daily is one of the few ways of easily achieving such intakes (in the UK the RNI is 1200 mg day^{-1}). Breast-feeding teenagers need even more calcium, as their own skeleton is still developing as well as that of the baby.

Milk and milk products remain a nutritional safeguard for other adults, especially those who choose to restrict their choice of foods because they are slimming or following a vegetarian diet. For elderly people, whose overall food intake and dietary variety can be limited, milk, cheese, and yogurt can be of particular importance in meeting nutrient needs, especially with the convenience of doorstep delivery.

Other Health Effects of Dairy Products

Several studies have reported an inverse association between dairy products consumption and the insulin resistance syndrome. One study reported a reduction of insulin resistance of 40% with consumption of 1 serving per day or more. However, this was observed only in men. In the CARDIA study, a reduction of 21% in insulin resistance was demonstrated among 18–30-year-old men who consumed at least one serving of dairy products per day. Similarly, results from at least 10 clinical trials show a beneficial effect of regular consumption of dairy products on cardiovascular disease risk. Taken together, these results indicate a consistent beneficial effect of milk products on risk for insulin resistance and cardiovascular disease, in addition to the already established benefits for osteoporosis. The overall effect threshold for this benefit appears to be 2 or 3 servings of dairy products per day.

The evidence for a beneficial effect of dairy products in weight management is less compelling, and mixed results have been reported. Several studies have shown a beneficial effect of calcium for weight loss, and it is possible that milk products exert their effect on body weight by being an excellent source of this nutrient. More studies are needed to clarify this potential benefit of diary products.

Yogurt and Health

Apart from its contribution to nutrient needs, the perception of yogurt as a 'healthy' food has been augmented by claims of health benefits attributed to specific live bacteria present in some yogurts, in particular *Lactobacillus acidophilus* and bifidobacteria. Both of these types of bacteria are to be found in the human gastrointestinal tract, especially in breast-fed infants, and it has been suggested that these microorganisms may be able to colonize the gut when consumed in yogurt, and protect against pathogens. It has also been speculated that they may be of benefit in a number of intestinal disorders, including those precipitated by antibiotic treatment or by diseases such as cancer and liver or kidney disease. Claims have been made that specific bacteria used in the production of a certain brand of yogurt have the potential to reduce blood levels of low-density lipoproteins (LDL). On the basis of existing research it is not possible to substantiate these various claims, although evidence is increasing and inconsistencies in the findings may in part be explained by differences in strain and species of bacterial cultures, and differences in experimental design.

There is, however, a substantial body of evidence to indicate that fermented dairy products such as yogurt are well tolerated by individuals who are lactose-intolerant. It has been suggested that this is because of the bacterial enzyme β-galactosidase (produced by the culture) in 'live' yogurt. This enzyme, which is able to digest lactose to glucose and galactose, is intracellular and hence is thought to survive gastric digestion. However, as lactose maldigesters tolerate yogurts with varying β-galactosidase activities equally well, it would seem that other factors may also be important, including rate of gastrointestinal transit of yogurt.

Intake of the types of lactic acid-producing organisms found in yogurt has also been postulated to prevent or inhibit intestinal growth of a variety of food-borne, disease-causing organisms. Most of the evidence supporting a role for cultured dairy products, or the bacteria used to make them, in controlling intestinal pathogens comes from experimental animal and *in vitro* studies. Findings are inconsistent, but various mechanisms have been put forward to explain reported protective effects. For example, the ability of lactic acid cultures to lower intestinal pH favors growth of lactic acid bacteria but provides a hostile environment for pathogens. It has also been suggested that lactic acid bacteria

may produce bacteriocins, proteins with a direct antibiotic effect.

In summary, while a fairly clear case has been made for tolerance of yogurt by lactose maldigesters unable to tolerate milk, the potential benefit of yogurt (or specific types of yogurt) in protecting against pathogens, in recolonizing the gut after illness, or in lowering LDL cholesterol concentrations in the blood needs further investigation.

Hygiene and Safety Aspects

Milk, in its raw state, does not stay fresh for very long and is an ideal medium for bacteria to grow. Various types of heat treatment are used to improve the keeping quality of milk and to kill any harmful bacteria present. These techniques are pasteurization, sterilization, and ultra heat treatment, and they are also used for cream.

Pasteurization is named after the French scientist Louis Pasteur and entails the heating of milk to at least 71.7 °C for a minimum of 15 s. After heating, the milk is quickly cooled to less than 10 °C. In the UK, pasteurization accounts for over 90% of all heat-treated milk and has little effect on the taste and nutritional value of milk.

Sterilization is a more severe process, in which milk is heated to a temperature of 115–130 °C for 10–30 min and then poured into sterile plastic or glass bottles. Unopened, sterilized milk will keep for 2–3 months without refrigeration, although once opened it has to be treated in the same way as pasteurized milk and will only keep for 4–5 days in a refrigerator. Sterilized milk has a slight caramel taste because the heat 'cooks' the lactose present in milk. Sterilization also reduces the levels of the heat-labile vitamins (see above).

Ultra heat treatment is a milder form of sterilization in which the milk is held at a temperature of not less than 135 °C for at least 1 s, and is then packed into sterile cartons. Such milk will keep unrefrigerated for many months, but once opened it needs to be refrigerated and used in 4–5 days.

Cheese and yogurt

The fermentation of milk to produce cheese and yogurt are traditional processes for preserving milk's nutrients. Hard cheeses, such as Cheddar, which have a low moisture content and contain salt as a preservative, will last for many months if stored appropriately. Ideally cheese should be eaten fresh, but if properly stored it will retain its flavor for long periods. It should be wrapped in clear film or foil to prevent drying and then stored in a cool larder or refrigerator. Soft, unripened cheeses, such as cottage cheese, are highly perishable, need to be stored in the refrigerator, and have a relatively short shelf life. At low temperatures, microbiological growth will be reduced, as will enzyme action and biochemical changes that might change the flavor, color or texture of the product. Ripened soft cheeses such as Brie should also be kept refrigerated, wrapped in airtight film or aluminum foil.

Nearly all yogurt sold in the UK contains live bacteria (derived from the starter culture used to produce the yogurt). It is necessary to refrigerate the product to restrict the activity of these bacteria, to prevent development of excess acidity and impairment of flavor. At temperatures of about 5 °C, yogurt has a shelf life of about 14 days, after which time acidity levels may rise above acceptable levels. Spoiled yogurts are often referred to as 'blown.' This is because pressure has built up in the pot via the fermentation of the sugar in the yogurt by the growth of yeasts.

A small proportion of yogurts are heat treated to prolong their shelf life. As a result, they no longer contain live bacteria and do not need to be refrigerated.

DEHYDRATION

A W Subudhi, University of Colorado at Colorado Springs, Colorado Springs, CO, USA
E W Askew, University of Utah, Salt Lake City, UT, USA
M J Luetkemeier, Alma College, Alma, MI, USA

Physiological Functions of Water

After oxygen, water is the most essential nutrient needed to sustain human life. In healthy individuals, water comprises between 45 and 70% of total body weight and is responsible for connecting the diverse physiological functions of the body (**Table 1**).

Water is necessary to maintain homeostasis of the internal environment. The most obvious roles of water in the human body are to provide an aqueous medium for transport of material in blood, to dissolve and pass nutrients between blood and cells, to serve as a medium for intracellular reactions, and to transfer metabolic products for redistribution or excretion via urine. Since both the quantity of reactants and the volume of fluid in which they are dissolved influence chemical reaction rates, imbalances in hydration status can alter cellular and tissue function.

Dehydration also adversely affects the body's ability to regulate temperature. Energy transformations during digestion, absorption, and metabolism as well as muscular contraction generate heat. The heat released from the digestion of a mixed meal (thermic effect of food) equals 10–15% of the caloric content of the food ingested. Muscular contraction is dependent on the transformation of chemical energy (ATP) to mechanical energy. Nearly three-fourths of the energy used for muscular contraction is released as heat. Unless localized heat production from metabolism and muscular contraction is dissipated, the heat burden can be structurally damaging to enzymes or other proteins. Water absorbs heat produced at the cellular level and transfers it to the surface of the skin, where it can be dissipated to the external environment (**Figure 1**).

Table 1 Major physiological functions of water

Function	*Example*
Waste product removal	Urea excretion by kidneys
Solvent for chemical reactions	Glycolysis in the cell cytosol
Transport medium	Blood
Lubrication	Synovial fluid of joints
Shock absorber	Disks between vertebrae of spinal column
Temperature regulation	Evaporative sweat loss

The evaporative dissipation of heat through sweating is a two-phase, water-dependent mechanism. Water is removed from capillary blood perfusing sweat glands to produce a thin layer of sweat over the surface of the skin. Simultaneously, the water component of blood carries heat produced from cellular metabolic processes to capillary beds located near the surface of the skin. Heat is transferred by conduction to the skin surface, where it vaporizes sweat coating the skin, thus transferring body heat to the external environment. The heat of vaporization of water is 586 kcal/l (2453 kJ/l) at 20 °C. Approximately 500 ml of sweat is lost per day under average ambient environmental conditions. Such obligatory water loss occurs without visible or tactile sensations and is termed 'insensible' sweat. However, given a sufficient thermal challenge, humans are capable of producing approximately 10 l of 'sensible' sweat per day. Theoretically, if the entire 10 l of sweat was evaporated, more than 5000 kcal (20 930 kJ) of heat per day would be dissipated via the sweating mechanism. Humidity of the air and sweat that drips from the surface of

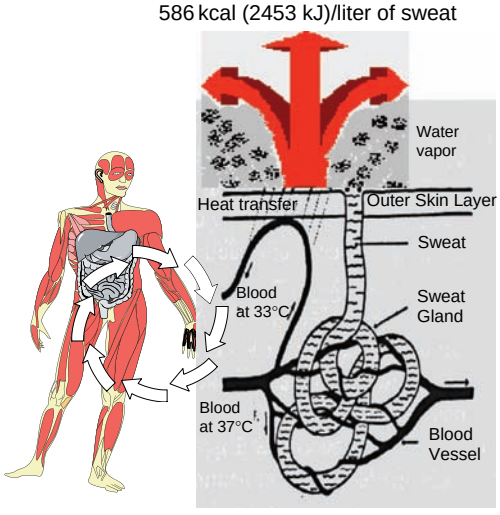

Figure 1 Metabolic heat transfer to the skin and dissipation of heat by evaporation of sweat. The body has more than 2 million sweat glands that secrete sweat to the surface of skin. Blood-perfusing skin capillary beds transfer heat by convection to the surface of the skin. Heat is dissipated by vaporizing the water in sweat. The heat of vaporization of water at 20 °C is 586 kcal/l (2453 kJ).

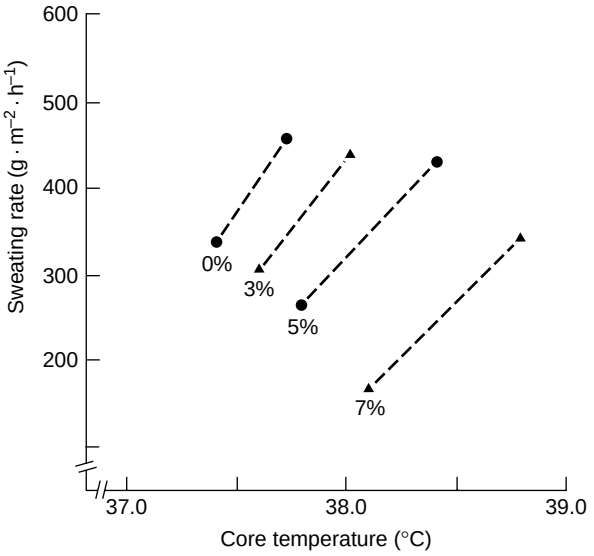

Figure 2 The influence of water loss by dehydration (hypohydration) on the sweating response to exercise following normal hydration (0%) and dehydration equal to 3, 5, and 7% of body weight. The primary stimulus for sweating is the increase in core temperature (thermal drive). Note that dehydration reduces the sweating rate at any given level of thermal drive. Hypohydration compromises exercise by reducing sweat rate and evaporative cooling and increasing body core temperature. (From Sawka MN, Young AJ, Francesconi RP *et al.* (1985) Thermoregulatory and blood responses during exercise at graded hypohydration levels. *Journal of Applied Physiology* **59**: 1394–1401, with permission.)

the skin considerably reduce the potential for evaporative heat dissipation; therefore, actual evaporative cooling is usually less than the theoretical maximum. Since water is the main component of sweat, it is not surprising that dehydration affects the sweat response. The relationship between body water loss by dehydration and the rate of sweating achievable during exercise is shown in **Figure 2**, which illustrates that dehydration reduces sweating rate at any given level of thermal drive (core temperature) during exercise. A diminished sweating response can lead to a dangerous heat buildup unless thermal strain is curtailed by other mechanisms.

Development of Dehydration

In physiological terms, dehydration is the process of progressing from the euhydrated (normally hydrated) to hypohydrated (less water than normal) state. In actual usage, dehydration means losing body water faster than it is replaced. The resultant condition is commonly referred to as the 'dehydrated state' and is associated with hypovolemia (low blood volume).

Contributing Factors

Water is lost through a variety of avenues, including urine, feces, breath, and sweat. In illness or disease, excessive diuresis, diarrhea, and/or vomiting are the main pathways of water loss. During exercise or heat exposure, sweating is the primary mechanism for dehydration. Significant water loss may be stimulated by cold- or altitude-induced diuresis. Additionally, some prescription drugs and over-the-counter herbal products have diuretic effects that exacerbate water loss. Under normal conditions, the body regulates its water contents tightly over a 24-h period (approximately ±200 ml); however, over short periods, water loss can significantly exceed water gain (**Figure 3**).

Body Fluid Balance

Body water losses are rapidly reflected in blood. Volume and electrolyte changes in response to decreased blood water content (increased osmolality) trigger the hypothalamus to stimulate antidiuretic hormone (ADH) release from the posterior lobe of the pituitary gland. ADH acts on the kidney to increase tubular water resorption and maintain plasma volume. Decreased plasma volume also

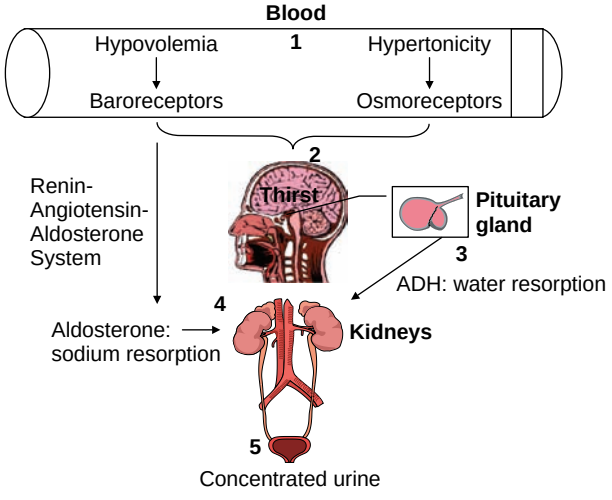

Figure 3 Water and sodium physiology: mechanisms controlling body water gain and loss. As water is lost from the body via sweat, urine, respiration, and feces, (1) plasma osmolality increases and plasma volume decreases with water loss. (2) The increase in osmolality acts on the 'thirst center' in the hypothalamus to secrete ADH and stimulates the conscious desire for water. (3) The release of ADH from the pituitary gland increases tubular resorption of water by the kidney. (4) Aldosterone is formed via a series of reactions involving renin, which is released from the adrenal cortex in response to decreased blood pressure, and a plasma protein, angiotensinogen. Aldosterone promotes sodium resorption by the kidney to maintain plasma volume. (5) These events conserve water and result in the production of concentrated urine.

results in a complex series of events resulting in the release of renin from the kidneys and the subsequent formation of angiotensin II and the minerocorticoid, aldosterone. Angiotensin II is a potent vasoconstrictor and stimulator of thirst. Aldosterone promotes sodium resorption, which allows the blood to retain more water. The net result of these regulatory mechanisms is concentrated urine and maintenance of plasma volume, provided that exogenous fluid intake increases proportionally. If fluid intake is not increased, dehydration will still result.

Thirst

Thirst is not a good short-term regulator of fluid balance. Humans frequently lose up to 2% of their body weight as water before the thirst mechanism is activated. The actual point at which the thirst mechanism is activated varies considerably between individuals. Some athletes are closely attuned to their anticipated fluid needs and develop the habit of drinking before they become dehydrated. However, the majority of individuals do not feel compelled to drink until they have become moderately dehydrated, even though fluids may be available. These individuals are called 'voluntary dehydrators.' Voluntary dehydrators frequently replace only approximately two-thirds of their short-term fluid losses.

Pathophysiology of Dehydration

Dehydration and Human Performance

Natives of desert regions have, over the years, habituated to being chronically dehydrated. A study of the desert inhabitants found that they had a curtailed thirst drive that was associated with excretion of low volumes of concentrated urine and a high incidence of kidney disease (kidney stones). When additional water intake (approximately twice normal) was ingested in a subsample of this population, they were able to exercise 10% longer in the desert environment, presumably due to improved thermoregulation. The results of this and other studies illustrate that humans probably do not adapt to dehydration but can become used to a mild chronic dehydration due to inadequate fluid intake. This is not a true physiological adaptation since there are negative health and performance effects associated with chronic dehydration.

Body Water Deficits

When fluid intakes are insufficient to maintain normal body water content (approximately 60% for males and 50–55% for females), deficits arise in all fluid compartments, with the reduction in plasma volume being of particular concern. Dehydration decreases plasma volume and increases tonicity. Plasma hypertonicity signals the circulatory system to conserve plasma volume for internal organs at the expense of skin blood flow. Reduction in skin blood flow decreases evaporative cooling. Additionally, decreased plasma volume reduces stroke volume and cardiac output, which impairs cooling capacity and exercise performance. The effects of dehydration on heart rate, body temperature, and endurance are shown in **Figure 4**. Consuming water to replace sweat loss while cycling for 6 h at 55% VO_2 max in the heat was associated with lower heart rates and core temperatures compared to a trial in which no water was ingested. The increase in heart rate while cycling without water replacement is a compensatory mechanism to maintain cardiac output in response to reduced plasma volume. Elevated core temperatures in cyclists not consuming water

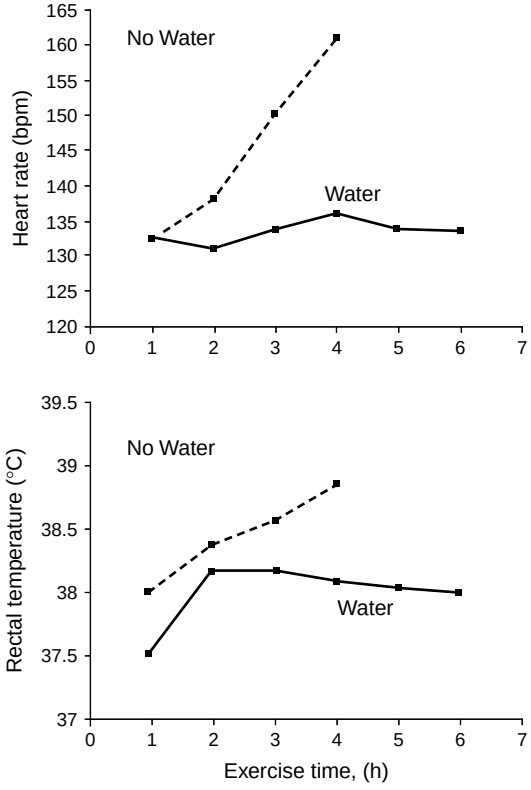

Figure 4 Consequences of consuming or not consuming water during cycle ergometer work (50% VO_2 max, 30 °C, 50% relative humidity). Subjects drank water to replace that lost during exercise (water group) or did not drink during exercise (no water group). Note that the no water group could not exercise as long as the water group. (Adapted from Barr SI, Costill DL and Fink WJ (1991) Fluid replacement during prolonged exercise: Effects of water, saline, or no fluid. *Medicine and Science in Sports and Exercise* **23**: 811–817.)

resulted from reduced skin blood flow and ultimately forced the cessation of exercise.

Dehydration and Heat Illness

If water loss due to sweating is not replaced during exercise, plasma volume and sweat rate will be decreased (**Figure 2**). The combination of reduced peripheral blood flow for heat exchange and reduced sweat volume for evaporative cooling leads to an overall reduction in the ability to dissipate heat.

The consequence of impaired heat dissipation is hyperthermia. Without evaporative cooling, human core temperatures can elevate ~5 °C/h during moderate intensity work. Heat production is proportional to the intensity and duration of work, ranging from ~75 kcal/h (314 kJ) at rest to ~300 kcal/h (1256 kJ) during moderate exercise and ~600 kcal/h (2512 kJ) for maximal sustained work. Brief periods of intense exercise can generate heat at the rate of ~900 kcal/h (3768 kJ).

Hyperthermia can lead to serious or even life-threatening heat injury if left unchecked. Heat injury can result if the rate of heat production is greater than the rate of cooling. When fluid losses are not replaced during activity, heat dissipation mechanisms are compromised. The buildup of heat in blood and tissues adversely affects various physiological systems. Minor heat injury syndromes include prickly heat (skin rash resulting from plugged sweat glands), heat syncope (light headedness due to pooling of blood in the extremities), and heat cramps (muscle cramps related to electrolyte loss). These heat illnesses are of concern but not life-threatening. Major hyperthermia syndromes involving dehydration are heat exhaustion and heat stroke. Conversely, overhydration (replacing large volumes of fluid loss) without sodium provision can, in certain instances, lead to an overdilution of blood sodium (hyponatremia). The symptoms of hyponatremia are similar to those of other forms of heat illness, but the treatment is critically different.

Heat exhaustion Two types of heat exhaustion can be distinguished: water depletion (inadequate consumption of water) and salt depletion (loss of large volumes of sweat that are replaced without adequate sodium intake). Heat exhaustion usually occurs on a continuum somewhere between these two extremes. During heat exhaustion, thermoregulatory mechanisms cannot dissipate heat effectively, primarily because of reduced skin blood flow. People who are unacclimatized to the heat or not in good physical condition are more susceptible to heat exhaustion. Symptoms vary but usually include a temperature of less than 39.5 °C, malaise, weakness, fatigue, headaches, anorexia, nausea, vomiting, diarrhea, and muscle cramps. Although irritability, anxiety, and impaired judgment may be present, the subject is usually alert and capable of responding to questions. If left untreated, heat exhaustion can progress to heat stroke.

Heat stroke Heat stroke is less common than heat exhaustion but is much more serious. Heat stroke is a life-threatening disorder that requires immediate medical treatment. Two forms of heat stroke are generally classified as exertional or classical. Exertional heat stroke generally occurs in young subjects working too hard for too long in the heat. Classical heat stroke is associated with environmental heat waves and primarily afflicts the very young, very old, poor, and debilitated. The pathophysiology of heat stroke involves failure of the body's thermoregulatory mechanisms following a severe heat overload. As core temperature elevates, cell function deteriorates culminating in massive cell damage. Dehydration is often a contributing factor to heat stroke, but the basic pathophysiology is uncontrolled heat overload. Core temperature is higher than that seen in heat exhaustion, generally 41 or 42 °C. Core temperatures higher than 39.5 °C reduce the function of motor centers in the brain and subsequently the ability to recruit motor units required for muscular activity. Extertional heat stroke is characterized by cessation of sweating, hot and dry skin, physical deterioration, confusion, collapse, and seizure. Rhabdomyolysis (muscle fiber destruction) may result from exertional heat stroke. In one reported case, an accelerated rhabdomyolysis resulting from exertional heat stroke occurred during an 8-km fun run when the ambient temperature was higher than 37 °C. This unfortunate runner collapsed with a rectal temperature of 42 °C and suffered acute renal failure as a consequence of an impaired immune system, infection, and decreased clotting ability. He eventually recovered, but it was necessary to amputate one of his legs that became infected following the rhabdomyolysis.

Other Consequences of Dehydration

There are other physiological consequences of dehydration that are not as serious as heat illness but can contribute to decreased performance capacity. Dehydration impairs thermoregulation in both hot and cold environments. Metabolic heat production in the cold may be less efficient in dehydrated individuals. The mechanism is not well understood, but it

may involve a concomitant reduction in energy intake, decrease in resting metabolic rate, impaired shivering response, impaired vasodilation/constriction response, or a combination of these factors. Dehydration also blunts appetite, which in turn may elicit energy and thermoregulatory defects.

Management of Dehydration

Identifying Types of Dehydration

Although prevention is the best management strategy for dehydration, water imbalances may also be treated after the recognition of dehydration by replacement of appropriate fluids, such as water or water containing electrolytes. Dehydration usually occurs along a continuum of fluid and electrolyte loss. The ratio of water to electrolyte loss determines the type of dehydration present. A convenient classification of types of dehydration, their characteristics, and how to treat them is shown in **Table 2**.

It should be noted that hypotonic dehydration is the result of treating isotonic dehydration with nonelectrolyte-containing fluids and can lead to a potentially dangerous condition know as hyponatraemia (low blood sodium). This may be a particular problem in the case of 'overzealous hydrators' such as athletes who overcompensate for sweat losses. Hypotonic dehydration is also seen in infants and children who may be afflicted with gastrointestinal disturbances such as diarrhea, stomach flu, or acute gastroenteritis if water alone is used to hydrate. The American Academy of Pediatrics has published guidelines for oral rehydration therapy of infants and children younger than 5 years old with acute gastroenteritis. **Table 3** gives the Academy's guidelines for the assessment of dehydration. An algorithm for the treatment and hydration of children with acute diarrhea is shown in **Figure 5**.

Clinical standards for assessing dehydration in adults have not been well established. Measurements of plasma osmolarity and urine-specific gravity and osmolarity can be used to assess relative dehydration if baseline (euhydrated) values are known. However, due to significant interindividual variation, the use of absolute specific gravity

Table 2 Types of dehydration

Mild hypovolemia
Fluid intake is insufficient to meet needs, 2–5% body weight loss, yellow urine, dry lips, reduced skin elasticity
Many people are chronically hypovolemic in outdoor environments
Simply need to be reminded to drink, easily corrected by fluids and consuming food

Hypertonic dehydration (hypernatremic dehydration)
Body water losses greater than sodium losses, elevated blood osmolality and hypernatremia
May be accompanied by fever, profuse sweating, and/or evaporative water loss
Acute weight loss; person eats but does not drink
Treatment is provided by additional fluids (water is best)

Isotonic dehydration
Body loses equal amounts of water and sodium from routes other than sweating
Gastrointestinal fluid loss—vomiting, diarrhea
Blood electrolytes normal
Acute weight loss, tachycardia, orthostatic hypotension
Treat by replacing lost fluid *and* electrolytes or hypotonic dehydration may develop

Hypotonic dehydration (dilutional hyponatremia)
Can develop when isotonic dehydration is treated with only water
Hypotonic dehydration can occur anytime the body sodium loss exceeds water loss (e.g., sodium-restricted diets, diuretic use, overzealous hydrators, fluid replacement with only water following repeated vomiting and diarrhea)

Table 3 Guidelines for the assessment of dehydration[a]

Variable	*Dehydration*		
	Mild, 3–5%	*Moderate, 6–9%*	*Severe, >9%*
Blood pressure	Normal	Normal	Normal to reduced
Quality of pulses	Normal	Normal or slightly decreased	Moderately decreased
Heart rate	Normal	Increased	Increased, severe cases bradycardia
Skin turgor	Normal	Decreased	Decreased
Fontanelle	Normal	Sunken	Sunken
Mucous membranes	Slightly dry	Dry	Dry
Eyes	Normal	Sunken orbits	Deeply sunken orbits
Extremities	Warm, normal capillary refill	Delayed capillary refill	Cool, mottled
Mental status	Normal	Normal to listless	Normal to lethargic or comatose
Urine output	Slightly decreased	<1 ml/kg/h	≪1 ml/kg/h
Thirst	Slightly increased	Moderately increased	Very thirsty or too lethargic to indicate

[a]The percentages of body weight loss and their corresponding categorization sometime vary depending on the author.

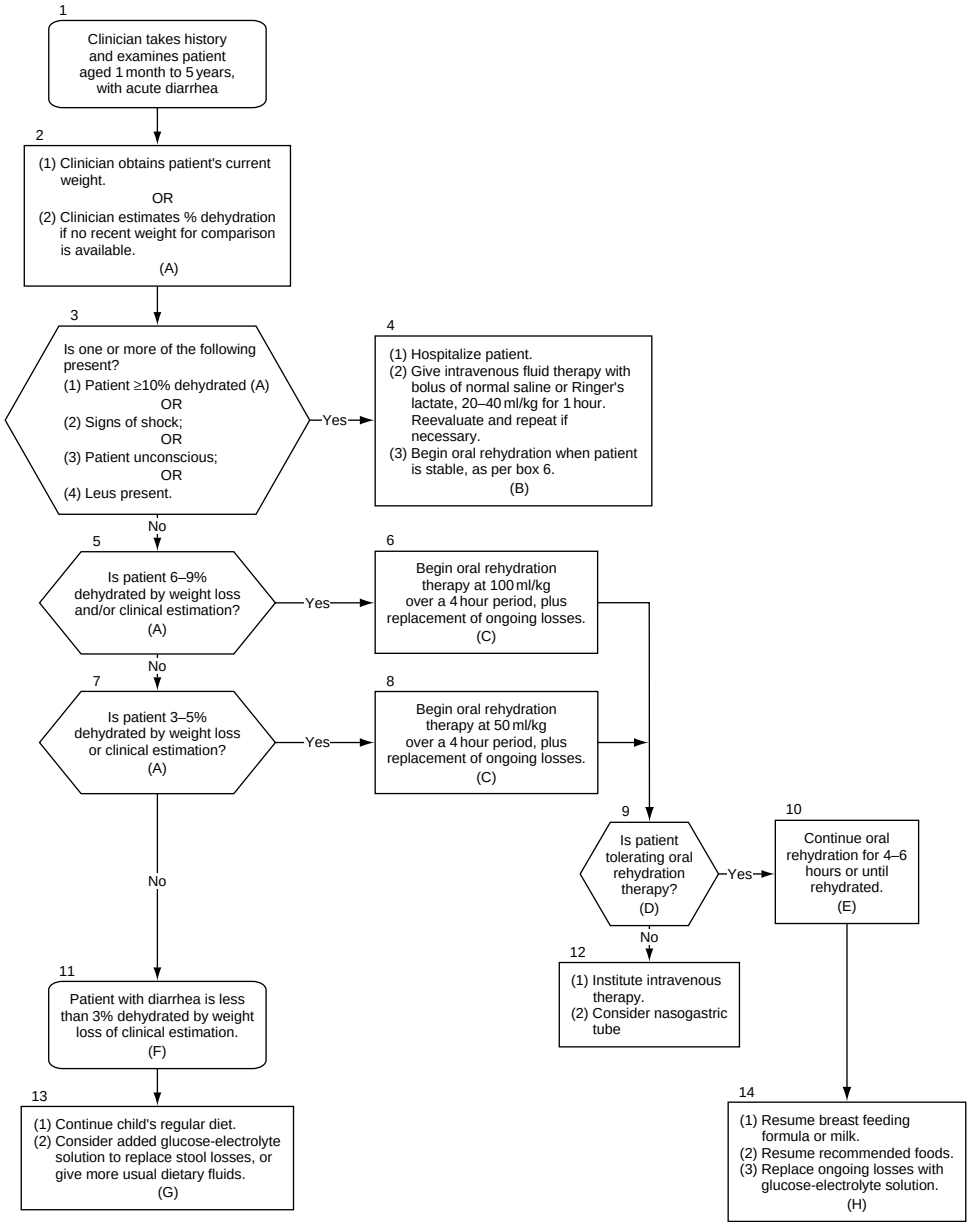

Figure 5 Algorithm for children with dehydration from acute diarrheal disease. The letters at the bottom of the decision boxes refer to the following: (A) See **Table 3** for guidance in the assessment of the degree of dehydration. (B) Restoration of cardiovascular stability is critical and is accomplished by giving bolus i.v. therapy. In the patient who does not respond, consider the possibility of an underlying disorder. When the patient is in stable condition and has achieved satisfactory mental status, oral rehydration therapy (ORT) can be implemented. (C) Solutions containing 45–90 mmol/l sodium should be given in a volume of 100 ml/kg for moderate dehydration and 50 ml/kg for mild dehydration. Giving the child these volumes requires patience and persistence, and progress must be monitored frequently. (D) Intractable, severe vomiting, unconsciousness, and ileus are contraindications to ORT. Persistent refusal to drink may require a trial of i.v. therapy. (E) The rehydration phase usually can be completed in 4 h; reevaluation should occur every 1 or 2 h. See referenced text for guidance to decide when rehydration has been achieved. (F) The type and intensity of therapy will vary with the individual clinical situation. (G) Often, a child has diarrhea but remains adequately hydrated. The parent can be reassured but should be taught to assess hydration and to identify a worsening condition. If the stool output remains modest, ORT may not be required if early, age-appropriate feeding is instituted and increased consumption of usual dietary fluids is encouraged. More significant stool losses can be replaced with an oral rehydrating solution at the rate of 10 ml/kg for each stool. (H) Breast-feeding should be resumed. Nonlactose formula, milk-based formula, or milk may be given, although a small percentage of children will not tolerate lactose-containing fluids. Lactose-containing solutions seem to be tolerated better when combined with complex carbohydrates in weaned children. Children who are eating foods may resume eating, although certain foods are tolerated better than others. Recommended foods include complex carbohydrates (rice, wheat, potatoes, bread, and cereals), lean meats, yogurt, fruit, and vegetables. Avoid fatty foods and foods high in simple sugars (including juices and soft drinks). Supplement feeding with an oral electrolyte solution, 10 ml/kg for each diarrheal stool and the estimated amount vomited for each emesis. (From American Academy of Pediatrics (1996) Practice parameter: The management of acute gastroenteritis in young children. *Pediatrics* **97**: 1–22, with permission.)

and osmolarity values for the diagnosis of dehydration remains questionable. Monitoring urine color has been suggested as a noninvasive way to measure hydration status, where light, pale yellow urine generally indicates a favorable hydration status. Assessing urine color may be a simple method to assess hydration status, but it can also be artificially influenced by dietary intake (i.e., nutritional supplements). Acute change in body weight is the most common and practical method used to assess hydration status. It is assumed that short-term body weight loss is primarily the result of water loss.

Treating Different Types of Dehydration

In the majority of simple, nonsevere dehydration cases, plain water is an adequate rehydration solution. However, there are instances (e.g., children younger than 5 years of age dehydrated by vomiting and diarrhea) when water containing sodium and potassium is the proper hydrating agent. The most effective way of preventing and treating mild to moderate dehydration in infants and children with acute diarrhea is the oral administration of oral rehydration solutions (ORSs). There are a number of commercially available ORSs. These solutions are designed to replace fluid and electrolytes when both water and food intake have been restricted or compromised by diarrheal disease. The World Health Organization recommends the ORS shown in **Table 4** for individuals afflicted with diarrheal disease and vomiting. Oral modes of fluid and electrolyte administration are always preferred in mild (3–5%) to moderate (6–9%) dehydration; however, intravenous fluids may be required in cases of severe dehydration (>9%) and vomiting or if the patient is in a comatose state. When i.v. fluids are administered, 0.45% saline with 5% dextrose is an effective hydrating agent.

In most instances involving heavy sweating, plain water containing 1.25 g of NaCl per liter is a suitable rehydration solution. Increasing the concentration of NaCl to 5 or 6 g per liter may promote the rate of rehydration but may not be palatable for some individuals. Most commercial sports drinks contain 1.2–1.8 g NaCl per liter and are also good rehydration solutions, especially when both fluid and electrolytes have been lost through sweating. Fruit juices can also provide fluid, energy, and electrolytes (e.g., fresh orange juice contains approximately 10 mg of sodium and 2000 mg of potassium per liter) but may be too concentrated and delay gastric emptying. Diluting fruit juices 1:3 with water may yield a more appropriate rehydration solution. The inclusion of carbohydrate in the rehydration solution provides energy for the intestinal sodium pump, which facilitates sodium transport across the intestinal cell wall into the blood, where it in turn exerts a positive osmotic effect on water absorption from the gut. Glucose and electrolyte sports beverages are useful rehydration solutions for sporting activities but are not a good choice for children with diarrhea since these beverages have lower electrolyte and higher carbohydrate concentrations than recommended.

Groups at Risk for Dehydration

Predisposing Factors for Heat Illness

Certain segments of the population are at greater risk for dehydration and subsequent heat illness than others (**Table 5**). The predisposing factors for dehydration and heat illness in these populations are obesity (extra exertion, heat production, and sweating are required to move a larger mass), insufficient heat acclimation (associated with reduced sweating and evaporative cooling and increased cardiovascular and renal stress), socioeconomic barriers to cooling methods (fans, air conditioners, etc.), pyrexial illness (fever), drug and alcohol abuse (interferes with fluid balance and thermoregulation), physical work in environments that contribute to dehydration (heat: sweating; cold: respiratory water loss and diuresis; altitude: respiratory water loss and

diuresis), and athletic competition and training (if athletes do not replace sweat loss). Even athletes who make a conscious attempt to drink during exercise only ingest approximately 300–500 ml fluid per hour; fluid loss through sweating (500–1000 ml/h) can easily surpass this intake of fluid.

Elderly and Children

The very young and the very old are two populations especially susceptible to dehydration. Children have less surface area-to-mass ratio for evaporative cooling and are less inclined to replace fluids; thus, they are less efficient thermoregulators than adults when exposed to high environmental temperatures. In the United States, approximately 9% of all hospitalizations of children younger than 5 years of age are due to diarrhea.

Aging is associated with decreased thirst, sweating, and renal responses that place the elderly at high risk during periods of extreme shifts in environmental temperature. Dehydration is a common cause for hospitalization and death in the aged population. Statistics from a 1991 U.S. survey of Medicare recipients revealed that almost half of the Medicare beneficiaries hospitalized for dehydration died within 1 year of admission. Older men and women may have a higher osmotic operating point (the point at which the thirst sensation is triggered), which may contribute to hypovolemia. Certain behavioral factors may also influence drinking patterns in older adults who may wish to avoid the physical difficulty associated with trips to the bathroom. Besides contributing to an increased risk for hyperthermia, dehydration also alters the effective dosage of medications through plasma volume changes, leading to further medical complications in the elderly. Dehydration in the elderly often accompanies or results from clinical conditions and/or medications.

Prevention of Dehydration

Dehydration resulting from nondisease causes can be easily prevented provided that people are inclined to drink and have access to cool, safe sources of fluids. Drink flavoring, beverage temperature, and sodium chloride content are important promoters of fluid intake in active children. Education of athletic coaches, the general public, and health care providers is necessary to increase awareness of the importance of proper hydration. The American College of Sports Medicine has issued a set of guidelines for fluid replacement (**Table 6**).

Table 6 Fluid replacement: Summary of recommendations of the American College of Sports Medicine

It is recommended that individuals consume a nutritionally balanced diet and drink adequate fluids during the 24-h period before an event, especially during the period that includes the meal prior to exercise, to promote proper hydration before exercise or competition.
It is recommended that individuals drink about 500 ml of fluid about 2 h before exercise to promote adequate hydration and allow time for excretion of excess ingested water.
During exercise, athletes should start drinking early and at regular intervals in an attempt to consume fluids at a rate sufficient to replace all the water lost through sweating, or consume the maximal amount that can be tolerated.
During exercise lasting less than 1 h, there is little evidence of physiological or physical performance differences between consuming a carbohydrate–electrolyte drink and plain water.
Inclusion of sodium (0.5–0.7 g per liter of water) in the rehydration solution ingested during exercise lasting longer than 1 h is recommended since it may be advantageous in enhancing palatability, promoting fluid retention, and possibly preventing hyponatremia in certain individuals who drink excessive quantities of fluid. There is little physiological basis for the presence of sodium in an oral rehydration solution for enhancing intestinal water absorption as long as sodium is sufficiently available from the previous meal.

From the American College of Sports Medicine (1996) Position stand on exercise and fluid replacement. *Medicine and Science in Sports and Exercise* **28**: i–vii.

Simple methods, such as recording body weight before and after exercise to determine fluid loss and observing the color of urine or the turgidity of skin, can be useful for monitoring hydration status. The simplest insurance against dehydration is to consume fluids prior to and during physical activity or heat exposure to match water loss. The amount of fluid needed to maintain a favorable hydration status is variable between individuals but often necessitates drinking in the absence of thirst. Excess fluid consumption is rarely a problem. However, caution should be used to avoid dilutional hyponatraemia from overzealous hydration. Humans can acclimate to work in a hot environment and enhance their ability to thermoregulate and conserve fluid, but they cannot adapt to dehydration. Acute dehydration can decrease physical performance and thermoregulation ability and increase the risk for heat illness. Chronic dehydration can reduce metabolic and thermoregulatory efficiency and increase predisposition to kidney disease. The deleterious effects of dehydration on physiological function are summarized in **Figure 6**.

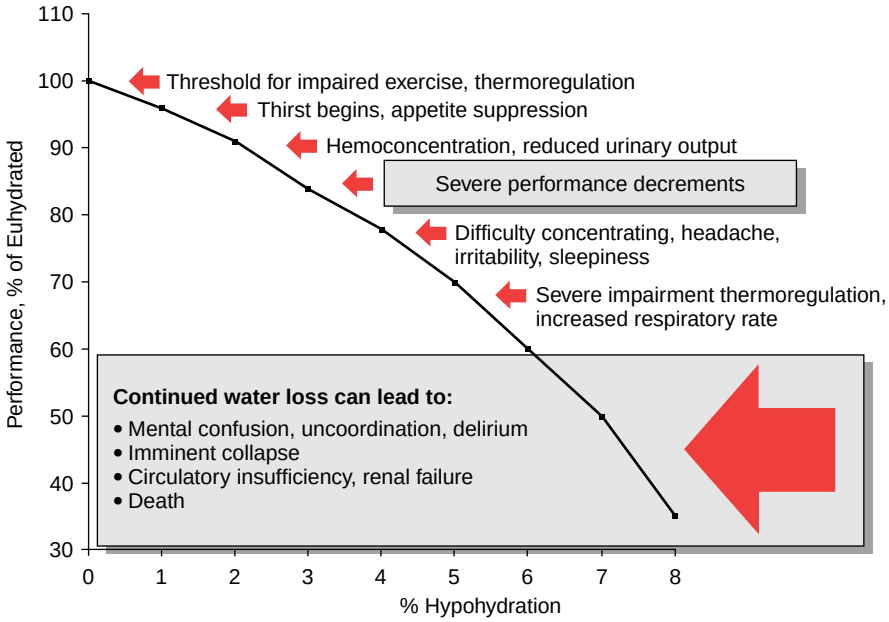

Figure 6 Progressive physiological effects of dehydration on physical performance and pathophysiology of hypohydration. The onset, magnitude, and severity depend on the workload, level of physical fitness, ambient temperature, relative humidity, and degree of heat accumulation of the individual. DENTAL DISEASE

R C Cottrell, The Sugar Bureau, London, UK

Introduction

A number of dental diseases are among the most common diseases that are influenced by diet. Dental decay (caries) is experienced to some degree by most people at some time in their lives; dental erosion is thought to be an increasing problem, although data on prevalence are scarce, and dental-enamel defects are still an issue in some communities. Bacterial gum disease, while also common, is not known to be influenced by diet.

Enamel Defects

The structural integrity of the hard tissues in the mouth is influenced by the nutritional status of the mother during fetal development and by that of the child during the early years, when the permanent teeth are being formed (especially important are adequate availabilities of calcium and vitamin D). An excessive intake of fluoride during the period when the enamel of the primary or secondary teeth is being formed will lead to the characteristic defect of fluorosis. Except in rare circumstances, when the intake of fluoride is very high, this condition is usually minor, with no functional significance, and is visible only on professional inspection.

Dental Caries, Erosion, and Gum Disease

Once the teeth have erupted, they may be subject to three main conditions, all of which may threaten their survival: dental caries, tooth wear, and gum disease. Inappropriate dietary habits are a necessary contributing factor to the development of dental caries and may contribute, in part, to tooth wear by causing acid erosion. In contrast, diet has no effect on the common forms of gum disease.

Etiology of Caries

The causes of dental caries and factors influencing their formation have been the subject of research for more than 100 years. The importance of oral bacteria was discovered well before the specific influence of sugars derived from the diet became known in around 1950. While the protective effect of fluoride has also been known for more than 50 years, the mechanism of this effect is still a subject of debate.

Different approaches have been used to try to understand the caries process. Experimental studies have either induced clinically apparent caries or attempted to model the early stages of caries. Ethical limitations on studies that might cause caries in humans and increasing resistance to animal experimentation have stimulated a great deal of imaginative recent work with laboratory modelling.

Direct studies of caries induction are rarely conducted nowadays. But, in the past, important evidence in this field has come from experiments in which caries were induced in laboratory animals and, in one important instance, from a similar experiment in human subjects. The animal experiments are now regarded with some suspicion, since the information gained cannot be readily interpreted in terms of human risk. The animals used differ appreciably from their human counterparts in the structure of their teeth, their way of eating, and other factors such as saliva and oral bacterial populations. These animal experiments have been useful, however, in establishing that all fermentable carbohydrates are capable of inducing caries under appropriate conditions.

A key human experiment was conducted in the 1950s, before it was entirely clear that sugar is capable of causing caries. It was important in that it demonstrated conclusively that the consumption of a large amount of sugar does not necessarily have a discernable influence on caries risk, provided it is eaten at mealtimes, whereas frequent consumption of quite small amounts of sugar had a marked influence. Subjects given $340\,g\,day^{-1}$ of sugar at meal times showed no increase in caries incidence, while subjects given $50\,g\,day^{-1}$ or $100\,g\,day^{-1}$ between meals showed an increase. Typical European intakes of sugar are less than $100\,g\,day^{-1}$.

The subjects in this study had little or no oral hygiene and no access to fluoride. It can therefore be readily concluded that the amount of sugar consumed in the diet, even in countries with high consumption, is unlikely to influence caries risk, especially with the regular use of fluoride toothpaste for oral hygiene. Whether frequent consumption of sugar will influence caries risk in an individual who cleans his or her teeth regularly with a fluoride toothpaste is more controversial. But, given the current state of knowledge, it seems unwise to assume that any dietary behavior would be safe, however outlandish. The current fashion of eating and drinking perpetually and of sipping sugar-containing drinks from a can over long periods seems designed to cause caries and cannot be recommended.

Research into the causes of dental caries has addressed a number of questions. These include why there are large differences in the disease experience of individuals within the same population or even family group, why the prevalence and severity of the disease are so different in different populations, and why these can change so dramatically with time. Entirely satisfactory answers to these questions are still being sought, but much has been learned over the last 100 years about the contributing factors and protective measures that determine the likelihood of this disease developing. This knowledge has been synthesized into the currently held view that clinically significant caries will develop only when a number of circumstances occur simultaneously. Inappropriate dietary habits (frequent consumption of sugars or starches) will allow the selective proliferation of bacteria attached to the tooth surface that are capable of metabolizing sugars to organic acids (especially lactic acid). These acids will facilitate dissolution of the tooth enamel whenever their production is sufficient to lower the local pH below a critical level. The presence of saliva or of other components of the food matrix will influence the pH attained and also the rate at which mineral is lost from the tooth surface.

The formation of dental caries is not, however, a simple unidirectional process of demineralization. Some tooth mineral may be removed almost every time something is eaten or drunk, but this loss will generally be made good by the subsequent accretion of mineral from saliva. Thus, a cavity develops only when the balance of repeated cycles of demineralization and remineralization results in localized overall mineral loss. It is for this reason that caries are most likely to occur at sites where food residues are likely to be trapped and access for saliva is limited (for example, between two closely abutting teeth).

The presence of fluoride not only radically alters both demineralization and remineralization but may also inhibit the activity of the acid-generating bacteria. To date, the most effective methods of reducing the incidence of dental caries have involved the use of fluoride either (at low concentrations) in community water supplies or (at higher concentrations) in toothpaste.

Caries-Causing Bacteria

The surfaces of all teeth are normally covered with a biofilm (plaque) composed of a range of bacterial species embedded in a sticky organic material produced by the metabolic activity of specialized bacteria. Colonization of the surfaces of the teeth starts as soon as they erupt in a baby's mouth (from about 6 months of age) and continues throughout life. There is evidence to suggest that the initial colonization of a baby's teeth with cariogenic bacteria may arise by infection from the mother's mouth. The common practice of sampling the food in a baby's dish, to check that it is not too hot, using the same spoon that is to be used to feed the baby may be a particularly effective way of transferring bacteria from carer to baby. Brushing the teeth with a toothbrush will remove part, but not all, of this film and its accompanying bacterial population. Many of the bacteria present are harmless, but a number of species are capable both of metabolically converting carbohydrates to acids (acidogenic bacteria) and of continuing to be metabolically active when the local pH has become too acid for most bacteria to tolerate. It is these bacteria that cause caries.

Fermentable Carbohydrate

Acidogenic bacteria metabolize (ferment) simple sugars (glucose, fructose, sucrose, lactose, and maltose) to acids. Sugars may be present as a result of their direct consumption or as a result of the enzymatic breakdown of starches within the mouth by salivary amylase. Thus, a substantial proportion of a typical diet will contain a source of fermentable carbohydrate, and many, if not all, eating and drinking occasions will give these bacteria one of these metabolic precursors. The more frequently an individual consumes carbohydrate, the more the acidogenic bacteria thrive and other, less acid tolerant, bacteria are disadvantaged.

A wide variety of foods contain carbohydrate that is capable of giving rise to acids as a result of bacterial metabolism (fermentation) within dental plaque. Of the common dietary sugars, sucrose, fructose, and glucose are found in fruit and fruit juices, soft drinks, jams, honey, chocolate and other confectionary, and an immense variety of composite foods and drinks. Lactose arises naturally in milk and milk products but is also widely used as an ingredient in its own right by the food industry.

Starches are also classed as fermentable carbohydrates because they are partially broken down by amylase in saliva during chewing to maltose and glucose. Residues of starchy foods are frequently caught between the teeth and in the fissures of the molar teeth, where they may be broken down to sugars over long periods. Measurements of the pH of plaque following the ingestion of starches have suggested that the depression of pH may be as great as and last even longer than that produced by some sources of sugars, such as drinks, because of slow clearance. Highly processed starchy products, such

as heat- and pressure-processed extruded snacks, are likely to be more readily converted to sugars than less processed starchy foods, such as bread.

Clearly, the wide range of individual dietary choices and eating habits may influence the risk of developing caries. The physical characteristics of fermentable carbohydrates will affect the rate at which they are cleared from specific sites in the dentition. Foods that are inclined to remain for long periods in stagnation sites (for example, between the teeth), such as toffees or raisins, are likely to give rise to a greater local fall in pH than are those that are rapidly cleared, such as chocolate. Clearance rates are also influenced by the increase in salivary flow that is stimulated by eating or drinking. When salivary flow is greater, for example after consuming a strongly flavored food, clearance will be faster and demineralization is likely to be less than that after consuming a bland food.

Susceptible Sites

Dental caries are more likely to occur at stagnation sites between teeth or in the fissures of molar teeth. Plaque will accumulate in these sites, where it is less likely to be disturbed by tooth brushing. At the same time, the protective buffering of saliva and the remineralization that arises from its mineral content are attenuated by the inaccessibility of such sites, while food debris is retained for longer periods. The reduction of salivary flow during sleep makes food debris remaining in these sites at night particularly damaging to the teeth.

Experimental Models of the Caries Process

Because direct manipulation of the caries process in human subjects is impossible for ethical reasons, a number of techniques have been developed that provide insights without risking clinical damage to the teeth of experimental subjects. Much of the earlier work relied on measurements of the change in plaque pH that followed a single consumption episode of a food or drink containing a source of fermentable carbohydrate. This approach provides an indication of the potential cariogenic challenge of these exposures and addresses the fundamental question of whether pH falls to a level that is expected to give rise to demineralization of the tooth enamel. Plaque pH measurements have thus been used to assess whether a food or drink may be considered safe for teeth. But this technique does not provide any information on the influence of the repair processes that follow exposure to a demineralizing challenge.

Approaches that provide an insight into the balance of demineralization and remineralization episodes over a period of time with naturalistic eating and drinking circumstances have now become more commonly used. These involve placing an enamel sample within a subject's dentition and carefully assessing any changes in the surface of this sample over a period of time. Particular cariogenic challenges can be applied, but, because they are continued for only a limited period of time, the subject's own teeth will not be appreciably affected. In many cases, the enamel sample is not cleaned with fluoride toothpaste, whereas the subject's own teeth are so protected (the additional enamel sample being removed while the teeth are brushed).

These models have provided useful information not only on the relative cariogenic potential of different foods and drinks but also on the protective effects of fluoride toothpaste (even though it may not be applied directly to the enamel sample) and on the influence of stagnation sites on caries risk with different dietary practices. Useful indications of answers to important public-health questions are beginning to emerge from this kind of research, such as the number of exposures to fermentable carbohydrate that can be tolerated without appreciable risk to the teeth, and the influence of fluoride toothpaste use on this number.

Etiology of Tooth Wear

The enamel surfaces of the crowns of the teeth may be damaged by wear arising from abrasion, attrition, or erosion. Abrasion can arise from the action of rubbing a hard substance across the surfaces of the teeth, for example when brushing too vigorously with a hard toothbrush. Attrition involves one tooth surface wearing down because of contact with another. A third form of wear involves the direct erosive action of acids present in foods (such as yoghurt or pickles) or drinks (especially citrus fruit juices). No bacterial metabolism is required for these processes to occur. It is unclear, however, whether the apparent increase in the prevalence of clinically apparent erosion of the teeth is the result of dietary habits or of some other factor. Only recently have dental-health surveys assessed this problem specifically, so it is possible that it has been noticed more, rather than actually occurring more, in these later surveys. It is also not always possible to distinguish acid erosion from other causes of tooth wear, such as over-vigorous tooth brushing. In addition, a common source of acid erosion is not dietary but arises from the regurgitation of the extremely acidic contents of the stomach. This is often seen in young children and, in adults, may be a presenting symptom of bulimia nervosa as a result of repeated vomiting.

Etiology of Gum Disease

Gum disease arises as a result of bacterial infection of the gums, especially at the tooth margins. It is often assumed that excessive accumulation of plaque, arising from inappropriate dietary habits, is a factor in this condition, but there is little evidence for any material influence of diet. The milder forms of gum disease are extremely common in all populations. More severe disease is the most frequent cause of tooth loss in older people. The best form of protection from gum disease is regular tooth brushing.

Protection from and Prevention of Dental Caries

Variations among individuals, and with time, will arise as a result of differences in acid generation from sugars at different localities within the dentition. These variations may be influenced by changing dietary habits and by the extent of the colonization of the relevant tooth surface by acidogenic bacteria. They may also be affected by changes in saliva flow, for example as a result of the use of certain medications or radiotherapy.

These factors may provide a reasonable explanation for many of the differences in caries experience observed between individuals and populations and between different locations within an individual's dentition. They do not explain the dramatic reduction in caries prevalence seen throughout the developed world in the last 30 years. There is no doubt that this improvement has been caused by the introduction of fluoride toothpaste.

Fluoride

Fluoride has provided the great success story in dental public health in the last 30 years. There are two main routes of delivery: water and toothpaste. Both are, in effect, dietary modifications.

The observation that tooth decay was less common in communities whose water supplies naturally contained low concentrations of fluoride led to the introduction of appropriate concentrations of fluoride into many public water supplies that did not naturally contain it. The prevalence of dental caries appeared to fall by between 20% and 50% as a result of this simple public-health measure.

There have been many thorough studies of the general health of populations receiving fluoridated water, which have found no credible evidence of adverse affects, except in a few areas where the fluoride content of the water is naturally very much higher than the level used for caries prevention. Despite vocal opposition to what is seen by some as compulsory medication of the population, many countries (for example, the USA and Ireland) still use this approach widely. Some, however, such as The Netherlands, have discontinued the practice.

Even greater improvements in dental health have followed the introduction of fluoridated toothpastes. The benefits seen at the population level from this innovation have been far greater than those predicted by the controlled clinical trials that preceded the widespread sale of fluoridated toothpastes to the public. Improvements of greater than 60% have been common. Interestingly, caries rates in The Netherlands continued to fall after the discontinuation of fluoridated water supplies, probably as a result of intense dental-health education of the population about the value of regular brushing with fluoridated toothpaste. In contrast, the abandonment of water fluoridation in the UK region of Anglesey was followed by a sharp rise in caries incidence.

A Practical Approach to the Prevention of Caries

The success of fluoridated toothpaste in preventing dental caries has resulted in a change in professional approaches to prevention. Instead of focusing simply on attempts to reverse the main causative factors, attention is now centered on exploiting protective influences. The interaction of the three main causative factors is illustrated in **Figure 1**. Numerous attempts to change the impact of any of these influences on caries have proved ineffective, except, perhaps, under the most extreme situations, such as during war time.

In contrast, exploiting the protective potentials of fluoride, tooth brushing, and salivary stimulation have proved successful. **Figure 2** illustrates the roles of these factors in comparison with the

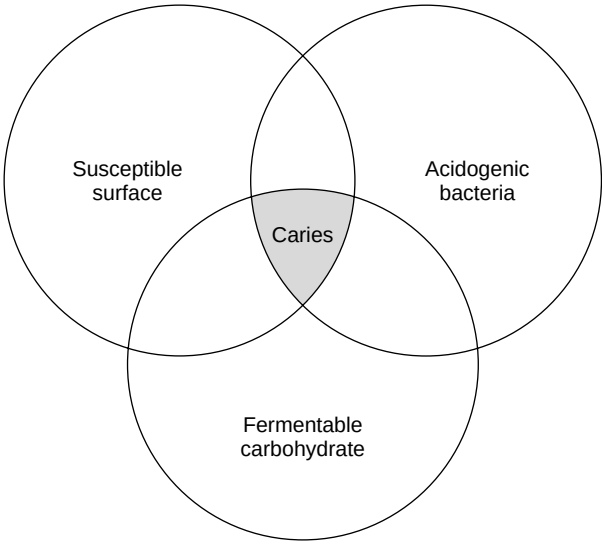

Figure 1 Interacting factors causing tooth decay.

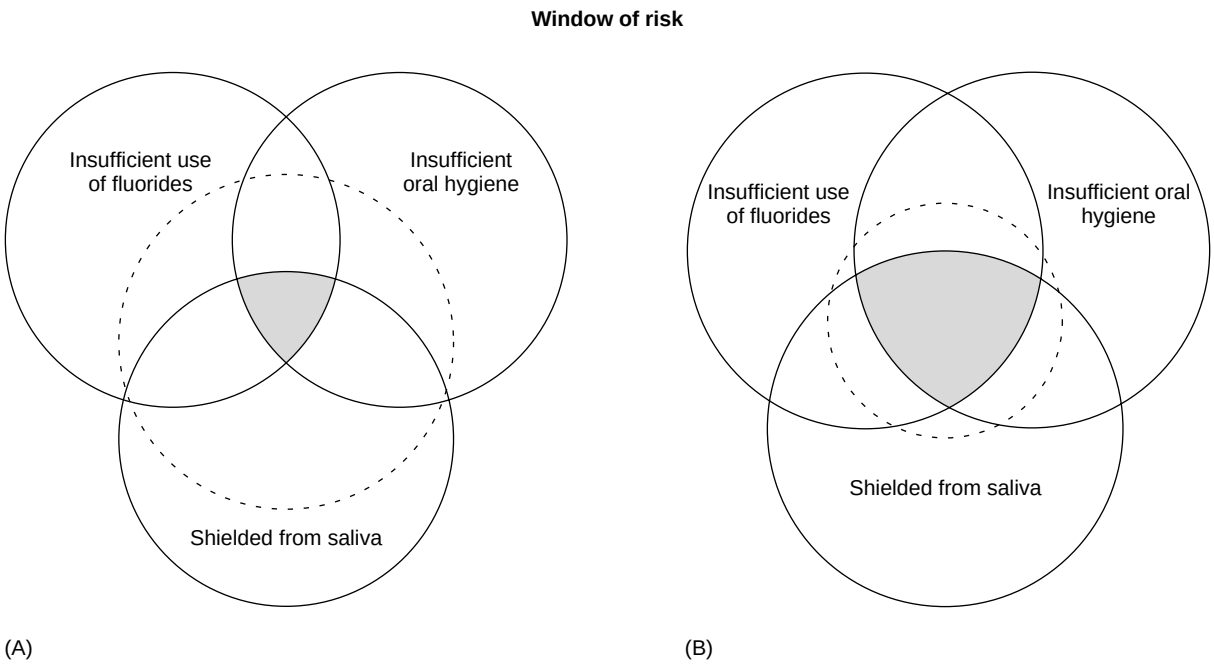

Figure 2 A new model to explain and guide caries prevention. The local factors – insufficient use of fluorides, insufficient oral hygiene, and protection from saliva – form a 'window of risk' through which the circle of cariogenic food (shown dashed) can be seen in the background. (A) In this example it is clear that it would be impossible to reduce the food circle to such an extent that the window is not completely filled (less caries risk). (B) If oral hygiene and, concomitantly, fluoride supply are neglected (large window of risk), a reduction in the burden of cariogenic food could reduce the caries risk. Reproduced with permission from van Loveren CM and Duggal MS (2001) The role of diet in caries prevention. *International Dental Journal* **51**: 399–406.

pervasive challenge of diet. Where a tooth site is shielded from saliva (stagnation site) and oral hygiene and the availability of fluoride are insufficient it is likely that a dietary modification of sufficient magnitude could exert some influence on the final outcome. But where these protective factors are adequate it is highly unlikely that dietary variations will exert any material effect. These predictions are borne out by epidemiological observations. In most developed countries, where fluoride use is adequate, wide variations in dietary exposure to fermentable carbohydrates between individuals are not accompanied by predictable differences in caries experience.

Epidemiology

Studies of Risk Factors

A large number of observational epidemiological studies have been conducted that have attempted to show associations between caries experience and one, or several, of the known risk factors. The large majority of these studies have been of poor design, examining insufficient numbers of subjects and ignoring important confounding influences. Many have been cross-sectional in design and have sought to draw conclusions about the causes of caries by assessing the dietary and other habits of subjects at the same time as measuring their caries experience. Such a study design is somewhat unsatisfactory for this purpose.

The few longitudinal studies in the scientific literature are equally weakened by poor data on dietary habits and, in some cases, idiosyncrasies in caries assessments. Taken together, these studies provide scant evidence about the relative importance of the different etiological factors. It is fortunate that more convincing evidence is available from experimental studies.

National Trends in Caries Prevalence

Data on the prevalence of dental caries within populations are nowadays very reliable as they are collected to internationally recognized standards. Surveys of 12-year-old children are carried out in most countries, and the data are collated by the World Health Organization (see **Table 1**). In contrast, data for adults are scarcer.

The general picture emerging from the repetition of these national surveys is clear. In many countries the prevalence of caries is falling, often dramatically. In poorer countries this is unlikely to be the case, and, even within the richest countries, the dental-health experience of the economically disadvantaged

is significantly poorer than that of those with a higher socioeconomic position. In many countries there is evidence that inequalities in dental health between the rich and the poor have widened.

Attempts to account for these trends are hampered by the unreliability of data on factors that are likely to attenuate caries risk. All assessments of these factors rely on people (often children) accurately remembering and reporting aspects of their everyday behavior, such as whether they clean their teeth and how often and what they have eaten and drunk and when. These data are subjective and notoriously unreliable. More secure conclusions about factors that have influenced caries rates must therefore come from more objective data (see below).

Fluoride Toothpaste

The effect, at a population level, of the introduction and widespread availability of fluoride toothpaste is clear. **Figure 3** shows the falls in caries incidence in 5-year-old and 12-year-old children in the UK seen in successive national representative surveys. A similar picture has been seen in Denmark (**Figure 4**). Fluoride toothpaste was introduced onto the UK market in around 1976 and rapidly became universal. The falls

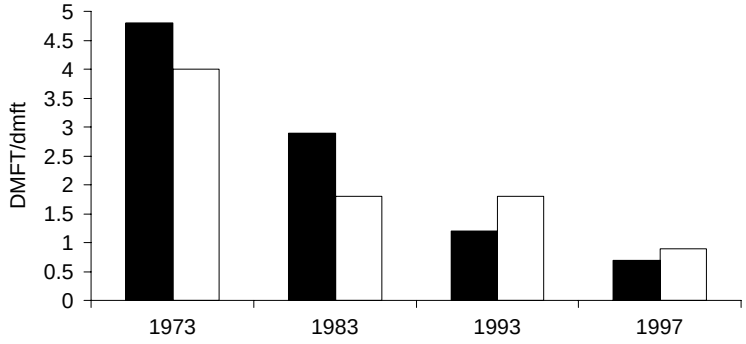

Figure 3 The change in the average decay experience of children in the UK. DMFT (decayed, missing, and filled permanent teeth) in 12-year-olds (filled bars) and dmft (decayed, missing, and filled primary teeth) in 5-year-olds (open bars). Data from OPCS (1973–1993) and NDNS (1997).

in caries prevalence seen at the next survey date (1983) exceeded expectations, based on earlier clinical trials, and led many experts to predict that no further fall would occur. In the event, an even greater decline was seen among 12-year-olds at the next decennial survey (1993). The caries prevalence among 5-year-olds appeared to have reached a plateau by 1993, but later data suggests that further falls in both age groups may have occurred. Regrettably, the self-reported use of fluoride toothpaste (almost certainly an overestimate of actual use) is still not universal, even among children in comfortable socioeconomic conditions.

The variation in caries experience with family income is illustrated for the UK in **Figure 5**. A clear gradient exists, with the poorest dental health seen in the lowest-income families. Trend data indicates that the greatest improvements have occurred among higher-income families and the least among those at the other end of the socioeconomic scale. The reasons for these differences are not entirely clear, but oral hygiene and the use of fluoride toothpaste appear to be important. Evidence of gum disease (an indicator of oral hygiene) is more common among poorer children.

Diet

Attempts to attribute the recent changes in caries prevalence to improvements in dietary habits have been unconvincing. Apart from the difficulty in determining what people are eating and drinking with any accuracy, data on when food and drink have been consumed are needed to assess the overriding dietary influence of frequency of exposure of the teeth to fermentable carbohydrate. These data are rarely collected in surveys and are then of uncertain reliability. All dietary surveys are seriously hampered by the unreliability of the subjective reporting of dietary habits by those surveyed.

The use of nationally aggregated data (such as food-supply data) is hardly more useful, since a large proportion (up to 50%) of the food available for consumption is never actually eaten. Nonetheless, some experts have pointed to changes in caries prevalence following dramatic changes in food supply as evidence of the practical utility of dietary

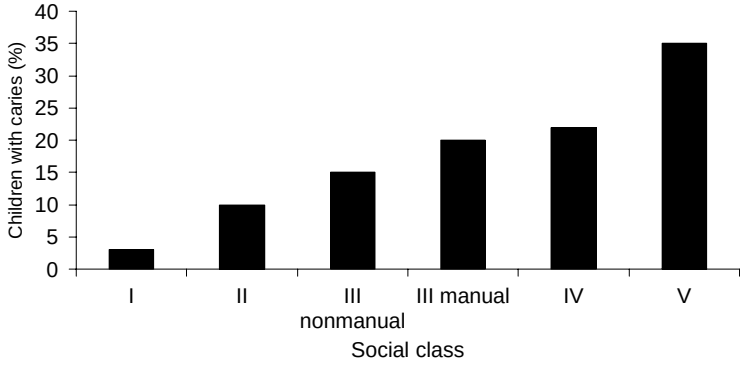

Figure 5 Percentage of children aged 1.5–4.5 years with caries across social-class groups in the UK, calculated from data presented in Hinds and Gregory (1995). Social class I has the highest income, social class V has the lowest.

manipulation as a means of reducing the remaining burden of this disease. The weakness of this argument is that predictable changes in caries prevalence at a population level have rarely been seen except under conditions of extreme dietary change, such as during war time. These changes all occurred before the advent of the widespread use of fluoride. When the food supply of fermentable carbohydrates is severely restricted, changes in the frequency of consumption may occur to a degree that is sufficient to alter caries risk when fluoride is not used. Where fluoride toothpaste and oral hygiene are adequate, even such extreme changes in diet are unlikely to alter caries experience materially. In addition, attempts to use dietary manipulation to reduce the risk of caries in free-living populations have proved unsuccessful.

Other Factors Affecting the Epidemiology of Caries

The influence of other factors that might be expected to have a bearing on caries experience has proved difficult to establish for practical reasons. These include the susceptibility of particular sites within the dentition or in an individual's mouth and local salivary flow rates. Both of these factors are known to be strongly influenced by genetic inheritance. The morphology of the teeth and, especially, the depth and shape of the fissures on the surfaces of the molar teeth are strongly heritable. It is generally difficult to predict, in advance of caries developing, which sites will be particularly susceptible. But one successful preventative approach has been to identify children with deep fissures in their molar teeth at an early age and offer prophylactic treatment in the form of sealants. This addresses the most common site of early childhood caries (the molars) and targets those children most at risk because of unfavorable tooth morphology.

The rate of salivary flow, both at rest and when stimulated by eating or drinking, is also known to be a crucial influence on risk. Patients who have had a salivary duct removed for any reason have a far higher risk of caries than those with normal function. Some people have low salivary flow rates and, again, have a greater risk. Older people are inclined to suffer from a dry mouth, and a number of medications reduce salivary flow.

Epidemiological studies to assess the importance of salivary flow rates in altering the risk of caries have not been carried out because of the practical difficulty of measuring this factor. But the stimulation of salivary flow that accompanies chewing has been successfully exploited to reduce caries risk in experimental studies using chewing gum (usually sugar-free). Reductions in caries incidence were seen when subjects were encouraged to chew the gum, especially between and immediately after meals, while continuing their normal regular oral-hygiene practices. Convincing evidence of an effect at the population level, however, is awaited.

DIABETES MELLITUS

Contents

Etiology and Epidemiology

J Sudagani and G A Hitman, Queen Mary's, University of London, London, UK

Introduction

Diabetes mellitus is a chronic metabolic disorder characterized by disturbance in glucose metabolism leading to a state of hyperglycemia and is associated with microvascular and macrovascular complications in the long term. Diabetes is the leading cause of noncommunicable diseases worldwide and it is true to say that diabetes has reached epidemic proportions in certain parts of the world and in certain ethnic groups. This has widespread implications for health resources.

Diabetes mellitus is an etiologically and clinically heterogenous group of disorders that share hyperglycemia in common. The two main types of diabetes, type 1 diabetes (T1D) and type 2 diabetes (T2D), are quite distinct from each other in their etiology and epidemiology. T2D is the most common form of diabetes worldwide accounting for 90% of cases globally and affecting approximately 4% of the world's adult population. Type 1 diabetes is an autoimmune disease that results in insulin deficiency. Both T1D and T2D are distinct from 'other causes of diabetes' as defined by the etiological classification of the World Health Organization (WHO); we will not comprehensively review the many types of diabetes but illustrate it with maturity onset diabetes of the young (MODY) and fibrocalculous pancreatic diabetes (FCPD). Gestational diabetes is the fourth category defined by the WHO.

Type 1 Diabetes

Worldwide Prevalence

In 1997 there were 11.5 million people with T1D in the world; this figure is expected to rise to 23.7 million in the year 2010. These increasing figures will have most impact in Asia, where there are currently 4.5 million people with T1D, and this is expected to rise to 12 million by the year 2010. One of the best incidence studies has come from Europe as part of a European collaboration, where the highest incidence of T1D is found in Finland and the lowest rates in Romania (**Table 1**). The incidence of T1D follows a north–south gradient, with the notable exception of Sardinia. The figures from countries such as India are less precise, although one study in Chennai suggested an incidence equivalent to that found in Southern European countries. These different rates of T1D are likely to reflect both the genetic background of individual countries and differences in exposure to environmental agents. In recent years,

Table 1 Extremes of incidence of childhood type 1 diabetes mellitus in different ethnic groups

Higher	*Incidence*[a]	*Lower*	*Incidence*[a]
Sardinia	35–40	Venezuala	0–5
Finland	35–40	Peru	0–5

the incidence of T1D has been increasing in several different countries. These changes must reflect environmental influences.

Etiology

Type 1 diabetes is due to autoimmune destruction of insulin-secreting pancreatic β cells of islets of Langerhans. T1D typically occurs in young individuals with an age of onset of less than 40 years. The autoimmune reaction is likely to be triggered by an environmental agent *in utero* or in very early life (**Figure 1**). The earliest markers of β cell destruction are the appearance of autoantibodies to glutamic acid decarboxylase(GAD), islet cells, and insulin. Autoantibodies have been detected 10–15 years before the onset of disease and, furthermore, have been known to disappear without T1D occurring in a few individuals. One to two years before onset of the disease, evidence of β cell impairment can be detected, initially evidenced by a reduction in the first phase of insulin response to intravenous glucose and in the later stages by an abnormal oral glucose tolerance. In contrast to the slow β cell destruction, the onset of T1D is acute and is usually measured in weeks. At this stage in the etiological process, it is likely that 70% of β cells have been destroyed and those remaining are inhibited by the action of cytokines.

There is a subgroup of patients who develop diabetes in adult life and do not require insulin during the first few years after diagnosis; they have an autoimmune component to their disease with positive GAD and islet cell antibodies. This condition is named latent autoimmune diabetes (LADA). There are several common features between T1D and LADA, including T cell insulitis, islet antibody positivity, and high rates of HLA DR3 and DR4. The prevalence of LADA in newly diagnosed diabetics has been shown to range from 2.8% to 22.3% in different studies depending on the markers used and characteristics of the patients. Although these patients present with type 2 diabetes, they have been shown to progress to insulin dependency especially if the diabetes is diagnosed at a younger age and the patient is not overweight. Therefore, there may be a role for measuring GAD antibody in newly diagnosed patients with type 2 diabetes to identify the LADA subgroup especially in the younger age groups. This group of patients is now classified as type 1 diabetes by the new WHO classification.

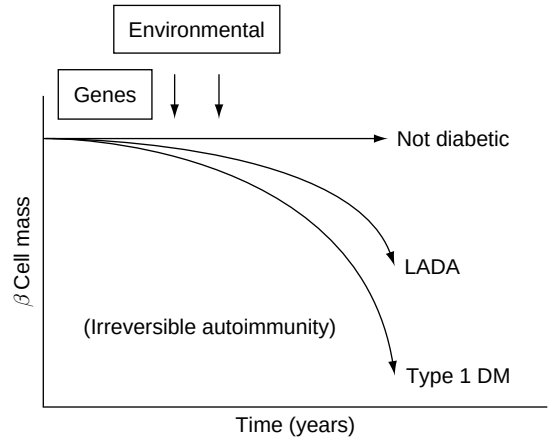

Figure 1 The etiology of type 1 diabetes mellitus. DM, diabetes mellitus; LADA, latent autoimmune diabetes.

Genetics

Type 1 diabetes is a multifactorial disease with both genetic and environmental components. The largest genetic contribution to T1D is determined by genes in the major histocompatibility complex (MHC) located to the short arm of chromosome 6 (IDDM1-HLA, 6p21). Initial associations between T1D and the MHC were described for the HLA class I antigens A1-B8 and B15. With advent of HLA class II serology, closer associations were found with HLA-DR with an increased frequency of DR3 and DR4 and a decreased frequency of DR2 in T1D subjects. At the population level the strongest genetic association with T1D is with HLA-DQ alleles. This is best defined by DNA typing of HLA-DQ1, DQB1, and DRB1. However, due to the strong linkage disequilibrium between these loci it has been very difficult to study the effect of individual HLA-DQ or HLA-DR genes separately. For the individual, susceptibility is best defined by allelic combinations of MHC genes located to all three major regions (classes I, II, and III) called HLA haplotypes. Haplotypes occur because of strong linkage disequilibrium observed in the MHC whereby the combinations of alleles are seen more frequently than would be expected by their individual gene frequencies. An example of a haplotype would be A2, Cw1, B56, TNFa6, DRB1*401, DQA1*0301, DQB1*0302. The haplotypes are likely to relate to functional groups of genes involved in the etiology of T1D. Thus, the critical residues of DR and DQ, accounting for the disease association with T1D, are located in the antigen-binding cleft of the HLA molecule and are likely to influence the binding of antigenic peptides for subsequent presentation to T helper cells. Similarly, polymorphism of the HLA class I molecules are likely to relate to antigen presentation to cytotoxic T cells, and polymorphisms of tumor necrosis factor (TNF) have been associated with differing TNF responses to mitogenic stimulation.

The MHC accounts for approximately 40% of the genetic component to T1D. Evidence from genome scans and candidate gene studies indicates the existence of a large number of putative non-MHC genes contributing to the etiology of T1D, although all of comparatively small effect compared to the MHC. The most reproducible T1D associations have been found with the insulin gene, cytotoxic T lymphocyte antigen 4 gene (*CTLA4*), and the vitamin D receptor. An association between the insulin gene (located on chromosome 11p15.5; *INS*), and T1D was described in the 1980s and subsequently confirmed by linkage studies. The *INS* locus on chromosome 11p15.5 contains a major polymorphism 5′ to the transcription site, which is a variable number of tandem repeats (VNTR) region. One functional hypothesis to explain the association between the insulin gene and T1D is that 'hypersecretors' of insulin determined by the disease-associated polymorphism might induce thymic tolerance to insulin, thus providing protection from the autoimmune reaction. A recent study showed association of the T-cell regulatory gene *CTLA4* with susceptibility to autoimmune disease, including type 1 diabetes. *CTLA4* (gene located on chromosome 2q33) plays an important role in the counter-regulation of CD28 T cell antigen receptor activation of T cells. In the mouse model of T1D, susceptibility was also associated with variation in *CTLA4* gene splicing with reduced production of a splice form encoding a molecule lacking the CD80/CD86 ligand-binding domain. There are associations reported between vitamin D receptor gene polymorphisms and type 1 diabetes. The *VDR* gene is located on chromosome 12q and polymorphisms of the *VDR* gene may be related to T-cell-mediated autoimmune destruction of β cells of pancreas. Vitamin D compounds suppress T cell activation and significantly repress the development of insulitis and diabetes in the nonobese diabetic (NOD) mouse, a mouse model of human type 1 diabetes. Results from other candidate gene studies and a 'total genome' analysis have identified at least another 19 chromosomal regions that may be involved in pathogenesis of the disease. The finding that so many genes are involved in T1D raises the possibility that there are several disease processes that might lead to β cell destruction. Furthermore, evidence is still emerging that the genetic susceptibility to T1D is graded both within and among populations.

Environmental Factors

Environmental factors play a significant part in the etiology of T1D and have been implicated in both initiation and progression of β cell damage. The majority of evidence points to the effects of viruses and/or dietary factors as etiological agents.

Many viruses have been implicated in the pathogenesis of T1D; they may have a direct effect on β cells by infection and cell lysis, or alternatively they may act as triggers to the autoimmune process. Among the viruses that have been implicated in humans are coxsackie A, coxsackie B, rubella, cytomegalovirus, mumps, and Epstein-Barr viruses. The enteroviruses (Coxsackie A, Coxsackie B, and Echovirus) are the most commonly associated viruses with diabetes and serve as a major trigger for T1D in the young possibly by induction of islet cell antibodies. The evidence for viral involvement in type 1 diabetes came from several sources, including anecdotal case reports, epidemiological studies, seasonal incidence studies, and animal models. There is data to support the theory that enterovirus infection either accompanies or precedes the development of T1D in young people in many instances.

Coxsackie B was first implicated in the early 1970s by Gamble, who found an increased titer of coxsackie B antibodies in newly diagnosed T1D patients. More recently, coxsackie virus has been identified in very young onset type 1 diabetes (in patients under 5 years of age) using the polymerase chain reaction. Furthermore, when the coxsackie virus was sequenced, although it had extensive homology to coxsackie virus B4, there was some unique sequence variation indicating an T1D variant. There have also been many anecdotal reports of coxsackie B virus causing T1D, presumably by a direct cytolytic effect on β cells. A previously fit child died in diabetic ketoacidosis 3 days after a flu-like illness. At, necropsy, there was an extensive lymphocytic infiltration into the β cells of pancreas and coxsackie B4 was found in the child's serum. This virus was extracted from the pancreas and, when used to infect mice, led to diabetes.

There is a high incidence of T1D among patients with the congenital rubella syndrome. Clearly, this results from an *in utero* infection, but the diabetes that ensues is indistinguishable from the primary type 1 diabetes: the disease presents in the second decade of life, the onset is preceded by islet cell antibodies, and the genetic predisposition is defined by the same HLA association as T1D. This is likely to be a good example of a virus triggering the immune process.

Dietary factors have also been implicated in the development of T1D. Among the dietary factors indirectly linked to either susceptibility or protection to T1D are cows' milk protein (including bovine serum albumin and β-lactoglobulin), β-cell-toxic drugs (alloxan, streptozotocin, rodenticides), dietary toxins (in particular nitroso-containing compounds), and

others such as coffee and sugar. There is an interesting interplay between vitamin D, vitamin D receptor (VDR), and association with T1D as discussed earlier. The contribution of vitamin D as a potent modulator of the immune system is well recognized. The main sources of vitamin D are ergocalciferol and cholecalciferol found in dietary sources and cholecalciferol produced in the skin by ultraviolet radiation of 7-dehydrocholesterol. Vitamin D deficiency in infancy and VDR polymorphisms may be risk factors for T1D. In nonobese diabetic (NOD) mice, long-term treatment with high doses of vitamin D_3 reduced the incidence of diabetes by changing the cytokine balance at the local pancreatic lesion.

The Future

The working out of the complete genetic basis of type 1 diabetes will lead to a better understanding of disease pathogenesis and, through studies of genetic and environmental interaction, direct evidence of environmental factors. T1D may be the first multifactorial disease to benefit from primary prevention of both insulitis (before immune process has been initiated) and of T1D (once autoantibodies have been detected). In the Diabetes Prevention Trial, low-dose insulin was administered to persons with high risk of T1D as ascertained by family history, islet antibodies, and HLA typing. It was concluded that low-dose insulin does not delay or prevent the onset of T1D. In a European study (European Nicotinamide Diabetes Intervention Trial, ENDIT) high-dose nicotinamide was used to protect the β cells in high-risk individuals for type 1 diabetes; unfortunately this trial also failed to show benefit on active treatment. However, 90% of type 1 diabetes patients do not have a family history of type 1 diabetes. The approach in this latter group might be to identify the genetically susceptible by the use of genetic markers and then test for autoantibodies. If the latter subjects are autoantibody positive then intervention may be considered in the future. The sensitivity and specificity that would be required for such sequential testing would depend on how safe the proposed intervention would be.

Type 2 Diabetes

Worldwide Prevalence

Type 2 diabetes is one of the most common noncommunicable diseases in the world with an estimated 147.2 million people suffering from this disorder; by 2010 this figure is expected to reach 212.9 million. Furthermore, it has been predicted that by the year 2010 over half the people with T2D will be living in Asia. This trend is likely to be due to increasing urbanization and industrialization. According to WHO estimates the figure is likely to double by the year 2025. The prevalence of T2D varies widely from the highest in Pima Indians (almost half of the population affected) to the lowest in Rural Africa (1%). As with T1D, the incidence of diabetes in different countries is likely to reflect the different genetic architecture as well as the differing environment. A good example is afforded by the population of Nauru. In full-blooded Nauruans over the age of 60 years the prevalence of T2D is 83%, whereas in those with genetic admixture as adduced by HLA typing the prevalence is 17%; this clearly reflects the genetic component. However, the rapid increase of T2D in the world in the last few decades, and the rise and a recent decrease in prevalence of T2D in the Nauruan community, can only be ascribed to environmental factors. This illustrates the multifactorial nature of T2D, with strong genetic and environmental contributions.

Etiology

Type 2 diabetes is a multifactorial disease with genetic and environmental factors playing a key role in its pathogenesis. Central to the etiology is a defect in insulin action, hepatic glucose output, and insulin secretion. Although insulin resistance is frequently the first detectable abnormality in the progression of T2D, insulin resistance by itself does not cause the disease, which is only manifested when there is a coexisting insulin secretory defect. T2D typically occurs in middle-aged and elderly people but there is an increasing trend of T2D occurring in young individuals. The main question yet to be answered is whether T2D is one disorder or a group of disorders with hyperglycemia as the end point in disease pathogenesis. Insulin resistance is common to several other disorders, including ischemic heart disease, hypertension, dyslipidemia, central obesity, and coagulation defects; the clustering of these disorders is known as the metabolic syndrome or the insulin resistance syndrome. The interface of T2D with obesity is a complex one, highlighted by the discovery of leptin and adiponectin. The cause of obesity and T2D in the ob mouse is a mutation of the *ob* gene. With administration of the ob gene protein (leptin) the ob mouse decreases its food consumption and increases exercise, leading to a dramatic weight loss; if given early enough it will also prevent diabetes. In contrast, common human obesity is associated with increased leptin levels, and which have been found to correlate with hyperinsulinemia. The newly discovered protein adiponectin signals adipose tissue mass; reduced

levels are found in obese subjects and there is an important interplay between adiponectin, insulin resistance, T2D, and atherosclerosis. Ghrelin is a gut hormone that is a signal of satiety and therefore has a direct effect on obesity. In the obese subject with T2D, there may be interplay between leptin, adiponectin, ghrelin, and insulin, contributing to insulin resistance and the metabolic syndrome.

Genetics

Type 2 diabetes is a complex disease and the heterogeneity both at the phenotypic and pathophysiological level indicates that the genetic component is likely to be heterogeneous with no single locus accounting for the disease. There are many strands of evidence to support a strong genetic component to T2D; these include a near 100% concordance in identical twins, familial clustering, genetic admixture and migration studies, complex segregation analysis, and the detection of gene variants leading to diabetes including the identification of genes responsible for human monogenic diabetes (MODY – see below).

Many groups worldwide have completed the first stages of genome scans for genes that predispose an individual to T2D. Currently, a large international research effort is being directed to those diabetes-associated linkage peaks that are overlapping in several genome scans; specifically on chromosomes 1, 12, and 20. One genome scan has been taken to completion with the identification of the calpain10 gene (located to chromosome 2q37) as a major susceptibility gene in Mexican-Americans. The majority of subsequent studies have confirmed an association between calpain10 and T2D as well as insulin action, insulin secretion, endothelial function, and aspects of adipose metabolism. This putative diabetes susceptibility gene encodes a ubiquitously expressed member of the calpain-like cysteine protease family, calpain-10. Functional studies would suggest a role in insulin secretion, insulin action, and adipocyte metabolism. For instance, reduced levels of calpain10 have been found in skeletal muscle associated with disease-associated polymorphisms and inhibition of calpain affects insulin secretion and translocation of glucose transporter-4 in an adipocyte cell line.

A large number of candidate genes have been studied in T2D. Only a few have produced consistent results, i.e., the genes for the insulin receptor substrate-1, insulin, *KCNJ11,* peroxisome proliferator-activated receptor gamma (*PPARγ*), and are critically dependent on the power of individual studies. Insulin receptor substrate 1 (*IRS-1*) is a protein involved in insulin signaling. After insulin binds to its insulin receptor, it stimulates autophosphorylation of its β chain, which, in turn, leads to phosphorylation of several multisite insulin receptor substrate (*IRS*) docking proteins including *IRS-1*. This then generates one of the signals for insulin action. Several variants of *IRS-1* have been detected, one of which (due to the substitution of a glycine for arginine at position 972 (G972R) in the molecule) is associated with insulin resistance, but only in the presence of obesity. This is a good example of a gene variant that is common in the population (at least 8% in the white population) and will only lead to disease in association with other contributing factors for diabetes. Recently a meta-analysis has confirmed the role of the G972R variant in T2D with an odds ratio of 1.25.

KCNJ11 encodes *Kir6.2*, which is an essential subunit of the pancreatic β cell potassium ATP (K_{ATP}) channel. Rare mutations of this locus lead to the monogenic syndrome of familial hyperinsulinemia, confirming the important role of *KCNJ11* in insulin secretion. Although there are a large number of rare variants of the *KCNJ11* gene only one common variant (E23K) has been associated with T2D, although by no means consistently in all studies. It is likely that the studies mentioned above were underpowered as a meta-analysis, that additionally included a large new study, has demonstrated a significant odds ratio for T2D of 1.23. However, it should be borne in mind that the E23K variant does not change protein function and therefore it is unlikely to be the predisposing mutation.

The *PPARγ* gene is mainly expressed in adipose tissue and is the target of the thiazolidinedione class of drugs used to treat T2D by improving insulin action and secretion. In man, rare mutations of *PPARγ* are associated with a monogenic syndrome of severe insulin resistance, T2D, and hypertension. In contrast, a common amino acid polymorphism (Pro12Ala) in *PPARγ* has been shown to be associated with a increased risk of typical T2D, confirmed by a meta-analysis with an odds ratio for diabetes of 1.25 for the common proline allele. Furthermore, a gene nutrient interaction has been demonstrated with an important interaction of the Pro12Ala variant and the ratio of dietary polyunsaturated fat to saturated fat in the diet. *PPARγ* is a nuclear receptor, which upon activation stimulates the transcription of genes responsible for growth and differentiation of adipocytes. This clearly indicates a role for *PPARγ* in fat cell biology and pathophysiology of obesity, diabetes, and insulin resistance.

One of the first candidate genes to be studied in T2D was the insulin gene with an association described with the class 3 allele. As mentioned in the section on the genetics of T1D the insulin gene hypervariable region is a determinant of insulin secretion. Although consistent associations were found of the insulin gene and T1D, this was not the case for T2D. However, the earlier T2D studies were very much underpowered and the controls and patients not well matched. Using a family-based design the association between T2D and the class 3 allele has been confirmed demonstrating paternal but not maternal transmission. This is in keeping with the fact that the insulin/insulin growth factor II gene locus is maternally imprinted. In addition to the importance of adequately powered studies, the paternal transmission is likely to be another explanation for variable results in a case–control study design, emphasizing the importance of family-based designs as an additional strategy in association studies. The insulin/insulin growth factor II gene locus is a determinant of fetal and postnatal growth, which is also an important factor in susceptibility to T2D.

Environmental Factors

Evidence of a strong environmental element to T2D has come from the studies of Barker and Hales. In a number of separate studies, a strong relationship of the development of glucose intolerance and other associated factors of the insulin resistance syndrome with low birth weight or thinness at birth has been demonstrated. Furthermore, these associations are not confined to those with growth retardation *in utero* but extend to the whole range of birth weights. As a consequence of these epidemiologic studies, the 'thrifty phenotype' hypothesis has been proposed, whereby nutritional deficiencies *in utero* lead to poor fetal and infant growth and the subsequent development of T2D in later life, especially when combined with obesity due to excess food intake and lack of physical activity. These changes are recognized to be due to insulin resistance, which is favorable for survival in the immediate postnatal period but plays a significant role in the progression to T2D and metabolic syndrome, and to a certain extent insulin secretion. While there is much discussion regarding this hypothesis, it illustrates the importance of environmental factors in early life, which might prime the fetus for T2D in later life.

Dietary factors and physical inactivity undoubtedly affect the progression of abnormal glucose tolerance to diabetes in a genetically predisposed individual. The best way to lower the risk of diabetes is to lead a healthy life style by eating a healthy balanced diet, engaging in regular physical activity, and balancing the energy intake with energy expenditure. Indeed, recent evidence would suggest that the adoption of a healthy life style in high-risk subjects can decrease the risk of developing T2D by 60%. There is a close relationship between diabetes and obesity, especially when the latter has central distribution. Apart from obesity, several other nutritional factors affect glucose metabolism and the risk of T2D. Current evidence suggests an association between different types of fats and carbohydrates and insulin resistance and T2D. Diets rich in saturated fats are associated with insulin resistance; a multicentre study in a group of healthy individuals showed that a diet high in saturated fat decreased insulin sensitivity compared with a diet high in monounsaturated fat with the same total fat content. Prospective and cross-sectional studies suggest a role of specific types of fat rather than the total fat content in the development of T2D, where high intake of vegetable oils, oils consisting primarily of polyunsaturated fat, was associated with reduced risk of developing diabetes and a positive association between saturated fat and hyperglycemia or glucose intolerance. In a 20-year follow-up of the Finnish and Dutch cohorts of the Seven Countries Study, it was found that a high intake of fat (in particular saturated fatty acids) contributed to the risk of glucose intolerance and T2D. Dietary carbohydrates are classified into simple or complex carbohydrates depending on their chemical structure. The traditional view is that simple carbohydrates be avoided and substituted with complex (starchy) carbohydrates to reduce postprandial glucose response, but this has been challenged by various studies that recognized that starchy foods such as baked potatoes and white bread produce even higher glycemic responses than simple sugars. Glycemic index (GI) was developed to quantify the different glycemic responses induced by different carbohydrate foods. A low GI diet with a greater amount of fiber and minimally processed whole-grain products seems to improve glycemic and insulin responses and lowers the risk of T2D. This shows that dietary recommendations to prevent and manage diabetes should focus more on the quality of fat and carbohydrate than the quantity alone.

A number of environmental toxins have been shown to cause diabetes in humans, including nitrosated compounds, as well as streptozotocin, the rat poison Vacor, and foods such as smoked mutton; depending on the amount consumed they could lead

to either T1D or T2D, presumably dependent on the amount of direct β cell destruction. It has also been proposed that vitamin D might modulate the diabetic process. Vitamin D deficiency has been shown to reduce insulin secretion. In a UK study of Bangladeshi subjects living in east London who were particularly prone to vitamin D deficiency, vitamin D levels were found to be low in those most at risk of diabetes. Furthermore, there was a correlation between vitamin D levels and 30 min oral glucose tolerance test, blood glucose, insulin, and C-peptide levels.

The Future

Research into the identification of genes involved in T2D is beginning to lead to insights into the pathogenesis of this common condition. With knowledge of the precise biochemical variants involved in disease pathogenesis, we will be in a better position to classify the disease and design more rational therapeutic maneuvers to prevent and ameliorate this condition. Research also needs to be directed at the gene–environment interaction, as this will indicate the appropriate population strategies to combat the increasing incidence of this common noncommunicable disease. Recently, life style interventions (healthy diet and exercise) have demonstrated significant reduction in onset of diabetes in high-risk individuals for T2D. In the future genetic profiling might be used to identify those likely to respond to such strategies including pharmacological treatment.

Other Types of Diabetes

Maturity Onset Diabetes of the Young (MODY)

MODY are a group of monogenic disorders inherited in an autosomal dominant pattern. MODY is characterized by early onset (usually before the age of 25 years) of T2D β cell dysfunction and there being a family history (at least two generations) of early onset diabetes. The defect is in insulin secretion due to mutations in the glucokinase and β cell transcription factor genes (**Table 2**). Hepatocyte nuclear factors *(HNF) 1*α, *1*β, and *4*α, insulin promoter factor (*IPF1*), and neurogenic differentiation-1 (*NEUROD1*) play an important role in the normal development and function of the β cells of the pancreas. In the UK mutations in *HNF1*α is the commonest cause of MODY accounting for 63% of cases, followed by mutations in the glucokinase gene (20% of cases). The clinical presentation and progression of diabetes is different among patients with mutations of glucokinase, *HNF1*α, and *HNF1*β. Subjects with glucokinase mutations are frequently asymptomatic but can be identified when diagnosed with gestational diabetes or with a milder form of diabetes, which is frequently treated with diet alone and is not associated with the complications of diabetes. In contrast subjects with *HNF1*α mutations are more like lean patients with T2D with susceptibility to microvascular complications and progressive loss of β cell function exacerbated by increasing body mass index. In comparison to patients with T2D, subjects with *HNF1*α mutations are very sensitive to sulfonylurea treatment as might be predicted from the genetic defect. Finally, patients with *HNF1*β mutations in addition to T2D have renal cysts that may lead to renal failure and hence such patients are more frequently found in the renal clinic.

Table 2 Maturity onset diabetes of the young

MODY subgroup	*Gene*	*Chromosome*	*MODY frequency*
MODY1	*HNF4*α	20q	Rare
MODY2	*GCK*	7p	10–65%
MODY3	*HNF1*α	12q	20–75%
MODY4	*IPF1*	13q	Rare
MODY5	*HNF1*β	17q	Rare
MODY6	*NEUROD1*	2q	Rare

Gestational Diabetes

Gestational diabetes (GDM) is defined as glucose intolerance first recognized in pregnancy. This therefore, excludes those women with either type 1 diabetes or type 2 diabetes diagnosed before conception. GDM is a relatively common occurrence in pregnancy affecting 1–14% in White European and North American populations and higher in certain ethnic groups such as South Asian and Afro-Caribbean populations.

GDM increases the risk to both mother and fetus although the levels of maternal glycemia that leads to an adverse outcome are not well defined. Furthermore, there is controversy as to who should be screened in pregnancy and the best available diagnostic test that has high sensitivity and specificity and the timing of the test during gestation. This is reflected in the lack of international agreement on diagnostic criteria ranging from the WHO critieria to a more pragmatic approach based on fasting and post prandial glucose levels. Those at particular risk for GDM are ethnic groups with a high prevalence of diabetes, women with a previous history of

delivering large babies, a family history of diabetes, obesity, older women and multiparous women.

Pregnancy is associated with an increase in insulin resistance and an increase in hormones with actions opposing insulin (i.e. cortisol, progesterone, growth hormone and human placental lactogen). GDM develops at a time when the beta cell reserve cannot cope with the prevailing state of insulin resistance. Therefore by definition after pregnancy when the insulin resistance reduces, then the subject becomes normoglycemic. However, GDM can be considered a pre-diabetic condition with an increased future risk of developing type 2 diabetes during their lifetime approaching 20–50%. The treatment of GDM consists of maintaining strict glycemic control. If dietary intervention fails to achieve normoglycemia, the treatment of choice is insulin.

The maternal risk due to GDM include increased risks in pregnancy, accelerated fetal growth leading to macrosomia and increased rates of caesarian section. The fetal risks include stillbirth, congenital malformations, shoulder dystocia, birth trauma and the risk of neonatal hypoglycemia and calcium and bilirubin disturbances in the neonatal period. There is also an increased risk of the child subsequently becoming obese and developing diabetes in adult life as a result of *in utero* hyperglycemia.

Fibrocalculous Pancreatic Diabetes

In tropical countries there is a form of nonalcoholic chronic pancreatitis characterized by pancreatic exocrine and endocrine insufficiency and associated with pancreatic calcification. This disease, tropical calcific pancreatitis, affects young individuals who are malnourished and present with abdominal pain, extreme emaciation characteristic of protein-energy malnutrition, glucose intolerance, and at a later stage diabetes. The diabetic stage of the illness is referred to as fibrocalcific pancreatic diabetes (FCPD). Several reports of FCPD have been reported from the tropical countries and many cases have been reported from the Indian subcontinent. The pathogenesis of the disease is still unclear and is attributed to various possible causes – malnutrition, cassava toxicity, oxidant stress due to micronutrient deficiency, genetic and environmental factors. Recently, a study showed the N34S variant of the *SPINK1* trypsin inhibitor gene as a susceptibility gene for FCPD in the Indian subcontinent. Although by itself it is not sufficient to cause FCPD, it indicates the role of gene–environment interaction in the pathogenesis of diabetes.

Patients with FCPD are at risk of long-term diabetic complications and require insulin to control their hyperglycemia. Given the underlying problem of malnutrition they benefit from high calorie intake, especially the protein content. There is a need for further investigation into the roles of nutritional, environmental, and genetic factors to establish the etiopathogenesis of this illness.

R J Smith, Brown Medical School, Providence, RI, USA

Diabetes mellitus is a common, serious metabolic disorder with diverse causes and multiple complications. In this article, the definition and classification are discussed and diagnostic criteria outlined. Subsequently, an overview of the physiology of normal blood glucose homeostasis and normal insulin action leads to consideration of the pathophysiologic events that occur in uncontrolled diabetes.

Definition

Diabetes mellitus is a chronic disorder that results from a deficiency of the hormone insulin. This occurs either because of an absolute decrease in the amount of insulin produced by the β cells of the islets of Langerhans in the pancreas or because of a relative deficiency of insulin in patients whose tissues are resistant to the hormone. The hallmark of untreated diabetes mellitus is elevated blood glucose concentrations. Frequently, there are associated disturbances of fat and protein metabolism. In addition to reversible acute metabolic abnormalities resulting from inadequate effects of insulin, long-term diabetes is often characterized by the development of irreversible complications that include damage to the kidney, retina, nervous system, and both large and small blood vessels.

The diagnosis of diabetes mellitus is based on the existence of hyperglycemia alone and does not require the presence of any of the associated metabolic or systemic complications. Although patients with diabetes mellitus exhibit a characteristic pattern of metabolic abnormalities and long-term complications, this disease state results from multiple underlying causes that include genetic as well as environmental influences and also certain pancreatic or hormonal conditions.

Diagnostic Criteria

Random Plasma Glucose Determination

In the presence of symptoms of hyperglycemia, a random plasma glucose >11.1 mmol/l is consistent with a diagnosis of diabetes in an ambulatory patient. Classic symptoms of hyperglycemia include thirst, polydipsia, polyuria, and unexplained weight loss.

Fasting Plasma Glucose Determination

Nondiabetic individuals have fasting plasma glucose levels below 5.6 mmol/l. The diagnosis of diabetes mellitus can be made when fasting plasma glucose levels are significantly elevated (>7.0 mmol/l) on at least two occasions. Fasting glucose below 7.0 mmol/l but above 5.6 mmol/l, although not normal, does not meet the criteria for definite diagnosis and is classified as impaired fasting glucose. Although not absolutely predictive of diabetes, individuals with impaired fasting glucose progress to overt diabetes at a rate of approximately 5% per year. Plasma or serum measurements are generally more reliable than whole blood glucose determinations (in which the normal range is lower) because they are independent of the hematocrit and are appropriate for accurate, automated analysis. For accurate measurement, blood samples must be put into tubes containing sodium fluoride (which prevents glycolysis) or be centrifuged within 30 min to remove cells. Fasting plasma glucose is considered the desired method to diagnose diabetes because of its simplicity and reproducibility.

Oral Glucose Tolerance Test

In the absence of an obvious elevation in fasting or random plasma glucose levels, the diagnosis of diabetes mellitus can be made with an oral glucose tolerance test (OGTT). This involves, for the nonpregnant adult, the ingestion of a solution containing 75 g of glucose over 5 min, with a measurement of baseline and 2-h plasma glucose. The criteria used to diagnose diabetes are listed in **Table 1**. The diagnosis can be made if the fasting glucose exceeds 7.0 mmol/l or the 2-h value exceeds 11.1 mmol/l. People with impaired glucose tolerance have normal fasting values but 2-h post-glucose load values above 7.8 mmol/l.

Table 1 Oral glucose tolerance test criteria for diabetes in nonpregnant adults (75 g glucose load)

	Venous plasma glucose (mmol/l)
Diabetes	
Fasting	>7.0
2-h	>11.1
Impaired glucose tolerance	
2-h	7.8–11.1
Impaired fasting glucose	
Fasting	5.6–6.9
2-h	<7.8

The standard OGTT must be performed under certain conditions for the previous thresholds to apply. Subjects need to ingest at least 200 g carbohydrates per day during the 3 days preceding the test, fast overnight (>8 h), not smoke on the day of the test, and have the test performed in the morning. Because glucose tolerance is reduced by bed rest and stressors such as recent surgery or burn injury, subjects must be ambulatory and have been so for at least 1 month prior to the test. Despite this standardization, results are not always precisely reproducible, even in the same person, which may relate in part to variable rates of absorption of glucose from the small intestine. For this reason, elevated fasting glucose is a more reliable diagnostic criterion. In children, if an OGTT is performed, the amount of glucose to be ingested should be determined by body weight (i.e., 1.75 g/kg ideal body weight).

Controversy has existed with regard to proper methods of diagnosis of diabetes in pregnancy. The National Diabetes Data Group (NDDG) of the National Institutes of Health recommends screening between 24 and 28 weeks with a 50 g oral glucose load test. No special preparations are required for this test, and fasting is unnecessary. Blood glucose is measured once only, after 1 h. Women with values above 7.8 mmol/l are evaluated with a full OGTT with a glucose load of 100 g. Clearly, use of a lower threshold (e.g., 7.2 mmol/l) minimizes the occurrence of false-negative tests. Opponents of the use of a lower threshold note that only the milder cases of diabetes in pregnancy are missed using the 7.8 mmol/l criteria to proceed to full OGTT. The NDDG criteria for diagnosis are listed in **Table 2**. The original data used in the determination of normal plasma glucose values during pregnancy have been reevaluated taking into account changes in the methodology for glucose measurement, which led to the American Diabetes Association using even lower threshold values on the 100 g OGTT to diagnose diabetes (**Table 2**, revised criteria). Controversy exists as to which set of values should be used, and cost-effectiveness evaluations of the different criteria are pending.

Table 2 Criteria for the diagnosis of gestational diabetes (100 g glucose load)

	Venous plasma glucose (mmol/l)	
	National Diabetes Data Group	*Modified criteria*
Fasting	>5.8	>5.3
1 h	>10.6	>10.0
2 h	>9.2	>8.6
3 h	>8.1	>7.8

The World Health Organization proposes that the test and criteria for gestational diabetes should be the same as for nonpregnant adults, with the exception that individuals fitting the category of impaired glucose tolerance be treated the same as diabetics because of the potentially harmful effects of hyperglycemia on the fetus.

Glycosuria

Glycosuria may indicate the presence of diabetes, but it is not diagnostic, nor does the absence of glycosuria exclude diabetes. In individuals with a low renal threshold, glucose may be present in the urine in the absence of hyperglycemia. Such "renal glycosuria" is particularly common during the later stages of pregnancy and in some renal tubular disorders. The excretion of other sugars, such as lactose (more common during pregnancy) or fructose, galactose, or xylose (people with inborn errors of metabolism), can yield false-positive results through cross-reactivity in the testing method unless glucose-specific test strips are used. In patients with compromised renal perfusion or function, glycosuria may be absent despite significant hyperglycemia.

Glycosylated Hemoglobin

Glycohemoglobin is formed when a ketoamine reaction occurs between glucose and the N-terminal amino acid of the β chain of hemoglobin. The amount of glycohemoglobin generated is proportional to the mean blood glucose during the 8–10 weeks before the test. Thus, the glycohemoglobin level is a useful indicator of long-term blood glucose control. This is not a useful test for diagnosing diabetes, however, since the normal range is broad, the test is not well standardized between laboratories, and it can be affected by conditions that alter the life span of the red blood cell.

Classification

A new classification system for diabetes mellitus was developed in 1997, which divides patients into four major groups and a number of subgroups, as shown in **Table 3**. It is probable that these categories will be further refined as knowledge of the underlying etiologies of various forms of diabetes progresses.

I. Type 1 Diabetes Mellitus

This form of diabetes is defined by insulin deficiency due to destruction of the β cells of the pancreas. It was formerly designated "insulin-dependent diabetes," but efforts are being made to eliminate this name because many patients with other types of

Table 3 Classification of diabetes mellitus[a]

I. Type 1 diabetes (formerly designated insulin-dependent diabetes)
A. Autoimmune
B. Idiopathic
II. Type 2 diabetes (formerly designated non-insulin-dependent diabetes)
III. Secondary diabetes
A. Genetic defects of β cell function (e.g., maturity onset diabetes of youth)
B. Genetic defects of insulin action pathway
C. Exocrine pancreatic disease
D. Endocrinopathies (e.g., Cushing's syndrome and acromegaly)
E. Drugs or chemicals
F. Infections (e.g., congenital rubella)
G. Other genetic syndromes (e.g., Down's and Klinefelter's syndromes)
IV. Gestational diabetes

[a]Classification proposed by the Expert Committee on the Diagnosis and the Classification of Diabetes Mellitus under the sponsorship of the American Diabetes Association (*Diabetes Care* **27**: S5–S10, 2004).

diabetes also require insulin for adequate control. The predominant cause is believed to be an autoimmune attack against the insulin-producing β cells within the islets of Langerhans (diabetes type 1A). At the time of diagnosis, most patients demonstrate antibodies to certain pancreatic autoantigens, which include antibodies to islet cell cytoplasmic components, glutamic acid decarboxylase, insulin, and tyrosine phosphatases IA-2 and IA-2β. Such autoantibodies, when present, help to confirm the diagnosis. This disease also has strong HLA antigen associations, which may either predispose to or protect from the development of diabetes. In a minor subset of patients classified as idiopathic type 1 diabetes (type 1B), the presentation and clinical course is similar to autoimmune type 1A diabetes, but all tests for autoimmune markers are negative.

Early diagnosis of autoimmune diabetes Type 1 diabetes has a variable presymptomatic phase that may extend for several years, during which time it is possible to make a diagnosis. This form of diagnostic testing is reserved for research purposes because the disease is not sufficiently common to warrant widespread screening strategies and because practical methods for preventing the progression to overt diabetes are not available. Because type 1 diabetes is occasionally familial, screening of individuals with strong family histories can be performed by measuring levels of the specific pancreatic autoantigens described previously; subjects with high titers of antibodies who possess unfavorable HLA subtypes, indicating significant risk of later development of diabetes, may then undergo intravenous glucose tolerance testing with quantitation of the insulin response. Diminution of the early phases of insulin release can be seen even years before the onset of symptoms of disease. Currently, such diagnosis is important only to enable participation in clinical trials of diabetes prevention.

II. Type 2 Diabetes Mellitus

This is a heterogeneous disorder in which there is both resistance to the action of insulin and relative insulin insufficiency. In contrast to type 1 diabetes, endogenous insulin secretion is at least partially preserved and thus most patients are not insulin dependent for acute survival (hence the former name, non-insulin-dependent diabetes). The circulating insulin levels are adequate to protect these patients from ketosis, except during periods of extreme stress. Some patients in this category can be treated with oral agents (sulfonylureas, metformin, and thiazolidinediones), but many are managed with insulin because their pancreases are unable to produce sufficient insulin to overcome their tissue insulin resistance. Obesity is a frequent contributing factor to the insulin resistance in this disorder.

Occasionally, it is difficult to determine whether a patient has type 1 or type 2 diabetes. This is particularly likely in a nonobese person older than 35 years of age who has never had significant ketosis but who has been treated with insulin. Unfortunately, there is no completely reliable diagnostic test. Measurement of autoantibodies in such people may not be helpful because patients with type 1 diabetes lose these markers with time. Several studies have shown that the plasma C-peptide level is a good discriminator between the two forms of diabetes. C-peptide is released during processing of proinsulin to insulin and, thus, is an indicator of endogenous insulin secretion. Values higher than 0.6 nmol/l, either basal or following provocation with a 1 mg glucagon stimulus, indicate sufficient residual insulin secretion for a person to be considered in the type 2 diabetes class.

III. Secondary Diabetes Mellitus/Other Specific Types

This broad category includes multiple disorders that are associated with either extensive pancreatic destruction or significant insulin resistance. Secondary diabetes as a consequence of decreased insulin production can occur following pancreatectomy, chronic pancreatitis, cystic fibrosis, or hemochromatosis. In the absence of pancreatic damage,

secondary diabetes can result from extreme insulin resistance induced by glucocorticoids (Cushing's syndrome); growth hormone (acromegaly); adrenergic hormones (pheochromocytoma); other medical conditions, such as uremia, hepatic cirrhosis, or polycystic ovary syndrome; or medications (diuretics or exogenous glucocorticoids).

Included in this category of secondary diabetes are patients who appear to have type 2 diabetes but in whom monogenic molecular defects in either the glucose-sensing or insulin action pathways have been defined. The best established molecular defects are mutations in the gene coding for the enzyme glucokinase, which has a role in the sensing of glucose by the β cell. Individuals with this autosomal dominant condition usually develop mild diabetes in early adulthood or adolescence. Hence, the condition is known as maturity onset diabetes of the young (MODY). Several other types of MODY have been defined, due to gene defects in β cell transcription factors. Rare causes of diabetes secondary to insulin resistance include various inborn errors of metabolism (e.g., insulin receptor mutations or type 1 glycogen storage disease), chromosomal abnormalities such as Down's and Turner's syndrome, and muscle diseases (e.g., myotonic dystrophy).

IV. Gestational Diabetes Mellitus

This disorder, which is defined as hyperglycemia first detected during pregnancy, occurs in 2–5% of pregnant women. Often, one cannot determine whether glucose intolerance antedated the pregnancy or whether hyperglycemia was provoked by the hormonal milieu associated with pregnancy. Hyperglycemia remits postpartum in 90% of women with gestational diabetes, but these women are at increased risk for subsequent development of diabetes, which is usually type 2. Although most cases of this form of diabetes are detected by blood glucose screening performed as a routine procedure early in the third trimester, the current recommendation is that universal screening is probably unwarranted. A woman younger than age 25 years, of normal body weight, without a family history of diabetes or a personal history of poor pregnancy outcome, and from an ethnic group with low rates of diabetes is at sufficiently low risk of gestational diabetes that glucose testing can be omitted. In contrast, women with clinical features associated with a high risk of gestational diabetes (obesity, positive family history, persistent glycosuria, and prior gestational diabetes) should be screened as early in the pregnancy as is feasible. In women who have documented gestational diabetes, a follow-up glucose tolerance test should be performed 6 weeks postpartum unless overt diabetes is evident.

Other Abnormalities of Glucose Tolerance

Impaired glucose tolerance This is a condition defined by oral glucose tolerance testing and includes nonpregnant individuals with normal fasting blood glucose but modestly elevated postprandial glucose. People with impaired glucose tolerance are at a high risk for subsequent development of diabetes, usually type 2 (approximately 5% per year). Thus, impaired glucose tolerance is a stage in the evolution of diabetes. Until overt diabetes develops, people with impaired glucose tolerance are not believed to have elevated risk of microvascular complications of diabetes. However, impaired glucose tolerance is associated with an increased risk of cardiovascular disease.

Impaired fasting glucose Some patients will have abnormal elevations in fasting plasma glucose, even though 2 h post-glucose challenge values are normal. These people are also at increased risk of developing diabetes, although diabetes incidence rates are highly variable between different populations. Fasting glucose is defined as impaired in the range 5.6–7.0 mM. Until recently, impaired fasting glucose was defined as 6.1–7.0 mM, and the change was recommended by the American Diabetes Association to align better with the category of impaired glucose tolerance discussed previously. However, people in this category who have normal postprandial glycemia, or normal 2-h post-challenge glucose values, have a lower risk of cardiovascular disease than people with impaired glucose tolerance.

Stress hyperglycemia This denotes an individual who is frankly hyperglycemic (>7.8 mmol/l) under conditions of intercurrent illness or during treatment with medications that provoke diabetes. Such people may revert to normal glucose tolerance following removal of the stress. Although not an official category of diabetes, such abnormal glucose values in hospitalized patients cannot be ignored since there is strong evidence that treatment to normoglycemia significantly lowers mortality, at least for patients with acute myocardial infarction or with critical illness in an intensive care unit. Precipitants of stress hyperglycemia are listed in **Table 4**.

Table 4 Risk factors for the development of stress hyperglycemia in critical illness

Factor	*Major mechanism*
Preexisting diabetes mellitus	Insulin deficiency (relative or absolute)
Infusion of catecholamine pressors	Insulin resistance
Glucocorticoid therapy	Insulin resistance
Obesity	Insulin resistance
Increasing APACHE score	Higher counterregulatory hormone levels
Older age	Insulin deficiency
Excessive dextrose administration	Glucose removal rates overwhelmed in the face of ongoing hepatic glucose production
Pancreatitis (acute and chronic)	Insulin deficiency
Sepsis	Insulin resistance
Hypothermia	Insulin deficiency
Hypoxemia	Insulin deficiency
Uremia	Insulin resistance
Cirrhosis	Insulin resistance

APACHE, Acute Physiology and Chronic Health Evaluation.

Pathophysiology of Diabetes

Physiology of Normal Blood Glucose Regulation

The metabolic fate of ingested glucose is determined by the interplay of multiple hormones. Insulin is of major importance in this homeostasis, but glucagon, glucocorticoids, catecholamines, and growth hormone also have significant effects that are interactive with insulin. Glucose ingested with a meal or derived from the digestion of other dietary carbohydrates is rapidly absorbed by the small intestine. It is carried first to the liver by the portal vein, where a substantial portion (30–70%) is removed; the remainder enters the peripheral circulation, where regulated insulin secretion and target tissue responses to insulin contribute to glucose clearance and control of blood glucose levels (**Figure 1**).

Following a meal, insulin is secreted from pancreatic β cells in response to increased circulating glucose concentrations. This direct effect of glucose on β cells is augmented by neural (vagal) and hormonal factors of intestinal origin (e.g., glucose-dependent insulinotropic peptide, cholecystokinin, and glucagon-like peptide 1), such that the insulin secretory response to oral glucose greatly exceeds the response to an equivalent intravenous glucose infusion.

The overall effect of the increase in insulin levels in parallel with increased glucose entry to the circulation is promotion of the net removal of glucose by the liver and stimulation of glucose transport into muscle and adipose tissue, where it is consumed as a metabolic fuel or stored. Insulin also inhibits the catabolism of the alternative energy sources, fat and protein. This is an appropriate response to the abundance of circulating nutrients that occurs after meals. During fasting, insulin levels are low, these processes are reversed, and stored fuel is made available to all tissues.

Liver Glucose enters the liver by facilitated (carrier-mediated) diffusion driven by the concentration gradient that exists in the fed state. A portion of the glucose taken up by the liver is metabolized via glycolytic pathways to produce ATP. A substantial amount is transformed into glycogen and stored. The maximal storage capacity of the liver is approximately 100 g glycogen (400 kcal). The specific molecular effects of insulin in the fed state lead to altered activities of enzymes that trap glucose inside the hepatocyte, promote glycolysis, and enhance glycogen synthesis (**Figure 1**). Insulin also inhibits enzymes important for both glycogenolysis and gluconeogenesis and thus shuts off hepatic glucose production. A portion of the glucose entering the liver is converted into triglyceride and exported to the adipocyte for storage.

Skeletal muscle In skeletal muscle, insulin directly stimulates glucose uptake, which is the rate-limiting step for muscle clearance of glucose. This appears to occur predominantly by causing the rapid translocation of glucose transporters (in particular the Glut-4 transporter) from an as yet undefined intracellular site to the muscle cell surface. Insulin also stimulates glycolysis and the net formation of glycogen in muscle. Even at low insulin concentrations, however, a rise in ambient glucose stimulates substantial glucose clearance by muscle, probably via the Glut-1 transporter. Glycogen stores in muscle (500–600 g glycogen in a 70 kg human) serve as a rapidly mobilized energy source during exercise but do not directly support blood glucose concentrations in the fasted state because muscle lacks the enzyme glucose-6-phosphatase, which is needed for release of free glucose to the circulation. Insulin-stimulated amino acid entry into muscle enhances insulin stimulatory effects on protein synthesis and decreases the availability of circulating amino acids as substrates for hepatic gluconeogenesis. Muscle proteolysis, which yields amino acid precursors that contribute to hepatic gluconeogenesis in the fasted state, is inhibited by insulin.

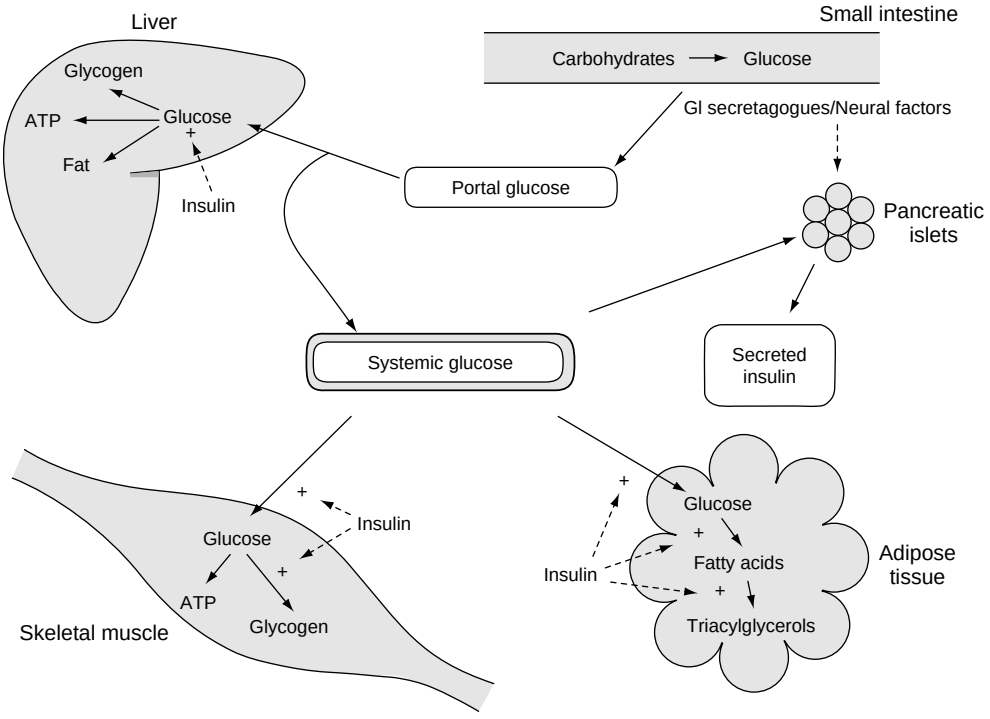

Figure 1 Insulin effects on glucose homeostasis in the fed state.

Adipose tissue In adipose tissue, insulin stimulates glucose uptake via the Glut-4 transporter, providing substrate for energy generation and glycerol synthesis. Even more important effects of insulin in adipose tissue are inhibition of lipolysis and stimulation of FFA uptake and triglyceride synthesis. This limits the availability of fat-derived fuels for other tissues and indirectly contributes to the lowering of blood glucose by favoring glucose utilization in multiple tissues.

From this brief overview, it can be seen that the rise in insulin following a meal has multiple tissue-specific actions that serve to lower blood glucose, prevent hyperglycemia, and inhibit the mobilization of alternative metabolic fuels. Many of the metabolic abnormalities that develop acutely in uncontrolled diabetes can be explained by the loss of these actions of insulin.

Pathophysiology of Uncontrolled Diabetes

Uncontrolled diabetes mellitus occurs when circulating insulin levels are inadequate to lower elevated blood glucose concentrations. This condition includes a spectrum of metabolic abnormalities that range from the effects of mild insulin deficiency (i.e., hyperglycemia) to the effects of marked and prolonged insulinopenia (i.e., ketoacidosis and fluid and electrolyte depletion). Diabetic ketoacidosis, which is the most severe acute manifestation of insulin deficiency, is almost entirely restricted to patients with type 1 diabetes, or those with severe pancreatic disease of other etiologies. In people without absolute insulin deficiency, although the combination of significant insulin resistance and relatively low levels of insulin can result in significant hyperglycemia, ketone body production sufficient to cause ketosis and metabolic acidosis does not occur. Even low levels of insulin, such as are typically present in type 2 diabetes, suffice to restrain lipolysis and limit the availability of free fatty acid precursors for ketone body formation. Otherwise, many of the derangements seen in uncontrolled diabetes are common to all forms of diabetes.

The pathophysiologic events that affect blood glucose levels in states of mild-to-moderate insulin deficiency are classified into two broad categories. First, the normal pathways for glucose clearance after a meal are ineffective; second, body fuel stores are broken down with release of other substrates that lead to inappropriate synthesis of more glucose. These events are brought about by insulinopenia and often are further promoted by the relative abundance of the counterregulatory hormones, glucagon, catecholamines, and, to a lesser extent, cortisol and growth hormone. In addition, hyperglycemia further inhibits pancreatic β cell insulin secretion, compounding the problem ("glucose toxicity").

Following the ingestion of a meal, a substantial portion of the glucose absorbed into the portal circulation is removed by the liver, where it is stored as glycogen, converted to lipid, or consumed via energy-generating pathways. Each of these processes is decreased by insulin deficiency, resulting in increased entry of absorbed glucose to the systemic circulation. Skeletal muscle represents the main tissue site for removal of circulating blood glucose following a meal. In diabetes, insulin deficiency leads to a marked decrease in activity of the Glut-4 glucose transporter largely as a consequence of decreased insulin-stimulated Glut-4 localization to the surface membranes. This decreases the normal postmeal flux of glucose into skeletal muscle. In addition, glucose that does enter muscle is metabolized inefficiently in the absence of insulin. Other insulin-sensitive tissues, such as adipose tissue and myocardium, are affected in a similar manner, with consequent reduction in both glucose uptake and metabolism, although their contribution to glucose clearance is quantitatively less than that of muscle.

In postabsorptive or fasted states, hyperglycemia in uncontrolled diabetes does not resolve and often worsens (**Figure 2**). Abnormally low insulin concentrations lead to an exaggeration of metabolic responses that normally serve to protect against the development of hypoglycemia during fasting. These responses to low insulin and elevated counterregulatory hormones include, initially, the conversion of stored glycogen to glucose. Simultaneously, the hepatic enzymes involved in gluconeogenesis are activated, which results in glucose production from such carbon sources as lactate and pyruvate (by-products of muscle glycolysis), amino acids (from muscle protein breakdown), and glycerol (derived from adipocyte triglyceride stores). With persistent insulin deficiency, glycogen stores are depleted, and hepatic gluconeogenesis becomes the most important contributor to the increasing hyperglycemia. Meanwhile, body stores of protein and fat are being depleted in the futile synthesis of new glucose that cannot be used efficiently and serves to aggravate the existing hyperglycemia.

Excessive glucose accumulation in the circulation and in the extracellular space leads to the movement of water out of cells to maintain osmotic balance, causing intracellular dehydration. The high filtered load of glucose at the renal glomerulus overwhelms the reabsorptive capacity of the renal tubule, and an osmotic diuresis results. Ultimately, this leads not only to water loss along with the glucose but also to excess excretion of potassium, sodium, magnesium, calcium, and phosphate in the urine. The magnitude of the total body electrolyte loss depends on the duration and severity of the hyperglycemia.

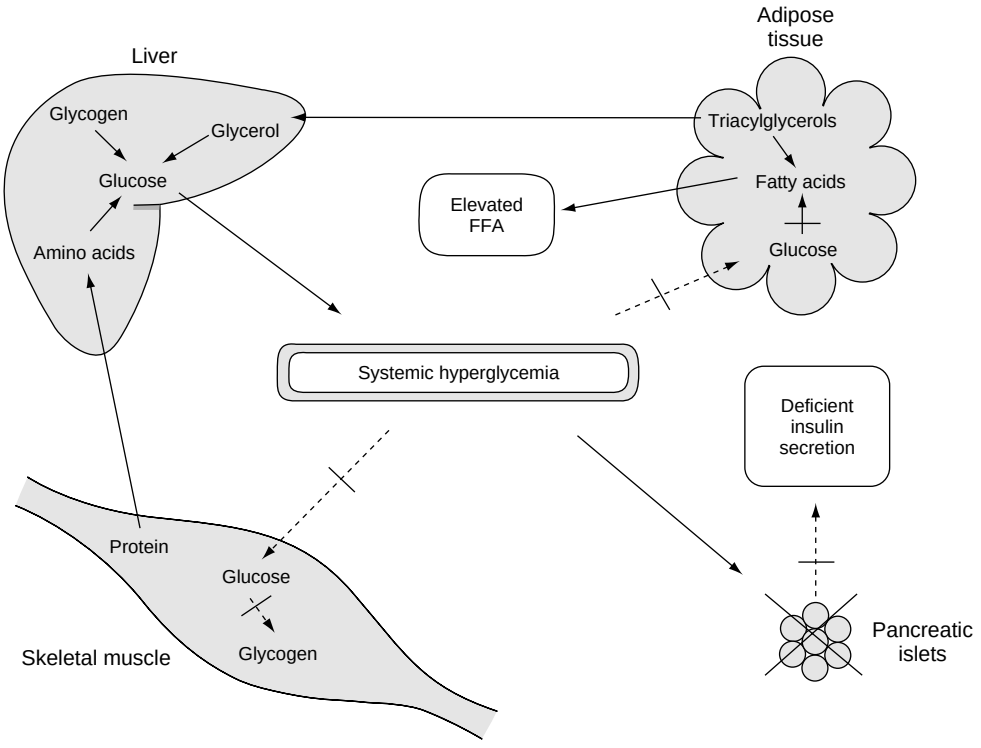

Figure 2 Metabolic events leading to hyperglycemia in the postabsorptive state in uncontrolled diabetes mellitus.

The main symptoms with moderate insulin deficiency are polyuria and consequent thirst and polydipsia. With more severe and prolonged insulin deficiency, loss of large quantities of glucose in the urine can lead to weight loss. If hyperosmolarity is not compensated by an adequate increase in water intake, patients can develop altered mental status and obtundation. In elderly patients with type 2 diabetes, this sequence can lead to the life-threatening state of nonketotic hyperosmolar coma.

In type 1 diabetes, the clinical picture of poor control differs from that described previously in that insulin deficiency is more severe (**Figure 3**). Glucose uptake by muscle is diminished, and glucose production by the liver is augmented. Marked insulinopenia, however, also leads to rapid, uncontrolled lipolysis. Triglyceride breakdown results in accelerated release of free fatty acids and glycerol. The increased delivery of glycerol from adipose tissue to the liver further promotes hepatic gluconeogenesis. In the absence of insulin, the liberated free fatty acids are taken up by the liver and converted at an accelerated rate to ketone bodies (β-hydroxybutyric acid, acetoacetic acid, and acetone).

In the fasting state in nondiabetic individuals, ketone bodies are metabolized under the influence of even low levels of insulin as a source of energy, particularly in skeletal and cardiac muscle. In extreme insulin deficiency states, ketone body utilization is inhibited at the same time that synthesis is increased. With increasing duration of insulinopenia, the ketoacid levels in the bloodstream rise. Ketones, like glucose, spill into the urine, either as free acids or, depending on the pH, as sodium or potassium salts, worsening the osmotic diuresis and electrolyte deficiency. Eventually, the blood buffering capacity for acid is overwhelmed and systemic acidemia occurs. Acidemia has a deleterious effect on all cell membranes and many cellular functions and, when severe, can cause arrhythmias, cardiac depression, and vascular collapse. In combination with the previously described hyperosmolarity and dehydration, diabetic ketoacidosis is a life-threatening situation.

In summary, poor control can lead to dangerous metabolic consequences and, occasionally, death. A primary goal of therapy is insulin replacement, which is needed to reverse the production of glucose and ketoacids by the liver, to promote muscle glucose and ketone body uptake, and to inhibit further breakdown of fat and protein. An equally important goal of therapy should be the replenishment of lost extracellular and intracellular fluids and electrolytes.

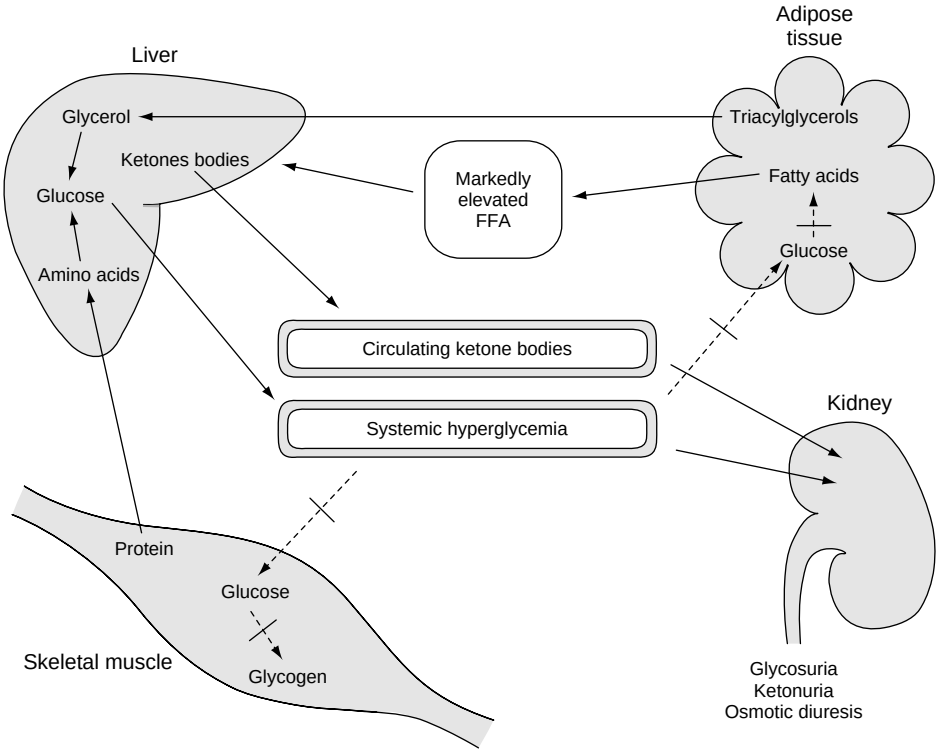

Figure 3 Metabolic events leading to the development of ketoacidosis in uncontrolled diabetes mellitus.

Dietary Management

C D Saudek, Johns Hopkins University School of Medicine, Baltimore, MD, USA
S H Oh, Johns Hopkins General Clinical Research Center, Baltimore, MD, USA

The successful treatment of diabetes mellitus starts with a sound diet, although the specifics of the diet vary depending on the kind of diabetes being treated and the individual circumstances. Individualization is the hallmark of medical nutrition therapy in diabetes. Since approximately 90% of all people with diabetes have type 2, and approximately 80% of them are obese, weight reduction is often the main therapeutic goal. Many also need treatment of comorbidities such as hypertension or dyslipidemia. People with type 1 diabetes, on the other hand, usually require far more attention to exactly how much carbohydrate they ingest and exactly how their intake matches their insulin dose and activity level. In all cases, education of the patient by a trained nutritionist is essential. Diabetes is rarely well controlled unless patients have at least a basic understanding of what they should eat and why.

Overall Objectives in the Management of Diabetes

Control of Blood Glucose Level

A first and very basic goal of diabetes care is to eliminate the symptoms of hyperglycemia. Treatment is inadequate if the person remains polyuric, thirsty, or continues to lose weight from hyperglycemia. To cause symptoms, however, hyperglycemia usually must average more than 11 mM (200 mg/dl). Since blood glucose in the 7–11 mM (125–200 mg/dl) range is distinctly abnormal and does cause long-term diabetic complications, freedom from symptoms is only the beginning of adequate therapy.

Irrefutable evidence exists that better control of blood glucose concentration reduces the risk of developing long-term complications from diabetes. This is especially true of microvascular complications such as retinopathy (eye disease), nephropathy (kidney disease), and nerve damage in both type 1 and type 2 diabetes. Control of blood glucose also reduces the risk of macrovascular disease (heart disease, stroke, and peripheral vascular disease), although the contribution of blood glucose to these complications is less strong.

Carbohydrate ingestion (rather than fat or protein) is the main determinant of postmeal blood glucose level.

Dietary intake, oral medications, insulin, exercise, and stress all contribute to blood glucose levels in the person with diabetes and must be understood when establishing and implementing medical nutrition therapy.

To determine the efficacy of treating glycemia, blood glucose must be monitored. There are two ways to assess diabetic control: self-monitoring of blood glucose (SMBG) laboratory monitoring of hemoglobin A1c (HbA1c). SMBG, done by obtaining a drop of blood and using a small, handheld meter, measures the blood glucose at the time the measurement is taken. It may be done as often as six to eight times per day or as infrequently as several times per week. The HbA1c is a laboratory test that reflects glycemic control during the previous 60–90 days and should be done every 3–6 months. Target HbA1c is generally considered to be <6.5–7% when the upper limit of normal is <6%.

Prevention or Control of Comorbidities

Morbidity and mortality among people with diabetes are rarely due to acute hyperglycemia or diabetic ketoacidosis. Rather, the long-term complications are either specific to diabetes (e.g., diabetic retinopathy or nephropathy) or accelerated by diabetes (e.g., atherosclerosis). Diabetes significantly increases the risk of coronary artery, cerebrovascular, and peripheral vascular disease, with these cardiovascular complications accounting for approximately 80% of deaths in diabetes. Prudent dietary management of diabetes therefore requires consideration of what can be done to prevent or control the various comorbidities of this disease. For example, all people with diabetes should be on a diet that minimizes the risk of atherosclerosis. At the first clinical sign of hypertension, dietary methods should be implemented to lower blood pressure.

Minimum Intrusion on Quality of Life

To people with diabetes, the 'diabetic diet' can be a fearsome thing, often made worse by the way it is presented. Many modern dieticians refuse even to use the word 'diet' since it conjures up so many bad associations, preferring 'nutrition plan' or 'medical nutrition therapy.' Most patients will not totally abandon their dietary habits of a lifetime, forgoing favorite ethnic flavors and socially accepted foods. Rather, the prescribed diet that intrudes least on a person's quality of life is the most successful nutrition plan. Expert professionals can identify exactly what changes are required and what favorite dishes, spices, or food groups can be built into a good nutrition prescription.

Dietary Approaches to Diabetes

Principles of Dietary Management of Diabetes

Assessment The first step for planning an appropriate nutrition plan is a full assessment of the diabetic patient. Topics covered in the nutritional assessment are included in **Table 1**.

Individualization Individualization is a cardinal principle of medical nutrition therapy for diabetes, facilitating individual lifestyle and behavior changes that will lead to improved metabolic control. Since no one diet fits all, the standard, printed diabetic diet is inadequate. Rather, people with diabetes need to consult a person trained in dietetics, one able to develop and teach an individualized nutritional prescription. **Table 2** indicates the range of goals that may need accommodation among different people with diabetes.

Developing the diabetes nutrition plan With the emphasis on individualization, the meal plan is driven by the diagnosis, pharmacologic treatment, lifestyle, and treatment goals. Important consideration is given to dietary preferences, socioeconomic factors, and the patient's ability to understand and implement instructions. Some patients will need instruction on fine points such as carbohydrate counting; others will benefit from the crudest of prescriptions, such as advice to stop buying concentrated sweets or frequenting fast-food restaurants.

Total energy intake The total energy requirement to maintain constant body weight may be calculated using the Harris–Benedict equation, taking into consideration the patient's activity level. The weight-maintaining requirement is then adjusted according to the therapeutic objective—to accomplish weight loss, maintenance of weight, or weight gain. Examples of how to make these calculations are shown in **Table 3**. Specific conditions such as childhood growth and development, pregnancy, malabsorption, or existing nutritional deficiencies are beyond the scope of this article.

Distribution of energy intake Distribution of carbohydrate, protein, and fat into the total energy target also depends on individual needs and therapeutic objectives. Most guidelines recommend that carbohydrate intake represent up to 50–60% of total energy, protein 15–20%, and fat 20–35%. Another approach groups carbohydrate and monounsaturated fats, recognizing that saturated fat should be restricted. This approach suggests that carbohydrate and monounsaturated fat should together account for 60–70% of energy intake.

Table 1 The Nutritional Assessment

Diet history/nutrition information—can be obtained using dietary assessment tools such as 24-h recalls, food records, food frequency questionnaires, or dietary intake interviews
Meal patterns: Usual distribution of meals and snacks throughout the day, including variations from day to day, weekdays versus weekends, skipped meals, and external influences such as work, school, travel, vacations, and holidays
Food choices: Types and amounts of foods consumed at meals and snacks
Nutritional adequacy: Dietary excess or deficiency; also considers overall dietary balance
Beliefs or misconceptions: Fears or misconceptions of a 'strict' diabetic diet or about certain foods; can also include certain religious beliefs or ethnic beliefs about foods
Personal information
Age, gender, socioeconomic status, ethnicity, occupation, education, and literacy level
Ability and willingness to change (stages of change)
Emotional and mental state if distressed by a new diagnosis of diabetes or other health complications related to diabetes
External stressors that may interfere with compliance
Smoking or drug history
Exercise or activity schedule
Clinical information
Type of diabetes and treatment, such as with insulin, oral hypoglycemic drugs, or diet alone
Physical activity, body weight, and blood pressure
Lab results, A1C, and lipid profile
Other medical conditions
Education
Diabetes education should be an ongoing interactive process between patient and health professional and cannot be given in a single session
Individualism is key to successful nutritional management
Most important aspect is to match the type and level of information to individual needs and abilities
Important to provide written information summarizing key messages that patient can take home and refer to later
Follow-up and monitoring progress
Follow-up and review of progress essential
Frequency will depend on type of treatment, glycemic control, and patient's ability to meet goals
Consider if specific dietary targets have been achieved and/or reasons why targets have not been met and what barriers need to be overcome
Consider acceptability of dietary changes and impact on patient's quality of life
Clinical picture should examine glycemic control, lipid profiles, weight changes, and blood pressure

Adapted from Conner H *et al.* Nutrition Subcommittee of the Diabetes Care Advisory Committee of Diabetes UK (2003) The implementation of nutritional advice for people with diabetes. *Diabetic Medicine* **20**(10): 786–807.

Even these broad goals are the subject of considerable controversy, with some experts recommending a lower carbohydrate intake and higher fat intake, particularly of monounsaturates. A common mistake is for the patients to think they have a diet low in both carbohydrate and fat without being low in total energy intake. It is unlikely that a person's dietary protein intake will exceed 15–30% of all energy consumed; therefore, 70–85% of intake is generally distributed between fat and carbohydrate.

Distribution of energy intake throughout the day may vary, too. Insulin-requiring diabetic patients, for example, may need a more evenly distributed energy intake, even including a bedtime snack to avoid hypoglycemia. This would not necessarily be indicated for someone with type 2 diabetes trying to lose weight, although weight-reducing diets are generally considered more effective if the total energy intake is spread more or less evenly throughout the day so that the patient does not build up a hunger and gorge late in the day. One report of Muslims observing daytime fasting during Ramadan found that more than half did not lose weight, suggesting a major redistribution of caloric intake to nighttime hours. A significant increase in hypoglycemia occurred during the days of Ramadan. Reduced energy intake for prolonged periods is most dangerous for patients taking insulin, but it may also be significant in those taking oral hypoglycemic agents such as sulfonylureas.

The utility of exchange lists There has been a shift on the part of patients and some health professionals away from the use of formal 'exchange lists' for meal planning. The traditional exchanges estimate not only carbohydrate but also certain proportions of fat and protein in similar foods. Food labels make the calculation of specific fat and carbohydrate content easier. The trend, therefore, is to emphasize the carbohydrate and fat awareness by teaching them directly rather than lumping mixed foods together in exchanges.

Gastroparesis An extremely difficult challenge is posed by the patient with diabetic gastroparesis. This

Table 2 Cases illustrating the variable clinical issues affecting people with diabetes and the resulting diversity of their nutritional needs

Type of diabetes	*Type 1*	*Type 1*	*Type 2*	*Type 2*
Age (years)	14	38	56	76
Duration of DM (years)	6	26	6	6
BMI	18	23	27	34
Physical activity	Vigorous	Moderate	Mild	Minimal
Prone to hypoglycemia	Yes	Yes	Yes	No
Prone to hyperglycemia	Yes	Yes	Yes	Yes
Blood lipids	Normal	Normal	High LDL cholesterol	High TG, Low HDL
Blood pressure	Normal	High	Normal	High
Dietary preferences	Likes sweets, snacks	Healthy, little carb awareness	Spicy foods, irregular meals	Fried foods, sweets
Pharmacologic therapy	Multiple-dose insulin	Multiple-dose insulin	Oral agents plus insulin	Oral agents
Life expectancy without diabetes	66 years more	44 years more	26 years more	8 years more
Major nutritional considerations	Adequate caloric intake for growth (see **Table 3**)	Stabilize carb intake, count carbs	Mildly hypocaloric (see **Table 3**)	Low salt, high vegetable for hypertension (DASH diet)
	Recognize carb portions, regularize carb intake	Low salt, high vegetable for hypertension (DASH diet)	Hypolidemic (low saturated fat)	Hypolipemic diet (low saturated fat)
	Avoid excess concentrated sweets		Regularity of meals, consistency of carb and fat intake	Moderately hypocaloric
	Learn factors causing hypoglycemia			Control of dietary carb, especially high-energy concentrated sweets
	Healthy heart diet			

BMI, body mass index; DM, diabetes mellitus; HDL, high-density lipoprotein; LDL, low-density lipoprotein.

condition, a severe autonomic neuropathy reducing gastric motility and gastric emptying time, is often difficult to diagnose by standardized testing, such as gastric emptying studies. Gastroparesis typically causes early satiety, nausea, vomiting, and abdominal pain, with markedly variable food ingestion. Along with pharmacologic management and good glycemic control, the dietary prescription should include small, frequent feeding as tolerated, but the condition can progress to the point that any oral intake is difficult, and tube feeding or a gastrostomy is required. Fortunately, diabetic gastroparesis tends to wax and wane in severity.

Glycemic control and weight gain Research studies have repeatedly found that when a patient with poor glycemic control achieves good glycemic control, there is a strong, almost inevitable, tendency to gain weight. This may simply be due to the retention of energy that was previously lost in the urine as glucosuria, but the patient should be warned of the likelihood of gaining weight when poor diabetic control is adequately treated. As for quitting smoking, the health benefit of glycemic control far outweighs the risk of weight gain.

Nutritional instruction To achieve a stable, healthy diet, the following key educational issues must be considered (adapted from Franz M, Krosnick A, Maschak-Carey BJ *et al.* (1986) *Goals for Diabetes Education*. Chicago: American Diabetes Association):

- Survival skills
  - Relation of food to insulin and activity
  - Importance of good nutrition in the control of blood glucose and lipid levels
  - Necessity of maintaining normal weight
  - Types and amounts of food in meal plan
  - Modification of food intake during brief illnesses
- In-depth counseling
  - Meal planning
  - Types of nutrients, their functions, relation to insulin, and effect on blood glucose and lipid levels
  - Caloric level of meal plan and percentages of carbohydrate, protein, and fat
  - Food sources of fiber
  - Importance of reducing total fat, saturated fat, and cholesterol in the diet
  - Relation of sodium to hypertension
  - Proper serving sizes
  - Changes in food intake based on activity level
  - Eating out and special occasions
  - Label reading and grocery shopping
  - Use of sweeteners, alcohol, and 'dietetic' foods
  - Food modifications for other disorders
  - Incorporation of favorite recipes

Table 3 Sample calculations of energy requirement in differing circumstances using the Harris–Benedict formula to determine caloric requirements for children and adults

Caloric requirements = basal metabolic rate × activity factor × injury factor

Basal metabolic rate (BMR)

For men: BMR = 66 + [13.7 × wt (kg)] + [5 × ht (cm)] − [6.8 × age (years)]

For women: BMR = 655 + [9.6 × wt (kg) + [1.8 × ht (cm)] − [4.7 × age (years)]

Multiply by the following factors:

Activity factors

1. Sedentary (little or no exercise): BMR × 1.2
2. Lightly active (light exercise/sports 1–3 days/week): BMR × 1.375
3. Moderately active (moderate exercise/sports 3–5 days/week): BMR × 1.55
4. Very active (hard exercise/sports 6–7 days/week): BMR × 1.725
5. Extra active (very hard daily exercise/sports and physical job or 2X day training): BMR × 1.9

Injury factors (not used for healthy individuals)

1. Generalized stress: 1.1–1.2
2. Surgery (minor): 1.1–1.5
3. Infection: 1.2–1.5
4. Trauma: 1.14–1.37
5. Cancer: 1.2

For weight loss, use the above calculated formula for caloric requirements and subtract by 500 calories:

Caloric requirements − 500 calories/day = modified calorie requirements

This is for a recommended 0.5–1 pound of weight loss per week

Special aspects: Type 2 diabetes There are two pathophysiologic mechanisms underlying type 2 diabetes: The body's cells are resistant to the action of insulin, and the pancreas is unable to secrete enough insulin to overcome that resistance. Although it is not entirely clear which of these processes occurs first, and although the balance of the two may vary from case to case, the most common cause of insulin resistance is overweight or obesity. Unfortunately, much evidence has shown that people of Asian ethnicity are especially prone to obesity-related type 2 diabetes even when their body weight, by Western standards, is normal. Japanese Americans, for example, show an increase risk of diabetes if their body mass index (BMI) increases to only 24. This excessive risk with even mild degrees of excess body weight may explain the marked rise in diabetes when previously undernourished populations begin to have adequate nutrition. In this sense, diabetes is a disease of prosperity.

Major objectives Approximately 95% of all people with diabetes have type 2, and the major increase in the prevalence of diabetes in recent years is almost entirely accounted for by increase in body weight. It cannot be overemphasized that medical nutrition therapy of type 2 diabetes should address normalization of body weight. In most cases, the focus is on reducing dietary intake of saturated fat and increasing energy expenditure through exercise. By reducing body weight, insulin resistance is reduced, making the patient's endogenous insulin more effective. Given that approximately 85% of people with type 2 diabetes die of cardiovascular cause, the second emphasis of medical nutrition therapy for type 2 diabetics must address dyslipidemia and blood pressure.

Hypoenergetic diets are remarkably effective in controlling hyperglycemia. Indeed, blood glucose levels improve, often dramatically, as soon as a low-energy diet is started, apparently by reducing hepatic glucose production. The correction of insulin resistance is more closely correlated with actual weight loss, which takes much longer. The best strategy for accomplishing and maintaining weight loss is unclear and may vary from person to person depending on the different factors involved, such as willingness to change and other lifestyle behaviors. Dosages of antidiabetic drugs may have to be altered as the person loses weight.

Persistent insulin resistance in type 2 diabetes, together with deteriorating pancreatic insulin secretion over time, means that many people with type 2 diabetes eventually require exogenous insulin therapy. This does not change the diagnosis to type 1 diabetes, which is a disease of entirely different pathogenesis. Because of the insulin resistance, people with type 2 diabetes taking insulin often need high doses, often 50–100 units per day or higher. Insulin requirements will predictably be less when energy intake is reduced.

Recently, in Western societies, many overweight teenagers have presented with type 2 diabetes. It can no longer be assumed that children with diabetes have type 1. Indeed, some reports find that half of all teenagers with diabetes have type 2, a marked shift from prior years. Furthermore, nutrition therapy for children with diabetes must be designed with a clear understanding of what type of diabetes they have. In cases of obesity-related type 2, calorie restriction may be indicated.

Coexisting risk factors Obesity, dyslipidemia, and hypertension are especially prevalent in type 2 diabetes. The constellation of comorbidities has been called metabolic syndrome, 'syndrome X,' or the insulin resistance syndrome (**Table 4**), and some investigators believe that insulin resistance is the primary lesion. Whatever the pathophysiologic mechanisms, it is clear that dyslipidemia and hypertension must be sought and aggressively treated if

Table 4 The Metabolic Syndrome

Three or more of the following components:
Central obesity as measured by waist circumference
Men: >102 cm (40 in.)
Women: >88 cm (35 in.)
Fasting blood triglycerides ≥1.69 mmol/l (150 mg/dl)
Blood HDL cholesterol
Men: <1.04 mmol/l (40 mg/dl)
Women: <1.29 mmol/l (50 mg/dl)
Blood pressure ≥130/85 mmHg
Fasting glucose ≥6.1 mmol/l (110 mg/dl)

present. In fact, most evidence suggests that the management of coexisting risk factors, particularly hypertension, dyslipidemia, and smoking, is more important than the treatment of hyperglycemia in preventing morbidity and mortality.

Special aspects: Type 1 diabetes With type 1 diabetes, there is essentially no endogenous insulin secretion, due to autoimmune destruction of the insulin-producing beta cells of the pancreas. This lack of an essential hormone for life means that insulin must be injected, often multiple times daily. Furthermore, the replacement of a very finely tuned normal insulin secretory mechanism, which provides insulin precisely 'on demand,' cannot be well reproduced by injections, explaining the glycemic lability of type 1 diabetes.

Major objectives Generally, the treatment objective in type 1 diabetes is stabilization of glycemic control in an acceptable range, control of other risk factors, and thus avoidance of long-term complications. This requires close attention not only to diet but also to its interrelationships with insulin dose and timing, activity, stress, and other life factors. In fact, despite the best efforts, almost all people with type 1 diabetes are prone to wide swings of blood glucose, sometimes from 2.8 to 17 mmol/l (50–300 mg/dl) or more during a day.

To control the intrinsic 'brittleness' of type 1 diabetes, the individual needs to learn to stabilize dietary intake, making it as reproducible as possible. If carbohydrate, in particular, varies significantly from day to day and meal to meal, the person must learn to adjust insulin doses to match the changed intake. Carbohydrate counting helps stabilization of the diet or adjustment in insulin doses. It is useful for the nutritionist to understand the various insulin regimens that people with type 2 diabetes are given. Several different typical regimens, with comments on the dietary implications, are shown in **Figure 1**.

In addition to carbohydrate awareness, dietary fat intake should be taken into consideration. Dietary fat is often the main determinant of serum lipids and contributes significantly to total energy intake and thus body weight. It also delays gastric emptying, prolonging the glycemic response to dietary carbohydrate.

Very few people continue to measure and weigh foods, but weighing is a useful tool during the instruction phase. Ultimately, people with type 1 diabetes should become proficient in estimating the carbohydrate content of food so that their food selection becomes second nature.

Energy intake distribution will depend on the type of insulin, the number of injections, and the glycemic targets (very tight blood glucose control or not as tight). Often, small changes in food ingestion can make a significant difference. If, for example, a patient tends to develop hypoglycemia at approximately noon, the skillful dietitian can either emphasize the necessity of eating lunch regularly before noon or suggest the patient consume some of the lunch carbohydrates as an 11 AM snack. These changes may eliminate the need to change insulin dose.

Especially with intensive insulin therapy (three or four daily injections or an external insulin pump), there is some flexibility in the timing of the meals but also a need for more accurate assessment of meal content. Some patients will learn their own ratio of grams of carbohydrate to insulin dose necessary to maintain blood glucose in a good range.

Eating disorders pose a serious problem to the management of type 1 diabetes. Presumably because people with diabetes are often diet conscious, the prevalence of eating disorders is surprisingly high among teenagers with diabetes. The problem is especially dangerous because young people may skip insulin injections in order to induce glucosuria, a sort of 'metabolic purging.' These conditions clearly require prompt professional help.

Growth and development The total daily energy intake of a person with type 1 diabetes should be calculated to maintain normal growth and development in a child and normal weight in an adult. Examples of these calculations are provided in **Table 3**. Since most people with type 1 diabetes are not overweight, most do not need low-energy diets. Indeed, underfeeding is a poor way to maintain blood glucose control. The energy needed to establish and maintain normal weight should be matched with the insulin needed to control glycemia. There is no need for a thin or normal-weight person with type 1 diabetes to be perpetually hungry.

Special aspects of dietary management of other types of diabetes Other types of diabetes include those with relatively well-recognized etiologies, such as

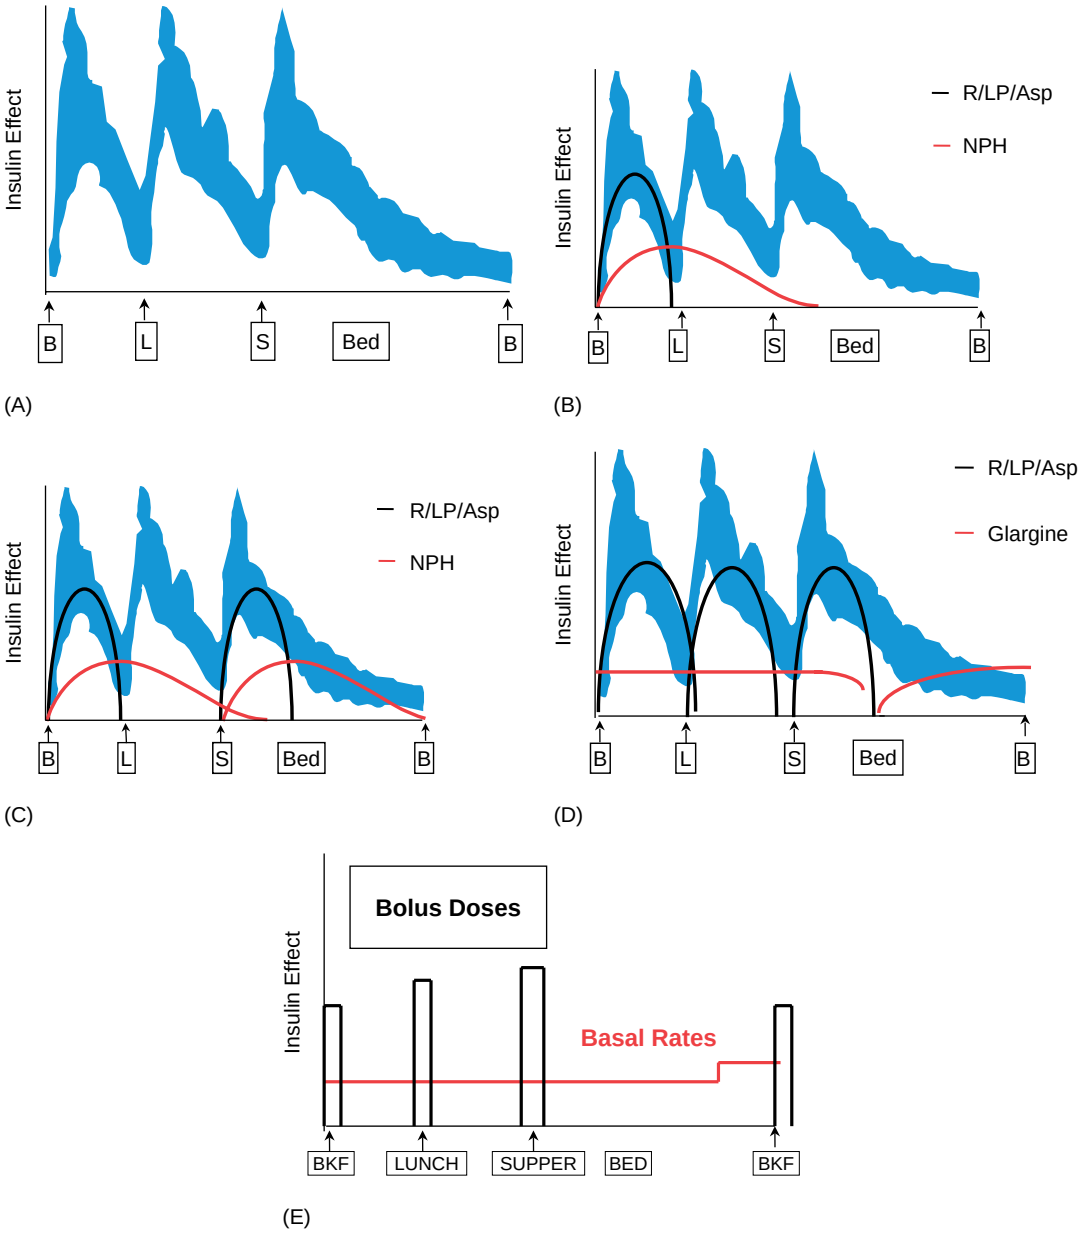

Figure 1 Insulin regimens and notes on the nutritional intake required. (A) The normal insulin response to three meals (breakfast (B), lunch (L), and supper (S)). Note that insulin increases sharply after ingestion of a carbohydrate-containing meal, declining to baseline within several hours. (B) When a combination of short-acting and intermediate-acting insulin is given only at breakfast, the normal response to breakfast is reproduced and the intermediate-acting insulin 'covers' lunch. It is important that the patient ingest a regular breakfast and lunch in order to avoid hypoglycemia from the insulin present at these times. (C) When a combination of short-acting and intermediate-acting insulin is given at breakfast and supper, there is better 'coverage' of the supper meal, but the intermediate-acting insulin peaks near bedtime and the middle of the night, so a bedtime snack may be necessary. (D) A more intensive regimen provides insulin as a 'basal' dose at bedtime, lasting the full 24 h, and short-acting insulin with every meal, for a total of four doses per day. The regimen usually requires patients to monitor their own blood glucose before each meal to adjust their short-acting dose to both the amount of carbohydrate to be ingested and the blood glucose level at the time. The regimen does provide more flexibility of meal timing. (E) Use of an external insulin pump infuses insulin at a precise basal rate, and the patient signals the pump to deliver bolus doses of insulin with each meal. As with D, regular monitoring is required as well as accurate understanding of the content of the meal to be ingested. Basal rate can be adjusted, for example, to avoid nighttime hypoglycemia, and there is flexibility of when meals are eaten.

pancreatectomy-induced diabetes, diabetes due to pancreatitis, cystic fibrosis, iron infiltration of the pancreas (hemochromatosis), or rare syndromes of insulin resistance.

Pancreatitis may be secondary to severe hypertriglyceridemia (triglyceride content >1100 mmol/l (1000 mg/dl)). In this case, a very low-fat diet is often indicated. When there is widespread

destruction of pancreatic cell mass, as with cystic fibrosis, pancreatectomy, or extensive cancer, the exocrine as well as endocrine functions are affected, leading to malabsorption and impaired glucagon secretion. Malabsorption causes steattorhea and may require pancreatic enzyme replacement to avoid marked variability in carbohydrate as well as fat absorption. Lack of the hormone glucagon increases the risk of severe hypoglycemia after insulin administration since there is less counterregulatory ability to raise blood glucose levels after mild hypoglycemia.

Effects of Ingested Nutrients on Blood Glucose

Carbohydrate

Carbohydrate ingestion causes blood glucose to increase. In people without diabetes, the normal increase in blood glucose is approximately 0.5–2.8 mmol/l (10–50 mg/dl) above baseline, returning to baseline within 1–3 h. The pancreatic hormonal response to dietary carbohydrate mediates the return to normal. Insulin is the central mediator of energy metabolism. The basics of insulin-dependent energy metabolism in the fed and the fasting states are depicted in **Figure 2**.

Although carbohydrate intake plays the major role in postprandial blood glucose, there are other factors to consider. The diet is not the only source of glucose in blood; hepatic gluconeogenesis maintains blood glucose in the absence of dietary intake. For example, when a person is ill and dietary intake is curtailed, it would be a mistake to stop insulin administration since hepatic glucose production may in fact be increased. Sick-day instruction is essential for people with diabetes so that they do not simply stop their treatment if they are not eating well. Pharmacologic therapies (insulin or oral agents), of course, also affect blood glucose.

A long-standing debate has surrounded the optimal proportion of intake from carbohydrate, fat, and protein. People with diabetes, especially when insulin is administered, will discover that if they hold back carbohydrate their blood glucose does not increase as much. Holding back carbohydrate, however, unless the diet is hypocaloric, inevitably leads to a high-fat diet, and carbohydrate restriction leaves insulin with no substrate to act on. In our experience, this can cause blood glucose levels to be more unstable, susceptible to swings of hypoglycemia and hyperglycemia. We support the recommendation of most professional guidelines that carbohydrate should make up a substantial percentage (50–60%) of total nutrient intake.

Two areas of controversy and of nutrition research deserve special attention: the glycemic response to oral sucrose (concentrated sweets) versus complex carbohydrates and the so-called 'glycemic index.'

Sucrose versus complex carbohydrate Careful metabolic studies suggest that, gram for gram, sucrose does not increase blood glucose more than complex carbohydrates, either acutely or over a matter of weeks. In these studies, sucrose was isoenergetically substituted for other carbohydrates, mostly under carefully defined research ward conditions in which precise substitutions can be made. Since complex carbohydrates and sucrose are both digested to monosaccharides before they are absorbed, it is not unexpected that each should cause the same glycemic excursion if administered in the same number of grams. It does run counter, however, to the traditional advice that people with diabetes should avoid concentrated sweets.

A number of organizations have cited these research studies in support of a recommendation that allows ingestion of concentrated sweets. The caveat, in the words of the American Diabetes Association, is that "sucrose should be substituted for other carbohydrate sources in the food/meal plan." In our view, there is a practical fallacy in this recommendation: People are unlikely to substitute sucrose for complex carbohydrates in equal amounts. Due simply to taste, concentrated sweets are likely to be taken in far greater quantity than the more filling and less sweet starches. Thus, in reality, people who routinely eat concentrated sweets are likely to have greater and less predictable glycemic excursions than those who stick to complex carbohydrates. There is also the significant risk that excess concentrated sweet intake will cause weight gain (as well as dental caries). However, if a person with diabetes can include a fixed amount of concentrated sweet in his or her diet and can demonstrate that his or her diabetes is well controlled and the postmeal glycemia is not excessive, there is no reason to deny the person the sweet.

Glycemic index The glycemic index (GI) is defined as the area under the 2-h curve of blood glucose after the ingestion of a set amount of carbohydrate compared to ingestion of the same amount of carbohydrate from a reference food (white bread or glucose). The GI is expressed as a percentage of the standard food value:

$$\text{Glycemic index} = \frac{\text{Area under the curve of test food}}{\text{Area under the curve of standard food}} \times 100$$

The glycemic load (GL) is an additional measure in which the amount of carbohydrate in a typical

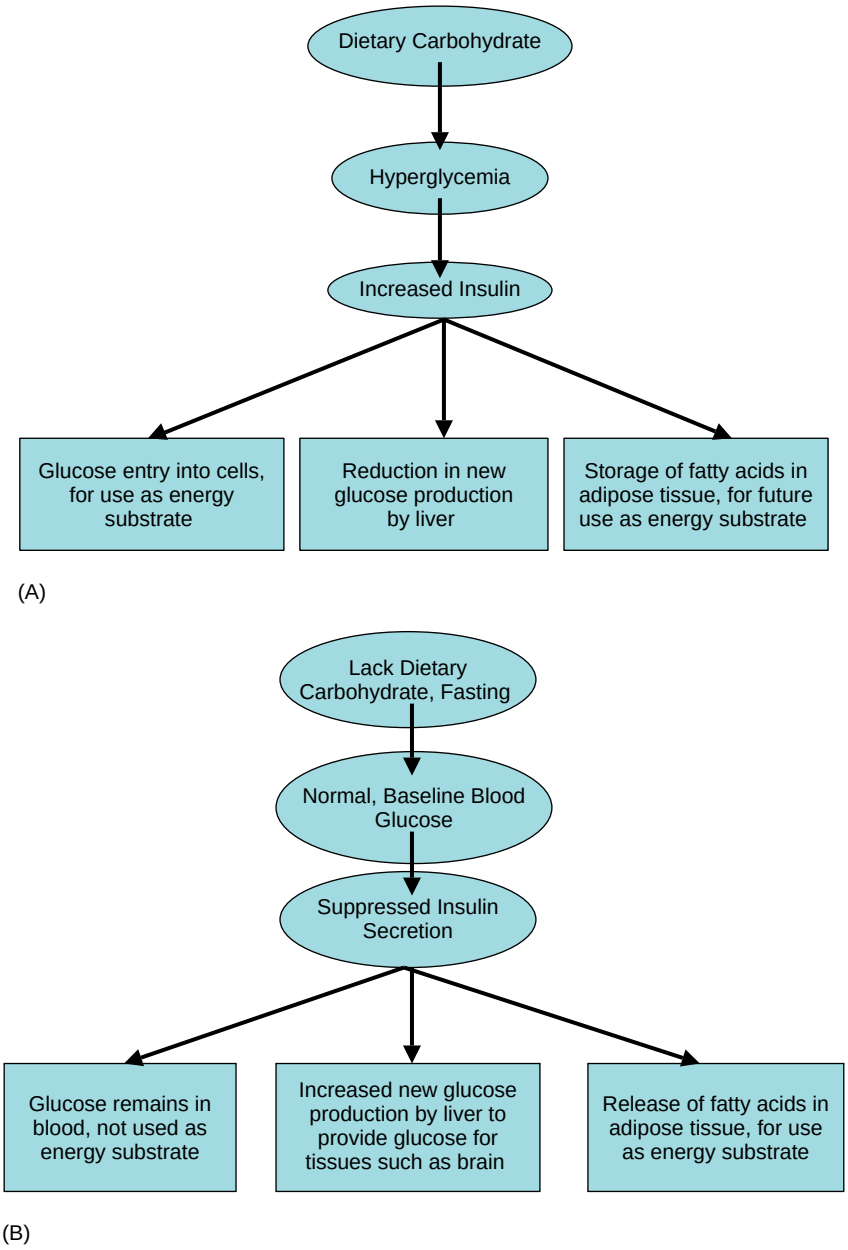

Figure 2 Influence of insulin on basic energy metabolism. (A) With dietary carbohydrate intake, hyperglycemia induces insulin secretion that acts to enhance glucose entry into cells for utilization as metabolic fuel. Simultaneously, insulin decreases new glucose production in the liver, since dietary glucose is already available, and stores excess caloric intake in adipose tissue as fat. (B) With lack of dietary carbohydrate, as in fasting, the reverse occurs: With lower blood glucose, insulin secretion is suppressed. This minimizes entry of glucose into cells but stimulates enough new glucose production from the liver to provide for obligate glucose using tissues such as the brain. Meanwhile, low insulin concentration promotes fatty acid release from adipose tissue to serve as an alternate fuel for metabolism.

portion is taken into account. **Table 5** provides examples of foods high and low in GI and GL. These indices have been calculated for more than 500 different carbohydrates, and values are readily available on the Internet. A number of factors in addition to the reported GI and GL actually affect the blood glucose response to meals, however, because mixed meals are ingested in everyday living. Among these are the fat and fiber content of the meal, type of cooking, the patient's absorptive rate, and micronutrient content.

In our opinion, the concept of the GI is valid in a research sense: Certain carbohydrates, gram for gram, do raise blood glucose levels more, or with different glycemic patterns, than others. However, we believe that basing nutrition plans on the GI and the GL of foods is usually too much of a burden for people with diabetes, who have to closely monitor

Table 5 Examples of foods high and low in glycemic index (GI) and glycemic load (GL)[a]

	GI	*Serving size (g)*	*GL*
Low GI/low GL			
Apple, NS (USA)	40	120	6
Oranges (Sunkist, USA)	48	120	5
Healthy Choice hearty 7-grain bread (USA)	55 ± 6	30	8
Ice cream, premium, French Vanilla—16% fat (Australia)	38 ± 3	50	3
Kidney beans (USA)	23	150	6
Pizza, Super Supreme, thin and crispy—13.2% fat, Pizza Hut (Australia)	30 ± 4	100	7
Low GI/high GL			
Barley (*Hordeum vulgare*) (India)	43 ± 6	150	26
High GI/low GL			
Watermelon, raw (Australia)	72 ± 13	120	4
White wheat flour bread	70	30	10
High GI/high GL			
Cornflakes (Kellogg's, USA)	92	30	24
Bagel, white, frozen (Lenders, Canada)	72	70	25
White rice, type NS, boiled 13 minutes (Italy)	102	150	31

[a]High GI is considered >70 and low <55. High GL is considered >20 and low <10.

Adapted from Foster-Powell K, Holt SH, and Brand-Miller JC (2002) International table of glycemic index and glycemic load values. *American Journal of Clinical Nutrition* **76**(1): 5–56.

the total amount of carbohydrates. It is more practical to encourage people to learn their own glycemic response to different foods from experience. They may learn, for example, that far more insulin is needed before eating pizza or a bagel; they may learn to avoid certain deserts. A general awareness of what preferred foods, in what amounts, raise blood glucose may be more practical than memorizing GI or GL.

Protein

Since the classic experiments by Benedict in the 1910s, it has been known that protein ingestion causes hyperglycemia and glucosuria. The effect of protein ingestion on blood glucose, however, is far less pronounced than the effect of carbohydrate ingestion. A rule of thumb is that a gram of protein raises blood glucose approximately one-third as much as a gram of carbohydrate. In most diets, approximately 50–100 g protein is ingested per day, compared to approximately 200–300 g carbohydrate. Therefore, protein is a calorically less significant part of the diet and far less important in regulating blood glucose. In people with type 2 diabetes, protein does not slow the postprandial absorption of carbohydrate. The same cannot be said about dietary fat.

Fat

Dietary fat has little, if any, immediate effect on blood glucose concentration because the constituent fatty acids do not produce new glucose and the glycerol moieties are insignificant in their contribution to blood glucose. However, there is considerable evidence that circulating free fatty acids promote gluconeogenesis and hyperglycemia. In a normal overnight fast this is good: Fatty acids help maintain normoglycemia. However, in uncontrolled diabetes, when fatty acids can be very high, they significantly worsen hyperglycemia. This has been referred to as 'fat toxicity.'

Fat ingestion slows gastric emptying. The delayed delivery of carbohydrate to the circulation can cause a late, slow postprandial rise in blood glucose, although people who do not self-monitor frequently are unlikely to be aware of this effect of dietary fat.

Nonnutritive Sweeteners

Sweeteners are important to the quality of life of people with diabetes. An essential distinction is to differentiate those with from those without significant energy content. **Tables 6** and **7** provide many of the available nonnutritive and nutritive sweeteners. The nonnutritive sweeteners have no or virtually no energy content, and they can be consumed without concern about their effect on blood glucose.

Table 6 Nonnutritive sweeteners

Type	*US brand names*	*kcal/g*	*Description*
Saccharin	Sweet and Low, Sweet Twin, Sweet 'N Low Brown, Necta Sweet	0	200–700 times sweeter than sucrose; noncarcinogenic and produces no glycemic response
Aspartame	Nutrasweet, Equal, Sugar Twin (blue box)	4	160–220 times sweeter than sucrose; noncarcinogenic and produces limited glycemic response
Acesulfame-K	Sunett, Sweet & Safe, Sweet one	0	200 times sweeter than sucrose; noncarcinogenic and produces no glycemic response
Sucralose	Splenda	0	600 times sweeter than sucrose; noncarcinogenic and produces no glycemic response

Table 7 Polyols and novel sugar sweeteners

Type	*kcal/g*	*Description*
Monosaccharide polyols or novel sugars		
Sorbitol	2.6	50–70% as sweet as sucrose; some people experience a laxative effect from a load ≥50 g
Mannitol	1.6	50–70% as sweet as sucrose; some people experience a laxative effect from a load ≥20 g
Xylitol	2.4	As sweet as sucrose
Erythritol	0.2	60–80% as sweet as sucrose; also acts as a flavor enhancer, formulation aid, humectant, stabilizer and thickener, sequestrant, and texturizer
Disaccharide polyols or novel sugars		
Isomalt	2	45–65% as sweet as sucrose; used as a bulking agent
Lactitol	2	30–40% as sweet as sucrose; used as a bulking agent
Maltitol	2.1	90% as sweet as sucrose; used as a bulking agent
Polysaccharide polyols		
HSH	3	25–50% as sweet as sucrose; other names include hydrogenated starch hydrolysates and maltitol syrup

Adapted with permission from the Journal of the American Diabetic Association Position Paper: Use of Nutritive and Nonnutritive Sweetners.

Many 'diet' sweeteners, such as sorbitol or fructose-based snacks, do cause at least some degree of hyperglycemia. Sugar alcohols (polyols) such as sorbitol, mannitol, and xylitol are classified as hydrogenated monosaccharides, hydrogenated disaccharides, and oligosaccharides. They do contain calories, but because they are only partially absorbed in the small intestine, they have a reduced energy value per gram. Excessive use of sugar alcohols has laxative effects and can cause diarrhea.

It is important for people with diabetes to understand clearly these distinctions because many calories can be ingested with foods labeled as 'diet' under the false assumption that they are without effect on blood glucose.

Trace Elements

There has been recurrent interest in whether such trace elements as chromium, potassium, magnesium, vanadium, and zinc affect blood glucose control in diabetes. It would obviously be attractive if simple oral supplements could facilitate normoglycemia. The evidence, though, is slim and unconvincing that supplementation of any of these trace elements has a beneficial effect except when there is a true deficiency. Such deficiency may occur in an undernourished setting, in the elderly with poor dietary intake, or in certain strict vegetarian diets.

The same conclusion can be reached regarding vitamin supplementation: It is indicated when vitamin deficiency is suspected or likely. For example, populations such as the elderly, those pregnant or lactating, strict vegetarians, or those on a calorie-restricted diet supplementation may require vitamin supplements. Folate supplementation is well documented to improve the outcome of pregnancy, with or without diabetes. However, there is no clear evidence that supplementation is helpful for those eating an adequate diet.

Antioxidants such as vitamins C, E, or A and α-lipoic acid are the object of intensive research. It is unclear whether or which of these actually prevent long-term complications of diabetes, but the literature should be monitored. Vitamins B_1, B_6, and B_{12} are sometimes used to treat diabetic peripheral neuropathy, but without much supporting evidence of benefit. On the other hand, calcium supplementation is indicated, particularly in the elderly, if daily intake is less than 1.0–1.5 g.

In summary, evidence is weak that vitamin or trace element deficiencies occur due to diabetes. Supplementation in more normal circumstances has little or no role in the control of diabetes, and general nutritional guidelines for vitamins and trace elements should be followed.

Major Nonnutrient Factors That Regulate Blood Glucose

No element of diabetes management exists in a vacuum, so it is essential to consider how dietary therapy interacts with other elements of management. Most prominent are insulin, oral hypoglycemic agents, activity, and stress.

Insulin

As two major types of diabetes (1 and 2) differ, so the use of insulin differs for each. As described earlier, in type 1 diabetes the insulin doses must be closely matched to the meals ingested. Too much insulin or too little ingested carbohydrate can cause serious hypoglycemia. Frequently, patients are on

intensive insulin regimens, sometimes four doses per day, and sometimes using an insulin pump. People with well-controlled type 1 diabetes have usually learned to pay close attention to their carbohydrate intake, recognize portion sizes, or even count grams of carbohydrate. They often adjust insulin dose or carbohydrate intake, but this can be done effectively only if they have a good, quantitative understanding of both. Meals skipped or eaten late can be a problem.

Intensive insulin regimens may involve the use of an insulin pump or insulin doses based on a 'sliding scale.' Ordinarily, sliding scales are developed for the patient based on the self-monitored blood glucose at the time of the meal. For higher blood glucose levels, more short-acting insulin is administered. In more intensive regimens, often with insulin pump use, the amount of insulin delivered is also adjusted depending on both blood glucose level at the time and the carbohydrate to be ingested. To be safe and effective, this self-adjusted fine-tuning of insulin dose requires considerable knowledge of diet as well as insulin.

Examples of sliding scales are provided in **Table 8**. Some people, particularly those with intensive insulin regimens, learn to adjust their insulin dose according to both the blood glucose at the start of a meal and the estimated amount that a unit of insulin will reduce their blood glucose. Examples are provided in **Table 9**. Also, although nutritionists do not usually prescribe changes in insulin dosage, it is useful to know the various types of insulin available (**Table 10**) and patterns of insulin action (**Figure 1**).

With type 2 diabetes, since there is usually some insulin secreted on demand from the pancreas and considerable resistance to insulin, dietary intake may not have to be so precisely regulated according to insulin dose. There is a risk of hypoglycemia but it is usually less than that seen in type 1 diabetes. As discussed previously, the nutritional emphasis is usually on reducing the caloric intake, with careful control of fat as well as carbohydrate.

Oral Antidiabetic Agents

Oral antidiabetic agents are not insulin; insulin is delivered only by injection or infusion. The variety of agents in use has escalated dramatically in recent years, so it is worth knowing how the various classes act and how they may interact with diet.

Sulfonylureas (e.g., glyburide, glimepiride, and glipizide) commonly act by stimulation of pancreatic insulin secretion. They therefore can cause hypoglycemia if taken in excess or without normal food intake.

The other most popular oral agent is metformin, which does not stimulate insulin secretion and therefore should not cause hypoglycemia by itself. Metformin can cause bloating and diarrhea, but it can also be mildly weight reducing in conjunction with diet.

The drugs called thiazolidinediones (TZDs), pioglitazone and rosiglitazone, improve insulin sensitivity but do not by themselves cause hypoglycemia. TZDs can, however, cause fluid retention and weight gain, so they are sometimes counterproductive in someone trying to lose weight.

Finally, a class of drugs called α-glucosidase inhibitors (acarbose and miglitol) inhibit digestion and absorption of carbohydrate. They do not cause hypoglycemia, but they may interfere with the treatment of hypoglycemia by oral carbohydrate.

Physical Activity

The effects of exercise on blood glucose levels are complex and sometimes unpredictable. Although moderate, extended aerobic exercise generally causes progressive lowering of blood glucose, intense exercise may transiently increase the blood glucose. We generally recommend modification of diet to accommodate exercise, rather than changing the dose of

Table 8 Examples of sliding scale insulin doses based on blood glucose level at the time of the meal[a]

Meal	*Blood glucose (mmol/l)*	*<3.33*	*3.33–6.7*	*6.8–8.3*	*8.4–11.1*	*11.2–13.9*	*14–16.7*	*>16.7*
	Blood glucose (mg/dl)	*<60*	*60–120*	*121–150*	*151–200*	*201–250*	*250–300*	*>300*
Breakfast	NPH/regular	8/0	8/4	8/5	8/6	10/7	10/8	10/9
Lunch	Regular	0	2	3	4	5	6	7
Supper	Regular	2	4	6	7	8	9	10
Bedtime	NPH/regular	6/0	6/0	7/0	7/0	8/0	8/2	8/3

Example: Prebreakfast blood glucose 10 mmol/l (180 mg/dl): Take 8 units NPH + 6 units regular.

[a]Each patient will have individual insulin requirements and needs. Longer acting insulin (such as glargine) may be used at bedtime, and faster acting insulins (such as lispro or aspart) may be used premeal.

Table 9 Examples of mealtime insulin dose based on blood glucose level *and* amount of carbohydrate to be ingested[a]

Short-acting or fast-acting insulin dose
'Correction factor': 1 unit per 2.8 mmol/l (50 mg/dl) >5.5 mmol/l (100 mg/dl)
plus
'Meal factor': 1 unit per 15 g carbohydrate
Example: Before ingesting a meal estimated to have 45 g of carbohydrate, the blood glucose is measured to be 150. Insulin dose would be 1 unit (for the blood glucose) + 3 units (for the carbohydrate) = 4 units.

[a]Both the correction factor and the meal factor will vary from patient to patient. Long acting insulins are used in addition to these prandial doses.

insulin or oral agents, since the duration and intensity of exercise may be unpredictable. Trained athletes or 'weekend warriors' often learn to take extra carbohydrate before a strenuous workout rather than anticipating exercise by reducing the morning insulin dose. They also learn that the time of greatest hypoglycemic risk may be 6–12 h after exercise.

Stress

Stress in normal life is difficult to quantify or study, but the usual experience is that diabetic control deteriorates under stress. This makes sense, considering the hyperglycemic effects of 'fight or flight' hormones such as adrenaline (epinephrine) and cortisol. However, it is likely that the main problem for people under unusual stress is less hormonal than behavioral—simply neglecting their diet or eating as a stress reliever. Therapists may be most effective by reminding patients to maintain their normal diet even when experiencing emotional stress.

Dietary Prevention and Management of Comorbidities

Accelerated Atherosclerosis

Essentially the same nutritional approaches to the prevention of atherosclerosis apply whether or not a person has diabetes. However, they are even more important for the patient with diabetes since hyperglycemia is a risk factor, and most people with diabetes die of atherosclerotic cardiovascular disease. Therefore, anyone with diabetes should follow a 'heart healthy' diet that focuses on lowering low-density lipoprotein (LDL) cholesterol level, which is a major contributor to the progression of atherosclerosis. Total fat intake can be held to 25–35% of total calories, less than 7% saturated fat and the remainder divided between monounsaturated fat and polyunsaturated fats. The recommendation allows for increased intake of unsaturated fats in place of carbohydrates in people with diabetes. In addition to the antiatherosclerotic diet, there should be routine screening for other specific risk factors, notably hypertension and dyslipidemia. If found, these risk factors, which are even more dangerous in diabetes, should be vigorously treated.

Dyslipidemia

If the dyslipidemia is predominantly elevation of LDL cholesterol, then dietary manipulations are no different in diabetes from those used to treat hypercholesterolemia generally: Low intakes of saturated fat and cholesterol are indicated, with cholesterol-lowering medications (usually statins) given as needed. Target goals for LDL cholesterol are <100 mg/dl, and there have been recommendations to lower LDL

Table 10 Types of available insulin by onset, peak, and duration of action

Category	*Insulin type*	*Approximate onset*	*Approximate peak*	*Approximate duration*
Fast acting	Aspart	5–10 minutes	1–3 h	3–5 h
	Lispro	<15 minutes	0.5–1.5 h	2–4 h
Rapid acting	Regular	0.5–1 h	2–3 h	3–6 h
Intermediate acting	NPH	2–4 h	4–10 h	10–16 h
	Lente	3–4 h	4–12 h	12–18 h
Long acting	Glargine	1.1 h	?	24 h
	UltraLente	6–10 h	18–20 h	20–24 h

Premixes
50/50: 50% NPH, 50% regular
70/30: 70% NPH, 30% regular
Mix 70/30: 70% aspart–protamine suspension (e.g., NPH), 30% aspart
75/25: 75% lispro–protamine suspension (e.g., NPH), 25% lispro

[a]Onset, peak, and duration will vary for each individual. Based on American Diabetes Association (2004) *Diabetes Forecast, Resource Guide*. Alexandria, VA: American Diabetes Association.

cholesterol to as low as <70 mg/dl if there are other risk factors for coronary artery disease.

Hypertriglyceridemia, on the other hand, is the more common dyslipidemia in diabetes, and especially it is dangerous when it is associated with low levels of high-density lipoprotein cholesterol. Insulin–glucose homeostasis is intrinsically and complexly related to triglyceride metabolism. Insulin stimulates both very low-density lipoprotein–triglyceride synthesis in the liver and its clearance via lipoprotein lipase in the periphery.

In extreme cases, reduced chylomicron clearance causes 'diabetic lipemia,' characterized by chylomicronemia and extreme hypertriglyceridemia. More moderate levels of hypertriglyceridemia, on the other hand, are considered to be due to overproduction of hepatic (endogenous) lipid under the influence of hyperinsulinism and peripheral insulin resistance.

Compounding the confusion is the phenomenon of 'carbohydrate induction of hypertriglyceridemia.' Most normal people switched isoenergetically from a low- to a high-carbohydrate diet (i.e., with less dietary fat) will actually increase their fasting triglyceride level. This carbohydrate induction of hypertriglyceridemia may be transient, lasting only a few weeks.

For the person with diabetes, treatment of hypertriglyceridemia begins with optimization of blood glucose control and a diet designed to achieve normal body weight. Weight reduction is often very effective.

If hypertriglyceridemia persists, evidence favors the use of monounsaturated fats when dietary fat increases. Since hypertriacylglyceridemia is sometimes associated with excess alcohol, reducing the amount consumed may be effective. For the unusual condition of fasting chylomicronemia, with triglyceride levels remaining over approximately 11 mmol/l (1000 mg/dl), a low-fat diet is necessary to avoid exacerbating the situation by adding dietary fat and precipitating pancreatitis from the chylomicronemia.

If pharmacologic treatment is necessary to treat hypertriglyceridemia, a fibric acid derivative, such as gemfibrazol or fenofibrate, or nicotinic acid should be used. Statins are usually the first drug of choice when LDL cholesterol is also elevated.

Hypertension

The current nutritional management of hypertension focuses on reducing dietary sodium intake and weight reduction, as well as the recently proven 'DASH' diet. There has been long-standing evidence that in both normal and hypertensive people, a reduction in sodium intake lowers blood pressure. The DASH diet was shown to be effective in a large trial of dietary intervention. It is a fruit and vegetable diet, with balanced consumption of foods emphasizing high fiber, grains, and low-fat dairy products. Potassium, magnesium, and fiber replace some snacks and sweets.

Modest amounts of weight loss and increased activity are also beneficial for the person with hypertension. Thus, overweight and obese individuals should be encouraged to lose weight as part of their medical therapy. In diabetes, ACE inhibitors or ARBs (Angrotensin Receptor Blockers) are usually the first line of medication used when diet and exercise are not effective in controlling blood pressure. Frequently, additional antihypertensives must be added.

Renal Disease

Nutritional therapy of established diabetic nephropathy continues to be studied. In both type 1 and type 2 diabetes, persistent microalbuminuria is a strong predictor of gross proteinuria and developing nephropathy. Evidence suggests that microalbuminuria actually reverses in many cases, but gross proteinuria (over approximately 300 mg/24 h) in most cases eventually progresses to end-stage renal disease. Therefore, treatment focuses on reversing or at least retarding the progression of nephropathy. In recent years, the nutrition recommendation has been to lower dietary protein intake to 0.8–1.0 g/kg of body weight per day for patients with microalbuminuria. For people with overt nephropathy, reducing dietary protein intake to 0.8 g/kg of body weight per day may slow the progression of nephropathy. Protein restriction should not be attempted if serious protein loss from nephrotic-range proteinuria has reduced total serum albumin concentration, in which case it is agreed that a low-protein diet is not indicated. In fact, a large study of the dietary treatment of kidney disease in nondiabetic subjects did not support the value of protein restriction in slowing progression of kidney damage.

The best documented therapies for proteinuria and reducing nephropathy are improved glycemic control and reduction of blood pressure using ACE inhibitors or ARBs. Cessation of smoking is also of established benefit.

Conclusions

Medical nutrition therapy is essential to all people with diabetes, of whatever type or severity. A healthy diet should contain important components, including foods containing carbohydrates from whole grains, fruits, vegetables, vitamins, and low-fat dairy

products. Although blood glucose control and management of coexisting risk factors are overall goals, the implementation of dietary management is a highly complex and individualized process. Principles of medical nutrition therapy that generally apply to all diabetes, and specific features that apply to the various types of diabetes, have been discussed; but it must be emphasized that good nutritional management requires the close interaction of each individual patient with a knowledgeable expert in dietetics.

DIARRHEAL DISEASES

A Baqui, R Heinzen, M Santosham and R Black, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, USA

Global Burden of Diarrhea and Epidemiological Trends

Diarrheal illnesses in young children are among the leading causes of morbidity and mortality in developing countries. Diarrhea is an important cause of morbidity in developed countries as well. In developing countries, children younger than 5 years old suffer 3–10 episodes of diarrhea per year, whereas in developed countries young children have on average 1 or 2 diarrheal episodes per year. The advent of oral rehydration therapy (ORT) and its use in the past three decades have dramatically reduced the case fatality rate for diarrhea. However, globally the estimated 3 billion annual episodes of diarrhea account for approximately 2 million deaths in children younger than 5 years old. The majority of diarrhea-related mortality occurs in developing countries and the highest rates of diarrhea occur among infants with malnutrition. The case fatality rate is highest among children 6 months to 1 year old. The primary reason is that for most children this is the period when the immune system is not yet fully matured and the maternal antibodies are reduced. In addition, they may receive contaminated foods to complement breast-feeding, and they begin to crawl, potentially to areas where they may have direct contact with human or animal feces.

Although dehydration is the most direct effect of diarrhea, there are many adverse and potentially fatal nutritional consequences when proper nutritional management is not followed. This article provides an overview of the epidemiology of diarrheal diseases, including the interaction of diarrhea and malnutrition, and discusses the treatment of diarrhea, including fluid therapy and dietary management to minimize the nutritional cost of diarrhea.

Diarrhea–Malnutrition Interaction

Diarrheal illnesses are more common, last longer, are clinically more severe, and are more likely to have a fatal outcome for impoverished children in less developed countries because of a complex interaction between infection, protein-energy malnutrition, and micronutrient deficiencies. Diarrhea and malnutrition have a bidirectional relationship in which malnutrition increases the incidence and duration of diarrhea and, conversely, diarrhea exerts a negative effect on nutritional status.

Malnourished children have defects in cell-mediated immune functions and a decrease in IgA-containing cells in the jejunal mucosa. Malnutrition produces morphological and functional changes in virtually all organs. Changes in the intestine include thinning of the gut epithelium, marked flattening and broadening of villi, extensive infiltration of the lamina propria, and diminished secretion of gastric acid. These changes lead to an increased risk of diarrhea. The risk of developing diarrhea may be predicted by a child's ability to respond to skin test antigens. This effect of impaired cellular immunity is independent of age and nutritional status. Studies have shown that patients with a variety of viral and bacterial infections, such as measles, influenza, tuberculosis, and streptococcal infections, develop impaired cell-mediated immunity (anergy). Anergy or reduced responsiveness may also be associated with single nutrient deficiency, such as deficiency of vitamin A, zinc, pyridoxine, folic acid, and iron. Therefore, it may be possible that in an otherwise healthy child, infection or micronutrient deficiencies induce immunodeficiency may increase susceptibility to diarrhea and other infections and lead to a vicious cycle of repeated infections, anergy, and deteriorating nutritional status.

Diarrheal diseases have generally been noted to have an adverse effect on growth of underprivileged children in developing countries. Community-based prospective studies in developing countries have consistently demonstrated a significant negative effect of diarrhea on short-term weight gain, but studies on the effect on short-term height gain are less consistent. On the contrary, some investigators have concluded that the effect of diarrhea on growth is transient and that efforts to control diarrhea are unlikely to improve children's nutritional status. One possible explanation for the discrepant findings is the heterogeneity of diarrheal illnesses. Most studies that have examined the effect of diarrhea on growth have considered diarrhea as a single entity. Studies that have examined the effect of diarrhea on growth by type of diarrheal illness have suggested that certain etiological (e.g., *Shigella* spp.) and clinical-type (dysentery) illnesses are associated with significant growth retardation. It has been estimated that diarrheal illnesses account for 10–80% of growth retardation in the first few years of life, with the magnitude of effect possibly modified by other factors, such as etiology and clinical type, the source and adequacy of dietary intake, treatment and feeding practices during and following illness, and the opportunity for catch-up growth after illness. A cohort study conducted in Bangladesh observed that dysentery had the most deleterious consequences on both ponderal and linear growth, although other types of diarrhea showed a similar but relatively less pronounced negative effect on growth. Losses of approximately 0.5 kg in annual weight gain and 1.25 cm in annual height gain were associated with dysentery in children <5 years old in this population.

Understanding the mechanisms of diarrhea-induced undernutrition and appropriate treatment of diarrhea is important for the immediate illness and also for the long-term well-being of children. Approximately 10% of diarrheal episodes result in persistent diarrhea lasting more than 2 weeks. These infants need specialized treatment in addition to rehydration therapy, such as antibiotics for concurrent infections, micronutrients, and careful dietary management. In many settings, up to 50% of diarrhea-associated deaths occur in children with malnutrition-associated persistent diarrhea.

Clinical Types and Etiology of Diarrhea

Since nutritional costs of diarrhea vary by etiology and clinical type, a discussion of different types of diarrhea is pertinent. Diarrheal episodes can be classified based on clinical presentation as inflammatory (dysentery) and noninflammatory (nondysentery) diarrhea. Therefore, the clinical presentation of diarrheal illnesses may suggest a causative diagnosis. Diarrheal episodes can also be classified based on duration as acute (<14 days) and persistent (≥ 14 days) diarrhea. The diarrhea is generally due to either infectious or noninfectious causes. This article focuses on infectious diarrhea. Pathogens that cause infectious diarrhea include bacteria, viruses, and parasites (**Table 1**).

Most diarrheal episodes are acute. Occasionally, they become prolonged, leading to a vicious cycle of malabsorption, malnutrition, and failure to thrive. Noninfectious diarrhea tends to be persistent because it is often due to a chronic health problem. However, most persistent diarrhea is due to infection or is a sequeale of infection. Infections can lead to persistent diarrhea in the following situations: (i) Some pathogens cause chronic symptoms, usually parasites but sometimes bacteria; (ii) immunosuppressed individuals, such as those with human immunodeficiency virus (HIV) infection, cannot effectively clear pathogens and can develop persistent diarrhea; and (iii) at times the infection clears, but people develop chronic symptoms, such as irritable bowel syndrome, with diarrhea. If the diarrhea is persistent, it can cause dehydration, malnutrition, and systemic infections. Diarrhea in combination with a severe case of malnutrition (e.g., marasmus and kwashiorkor) is very dangerous and can lead to

Table 1 Infectious causes of diarrhea

Clostridium difficile

systematic infections and death. Although many different mechanisms may contribute to persistent diarrhea, the result is a similar pathophysiologic syndrome of mucosal atrophy, inflammation, and malabsoption. Therapeutic efforts should concentrate on nutritional rehabilitation.

Factors Influencing Nutritional Decline in Diarrhea

Factors that influence a nutritional decline during a period of diarrhea include reduced food intake, diminished nutrient absorption due to malabsorption of macro- and micronutrients and shorter intestinal transit time, direct loss of protein and other nutrients, and an increase in the body's demand for nutrients. In addition, diarrhea of infectious origins causes cytokine-induced malnutrition, which results from the action of proinflammatory cytokines such as tumor necrosis factor and interleukin-1, -6, and -8.

Food Intake during Diarrhea

Food intake during diarrhea is often reduced due to poor appetite (anorexia), vomiting, deliberate withholding of food, and inappropriate dietary supplementation with diluted food items. Diarrhea can also be associated with fever. Both fever and anorexia have clear effects on the nutritional status of the host. An increase in body temperature of 1 °C causes an increase in the basal metabolic rate of 12–23%. Although the reason for anorexia is not clear, its effect can be important. In a controlled study in Bangladesh, 41 hospitalized children with acute diarrhea consumed only about half of the total calories consumed by healthy children despite an educational intervention.

Malabsorption of Nutrients

Malabsorption in diarrheal illness may result from the epithelial destruction by the pathogen. Diminished nutrient absorption often begins during acute diarrhea. At this time, the body is less able to absorb needed macronutrients, including fats and proteins, as well as some carbohydrates. This is most severe in undernourished children who suffer from persistent diarrhea due to damage to the gut epithelium. When the gut is damaged, food is not properly digested or absorbed. The causes of insufficient nutrient absorption include diminished concentration of bile acids, which are used for fat absorption; damaged epithelial cells, which provide the absorptive surface on the bowel; and a deficiency of disaccharides due to damaged microvilli, which normally produce the needed enzymes. In symptomatic rotavirus infection, the most common cause of acute severe diarheal illness worldwide, there is a 42% decrease in the absorption of nitrogen and fat, a 48% decrease in absorption of carbohydrates, and a 55% decrease in the total carbohydrate absorption. Malabsoption is more severe in both ETEC and shigella diarrhea. In shigellosis, loss of protein and vitamin A is sizeable. Giardiasis leads to malabsorption of vitamin A. A large amount of zinc is lost in diarrhea, usually resulting in a negative net zinc balance during the illness.

Increased Demand for Nutrients

During episodes of diarrhea, the body requires more nutrients than normal. This is due to the need to repair the damage to the gut epithelium, the increased metabolic demand on the body made by a fever, and, during dysentery, the need to replace

serum protein lost by exudation through the damaged intestinal mucosa.

Management of Diarrhea

An invariable accompaniment of diarrhea, particularly persistent diarrhea, is protein-energy malnutrition. However, dehydration is the most immediate complication of diarrhea. Clinical management of acute diarrhea includes four major components: (i) replacement of fluid and electrolyte losses, (ii) zinc therapy, (iii) antimicrobial therapy when indicated, and (iv) continued feeding to supply a sufficient quantity of nutrients to meet both the patient's usual maintenance requirement and the increased needs imposed by infection and malabsoption.

Fluid Therapy

The majority of the diarrhea-associated deaths result from dehydration. Parents should be encouraged to increase fluid intake as soon as diarrhea begins and to give oral rehydration solution if available. Children presenting with diarrhea should be assessed for dehydration. Thirst is an early sign of dehydration in a child. Other signs are mucosal dryness (e.g., dry mouth), sunken eyes, and loss of skin turgor. The coexistence of fever or vomiting exacerbates dehydration. The World Health Organization (WHO) guidelines classify dehydration into two categories—some dehydration and severe dehydration. Weight loss is the main clinical index of degree of dehydration. A vast majority of children with diarrhea present with some dehydration or no clinical signs of dehydration. The cornerstone of treatment for these children is oral rehydration solution (ORS) containing glucose or sucrose and electrolytes. ORS is effective but it must start as soon as diarrhea starts. In children with some dehydration, approximately 100 ml/kg of body weight of ORS should be given within 4 h. Ongoing stool losses should be replaced with ORS. Rehydration and maintenance of hydration in a vomiting child is feasible using ORS by giving small amounts frequently. Severe dehydration is a medical emergency that requires immediate intravenous fluid replacement, and children should preferably be hospitalized. Patients presenting with severe dehydration should receive 40 ml/kg body weight of Ringers lactate or similar intravenous solutions over a 4-h period. ORS should be given as soon as the child is able to drink.

Regardless of etiology, watery diarrhea requires fluid and electrolyte replacement. For more than three decades, an ORS containing 90 mmol/l of sodium and 111 mmol/l of glucose was used throughout the world. This solution has been credited with saving millions of lives. WHO and UNICEF have recommended the use of a new reduced osmolarity ORS formulation consisting of 75 mmol/l of sodium and 75 mmol/l of glucose and total osmolarity of 245 mOSm/l. This recommendation was made on the basis of studies that have demonstrated that the reduced osmolarity ORS was at least as efficacious as the standard ORS containing 90 mmol/l of sodium and an osmolarity of 311/l. In addition, in a meta-analysis, the reduced osmolarity ORS was shown to decrease the need for unscheduled intravenous therapy by 33%, the stool output was reduced by 20%, and the incidence of vomiting was reduced by 30%. However, there is concern that this low osmolar ORS may lead to asymptomatic and symptomatic hyponatremia in adults with severe diarrhea. This issue needs to be evaluated in large-scale effectiveness trials. Despite the proven efficacy of ORS, only approximately 20% of children receive appropriate ORS therapy during diarrheal episodes. The barriers to use of ORS include lack of knowledge of the importance of rehydration therapy, lack of access to ORS, and the perception that ORS is not a medicine since it does not stop the diarrhea.

The management of a child with persistent diarrhea is often difficult due to other related heath issues. These children are more likely to be severely undernourished due to micronutrient and protein-energy malnutrition as well as more prone to systematic infections. Due to the systematic infections, appropriate antibiotic therapy is needed.

Dietary Management of Diarrhea, Including Persistent Diarrhea

Data suggest that continued feeding during diarrhea is generally well tolerated and it minimizes the nutritional cost associated with diarrhea. A child should receive the same type of food during an episode of diarrhea as when the child is healthy. Feeding is usually tolerated, with the occasional exception of lactose intolerance. A small subgroup of children exclusively receiving nonhuman milk may have a higher rate of complications. These children should be closely supervised and provided with alternatives if needed. Full feedings will help to minimize growth faltering and a decline in nutritional status. Growth faltering may still occur, especially in severely undernourished children, due to poor nutrient absorption.

Importance of Continued Breast Feeding

Breast feeding should be continued for as long as the child can tolerate it during episodes of acute

diarrhea as well as during persistent diarrhea. It is normally well tolerated during such episodes and has been shown to reduce stool output and decrease the duration of the illness compared to those of non-breast-fed children.

Milk Intolerance: Lactose Intolerance

The majority of children can tolerate lactose during a diarrheal episode. A small proportion of children with diarrhea may not be able to digest lactose and are therefore not tolerant of milk- and lactose-containing formulas. This is more likely to occur among young children who only receive animal milk or formula in their diet and who have persistent diarrhea, and it rarely occurs in children on a diet of breast milk. In a lactose-intolerant child, milk- and lactose-containing formulas result in a significant increase in stool output. Stool output reduces dramatically when the milk- or lactose-containing formula is stopped. The warning signs of lactose intolerance include deterioration of the child's clinical condition, signs of dehydration, and an increase in the stool volume when milk feedings are given. However, only when the child is not gaining weight, eating less, and not fully alert is this a real cause for concern. This condition can be managed by continuing breast feeding. If the child is not yet in the weaning period but takes animal milk, yogurt or diluted milk (equal water and milk) or soy milk can be used as a substitute given in small feedings. The child should be taken to a health care provider if the condition does not improve in 2 days.

If the child eats soft or solid foods, the lactose in the diet should be substituted in the same manner as for the infant (with diluted milk or soy milk) but mixed with cooked cereals and vegetables. If this does not improve the condition of the child, all animal milk should be excluded from the diet, and protein- and energy-rich foods such as finely ground chicken should be given. The treatment should be continued for a few days after the cessation of the diarrhea, when the milk is slowly replaced in the diet.

Soft or Solid Food, Energy Density of Diet, and Protein and Energy Requirements

A child's diet during the period of diarrhea should not be drastically different from his or her normal healthy diet. Therefore, for children who are currently breast-feeding, they should continue to do so, and for children who are in the weaning period and have a mixed diet, they should continue to have a mixed diet of soft or solid food. If the child on a mixed diet is dehydrated, his or her soft and solid foods should be temporarily stopped for a period of approximately 4 h when he or she rehydrates. However, it should then be resumed. For children who are in the weaning stages, WHO recommends small, frequent feedings (six or more times a day) to increase nutrient absorption. The type of food should be energy rich, low in bulk, locally available, and nutritious. The diet should contain complementary protein sources and easily digestible fats, and complex carbohydrates should be avoided. All the foods should be well cooked. Easily digestible staple foods that can be easily mashed include rice, corn, potatoes, and noodles. These staple foods should be mixed with vegetables as well as sources of protein if possible. It is also important to ensure adequate rehydration. In addition, the consumption of fresh fruit juices and mashed bananas is highly encouraged because they provide a good source of potassium.

Feeding during the Convalescent Period

The convalescent period is the recovery period for the body during which the child's diarrhea has stopped but the body has not yet fully recovered to its initial condition. During the first few weeks, the child's appetite will be returning and the child may consume up to twice as much as usual. This is a necessary part of the process because even if the child was fully fed during diarrhea, he or she most likely did not absorb sufficient nutrients. During this time, the child's nutritional state should return to at least the level before the child became ill. The desired energy intake ranges from 100 to 160 J/kg per day, which is achieved with a high-energy, low-bulk, and low-viscosity diet. This is needed for a catch-up growth period and rapid nutritional recovery.

Supplementation with Micronutrients

ORT reduces mortality from dehydrating diarrhea, but it does not decrease the duration of episodes or their consequences, such as malnutrition. In addition, adherence to recommendations regarding ORT in children is poor because caregivers want to reduce the duration of illness. This often leads to use of antibiotics and other treatment of no proven value. In addition, there are indications that knowledge and use of appropriate home therapies, including ORT, to manage diarrhea successfully may be declining in some countries. The limitations of ORT and continued high diarrhoeal morbidity, mortality, and associated malnutrition led to a search for adjunct therapies. Zinc and vitamin A are essential to repair the intestinal mucosa and boost

immunological responses. These supplements should be given during periods of diarrhea.

Zinc

Based on the results of a large number of randomized controlled trials that have demonstrated the therapeutic benefits of zinc supplementation during diarrhea, WHO and UNICEF have recommended the use of zinc supplementation at a dose of approximately 2 RDAs per day (10–20 mg) for 10–14 days. This strategy has the advantage of having a good delivery mechanism (i.e., during the delivery of ORS packets). The effectiveness of different delivery strategies is being evaluated in large-scale trials.

A study from India evaluated the efficacy of zinc-fortified ORS and reported that zinc–ORS was moderately efficacious in reducing the severity of acute diarrhea. If these results are confirmed by other studies, this strategy has the advantage of reducing the need to deliver the zinc supplementation separate from the ORS packets. However, it will probably result in increased cost of ORS production and not all countries will be able to rapidly scale up the production of zinc–ORS in the near future. Additional potential disadvantages of this strategy are that coverage with ORS is low, ORS is usually needed only for 2 or 3 days, and the volume of ORS taken is generally low. Therefore, it will be difficult to ensure adequate zinc intake.

Vitamin A

The body's ability to absorb vitamin A during diarrhea is reduced, which may lead to acute vitamin A deficiency. Repeated episodes may lead to blindness and signs of xerophthalmia. If these are recognized, 200 000 units of vitamin A should be orally administered to children (100 000 units for infants). There should be two subsequent doses, one the following day and another in 4 weeks. In areas where vitamin A deficiency is a problem, any foods that are rich in carotene should be administered (including dark leafy vegetables and yellow or orange fruits and vegetables). Vitamin A deficiency is most common among severely undernourished children and among children who have recently recovered from the measles.

Medications

Antimicrobials and antiparasitics should not be regularly used. Most episodes do not benefit from these treatments, with the following exceptions: in suspect cases of cholera, in cases of persistent diarrhea when cysts or trophozoites of Giardia are identified in the feces, and antibiotics that are effective for Shigella are only used for cases of dysentery (blood in the stool).

Management of Diarrhea in Children with Severe Malnutrition

Children who are severely undernourished and have diarrhea often have other infections. Infections can cause hypothermia as opposed to fever. An appropriate antibiotic should be give if an infection is identified.

Assessment of Dehydration in a Severely Malnourished Child

Children who are severely undernourished have different, unreliable signs and symptoms to assess the status of their hydration. For example, children with marasmus have poor skin elasticity even though they are not dehydrated, and sunken eyes are also not a reliable sign. Irritability in these children may be a sign of systemic infection rather than dehydration. The skin of children with kwashiorkor, on the other hand, may appear to be normal even if they are dehydrated. These children generally have apathetic attitudes. Undernourished children do not readily cry, so determining the absence of tears is also a challenge. Signs that prove to be more indicative to the status of a child's level of hydration include cool and clammy extremities, eagerness to drink, dry mouth and tongue, and a weak radial pulse.

Rehydration

Severely undernourished children should be hospitalized. ORS should be started as soon as possible. A standard ORS treatment with additional potassium should be given orally (preferred method) or using a nasogastric tube. An intravenous solution should be avoided since fluid overload may potentially cause heart failure and increase the risk of septicemia. By dissolving 7.5 g of potassium chloride in 100 ml of water, it is possible to prepare 1 mmol of potassium per milliliter of solution. Every 24 h, 4 ml/kg body weight should be given, mixed with food, for 14 days.

Feeding

Children with marasmus must limit their food intake to approximately 110 kcal/kg/day for the first week. On the other hand, children with kwashiorkor must begin a slow feeding treatment starting as low as 50 kcal/kg/day and work their way up to approximately 110 kcal/kg/day after approximately 1 week. This can be a difficult task since these children are often apathetic and have

severe anorexia. The initial diets of all severely undernourished children must be given in small, frequent (every 2 h day and night), semiliquid doses. An example of an initial diet packet is 8 g skim milk powder, 6 g vegetable oil, 5 g sugar, and 100 ml water to make a high-energy (100 kcal/100 ml) meal with additional minerals, including 60 mg iron, 100 mg folic acid, and 200 000 units of vitamin A and vitamins B (complex), C, and D.

Conclusion

Diarrhea, a disease of fluid and electrolyte imbalance, is an important worldwide cause of morbidity and mortality among infants and children, especially in developing countries. However, it is also very much a nutritional disease. This is primarily because during periods of diarrhea, nutrient intake and absorption are dramatically decreased, which results in undernutrition even when sufficient food is available. The losses of nutrients affect growth rates, and where diarrhea occurs frequently the child may not grow properly. This is a cyclical pattern in that undernourishment in children makes them more prone to diarrhea. Their immune systems are less robust and the episodes affect them more than well-nourished children. Undernourishment and diarrhea can be a fatal combination that can result in a vicious cycle. This cycle requires intervention, sometimes at a treatment center if the case is severe enough. Therefore, is a matter of not only replacing the fluids and electrolytes but also of managing good feeding practices at all times before, during, and after the illness.

Sixty percent of the 10 million deaths among children younger than 5 years old are associated with malnutrition. Approximately 2 million of the deaths are due to diarrhea. Repeated episodes of diarrhea result in malnutrition, which in turn puts the child at an increased risk of recurrent infections, including diarrhea. To break this cycle, diarrheal episodes should be managed with appropriate fluid and nutritional therapy.

DIETARY FIBER

Contents

Physiological Effects and Effects on Absorption

I T Johnson, Institute of Food Research, Norwich, UK

Introduction

It has long been recognized that both animal feedstuffs and human foods contain poorly digestible components, which do not contribute to nutrition in the classical sense of providing essential substances or metabolic energy. With the development of scientific approaches to animal husbandry in the nineteenth century, the term 'crude fiber' was coined to describe the material that remained after rigorous nonenzymic hydrolysis of feeds. During the twentieth century, various strands of thought concerning the virtues of 'whole' foods, derived from plant components that had undergone only minimal processing, began to converge, leading eventually to the dietary fiber hypothesis. Put simply, this states that the nondigestible components of plant cell walls are essential for the maintenance of human health.

In the early 1970s the physician and epidemiologist Hugh Trowell recognized that the crude fiber figures available at the time for foods had little physiological significance and were of no practical value in the context of human diets. He was amongst the first to use the term dietary fiber to describe the 'remnants of plant cell walls resistant to hydrolysis (digestion) by the alimentary enzymes of man.' This definition was later refined and given the more quantitative form: "The sum of lignin and the plant polysaccharides that are not digested by the endogenous secretions of the mammalian digestive tract." This definition paved the way for the development of analytical methods that could be used to define the fiber content of human foods. Broadly, these techniques are based on enzymic removal of the digestible elements in food, followed by either gravimetric analysis of the residue ('Southgate' and Association of Analytical Chemists (AOAC) methods), which results in the retention of some undigested starch, or chemical analysis ('Englyst' method), which enables a more precise separation of starch from the structural polysaccharides of the cell wall. In the latter case, the cell wall components are defined as 'nonstarch polysaccharides' (NSP). Whatever analytical approach is used, both 'dietary fiber' and nonstarch polysaccharides are shorthand terms for large and complex mixtures of polysaccharides. The components of such mixtures vary widely among foods and they often share few properties other than resistance to digestion in the small intestine. A summary of the main types of plant cell polysaccharides contained in the general definition of dietary fiber is given in **Table 1**.

In recent years this problem has been made more complex in some ways because of the explosion of interest in functional foods for gastrointestinal health. These often contain high levels of novel oligo- and polysaccharides, which might perhaps be regarded as analogs of dietary fiber. Fructose oligosaccharides, which are nondigestible but highly fermentable, are now often added to foods as prebiotic substrates for the colonic microflora. Such materials may not fit the original definition of dietary fiber, but it is certainly not helpful to exclude them from the contemporary concept, which needs to expand to accommodate modern developments.

The presence of large undigested cell wall fragments, finely dispersed particulates, or soluble polysaccharides can alter physiological processes

Table 1 Major components of dietary fiber

Food source	*Polysaccharides and related substances*
Fruits and vegetables	Cellulose, xyloglucans, arabinogalactans, pectic substances, glycoproteins
Cereals	Cellulose, arabinoxylans, glucoarabinoxylans, β-D-glucans, lignin, and phenolic esters
Legume seeds	Cellulose, xyloglucans, galactomannans, pectic substances
Manufactured products	Gums (guar gum, gum arabic), alginates, carrageenan, modified cellulose gums (methyl cellulose, carboxymethyl cellulose)

throughout the gut. The effects of different fiber components depend upon their varied physical and chemical properties during digestion, and also upon their susceptibility to degradation by bacterial enzymes in the colon. The complex nature of the various substances covered by the general definition of dietary fiber means that a single analytical value for the fiber content of a food is a poor guide to its physiological effects. This article will review the main mechanisms of action of resistant polysaccharides in the alimentary tract and their implications for human health.

Sources and Types of Dietary Fiber

The main sources of dietary fiber in most Western diets are well characterized, and high-quality data are available for both food composition and dietary intakes. This is not always true for diets in developing countries, however, and this problem bedevils attempts to investigate the importance of fiber by making international comparisons of diet and disease. Another problem is that different analytical approaches give slightly different values for the dietary fiber content of foods, and do not reflect the physical and chemical properties of the different polysaccharide components. The use of enzymic hydrolysis to determine the 'unavailable carbohydrate' content of foods was refined by Southgate, and his technique was used for the 4th edition of the UK standard food tables, *The Composition of Foods* published in 1978. The 6th edition, published in 2002, contains values for nonstarch polysaccharides, derived using the Englyst technique, but recommends use of AOAC methods for food labeling purposes. A comparison of values for nonstarch polysaccharides and dietary fiber values obtained by the AOAC method is given in **Table 2**.

Table 2 A Comparison of values for nonstarch polysaccharides and dietary fiber

Food source	*Nonstarch Polysaccharides (Englyst method)*	*Total dietary fiber (AOAC method)*
White bread	2.1	2.9
Brown bread	3.5	5.0
Wholemeal bread	5.0	7.0
Green vegetables	2.7	3.3
Potatoes	1.9	2.4
Fresh fruit	1.4	1.9
Nuts	6.6	8.8

Data modified from McCance and Widdowson's (2002) *The Composition of Foods*, 6th Edition, Cambridge: Royal Society of Chemistry.

In the UK about 47% of dietary fiber is obtained from cereal products, including bread and breakfast cereals. The level of cell wall polysaccharides in a product made from flour depends on the extraction rate, which is the proportion of the original grain present in the flour after milling. Thus a 'white' flour with an extraction rate of 70% usually contains about 3% NSP, whereas a 'wholemeal' flour with an extraction rate of 100% contains about 10% NSP. The terms 'soluble' and 'insoluble' fiber have been coined in order to partially overcome the problem of the lack of correspondence between the total analytical value for fiber and the physical properties of the measured polysaccharides. By adopting the Englyst technique for the separation and chemical analysis of nonstarch polysaccharides it is possible to specify both the soluble and insoluble fiber content of foods. Some representative values for soluble and insoluble fiber in cereal foods are given in **Table 3**, and those for fruits and vegetables, which provide a further 45% of the fiber in UK diets, are given in **Table 4**.

Fiber in the Digestive Tract

The primary function of the alimentary tract is to break down the complex organic macromolecules of which other organisms are composed into smaller molecules, which can then be selectively absorbed into the circulation by specialized mucosal epithelial

Table 3 Soluble and insoluble nonstarch polysaccharides in some cereal products and nuts

Food source	*Nonstarch polysaccharides (g per 100 g fresh weight)*		
	Total NSP	*Soluble NSP*	*Insoluble NSP*
Sliced white bread	1.5	0.9	0.6
Sliced brown bread	3.6	1.1	2.5
Wholemeal bread	4.8	1.6	3.2
Spaghetti	1.2	0.6	0.6
Rye biscuits	11.7	3.9	7.8
Cornflakes	0.9	0.4	0.5
Crunchy oat cereal	6.0	3.3	2.7
Walnuts	3.5	1.5	2.0
Hazelnuts	6.5	2.5	4.0
Peanuts	6.2	1.9	4.3
Brazil nuts	4.3	1.3	3.0

Table 4 Soluble and insoluble nonstarch polysaccharides in some vegetables and fruits

Food source	*Nonstarch polysaccharides (g per 100 g fresh weight)*		
	Total NSP	*Soluble NSP*	*Insoluble NSP*
Apples (Cox)	1.7	0.7	1.0
Oranges	2.1	1.4	0.7
Plums	1.8	1.2	0.6
Bananas	1.1	0.7	0.4
Potatoes	1.1	0.6	0.5
Sprouts	4.8	2.5	2.3
Peas (frozen)	5.2	1.6	3.6
Carrots	2.5	1.4	1.1
Courgettes	1.2	0.6	0.6
Runner beans	2.3	0.9	1.4
Baked beans	3.5	2.1	1.4
Tomato	1.1	0.4	0.7
Lettuce	1.2	0.6	0.6
Onion	1.7	0.9	0.8
Celery	1.3	0.6	0.7

Data modified from Englyst HN, Bingham SA, Runswick SS, Collinson E, and Cummings JH (1989) Dietary fibre (non-starch polysaccharides) in fruit vegetables and nuts. *Journal of Human Nutrition and Dietetics* **1**: 247–286.

cells. Food is conveyed progressively through the alimentary tract, stored at intervals, and broken down mechanically as required, by a tightly controlled system of rhythmic muscular contractions. The digestive enzymes are released into the lumen at the appropriate stages to facilitate the decomposition of carbohydrates, proteins, and complex lipids. By definition, the polysaccharides that comprise dietary fiber are not digested by endogenous enzymes, though they are often fermented to a greater or lesser degree by bacterial enzymes in the large intestine.

The Mouth and Pharynx

The earliest stages of digestion begin in the mouth, where food particles are reduced in size, lubricated with saliva, and prepared for swallowing. The saliva also contains the digestive enzyme salivary amylase, which begins the hydrolysis of starch molecules. Cell wall polysaccharides are an important determinant of food texture, and they exert an indirect effect on the degree of mechanical breakdown of plant foods prior to swallowing. Hard foods tend to be chewed more thoroughly than soft ones, and hence the presence of dietary fiber in unrefined foods may begin to regulate digestion at a very early stage.

The Stomach

The first delay in the transit of food through the digestive tract occurs in the stomach, where large food fragments are further degraded by rigorous muscular activity in the presence of hydrochloric acid and proteolytic enzymes. The need to disrupt and disperse intractable food particles and cell walls appears to delay the digestive process significantly. For example, the absorption of sugar from whole apples is significantly slower than from apple juice. Similarly, the rate at which the starch is digested and absorbed from cubes of cooked potato has been shown to be much slower when they are swallowed whole than when they are chewed normally. Thus, simple mechanical factors can limit the rate at which glucose from carbohydrate foods enters the circulation.

The Small Intestine

The small intestine is the main site of nutrient absorption, and it is in fact the largest of the digestive organs in terms of surface area. The semi-liquid products of gastric digestion are released periodically into the duodenum, and then propelled downstream by peristaltic movements, at about 1 cm per minute. The hydrolysis of proteins, triglycerides, and starch continues within the duodenum and upper jejunum, under the influence of pancreatic enzymes. The final stages of hydrolysis of dietary macromolecules occur under the influence of extracellular enzymes at the mucosal surface. The released products are absorbed into the circulation, along with water and electrolytes, via the specialized epithelial cells of the intestinal villi. Muscular activity in the small intestinal wall, together with rhythmic contractions of the villi, ensures that the partially digested chyme is well stirred. In adults, the first fermentable residues from a meal containing complex carbohydrates enter the colon approximately 4.5 h after ingestion. When a solution containing indigestible sugar is swallowed without food it reaches the colon about 1.5 h earlier than when the same material is added to a solid meal containing dietary fiber. The presence of solid food residues slows transit, probably by delaying gastric emptying and perhaps also by increasing the viscosity of the chyme so that it tends to resist the peristaltic flow. Soluble polysaccharides such as guar gum, pectin, and β-glucan from oats increase mouth to cecum transit time still further.

In creating the dietary fiber hypothesis, Trowell's principal interest was its role in the prevention of metabolic disorders. In particular, he believed that dietary fiber was a major factor in the prevention of diabetes mellitus, which, he argued, was probably unknown in Western Europe prior to the introduction of mechanized flour milling. In earlier times the near-universal consumption of unrefined

carbohydrate foods would have ensured that intact indigestible cell wall polysaccharides were present throughout the upper alimentary tract during digestion. This, according to Trowell and others, favored slow absorption of glucose, which in turn placed less strain upon the ability of the pancreas to maintain glucose homeostasis. There is no doubt that type 2 diabetes has become more common in Western countries as prosperity, and an excess of energy consumption over expenditure, has grown. It is not established that rapid absorption of glucose due to consumption of refined starches is a primary cause of diabetes, but the control of glucose assimilation is certainly a key factor in its management. Cell wall polysaccharides influence the digestion and absorption of carbohydrates in a variety of ways, and are a major determinant of the 'glycemic index,' which is essentially a quantitative expression of the quantity of glucose appearing in the bloodstream after ingestion of a carbohydrate-rich food. To calculate the index, fasted subjects are given a test meal of the experimental food containing a standardized quantity of carbohydrate. The change in concentration of glucose in the blood is then measured over a period of time. The ratio of the area under the blood-glucose curve in response to the test meal to that produced by an equal quantity of a standard reference food is then calculated and expressed as a percentage. When glucose is used as the standard, most complex starchy foods have glycemic indices lower than 100%.

The physical resistance of plant cell walls during their passage through the gut varies considerably from one food to another. Cell walls that remain intact in the small intestine will impede the access of pancreatic amylase to starch. This is particularly true of the cells of legume seeds, which have been shown to retain much of their integrity during digestion. Legume-based foods such as lentils and chilli beans have glycemic indices that are amongst the lowest of all complex carbohydrate foods. Even when enzymes and their substrates do come into contact, the presence of cell wall polysaccharides may slow the diffusion of hydrolytic products through the partially digested matrix in the gut lumen. These effects of dietary fiber on carbohydrate metabolism emphasize once more that physiological effects cannot be predicted from simple analytical values for total fiber, because they are consequences of cellular structure, rather than the absolute quantity of cell wall polysaccharides within the food.

Many studies on postprandial glycemia have been conducted using isolated fiber supplements such, as pectin or guar gum added to glucose testmeals or to low-fiber sources of starch. They demonstrate that, contrary to Trowell's original hypothesis, wheat bran and other insoluble cell wall materials have little effect on glucose metabolism. However, certain soluble polysaccharides, such as guar gum, pectin, and oat β-glucan, which form viscous solutions in the stomach and small intestine, do slow the absorption of glucose. Highly viscous food components may delay gastric emptying and inhibit the dispersion of the digesta along the small intestine, but the primary mechanism of action appears to be suppression of convective stirring in the fluid layer adjacent to the mucosal surface. The rapid uptake of monosaccharides by the epithelial cells tends to reduce the concentration of glucose in this boundary layer, so that absorption from the gut lumen becomes rate-limited by the relatively slow process of diffusion. The overall effect is to delay the assimilation of glucose and hence suppress the glycemic response to glucose or starchy foods in both healthy volunteers and in people with diabetes. A similar mechanism probably inhibits the reabsorption of cholesterol and bile salts in the distal ileum and this may account for the ability of some viscous types of soluble dietary fiber such as guar gum and β-glucan to reduce plasma cholesterol levels in humans.

One of the main reasons for developing analytical methods to distinguish between soluble and insoluble components of dietary fiber was to provide a means of assessing the capacity of fiber-rich foods to influence carbohydrate and lipid metabolism. There is evidence that diets that provide 30–50% of their fiber in the form of soluble polysaccharides are associated with lower cholesterol levels and better glycemic control than diets that contain mostly insoluble fiber. Several officially recognized sets of guidelines for patients with impaired glucose metabolism and its complications (syndrome X) now specifically recommend a high intake of carbohydrate foods that are rich in soluble fiber.

Some of the interactions between cell wall polysaccharides and other food components in the small intestine are much more specific. There has been considerable interest over a number of years in the possibility that the polysaccharides and complex phenolic components of cell walls contain polar groups that could interact with and bind ionized species in the gastrointestinal contents, thereby reducing their availability for absorption. Intraluminal binding of heavy metals, toxins, and carcinogens might be a valuable protective mechanism, but binding of micronutrients could seriously compromise nutritional status.

Interactions of this type can be shown to occur *in vitro*, and studies with animals and human

ileostomists suggest that charged polysaccharides such as pectin can displace cations into the colon under experimental conditions. However, there is little objective evidence that dietary fiber *per se* has much of an adverse effect on mineral metabolism in humans. Indeed, highly fermentable polysaccharides and fructose oligosaccharides have recently been shown to promote the absorption of calcium and magnesium in both animal and human studies. The mechanism for the effect is not entirely clear, but it is probably a consequence of fermentation acidifying the luminal contents of the colon and enhancing carrier-mediated transport of minerals across the colonic mucosa.

In unprocessed legume seeds, oats, and other cereals phytate (myo-inositol hexaphosphate) is often present in close association with cell wall polysaccharides. Unlike the polysaccharides themselves, phytate does exert a potent binding effect on minerals, and has been shown to significantly reduce the availability of magnesium, zinc, and calcium for absorption in humans. Phytate levels in foods can be reduced by the activity of endogenous phytase, by hydrolysis with exogenous enzymes, or by fermentation. Dephytinized products may therefore be of benefit to individuals at risk of suboptimal mineral status. However, there are indications from animal and *in vitro* studies that phytate is an anticarcinogen that may contribute to the protective effects of complex fiber-rich foods. The overall significance of phytate in the diet therefore requires further assessment in human trials.

The Large Intestine

Microorganisms occur throughout the alimentary tract but in healthy individuals their numbers and diversity are maintained within strict limits by the combined effects of intraluminal conditions, rapid transit, and host immunity. The colon and rectum, however, are adapted to facilitate bacterial colonization, and the typical adult human colonic microflora has been estimated to contain about 400 different bacterial species. The largest single groups present are Gram-negative anaerobes of the genus *Bacteroides*, and Gram-positive organisms including bifidobacteria, eubacteria, lactobacilli, and clostridia. However, a large proportion of the species present cannot be cultured *in vitro* and are very poorly characterized.

The proximal colon, which receives undigested food residues, intestinal secretions, and the remnants of exfoliated enterocytes from the distal ileum, contains around 200 g of bacteria and substrates in a semiliquid state. These conditions are ideal for bacterial fermentation. Most of the bacteria of the human colon utilize carbohydrate as a source of energy, although not all can degrade polysaccharides directly. Many that are ultimately dependent upon dietary carbohydrate residues for energy are adapted to utilize the initial degradation products of the polysaccharide utilizers, rather than the polymers themselves. It has been estimated that somewhere between 20 and 80 g of carbohydrate enter the human colon every day, about half of which is undigested starch. Around 30 g of bacteria are produced for every 100 g of carbohydrate fermented.

Apart from dietary fiber, there are three major sources of unabsorbed carbohydrate for the colonic microflora. Perhaps the most important is resistant starch, which consists of retrograded starch polymers and starch granules enclosed within intact plant cell walls. Nondigestible sugars, sugar alcohols, and oligosaccharides such as fructooligosaccharides and galactooligosaccharides occur only sparingly in most plant foods, but they are now of great commercial interest because they can be used as prebiotics to selectively manipulate the numbers of bifidobacteria in the human colon. Endogenous substrates including mucus are also important for the colonic microflora. Mucus is an aqueous dispersion of a complex group of glycoproteins containing oligosaccharide side-chains, which are a major source of fermentable substrates. Even when the colon is surgically isolated and has no access to exogenous substrates it still supports a complex microflora.

The beneficial effects of dietary fiber on the alimentary tract were emphasized by another of the founders of the dietary fiber hypothesis, Denis Burkitt, who based his arguments largely on the concept of fecal bulk, developed as a result of field observations in rural Africa, where cancer and other chronic bowel diseases were rare. His hypothesis was that populations consuming the traditional rural diets, rich in vegetables and cereal foods, produced bulkier, more frequent stools than persons eating the refined diets typical of industrialized societies. Chronic constipation was thought to cause straining of abdominal muscles during passage of stool, leading to prolonged high pressures within the colonic lumen and the lower abdomen. This in turn was thought to increase the risk of various diseases of muscular degeneration including varicose veins, hemorrhoids, hiatus hernia, and colonic diverticulas. Colorectal neoplasia was also thought to result from infrequent defecation, because it caused prolonged exposure of the colonic epithelial cells to mutagenic chemicals, which could initiate cancer. Burkitt's overall hypothesis for the beneficial effects of fecal

bulk has never really been refuted, and epidemiological evidence continues to support a protective role of fiber against colorectal cancer, particularly within Europe. However, the origins of intestinal neoplasia are now known to be far more complex than Burkitt was able to envisage, and there is little evidence to suggest a direct causal link between chronic constipation and colorectal cancer. Indeed, in one recent prevention trial, the risk of recurrence of colorectal polyps was slightly increased by prolonged supplementation with a bulk laxative based on one specialized source of cell wall polysaccharides.

Whatever the relationship to disease, it is certainly true that the consumption of dietary fiber is one major determinant of both fecal bulk and the frequency of defecation (bowel habit). However, the magnitude of the effect depends upon the type of fiber consumed. Soluble cell wall polysaccharides such as pectin are readily fermented by the microflora, whereas lignified tissues such as wheat bran tend to remain at least partially intact in the feces. Both classes of dietary fiber can contribute to fecal bulk but by different mechanisms. The increment in stool mass caused by wheat bran depends to some extent on particle size, but in healthy Western populations it has been shown that for every 1 g of wheat bran consumed per day, the output of stool is increased by between 3 and 5 g. Other sources of dietary fiber also favor water retention. For example, isphagula, a mucilaginous material derived from *Psyllium*, is used pharmaceutically as a bulk laxative. Soluble polysaccharides such as guar and oat β-glucan are readily fermented by anaerobic bacteria, but solubility is no guarantee of fermentability, as is illustrated by modified cellulose gums such as methylcellulose, which is highly resistant to degradation in the human gut. Fermentation reduces the mass and water-holding capacity of soluble polysaccharides considerably, but the bacterial cells derived from them do make some contribution to total fecal output. Thus, although all forms of dietary fiber are mild laxatives, the single analytical measurement of total fiber content again provides no simple predictive measure of physiological effect.

Although fermentation of fiber tends to reduce its effectiveness as a source of fecal bulk, it has other very important benefits. The absorption and metabolism of short-chain fatty acids derived from carbohydrate fermentation provides the route for the recovery of energy from undigested polysaccharides. Butyrate functions as the preferred source of energy for the colonic mucosal cells, whilst propionate and acetate are absorbed and metabolized systemically. There continues to be much debate about the importance of butyrate for the colon. *In vitro*, butyrate causes differentiation of tumor cells, suppresses cell division, and induces programed cell death (apoptosis). These effects are thought likely to suppress the development of cancer, but it is not yet entirely clear whether they also occur in the intact intestine. Research continues on the importance of butyrate and other short-chain fatty acids for human health.

The other major breakdown products of carbohydrate fermentation are hydrogen, methane, and carbon dioxide, which together comprise flatus gas. Excess gas production can cause distension and pain in some individuals, especially if they attempt to increase their fiber consumption too abruptly. In most cases, however, extreme flatus is probably caused more by fermentation of oligosaccharides such as stachyose and verbascose, which are found principally in legume seeds, rather than the cell wall polysaccharides themselves.

Conclusion

Several decades of research have confirmed that cell wall polysaccharides modify physiological mechanisms throughout the alimentary tract. Delayed absorption of glucose and lipids in the small intestine makes an important contribution to metabolic control in type 2 diabetes, and certain types of hypercholesterolemia, respectively. Any loss of carbohydrates to the colon will lead to increased fermentative activity, and through this pathway, most of the unabsorbed energy will be recovered as short-chain fatty acids. Unfermented cell wall polysaccharides and increased bacterial mass contribute to fecal bulk. All these established physiological effects, coupled with the possibility of using oligosaccharides as prebiotics to modify the colonic microflora, have greatly stimulated interest in nondigestible carbohydrates amongst food manufacturers and consumers in the past few years. There is little to suggest that conventional sources of fiber compromise micronutrient metabolism in otherwise healthy individuals, but the possibility of this and other adverse effects needs to be considered, as the use of novel polysaccharides as sources or analogs of dietary fiber, both for conventional products and for functional foods, continues to expand.

Potential Role in Etiology of Disease

D L Topping and L Cobiac, CSIRO Health Sciences and Nutrition, Adelaide, SA, Australia

Noninfectious diseases cause much morbidity and mortality in developed countries in Europe, the Americas, Asia, and Australasia. They are expected to increase due to an alarming increase in obesity, with its attendant risk of diabetes, coronary heart disease (CHD), and some cancers. Equally important, they are becoming an issue in developing countries through greater affluence. In every case, they have serious negative socioeconomic impacts, and their prevention through appropriate dietary and lifestyle change is the optimal strategy to minimize personal and community costs. This strategy is believed to have contributed substantially to economic growth in countries where it has been applied.

Obesity is a fairly visible problem that tends to overshadow other considerations. Energy intake in excess of expenditure is the root cause of obesity, and dietary carbohydrates are implicated specifically in the development of overweight. Exclusion of carbohydrates is attracting attention as a weight control strategy but this ignores the fact that digestible carbohydrates (including starch) provide the same amount of energy per gram as protein and less than 45% of the energy of fat and 60% of the energy of alcohol. Furthermore, it overlooks the many early comparative population studies that showed that several low-risk groups ate high-starch diets compared to high-risk populations that consumed processed foods high in refined carbohydrates and fat and low in fiber. With time, dietary fiber (rather than the whole diet) received specific attention, and many studies were conducted on the health benefits. This may have contributed to some of the current lack of clarity of the role of fiber and complex carbohydrates in health promotion. It may be compounded by the inadequacy of population data linking fiber (and also starches) to disease processes for important conditions such as colorectal cancer. Only recently have good population data emerged for a protective role for fiber in this condition. This is in marked contrast to the well-established therapeutic and preventive action of fiber in constipation and diverticular disease. Furthermore, it is critical to determine what is meant by the term 'dietary fiber' because other food components may contribute to the major effects ascribed to fiber. This is important when considering the apparent protection conferred by whole grains against disease risk, especially because a health claim is permitted in the United States for their consumption.

Associations between Dietary Fiber and Disease Processes

The early population studies of Walker, Burkitt, and Trowell in Africa in the 1950s showed that serum cholesterol concentrations were low in South African Bantus (at low risk of CHD) who consumed a diet apparently high in fiber and low in fat. Additionally, colon cancer was virtually

unknown among the latter, in contrast to white South Africans. Dietary fiber was known to resist digestion by human intestinal enzymes, which helped to explain the greater fecal bulk seen with higher fiber intakes. This was thought to lower colonic exposure to carcinogens through a simple dilution effect with fiber consumption. Subsequently, it was suggested that diabetes may be related to a deficiency of fiber in the diet whereas other epidemiological studies have shown associations between more dietary fiber consumption and lower risk of some of the hormone-dependent cancers (prostate and breast). Many of these observational population studies are limited by their reliance on reported food intakes which may be compromised in turn by food compositional data because the latter can be limited by the analytical methodology used. Multinational comparisons may be affected by the fact that food sources and processing vary between countries. There are other potential confounders. For example, diets high in fiber-rich foods may contain other protective agents (e.g., phyotoestrogens folate and antioxidants) that could be the actual mediators of protection. Finally, some of the experimental studies and human interventions, especially in colorectal cancer, have given ambiguous or negative outcomes due to limitations of study design.

Dietary Fiber, Complex Carbohydrates, and Health Outcomes: A Need for Fiber Equivalents?

Technology has proved to be a significant issue in human fiber research. Early studies were limited by the relatively simple analytical methods then current. These were designed to measure the fiber components of forage consumed by important ruminant farm animals. Forage foods are high in insoluble polysaccharides and contain lignin (which is not a carbohydrate but a complex polyphenolic ether) and look 'fibrous,' so dietary fiber was equated with roughage and was defined as "those structural and exudative components of plants that were resistant to digestion by human gut enzymes." The methods used initially were quite severe and, with increasing sophistication of analytical methodology (notably chromatography), it became apparent that lignin was only a minor component of fiber compared with nonstarch polysaccharides (NSPs). Technological advances have revealed the importance of fractions such as soluble NSPs. As their name suggests, these dissolve in water but not necessarily under gut conditions. Fiber was then redefined as NSPs plus lignin, which has moved the concept of away from the roughage model. Recently, there has been a further substantial revision of the view of what exactly constitutes dietary fiber with the emerging recognition of the contribution of resistant starch (RS) and oligosaccharides (OSs) to 'fiber' action. It was thought that all of dietary starch consumed in cooked foods was digested in the human small intestine. It is becoming clear that this is not so, and that a substantial fraction of ingested starch, RS, escapes from the small intestine and enters the colon of healthy humans. In terms of the dietary polysaccharides entering that viscus, RS may exceed NSPs in quantity and in the range of its actions. Indeed, some populations that were thought to consume high-fiber diets actually eat less than higher risk groups. An example is the native Africans studied by Burkitt and colleagues who eat unrefined diets based on maize but in fact eat less fiber than the high-risk whites.

Unlike NSPs (which are intrinsically resistant to human digestive enzymes), RS is influenced greatly by physiological and physical factors. Thus, raw starches are highly resistant and gelatinized starches (cooked in the presence of water) are much more digestible due to hydration and the loss of granular structure. However, cooling of cooked starchy foods leads to the generation of RS through retrogradation (which is a realignment of the polysaccharide chains). Other factors, including the relative proportions of amylose and amylopectin and the presence of other food components such as NSPs and lipids, influence RS. High-fiber foods tend to be higher in RS, whereas fats can form complexes with starch that resist digestion. Mastication, transit time, and gender can influence the amount of RS, which means that purely chemical determinations probably give an underestimate of the quantity of starch entering the large bowel. Physical breakdown of foods (especially whole grains) may be particularly important because access to upper intestinal digestive enzymes is limited in large particles, especially in the presence of NSPs. RS has been classified into four types based on the main factors that influence its presence, including physical inaccessibility, cooking, and retrogradation (RS types RS_{1-3}). Of particular interest is the emergence of chemically modified starches (RS_4) as RS because these are used widely in food processing.

In the large bowel NSPs and RS are fermented by the microflora, yielding metabolic end products, principally short-chain fatty acids (SCFAs), which may mediate some of the health benefits ascribed to the carbohydrates. Undigested protein (resistant protein) and other nondigested carbohydrates

(e.g., OSs) also contribute to large bowel fermentation. These nondigested fractions contribute to dietary fiber via fermentation and could be considered in net dietary fiber intake. This problem could be overcome relatively easily by classifying them (and other non-NSP carbohydrates) as fiber equivalents in which their actions are compared against an agreed standard. This is similar to the situation with other nutrients such as vitamin A, where retinol equivalents include carotenoids, which are retinol precursors. It follows that classifications based on chemical composition alone appear to be quite inadequate if one considers as improved health and diminished disease risk as the most important issues.

Dietary Fiber and the Etiology of Coronary Heart Disease

Population Studies

Consumption of unrefined plant foods has been related to lower risk of CHD for some time, but the hypothesis that dietary fiber (i.e., NSP) intake could protect directly against the disease is relatively recent. The suggestion has been supported by a number of epidemiological studies linking higher intakes with lower risk. Vegetarians who consume more plant foods tend to have lower plasma lipids and blood pressure than age- and gender-matched omnivores. However, the strongest evidence derives not from these studies but from a number of very large cohort studies in several countries showing a consistent protective effect of whole grain consumption and CHD risk. Whole grain cereal consumption has been related to substantially lower risk of CHD in both men and women. The evidence for the latter is considered to be sufficiently strong for the US Food and Drug Administration to permit a health claim for consumption of whole grain cereal foods and lowering of the risk of CHD. Similar claims are being considered in Europe. However, these relationships are a long way from proving a specific protective effect of dietary fiber. A study of the relationship of long-term intake of dietary fiber by 68 782 women showed a substantial lowering of relative risk of 0.53 for women in the highest quintile of fiber consumption (22.9 g/day) compared with the lowest (11.5 g/day). These intakes are low compared to those recommended by health authorities. Nevertheless, they do support the view that fiber is protective against CHD. Only the effect of cereal fiber was significant; that of fruits and vegetables was not. However, they leave unanswered the question of the relationship of other contributors to the effects of dietary fiber (e.g., RS) and CHD risk.

Potential Mechanisms Indicating a Role in the Etiology of Coronary Heart Disease

The mechanism for risk reduction and the fiber components responsible need resolution. Elevated plasma total and low-density lipoprotein (LDL) cholesterol concentrations are established risk factors for coronary morbidity and mortality. There are abundant human and animal data showing that diets high in soluble fiber lower plasma cholesterol. One population study has shown a significant negative relationship between viscous (soluble) fiber intake and carotid artery atherogensis as measured by intima–media thickness. This association was significant statistically even though average fiber intakes were not particularly high. When dietary fiber intakes have been related to measures of actual disease outcomes, the evidence is less convincing. A protective effect is often observed on univariate analyses, but once confounding variables are added, dietary fiber intake tends not to be a significant independent predictor of risk for developing CHD. However, in one 12-year follow-up study of men and women, a 6-g increase in daily dietary fiber intake was associated with a 25% reduction in the risk of developing CHD. The most likely direct protective role for dietary fiber in CHD etiology is through plasma lipid lowering. The effect appears to be specific for plasma total and LDL cholesterol, and, possibly, triacylglycerols (TAG). Of the main fiber components, soluble NSPs seem to be effective, but insoluble NSPs and RS (and probably OSs) are not. Indeed, it appears that some insoluble NSP preparations, such as wheat bran, may raise plasma cholesterol slightly. There is good evidence from animal and human studies to support a hypocholesterolemic effect of soluble NSPs either in enriched plant fractions (e.g., oat bran) or as natural (e.g., pectins and guar gum) or synthetic isolates (e.g., hydroxypropylmethylcellulose). The magnitude of the effect varies with dose, but reductions of approximately 5–10% at intakes of 6–12 g of NSPs/day appear to be reasonable. This lowering response approaches that seen with certain drugs, such as cholestyramine, used to manage hypercholesterolemia. Some studies have also shown a reduction in TAGs with soluble fibers such as oat bran. However, it is important to recognize that many of the demonstrations of plasma cholesterol lowering by soluble fiber products are against insoluble NSPs such as wheat bran.

There are several hypotheses to explain the NSP action on plasma cholesterol, including enhanced bile acid and neutral sterol excretion, the slowing of fat and cholesterol absorption and direct inhibition of hepatic cholesterol synthesis by propionate formed by large bowel fermentation of NSPs. Whole body cholesterol homoeostasis represents a balance between influx and loss. Cholesterol influx can come from dietary intake and *de novo* synthesis. Losses occur through the sloughing of epithelial cells and through the fecal excretion of nonabsorbed dietary cholesterol and biliary steroids (bile acids and neutral sterols). Bile acids are generally recovered in the ileum, and those that are not absorbed are excreted in the feces. Any increase in bile acid excretion leads to enhanced hepatic uptake of cholesterol and its conversion to bile acids with a consequent depletion of the plasma cholesterol pool.

It was initially thought that fiber could bind some bile acids selectively, in a similar manner to cholestyramine, an ion exchange resin that binds bile acids. Bile acid binding *in vitro* by insoluble fiber preparations appears to be an artefact. Cholestyramine is strongly charged, whereas most NSPs with cholesterol-lowering potential are neutral or even acidic (e.g., pectins). Neutrality is not consistent with ionic binding and uronic acid residues would repel bile acids at the pH of the small intestine. The property that appears to mediate the increased steroid excretion is the viscosity in solution. Most (but not necessarily all) NSPs that lower cholesterol form viscous solutions in water. Presumably, bile acids are lost from the ileum through a form of entrapment in a viscous gel. This would also contribute to the loss of cholesterol and the slower digestion of fat seen with ingestion of NSPs. Abundant animal and human data show that feeding soluble NSPs increases fecal steroid excretion. However, the major problem with these relationships is that although soluble fibers may lower plasma cholesterol, the strongest evidence of a protective effect is for insoluble fibers which do not lower plasma cholesterol. It may be that other components in the grain are actually mediating the effect and fiber is the surrogate marker for their intake.

Dietary Fiber and the Etiology of Cancers—Colon and Rectum

Population Studies

This is one long-standing association that has been surprisingly problematic. Early studies on native Africans who consumed an unrefined diet showed them to have a very low incidence of this cancer. Although subsequent studies have shown a negative association between greater fiber intake and lowered risk, it has proved to be relatively weak. Indeed, in one US study there was no real association between fiber intake and cancer susceptibility. Some of the loss of significance seen in this evaluation may reflect the lack of allowance for confounding variables. For example, in a 6-year follow-up of women, the association between low fiber intake and the incidence of colon cancer disappeared after adjustment was made for meat intake. In another study of men, low fiber intake was an independent risk factor for the incidence of adenomatous polyps during a 2-year follow-up period.

Fruit and vegetable fiber has been consistently associated with a lower risk of colon cancer, but the relationship with cereal fiber is less clear. However, whole grain cereals appear to be protective—a further anomaly in the relationships between plant foods and disease risk. These discrepancies may be in the process of resolution. First, it seems that the early observational data were confounded by the analytical technologies available, and the perception that native populations consuming unrefined diets had high fiber intakes is incorrect. It seems likely that they ate relatively little fiber but had high intakes of RS. Population studies have shown a protective effect of apparent RS intake and colorectal cancer risk. The word 'apparent' is pivotal because there is currently no accepted method for RS determination and thus, there are no reliable data on dietary intakes. There are also issues regarding the intakes of dietary fiber and cancer risk. Part of the problem inherent in the study of colonic cancer is that, in contrast to CHD (in which there are easily measurable risk markers such as plasma cholesterol that can be modified by diet), the only indices for colon cancer are not easily measurable: the appearance of aberrant crypts, adenomatous polyps, or the disease itself. Hitherto, animal studies have largely been confined to rodents treated with chemical carcinogens (usually dimethylhydrazine), and they suggest that dietary fiber from wheat bran and cellulose may afford greater protection against the development of colon cancer when associated with a low-fat diet compared with soluble NSPs. These data stand in contrast to observational studies but are supported by interventions in humans with familial adenomatous polyposis. These people are at genetically greater risk of colonic cancer and represent one means of assessing risk modification through dietary intervention and monitoring polyp size and frequency through colonoscopy. In the Australian

Polyp Prevention Trial, subjects consumed 25 g of wheat bran per day and there was a decrease in dysplasia and total adenoma surface area when the diet was also low in fat. This supports epidemiological studies that show that increased fat and protein intakes increase risk. Other prevention trials have examined the effects of increasing fiber intake on the recurrence of polyps following a polypectomy. In a Canadian study of 201 men and women, a high-fiber, low-fat diet protected against polyp recurrence in women but in men there was actually an increase. A third trial examined the effects of diet on the prevalence of rectal polyps in 64 people with familial polyposis coli who had a total colectomy. Those who received and actually took the high-fiber (22.5 g fiber as a breakfast cereal) showed a reduction in polyps. These data are not conclusive but are reasonably consistent with overall knowledge.

Complex Carbohydrates and Colorectal Cancer

An obvious factor for the inconsistent results of the effect of different intakes of dietary fiber on colorectal cancer is the variation in the analytical methodology used in different studies. There is also increasing evidence that total dietary complex carbohydrates may be as important as fiber. Analysis of stool weight from 20 populations in 12 countries showed that larger stools were correlated with a lower incidence of colon cancer. Intakes of starch and dietary fiber (rather than fiber alone) were the best dietary correlates with stool weight. A subsequent meta-analysis showed that greater consumption of starch (but not of NSPs) was associated with low risk of colorectal cancer in 12 populations. The examination also showed that fat and protein intakes correlated positively with risk. This meta-analysis is probably the first of its kind to suggest a protective role for starch in large bowel cancer and underscores the need to consider complex carbohydrates as fiber equivalents and not just as NSPs and starch. The need for better information on dietary intake data and risk is underscored by the data from the European Prospective Investigation of Cancer and Nutrition, which showed a substantial reduction in risk with increasing fiber intake. This multinational study is important because it has sufficient power (expressed as a range of fiber intakes and individuals observed) to give confidence in the observations. Follow-up of 1 939 011 person-years throughout 10 countries showed that a doubling of fiber intake from foods could reduce risk by 40%.

Potential Mechanisms Indicating a Role in the Etiology of Colorectal Cancer

Colorectal tumorigenesis is a multistep process. These steps involve a number of genetic alterations that convert a normal epithelium to a hyperproliferative state and then to early adenomas, later adenomas, and, finally, frank carcinoma and metastasis. Fiber may, and probably does, play a role in all of these stages, and several mechanisms have been proposed by which it could play a role in the etiology of the disease (**Table 1**).

A number of agents may induce genetic damage in the colonocyte, including mono- and diacylglycerols, nonesterified fatty acids, secondary bile acids, aryl hydrocarbons and other pyrrolytic products of high-temperature cooking, and ammonia and amines and other products of large bowel bacterial protein degradation. One of the simplest protective mechanisms for dietary fiber is purely physical. By increasing fecal bulk, fiber could produce a more rapid transit time as well as act as a diluent and thus reduce exposure to potential mutagenic agents. It is also possible that fiber components could bind mutagens. However, because this appears to be unlikely for bile acids, the same may apply to other carcinogens.

Table 1 Effects of dietary fiber and resistant starch that could impact on the etiology of colorectal cancer

Increased stool bulk (mainly insoluble NSPs)
Decreases transit time, minimizing contact between colonocytes and luminal carcinogens
Reduces exposure through dilution of carcinogens
Binding of bile acids and other potential carcinogens (mainly insoluble NSPs)
Lowers free concentrations of mutagens
Modifying fecal flora and increasing bacterial numbers (soluble and insoluble NSPs and RS)
Decreases secondary bile acids, which are potential carcinogens
Lowers colonic NH_3 (a cytotoxic agent) by fixing nitrogen in the bacterial mass
Lowering fecal pH through SCFA production (NSPs but mainly RS)
Inhibits growth of pH-sensitive, potentially pathogenic species, which may degrade food constituents, and endogenous secretions to potential carcinogens
Lowers absorption of toxic alkaline compounds (e.g., amines)
Lowers solubility of secondary bile acids
Fermentation to SCFAs (NSPs but mainly RS)
Depending on source, raises butyrate which is a preferred substrate for normal colonocytes, and (*in vitro*) promotes a normal cell phenotype, retards the growth of cancer cells, and facilitates DNA repair

NSPs, nonstarch polysaccharides; RS, resistant starch; SCFAs, short-chain Fatty acids.

Production of SCFAs by the resident microflora induces a number of general changes in the colonic environment, including a lowering of pH. Case–control studies show that pH is higher in patients with cancer compared to controls but this may reflect altered dietary habits rather than long-term risk. However, at lower pH, basic toxins are ionized while secondary bile acids are less soluble so that the absorption of both would be reduced. The activities of both of the enzymes 7α-dehydroxylase and glucuronidase are decreased at lower pH. These changes would diminish the conversion of primary to secondary bile acids and the hydrolysis of glucuronide conjugates, respectively and thus limit their carcinogenic potential. However, there is consensus that the effects of SCFAs may be rather more specific and mediated through one acid—butyrate. Butyrate is a preferred substrate for normal colonocytes and numerous studies *in vitro* have shown that it has several actions that promote a normal cell phenotype. Cell studies show that butyrate induces hyperacylation of histones, leading to downregulation of gene expression and arrest of proliferation. Other actions include DNA hypermethylation which would have similar effects on tumor cell growth. Butyrate also has favorable effects on apoptosis so that a normal program of cell death is maintained. One marker of a differentiated colonocyte is its ability to produce alkaline phosphatase and butyrate is a powerful promoter of alkaline phosphatase *in vitro*. There is reciprocal downregulation of various oncogenes in colorectal cancer cell lines. These data are very promising for a direct role of butyrate in protecting against colonic cancer but there is an emerging paradox. In the presence of butyrate, there is either increased proliferation or no effect in normal cells but the proliferation of neoplastic cells is reduced. The differentiation of the normal cells is unchanged or suppressed with butyrate but is induced in cancer cells. These differing effects may be explained by neoplastic alterations (perhaps as a result of mutations in oncogenes) in cell signal systems.

It must be emphasized that none of the effects of butyrate *in vitro* have been duplicated *in vivo*, but they are of great promise and supportive evidence continues to accumulate. This is especially true for RS which appears to produce relatively more butyrate than other nondigestible carbohydrates. However, consideration may also need to be given to the existence of interindividual differences in the fermentative capacity of the microflora, the fact that RS from different sources may be fermented to different extents, and the actual colonic site at which fermentation takes place (i.e., whether in the proximal or distal colon).

Inter alia, the data suggest that protection against colorectal cancer is due to several mechanisms and that these can interact. One factor of considerable importance is the issue of overweight which is an independent risk factor for colorectal cancer. Obesity may have to be taken into account much more than has been the case in earlier studies. It appears that some of the effect may be mediated through raised plasma insulin and insulin-like growth factors (which may well be influenced by dietary carbohydrates).

Dietary Fiber and the Etiology of Hormone-Dependent Cancers

Population Studies

Cancers of the breast, endometrium, ovary, and prostate fall into the hormone-dependent classification. An association between hormonal status and cancer risk arose from observations of oestrogen deprivation and breast cancer and testosterone deprivation and prostate cancer. Nutritional influences on breast cancer have been studied extensively and several (but not all) studies show diminished risk with greater intakes of dietary fiber. The situation for other cancers, especially prostate cancer, appears to be rather unclear, but given the commonality of the proposed protective mechanisms, it is reasonable to expect that some linkage may be found. Male vegetarians have been reported to have lower testosterone and oestradiol plasma concentrations compared to omnivores, and inverse correlations of testosterone and oestradiol with fiber intake have been reported.

Potential Mechanisms Indicating a Role in the Etiology of Hormone-Dependent Cancers

There are many published studies that have produced mixed and inconsistent results on the potential mechanisms involved. Dietary fiber could act by reducing circulating concentrations of oestrogen and testosterone. Such an effect would not be unexpected in view of the fact that soluble NSPs can increase bile acid and neutral steroid excretion and fecal steroid outputs are higher in vegetarians than in omnivores. However, one anomaly is the finding that wheat bran (which does not enhance biliary steroid excretion) lowers circulating and urinary oestrogens. It is possible that fiber acts rather differently on hormones than on bile acids and neutral sterols. For example, the colonic flora may be modified so as to increase deconjugation of the sex hormone precursors or their conversion to other

metabolites. Direct binding of sex hormones is possible but is subject to the same concerns as were raised for cholesterol reduction. In addition, it is possible that other components in, or associated with, fiber (phytooestrogens or antioxidants) may be responsible for any observed protective effect. Soy phytooestrogens are believed to play a role in lowering the risk of breast cancer in Asian populations. Lycopenes are antioxidant carotenoids from tomatoes, and their intake has been correlated with a lower risk of prostate cancer.

Dietary Fiber, Obesity, and the Etiology of Diabetes

In 1975, Trowell suggested that the etiology of diabetes might be related to a dietary fiber deficiency. This is supported by several key pieces of evidence. Vegetarians who consume a high-fiber lacto-ovo vegetarian diet appear to have a lower risk of mortality from diabetes-related causes compared to nonvegetarians. Consumption of whole grain cereals is associated with a lower risk of diabetes. Importantly, the same dietary pattern appears to lower the risk of obesity, itself an independent risk factor in the etiology of type 2 diabetes. Obesity is emerging as a problem of epidemic proportions in affluent and developing countries. Consumption of whole grain cereal products lowers the risk of diabetes. A report showed that in 91 249 women questioned about dietary habits in 1991, greater cereal fiber intake was significantly related to lowered risk of type 2 diabetes. In this study, glycemic index (but not glycemic load) was also a significant risk factor, and this interacted with a low-fiber diet to increase risk. These results provide epidemiological evidence of a role of fiber in the etiology of diabetes.

Potential Mechanisms Indicating a Role in the Etiology of Diabetes

It can be hypothesized that a reduction in the general and postprandial glycemic and insulinemic response may delay the development of insulin resistance and thus the development of diabetes (NIDDM) although there is very little direct evidence to support this hypothesis. However, diets high in both carbohydrate and dietary fiber have been reported to improve insulin sensitivity. Much of the research in this area has studied the effect of dietary fiber on the management rather than the prevention or etiology of diabetes.

There is good evidence that diminished glucose absorption lowers the insulin response to a meal. The action of fiber in this regard may be through slowing the digestion of starch and other nutrients. It seems that soluble fiber may play a role because large amounts of soluble dietary fiber have been shown to reduce postprandial glucose concentration and insulinemic responses after a single meal in both normal and diabetic subjects. However, the effect appears to be dependent on viscosity rather than on solubility *per se*. The very viscous gum, guar gum, gum tragacanth, and oat gum are all very effective whereas psyllium and some pectins are less viscous and less effective. One suggested mechanism for reducing the glycemic response is an impairment in the convective movement of glucose and water in the intestinal lumen due to the formation of a viscous gel: Glucose is trapped in the gel matrix, such that there is less movement toward the absorptive brush border of the surface of the intestinal wall and the glucose needs to be squeezed out by the intestinal motor activity of the intestine. However, other factors may also be important. There may be some impairment in digestive activity in the lumen, an alteration in hormonal secretion by cells in the gut mucosa, and a reduced gut motility that delays transit time. In the case of whole grains, there is scope for the fiber to interfere with the physical accessibility of starch to small intestinal α-amylase. Clearly, there is also potential for foods of low glycemic index to be high in RS and this does seem to be the case. A specific instance is a novel barley cultivar that exhibits both characteristics. It should be noted that there are reports of a second meal effect (i.e., the dietary fiber ingested at one meal can affect the glucose rise after the subsequent meal). The mechanism for this is unknown.

A Role for Fiber in the Etiology of Other Diseases?

Although much of the earlier observational studies in native African populations were wide ranging, most attention has subsequently focused on CHD and cancer. Probably this is a reflection of the socioeconomic importance of these conditions in economically developed societies. However, fiber has a role in the prevention and management of other conditions, but much of the relevant information has come from interventions, not from case–control or cross-sectional studies.

Constipation, diverticular disease, and laxation Unquestionably, fiber is of direct benefit in relieving the symptoms of constipation and diverticular disease but there is little information about its role in the etiology of these conditions. Numerous

interventions have shown that foods high in insoluble NSPs (e.g., certain cereal brans) and some soluble NSP preparations (e.g., psyllium) are very effective at controlling constipation and diverticular disease and enhancing laxation. The actual effect can vary with source. Wheat bran increases undigested residue, and fiber from fruits and vegetables and soluble polysaccharides tend to be fermented extensively and are more likely to increase microbial cell mass. Some NSP (and OS) preparations retain water in the colon. The physical form of the fiber is also important: Coarsely ground wheat bran is a very effective source of fiber to increase fecal bulk, whereas finely ground wheat bran has little or no effect and may even be constipating. RS appears to be a mild laxative and seems to complement the laxative effects of NSPs. The effective dose appears to be approximately 20–30 g of total fiber/day consumed either in food or as a supplement. In addition, animal studies show that NSPs and RS appear to prevent colonic atrophy seen in low-fiber diets. The mechanism of action appears to be greater fecal bulking and fermentation and the generation of SCFAs, which is necessary to prevent atrophy.

Diarrhea Colonic SCFA absorption stimulates fluid and electrolyte uptake in the colon and thus can assist in reducing diarrhea. Complex carbohydrates may also play a role in modifying the colonic microflora thus reducing the number of pathogens. An etiological role for fiber is unknown, but there is good evidence that RS can act to minimize the fluid losses that occur in serious conditions such as cholera.

Inflammatory bowel diseases (colitis and Crohn's disease) Clearly, inflammatory conditions have an immune component. In the case of Crohn's disease, there appears to be no established therapeutic or etiological role for fiber. The situation is slightly different for distal ulcerative colitis, in which fiber intake seems unrelated to incidence. However, rectal infusion of SCFAs (especially butyrate) has been reported to lead to remission, so it appears that either the generation of these acids or their delivery to the distal colon may be the issue.

Role in Nutritional Management of Disease

A R Leeds, King's College London, London, UK

Introduction

Dietary Fiber was an unknown phrase to all but a handful of individuals in the early years of the 1970s when a wide range of potential therapeutic applications were suggested by Hugh Trowell, Denis Burkitt, and Alexander Walker. Twenty-five years later there can hardly be an ordinary mortal who has not heard the term, though he may not be able to define it. In some cases the claims remain largely unsubstantiated but in three areas, hyperlipidemia, diabetes, and bowel function, there is sufficient evidence to allow dietary advice to be given.

Hyperlipidemia

Some forms of dietary fiber lower blood lipids, notably total cholesterol and low-density lipoprotein (LDL) cholesterol. The earliest observations on fiber preparations and blood lipids date from the mid 1930s when there was a fairly extensive investigation of the effects of pectin (polygalacturonic acid). The next period of investigation dates from 1974 when extracted and purified dietary fiber preparations such as guar gum – a glucomannan – were tested in normal subjects, diabetics, and hyperlipidemic subjects and were found to lower blood cholesterol when given in sufficient quantities. In very large doses these materials increase fecal excretion of fat and sterol compounds and would be expected to reduce the body bile salt pool. Subsequent work has shown that at lower doses preparations of soluble dietary fiber have a mild cholestyramine-like effect: they bind bile salts rendering them unavailable for reabsorption in the terminal ileum, thus interfering with the normal entero-hepatic cycle of bile salts and depleting the bile salt pool. Total and LDL cholesterol fall as cholesterol is diverted for the resynthesis of lost bile salts. There have been few direct clinical applications of the early experimental work on pectin and guar gum. No pectin compounds have been developed commercially, but there are a few pharmaceutical preparations of guar gum presented primarily as adjuncts to dietary therapy in diabetes rather than for lipid lowering. Dietetic food products containing guar gum have been developed, again for use in controlling diabetes.

Preparations of soluble dietary fiber have been shown to lower blood cholesterol whereas most preparations of predominantly insoluble fiber, such as wheat bran, have little or no effect. The major food sources of soluble fiber are oats, beans, lentils, rye, and barley, and these foods have naturally become the subject of investigations. The addition of oats to the diet in normolipidemic and hyperlipidemic subjects following either their normal diets or where pretreated with low-fat diets has been the subject of extensive research. In sufficient quantity oats, oat products, and oat β-glucan (providing at least 3 g oat β-beta glucan per day) lower blood total cholesterol and LDL cholesterol (usually by 5–10%) while leaving triglycerides and HDL cholesterol largely unchanged. A sufficiently large number of good-quality studies have now been done on oats that the Food and Drug Administration (FDA) has allowed the first ever food-specific health claim: "Soluble fiber from oatmeal, as part of a low saturated fat, low cholesterol diet, may reduce the risk of heart disease." Products that are labeled with this claim must provide at least 0.75 g of soluble fiber (as β-glucan) per serving. When considering the above claim the FDA reviewed 37 studies and found that a sufficient number provided convincing evidence of efficacy. An earlier meta-analysis of some of those trials had shown that the efficacy of oats and oat products was influenced by the initial values of blood cholesterol in the subjects: patients with high starting values (over 6.7 mmol per liter total cholesterol) showed the greatest reductions when treated with oats, while healthy young subjects with low–normal starting values showed little response. There was a dose effect: food products providing more than 3 g soluble fiber per day had a greater blood cholesterol lowering effect than diets that provided less than 3 g per day.

Other soluble fiber-containing products have been shown to lower blood cholesterol. Recent extensive studies on psyllium (*Plantago ovata*) presented both as a pharmaceutical preparation and as a food product (a ready to eat breakfast cereal) have shown blood cholesterol-lowering properties where the dose–effect relationship is such that a useful additional therapeutically meaningful lipid-lowering effect can be achieved by prescribing a daily portion of psyllium-fortified breakfast cereal. Products of this type are now marketed in the US and Australia, and the US FDA has now allowed a food specific health claim for psyllium.

There is also a small literature on the effects of beans on blood lipids and the findings of a blood cholesterol-lowering effect are as expected.

Virtually all of the reports of the effects of soluble fiber products on blood lipids report lowering effects on total cholesterol and LDL cholesterol without any effect on HDL cholesterol or triglycerides – this contrasts with the effects of some drugs that may cause slight rises of triglycerides and falls of HDL cholesterol. The relationship between lowering of blood cholesterol and lowering of risk of heart disease is now generally accepted and a proven lipid-lowering effect is taken to mean a beneficial effect on risk of coronary heart disease. This means that in clinical practice it is perfectly reasonable to include advice on use of foods high in soluble dietary fiber in a lipid-lowering diet, and perfectly proper to emphasize the benefits of oats and oat products. Generally, a high-soluble-fiber diet is more acceptable when the soluble fiber is drawn from smaller quantities of a larger range of foods; thus the diet includes beans, lentils, rye breads, and barley as well as generous use of oats. A range of foods containing mycoprotein and fungal mycelial cell walls (chitin) may also help to lower blood cholesterol.

Diabetes

Diabetes mellitus is characterized by either an absolute or relative lack of insulin, which has short-term and long-term consequences. Diabetic people may develop both microvascular complications (mainly affecting the eyes, kidneys, and nerves) and macrovascular complications (essentially accelerated development of atherosclerosis presenting mainly as heart attack and peripheral vascular disease). Medical management aims to replace the insulin, or modulate its production or efficacy using oral (hypoglycemic) drugs, in a metabolic environment enhanced by good control of diet and body composition. Medical management also aims to achieve early detection of complications and other risk factors for cardiovascular disease by regular testing of blood and urine biochemical variables and blood pressure and by regular physical examination of the eyes, neurological, and cardiovascular systems.

Control of dietary energy intake (in relation to the varying demands for growth, maintenance, physical activity, etc.) remains the key feature of dietary control affecting metabolic fluxes, blood glucose levels, and body weight. Views on the appropriate proportional sources of energy from fat, carbohydrate, and protein have changed enormously over the last century from seriously energy-restricted high-fat diets (with percentage energy from fat as high as 70% raising some doubts about the level of compliance) through to very high-carbohydrate diets (sometimes 60–65% energy from carbohydrate) used in specialist centers in the US. Today, for most diabetic patients in most countries the target is to achieve 50–55% energy from carbohydrate sources. Prior to the 1970s, when the move towards high-carbohydrate diets began, the high fat content of the diet along with less tight blood glucose (and urine glucose) control than is customary today was partly responsible for the high relative mortality from cardiovascular disease seen among diabetic patients. At that time young male diabetics were up to nine times more likely to die from heart attack than matched nondiabetic individuals. Reduction of fat in the diet and achievement of an optimal distribution from saturated, monounsaturated, and polyunsaturated sources (<10%, 10–20%, and no more than 10%, respectively, for patients with diabetes in the UK) remain a major aspect of dietary management of diabetic people in order to reduce the risk of developing coronary heart disease.

Control of blood glucose is critical in order to achieve avoidance of prolonged periods of hyperglycemia, which is associated with glycation of proteins and the risk of development of microvascular complications, and avoidance of hypoglycemia with its attendant risks of coma. In day-to-day practice, the avoidance of hypoglycemia is very important to patients and any new method of achieving normalization of blood glucose profiles is an advance. Dietary fiber offered such an advance from the mid 1970s when some forms (notably isolated polysaccharides such as guar gum, a glucomannan, and pectin, polygalacturonic acid) were shown to reduce the area under the blood glucose and insulin curves after acute test meals. Subsequent long-term (6-week) clinical trials showed that diets high in foods containing soluble dietary fiber, such as beans, oats, and barley, were more effective in reducing the area under the 24-h blood glucose profiles than diets containing more high-fiber foods based on wheat products.

Research in this area led David Jenkins to describe (in 1981) the concept of the 'glycemic index' (GI) which is a numerical expression of the ability of a food to raise blood glucose levels. In practice it is measured by comparing the blood glucose response to a 50-g carbohydrate portion of food with the response to 50 g glucose (in some papers the comparison is with a 50-g carbohydrate portion of bread). The dietary fiber (especially soluble fiber) content of a food slows down the rate of digestion and absorption of starch in foods giving flatter blood glucose responses and a lower GI; however, the structure of the starch (whether amylose or

amylopectin) influences its rate of degradation and the extent to which the starch granules are hydrated by processing (including cooking) is also important. The physical structure of the food (particularly the extent to which plant cells are intact), the presence of fat, which may slow gastric emptying, and the presence of some 'antinutrient' substances may all influence the GI. Low-GI diets have been shown in many clinical trials to improve important variables that are secondary indicators of blood glucose control, and to reduce blood lipids. Low-GI diets may be particularly helpful to patients who are frequently troubled by episodes of hypoglycemia though adequate proof of this is still awaited. Low-GI diets are not just relevant to treatment of diabetes but have been shown in two large-scale epidemiological surveys published in 1997 to result in a significant reduction in the risk of development of maturity onset (type 2) diabetes in middle-aged American men and women. Thus, there is good reason to believe that there should be greater emphasis on the GI of diabetic diets and the fiber content, as well as emphasis on GI for those at risk of developing diabetes, especially the older obese person. Expert committees in many developed countries of the world have set target values for dietary fiber intake for diabetic patients (e.., the American Diabetes Association (ADA) recommends 20–35 g day^{-1} total dietary fiber by the AOAC method) and many, especially the Australian Diabetes Association and with the notable exception of the ADA, have recommended an increase in low-GI foods. In 2003 even Diabetes UK (the UK Diabetes Association) noted that there might be merit in taking account of GI in dietary management for those with diabetes. Some physicians believe that the GI of foods is too complex an issue for patients to grasp, but in essence simply requires a partial substitution of bread and potatoes with pasta products, an increased use of high-fiber breakfast cereals including oats, increased use of beans and lentils, and emphasis on the use of temperate fruits (e.g., apples and pears).

Obesity (body mass index (weight in kilograms divided by height in meters squared) in excess of 30 kg m^{-2}) is becoming more prevalent in developing countries and attracts an increased risk of the development of diabetes mellitus; a high proportion of established type 2 diabetics are obese and overweight. In the popular diet book 'The F-Plan Diet,' published in 1982, Audrey Eyton claimed that dietary fiber would help people lose weight by a number of mechanisms including reducing the efficiency of dietary energy absorption and by making people feel full for longer after meals thus having an overall effect on reducing food intake. At the time of publication these ideas were hypothetical - subsequent investigation has shown that increasing fiber intake two- or threefold by a variety of dietary changes can increase fecal energy losses by 75–100 kcal day^{-1}. Studies on the effects of dietary fiber on postprandial satiety where experimental meals are carefully designed to differ little except for fiber content have given variable results. However, there is a clear effect of fiber on chewing (the number of chews necessary to eat the same energy equivalent of food) where high- and low-fiber types of commonly consumed foods are eaten and this may have an important satiating effect. Clinical trials of high-fiber weight loss regimens have given variable results. Double-blind placebo-controlled trials using pressed barley fiber and pectin tablets compared to a starch control have been undertaken in Scandinavia and have demonstrated statistically significantly greater weight losses in the fiber-treated groups up to 26 weeks of treatment. It seems reasonable to conclude that under some conditions the right kind of high-fiber diet can facilitate weight loss, but may not always do so.

Diabetic people are more likely to have dyslipidemia than nondiabetic people. When control of diabetes is lost, patients may demonstrate gross hypertriglyceridemia due to increased production of very-low-density lipoprotein (VLDL) particles in the liver as a consequence of the increased flux of free fatty acids from the peripheral tissues. At the same time total and LDL cholesterol may be raised. Improvement in diabetic control often achieves normalization of blood lipids, but where hyperlipidemia persists there may be a place for use of dietary fiber, especially soluble fiber, and especially oat β-glucan-containing foods as an adjunct to dietary and pharmacological therapy (see above).

Bowel Disorders

Denis Burkitt first suggested a role for dietary fiber in bowel disorders in 1971. In the intervening period understanding of the normal physiology and pathophysiology of the colon have improved enormously. During the same period methods of analysis have been refined and a distinction is drawn between dietary fiber (as determined by the AOAC gravimetric method) and nonstarch polysaccharide (NSP; determined by GLC analysis of component sugars), and starch not digested in the small gut is now defined as being resistant. Three types of resistant starch have been described. These advances in analysis have helped physiologists appreciate the

contributions of various substrates to colonic fermentation and stool bulking.

The intake of dietary fiber (nonstarch polysaccharides) is directly related to the amount of wet stool passed each day in large population groups. An average wet stool weight for the UK is about 105 g day^{-1}, which corresponds roughly to a nonstarch polysaccharide (Englyst method) intact of 12.5 g day^{-1}. Nearly half of the members of groups studied in the UK have stool weights of less than 100 g day^{-1} below which complaints of constipation are common. Stool weight has been shown to be clearly inversely related to colon cancer incidence in population groups: a mean daily stool weight of 105 g corresponding to a relatively high population colon cancer incidence of about 22 per 100 000 per annum. An incidence rate of 11 per 100 000 per annum corresponds to a mean daily stool weight of about 175 g day^{-1}. This information was used as the numerical basis for calculating the UK's dietary reference value (DRV) for nonstarch polysaccharide (NSP) in the late 1980s. In the UK the population is urged to increase NSP intake by 50% to a population averageof 18 g day^{-1} in order to shift the distribution of wet stool weight upwards.

Constipation is generally considered to be infrequent opening of the bowels with straining to pass stools (less than three defecations per week and straining and or the passing of hard stools in more than one in four defecations). Constipation is sometimes caused by other specific disease of either an endocrine nature (e.g., myxoedema – reduced thyroid function) or physical obstructive nature (e.g., colon cancer). Where constipation has developed recently in a previously nonconstipated individual over the age of 40 years colon cancer must be excluded as the cause of the change of bowel habit. In the absence of evidence that the constipation is secondary it is probably due to dietary and life-style factors. The mucosa of the lower colon has a great capacity to desiccate its contents. If the call to stool does not occur or is ignored residual material drys out and individual fecal pellets become smaller. There is experimental evidence to suggest that greater abdominal pressures are needed to expel pellets that are 1 cm in diameter than those that are 2 cm in diameter. Thus, factors that result in the call to stool being ignored, like not allowing sufficient time for defecation after a stimulus such as breakfast or the walk to the station or being unprepared to defecate anywhere except at home (a common characteristic consistent with mammalian behavior), are likely to cause constipation. Simple solutions include going to bed earlier and getting up earlier in the morning, and finding another acceptable location for defecation at the workplace. Increasing fiber in the diet, most easily achieved by making breakfast a high-fiber meal with either high-fiber breakfast cereals or high-fiber breads, will increase stool bulk, shorten transit time (the time for a marker to pass from the mouth and be passed in the stool), and alleviate symptoms in many cases. The importance of exercise in maintaining normal colon function is gradually being recognized – the importance of brisk walking should not be underestimated. However, some specific types of simple constipation have been identified which do not necessarily respond to high-fiber diets. Grossly prolonged transit times reflecting seriously slow colonic motility has been seen particularly in young women and do not respond well to high-fiber diets, and some 'outflow abnormalities,' which sometimes have a basis in abnormal rectal conformation, may also not respond.

Diverticular disease of the colon, characterized by the development of protrusions of mucosa through the bowel wall, is common and usually asymptomatic. It has been shown to be less likely to develop in those following a high-fiber diet, and once acquired can be managed, in many cases, by ensuring an adequate amount of fiber in the diet. Experimentally, various fiber supplements and 'bulking agents' have been shown to reduce the abnormally high peak intracolonic pressures that are characteristic of diverticular disease. Sometimes 10–20 g of coarse wheat bran as a supplement is all that is required, but some patients develop flatulence and distension at least initially. Other fiber supplements such as ispaghula husk (psyllium) may be as effective, without the initial adverse side effects. Sometimes, simple dietary changes to achieve an adequate total daily intake of dietary fiber particularly from wheat-based foods are effective. Diverticulitis (inflammation of the diverticula) is a complication requiring medical management, which will usually include a short period of abstention from food. Many patients remain largely without symptoms once the right 'fiber' regimen has been determined.

The irritable bowel syndrome (IBS) is a 'functional' disorder of the bowel, which is said to affect up to 15% of the population and is characterized by some, but not necessarily all, of a range of symptoms including abdominal pain relieved by constipation, alternating diarrhea and constipation, recurrent abdominal pain, and urgent or frequent defecation. An important part of management is the exclusion of other serious organic disease such as inflammatory bowel diseases. In IBS the gut is abnormally sensitive to distension, and symptoms may be related to or

exacerbated by external emotional events. The role of high-fiber diets in IBS has been investigated and not surprisingly is only of benefit in some cases: in those patients in whom the predominant feature is constipation. In some patients high-fiber diets may make their symptoms worse.

In inflammatory bowel disease (IBD) high fiber diets have no special part to play in the management of Crohn's disease where enteral feeding (with formula low-residue, low-fiber preparations) is especially beneficial where there is acute extensive small bowel disease. In ulcerative colitis specific dietary advice is usually unnecessary though fiber supplements may be of benefit in patients whose disease is limited to proctitis (inflammation of the rectum).

The treatment of newly diagnosed colon cancer does not include diet therapy, but treatment of those at increased risk of developing colon cancer by dietary and other means will become increasingly common as more information about the effects of high fiber diets and supplements on colon function becomes available. The critical step in the adenoma-carcinoma sequence in the human large bowel is the enlargement of the small adenoma (which has a low risk of malignant transformation) to a large adenoma (which has a high risk of malignant transformation); dietary factors, including low amounts of fiber in the diet, enhance adenoma growth. Bile acids are strongly linked to adenoma growth and bile acid concentrations in the colon are influenced by dietary fat and dietary fiber. Other effects of fiber may also be protective: bulking the stool and accelerating material through the colon, and provision of substrate for fermentation particularly with production of butyrate, which may have antineoplastic properties. However, despite a great deal of epidemiological and experimental work the potential role of dietary fiber in modulating the risk of colon cancer remains controversial.

DIETARY GUIDELINES, INTERNATIONAL PERSPECTIVES

B Schneeman, University of California—Davis, Davis, CA, USA

Introduction

The use of food-based dietary guidelines (FBDG) has emerged as an important food and nutrition policy and education program since the late 1970s and is valuable for addressing issues of both nutrient adequacy and excess. Importantly, FBDG communicate nutritional principles in a manner that is relevant to the population. Most FBDG encourage energy balance, physical activity, a healthful variety of foods including fruits and vegetables, whole-grain products, food sources of protein, calcium, and unsaturated fatty acids, and safe food handling. Cautionary messages focus on excess energy intake, saturated and *trans* fatty acids, added sugars, salt, and alcohol. To develop relevant FBDG, each country must identify local public health issues and appropriate diet-related strategies for the population.

Historical Background

Throughout the ages, religious and philosophical writings have included dietary recommendations, and this is reflected in an oft-quoted line from Hippocrates: 'Let thy food be thy medicine'. In the late 1800s, modern science began to influence the nature of recommendations regarding foods and beverages. The original focus of guidelines developed from Pasteur's discoveries of the disease-causing organisms that could be present in foods such as milk; thus, recommendations emphasized sanitation in food handling. In the early 1900s the discovery of vitamins and minerals led to the realization that foods contain factors that are essential for health. This 'vitamin theory of disease' led to research throughout the first half of the twentieth century to discover these factors and determine their essential functions in the treatment of deficiency diseases. The knowledge that food was important in the prevention of diseases that were major public health problems, such as scurvy, beri-beri, night blindness, and pellagra, led to early efforts to develop and promote dietary recommendations or guidelines, even though the specific curative factors in foods had not been identified. Among the earliest examples, Egyptians were known to promote the use of liver to correct night blindness, the British Navy used lemons or limes to prevent scurvy, and alkali treatment of corn was associated with a lower incidence of pellagra in Mexico. The understanding of the linkage between certain foods and the prevention of disease resulted in the development of food guides or groups illustrating a pattern of food choices that was most likely to prevent deficiency diseases. As the chemical nature of the factors in food that prevented or cured nutritional deficiencies became known, it was possible to determine the specific amount required in the diet to maintain health. These studies led to the development of recommended dietary allowances (RDA), which are numeric recommendations of the nutrient intakes that will meet the needs of the majority of the population. RDA have also been used to evaluate the adequacy of diets in many populations.

By the second half of the twentieth century, it had become clear that in many developed countries the primary causes of disease were shifting from dietary deficiencies to those associated with dietary excess. As noted by the Surgeon General of the USA, by 1988 micronutrient deficiencies were no longer major public health problems in the USA, and diseases associated with excess intakes of energy, saturated fat, total fat, cholesterol, alcohol, and sodium, in conjunction with inadequate fiber intake, were the major causes of death in the USA. The economic transition experienced by many developing countries has led to a similar pattern; this is sometimes referred to as the double burden of disease. While nutritional deficiencies continue to be prevalent in large segments of the population, an increasing proportion of the population is at risk of developing diet-related chronic diseases, such as obesity, cardiovascular disease, cancer, and diabetes. This emerging pattern of disease has resulted in the development of FBDG, which recommend dietary patterns that are adequate in nutrient content and encourage food choices to lower the risk of noncommunicable diet-related diseases.

Types of Guidelines

This section outlines the evolution of three interrelated general types of nutrition recommendations that are developed and used in most areas of the world by national or regional government agencies: technical recommendations, which provide specific numeric criteria for nutrient intake; FBDG, which outline strategies to lower the risk of chronic disease; and food guides, which illustrate dietary patterns or food choices to encourage individuals to meet the recommended nutrient requirements and to follow the advice in dietary guidelines. The more technical quantitative guidelines are typically used by health professionals to develop educational materials and evaluate the adequacy of diets. Food guides and FBDG are important components of educational materials for healthy individuals. Although this section will focus on FBDG, it is important to understand how they are related to the other types of nutritional recommendations, and also that recommendations categorized as FBDG ideally are related to and supportive of other types of nutritional recommendations that are part of national or regional health policy. Frequently, non-governmental groups develop food guides or FBDG to suit a specific purpose (such as weight loss, treatment of cardiovascular disease, or promotion of a food culture) or a specific population (such as older individuals); however, before accepting these recommendations, it is important to determine how they have been validated in terms of other criteria such as the dietary reference intakes. These non-governmental recommendations do not have the same policy status as recommendations developed by government agencies or through government-sponsored scientific organizations and may be suitable only for a specific targeted function.

In 1992 a recommendation of the International Conference on Nutrition organized by the World Health Organization (WHO) and the Food and Agriculture Organization (FAO) was that each country should to develop nutritional recommendations that included FBDG. To encourage this activity, FAO and WHO convened a group of experts to recommend a process for developing FBDG; their findings are published in a WHO technical report.

The Development of Food-Based Dietary Guidelines

FBDG express the principles of nutrition education in terms of the food and food choices available to the population rather than in terms of specific nutrients or food components. Scientifically, these guidelines are based on the association between dietary patterns and the risk of diet-related diseases and incorporate recommendations that address major diet-related public health issues. In addition to communicating scientific knowledge about the association between food, dietary patterns, and health, development of FBDG provides an opportunity to strengthen consensus among various government and non-government organizations on important nutrition recommendations to be incorporated into educational programs. In addition, by expressing scientific principles in terms of food, FBDG recognize the consumer awareness of food rather than nutrients and emphasize to consumers the importance of meeting nutrient needs with foods. Thus, both the content of the FBDG and the process of development are important.

Researchers often focus their studies on a specific nutrient or food component that may alter the risk of developing a disease. These studies are reviewed in the development of FBDG, but the information must be reorientated from a nutrient-based focus to a food recommendation by addressing the questions in **Table 1**. As indicated by these questions, the process is driven by the identification of diet-related public health issues and the development of food-based strategies that are relevant to the target population.

The process for developing FBDG is based on building consensus among various sectors and groups involved in public health. **Table 2** provides a general outline of the steps in the process, which can be adapted to the specific needs of a country or region. The goal is to have a set of guiding principles for food-based recommendations that lay out the overall policy agreed by various agencies and groups.

The product of the working group is likely to be a document that outlines recommendations and includes background information on the rationale for the guidelines as well as guidance on implementing the recommendations. The guidelines from three countries are shown in **Table 3** as an example of the types of message developed during this process. In all cases, the messages are accompanied by a document containing background information. **Table 4** presents common themes emerging from the FBDG that have been developed in a variety of countries. Based on foods available and cultural practices, the types of fruits, vegetables, and whole grains and the specific types of food that are emphasized as sources of protein, calcium, or unsaturated fatty acids may vary. In

Table 1 Reorientating from nutrients and food components to foods

What are the important public health issues for the population? Do they have diet-related factors?
Health statistics will indicate the major causes of morbidity and mortality in a population. Diet-related diseases include nutritional-deficiency diseases and noncommunicable diseases such as obesity, type 2 diabetes, certain types of cancer, and cardiovascular disease. It is important to determine whether nutrition is the primary cause of the disease or secondary to some other more prevalent problem (e.g., smoking, infectious agents)

What are the target nutrients linked to the major public health issues? Are there related nutrients or other factors?
In many nutrition-related problems several nutrients or food factors may interact to cause the nutritional problem. For example, the fat content of the diet affects absorption of fat-soluble vitamins, obesity can be related to either excess energy intake or inadequate expenditure, multiple factors contribute to adequate bone formation, folic acid can mask vitamin B_{12} deficiencies, etc. Simply increasing the intake of a target nutrient and ignoring these other factors may not address the problem adequately

What foods are high in the nutrient(s) or consumed in sufficient quantity to be a significant source of the nutrient(s)?
Using both food-composition databases and food-consumption data, foods that are good sources of the nutrient and foods that are consumed in sufficient quantity to meet the target intake can be identified. Likewise, dietary patterns that lower the risk for the public health problem and are associated with adequate intake of the nutrient can be identified

What is likely to be acceptable by the target audience?
For nutrition interventions to achieve success, recommendations must target food choices that can be integrated into the diet based on cost and acceptability of the foods

How do diet strategies integrate with other food policies?
Economic, agricultural, and trade analysis is useful to determine which diet strategies are sustainable

Table 2 Steps in the development of food-based dietary guidelines

1. Develop support from key government agencies
The successful implementation of FBDG will depend on support from key ministries such as health, agriculture, education, sports, and recreation. Building consensus among these agencies will result in consistent messages regarding diet, health, and lifestyle for the public. Examples of support include technical support for data analysis or a Secretariat to maintain and coordinate activities

2. Form a working group of experts
The working group should include diverse expertise in areas such as public health, nutrition, food science, agriculture, and behavioral sciences

3. Solicit public comment and input
The expert panel needs to gather and evaluate scientific information to determine the guidelines that are most relevant to the target population. This information can be obtained from the scientific literature. In addition, professional groups may have important information to submit to the panel for consideration. Solicitation of information is consistent with an open process; however, the panel is responsible for evaluating the relevance of the information submitted

4. Review and identify key public health issues and evaluate the diet–health relationships of concern for the population, determine the critical health, food, and nutrition issues to be targeted in the FBDG, and define the purpose, target groups, and content of the FBDG
Even if data are limited, it is important for the working group to identify the key public health issues. This step may be especially important in countries in which both under-nutrition and over-nutrition are of concern. Identification of the public health issues allows the working group to address the questions in **Table 1**

5. Develop and draft the main messages for the FBDG
The working group will need to decide whether the draft document will be targeted primarily at health professionals, and hence may be more technical, or will be targeted toward the general public. In developing the main messages, they may identify consumer-orientated materials, such as a food guide that will be useful in communicating the FBDG to the public

6. Assess the cultural and economic appropriateness and credibility of the messages as perceived by the target groups
Through focus groups or other types of consumer testing the effectiveness of the FBDG can be assessed. This information can be used to revise the guidelines before developing the final draft

7. Release and implement the FBDG
It is valuable to have government leaders from key ministries involved in the release and implementation of the FBDG so that there is a commitment to integrate the guidelines into departmental policies. In addition, the implementation can require development of educational materials for different target groups as well as public–private partnerships to aid in dissemination of the messages to the public

8. Monitoring and revision
Monitoring can be used to assess the impact and implementation of the FBDG. In addition, monitoring data are useful for making appropriate revisions and updates to the guidelines on a periodic basis

FBDG, food-based dietary guidelines.

Table 3 Dietary-guideline messages from three countries

USA	*China*	*Thailand*
Aim for fitness		
Aim for a healthy weight Be physically active each day	Eat a variety of foods, with cereals as the staple Consume plenty of vegetables, fruits, and tubers	Eat a variety of foods from each of the five food groups, and maintain proper body weight Eat adequate amount of rice or alternative carbohydrate sources
Build a healthy base		
Let the pyramid guide your food choices Choose a variety of grains daily, especially whole grains Choose a variety of fruits and vegetables daily Keep food safe to eat	Consume milk, beans, or diary or bean products every day Consume appropriate amounts of fish, poultry, eggs, and lean meat; reduce fatty meat and animal fat in the diet	Eat plenty of vegetables and fruits regularly Eat fish, lean meats, eggs, legumes, and pulses regularly
Choose sensibly		
Choose a diet low in saturated fat and cholesterol and moderate in total fat Choose beverages and foods to moderate your intake of sugars If you drink alcoholic beverages, do so in moderation	Balance food intake with physical activity to maintain a healthy body weight Choose a light diet that is also low in salt If you drink alcoholic beverages, do so in limited amounts Avoid unsanitary and spoiled foods	Drink milk in appropriate quality and quantity for one's age Eat a diet containing the appropriate amounts of fat Avoid sweet and salty foods Eat clean and safe food Avoid or reduce the consumption of alcoholic beverages

Table 4 Common themes for food-based dietary guidelines

Foods or behaviors that are encouraged	*Cautionary messages*
Energy balance Includes physical activity Encouraging a healthful variety of foods Fruits and vegetables Use of whole grains Protein-based foods Foods that are calcium sources Sources of unsaturated fatty acids Safe food handling	Saturated fatty acids and *trans* fatty acids Energy balance Total energy from fat Consumption of foods high in added sugar Use of salt and salty foods Alcohol

all countries concerns about the increasing incidence of obesity have placed greater focus on energy balance, in terms of both food selection and physical activity. As a part of their effort to support the development of FBDG, the FAO launched a public information initiative for consumers entitled 'get the best from your food'. This initiative promoted four simple principles (**Table 5**) that can be adapted for educational programs in a variety of settings.

Most countries that have developed FBDG have also developed a food guide to accompany the messages in the guidelines. The food guide is typically a simple graphic illustration of food choices and dietary patterns. The food guides that accompany the FBDG shown in **Table 4** are illustrated in **Figure 1**. Criteria for a food guide should include representation of foods common to the population, consistency with the FBDG, use of simple graphics that are meaningful to the target population, and developing a food pattern that meets the nutrient requirements of the population. Although a simple graphic is useful for visual communication, it should be clear that proper use of the food guide depends on understanding the more complete information in the FBDG.

Table 5 Food and Agriculture Organization initiative: get the best from your food

	Key concept
Enjoy a variety of food	Recognizing the importance of food in understanding nutrient requirements, nutrient and non-nutrient interactions, and diet–health relationships
Eat to meet your needs	Importance of energy balance and different needs across the life cycle
Protect the quality and safety of your food	Recognizing the importance of food and water sanitation, especially in developing countries
Keep active and stay fit	Importance of physical activity in maintaining well-being

(C)

Figure 1 *Continued.*

Conclusion

The use of food-based dietary guidelines (FBDG) has emerged as an important food and nutrition policy and education program since the late 1970s and is valuable for addressing issues of both nutrient adequacy and excess. Importantly, FBDG communicate nutritional principles in a manner that is relevant to the population. As a policy document, they should be revised periodically so that the information reflects current science on food and nutrition factors that promote health and prevent disease. Additionally, it is important for each country to develop their own set of FBDG so that the recommendations and presentation are relevant to the local population.

DIETARY INTAKE MEASUREMENT

Contents
Methodology
Validation

Methodology

A A Welch, University of Cambridge, Cambridge, UK

Introduction

Dietary intake measurements are used to assess food or nutrient intake of individuals, groups, or populations. The purpose of collection of measurements varies from individual assessments in clinical situations (nutrition screening) or the adequacy of intake of population groups (nutrition surveillance) to use in research relating diet to health status, particularly in epidemiology. Measurements are also used to establish exposure to food-borne contaminants, in the evaluation of nutritional intervention programs, and to develop nutritional guidelines for governmental health policy.

This article describes the dietary intake measurements available, issues associated with data collection, conversion to nutrients and food types, measurement error when using dietary intake methods, validation and calibration of dietary methods, and future developments.

Dietary Intake Measurements

Table 1 describes the advantages and limitations of the main types of dietary methods, which are suitable for different purposes.

Of the individual methods weighed records, estimated food records, 24-h recalls (24-h), and dietary histories are more intensive. The quantity of food consumed may be weighed directly or estimated using household measures such as cups and spoons, photographs, standard units, or average portions (see **Table 2**). For all methods the amount consumed can be measured or described either including or excluding wastage material usually discarded during food preparation, e.g., outer leaves and peel from vegetables or bones from cuts of meat.

Some considerations when choosing a dietary method are shown in **Table 3**.

Methods for Measuring Food Consumption at the National Level

Food Balance Sheets

The FAO (Food and Agriculture Organization) publishes food balance sheets (FBSs) for around 200

Table 1 Names and characteristics of dietary methods used for estimating food and nutrient intake

Name of method	*Advantages*	*Limitations*
National level		
Food balance sheets	Available for 200 countries; suitable for monitoring change	Per caput not individual intake; intake overestimated as nutrient losses during storage and preparation not accounted for; should not be used to provide estimates of nutritional adequacy of particular regions
Household level		
Food account method	Low respondent burden; relatively inexpensive	No estimates of change in larder stocks; measurements confined to food brought into the home (unless method modified to measure food consumed outside the home, which can be quite large); consumption of confectionery, alcoholic, and soft drinks excluded
Inventory method	Low respondent burden; relatively inexpensive	Consumption of confectionery, alcoholic, and soft drinks excluded
Household record	Suitable for populations with high proportion of home-made foods; useful if literacy levels are low; provides direct measure of food available for consumption	High input from field workers or interviewers
List recall methods	Relatively rapid and inexpensive; only 1 interview required; suitable for populations with higher proportion of purchased than home-produced food	Advance warning of interview may distort food consumption patterns; subject may fail to record items from memory; no record of foods eaten outside the home
Individual level		
Retrospective methods		
24-Hour recall (24-HR) (single or multiple days)	If interviewed, respondent literacy not important; not reliant on long-term memory; providing not forewarned, individuals do not alter food consumption; interview length 20–45 min	Single 24-h should not be used for estimating intake of individuals but can be used for group assessments
Diet history	Respondent literacy not required	Report of past intake is influenced by current diet; trained interviewers required; average interview length 1–1.5 h; high processing costs
Food frequency questionnaire (FFQ) (if includes portion estimates termed semiquantitative FFQ)	Useful for large numbers; relatively straightforward to complete; administration simpler and less costly than other individual methods; more rapid data processing	Needs to be developed for specific population group to ensure important food items are covered and requires updating to accommodate changes to supply of foods; less flexible for later analysis as food lists are fixed; responses governed by cognitive, numeric, and literacy abilities of respondents also by length and complexity of the food list
Current methods		
Weighed food record (weighed inventory technique)	No requirement for memory retrieval as it records current intake; food intake weighed so estimates of quantity consumed not required	Literate, cooperative respondents required as burden is high; possible that respondents change usual eating patterns to simplify the record; high processing costs
Food record with estimated weights	No requirement for memory retrieval as it records current intake	Literate, cooperative respondents required as burden is high; possible that respondents change usual eating patterns to simplify the record; necessary to find values for estimates of quantity of food consumed; high processing costs
Duplicate analysis	Greater accuracy	Highly labor intensive; requires laboratory to do food composition analysis; limited applicability in population studies

In all methods 'foods' refers to consumption of foods, beverages, and snacks both inside and outside of the home.

countries. Food balance sheets present a comprehensive picture of the pattern of a country's food supply during a specified reference period. Food balance sheets may also be termed national food accounts, food moving into consumption, food consumption statistics, food disappearance data, and consumption level estimates, reflecting differences in the method of calculation but providing similar information.

Table 2 Types of portion used for methods using estimated portions

Portion types
Average or small, medium, large portions, weights – available from studies of weighed intake
Photographs (ideally should be 5 or more representing the population range of intake)
Household measures (spoons, cups, mugs, liquid measures)
Standard units (1 apple, 1 banana)
Food models/replicas (three-dimensional models representing foods)

Data should be derived from weighed intakes, government surveys, and research groups in populations similar to the one to be studied.

The supply available during a period is calculated from the total quantity of foodstuffs produced in a country, added to the total quantity imported and modified for any change in stocks that may have occurred. Calculation of quantities used for purposes other than human consumption (exports, livestock, used for seed, nonfood uses) and losses during storage and transportation are made. The per caput supply of each food item available for human consumption is calculated by dividing the total of available food by the number of the population actually consuming it and expressed in terms of quantity and nutrients. Estimates from FBSs include household wastage material, plate waste, and food fed to pets. Nutrient losses during storage, preparation, and cooking are not calculated and so figures for available food are greater than those reported by individual dietary surveys.

Table 3 Factors determining choice or suitability of method

Size and scale of the data collection
Screening, clinical, research, surveillance purposes?
Literacy or numeracy of the population
Age of the individual or population (the very young or very old may need assistance with completion)
Intended or potential use of the data (immediate short-term assessment versus prospective research)
Requirement for group or individual estimates for nutrient intake
Requirements from the data for nutrients, food groups, or phytonutrients
Detail and comprehensiveness of the information to be extracted for analysis (if information only required for particular nutrient or food type, shortened questionnaires may be administered)
Has repeatability of the method been assessed?
Have previous validation studies performed on the method by other researchers in similar population group to be studied?
Availability of resources for interviewers and including training
Availability of suitable coding program (record and recall methods require greater resources than frequency methods but frequency programs are more complex to develop)

Food balance sheets can be used to formulate agricultural policies concerned with production, distribution, and consumption of foods and as a basis for monitoring changes and forecasting food consumption patterns, as well as to provide intercountry comparisons of available supplies.

Methods for Estimating Dietary Intake at the Household Level: Household Budget Surveys

Techniques for estimating intake at the household level include the food account method, the inventory method, the household record, and the list recall method. These methods measure all foods and beverages available for consumption by a household or family group during a specified time period of between 1 and 4 weeks, although some last for 2–3 months. Wastage factors are sometimes applied. Household surveys provide data for per capita consumption of foods or nutrients, not intake for specific individuals. Data are calculated irrespective of the age and gender distribution in the household. These methods provide population data for annual mean food consumption and selection patterns, and are used for analyzing trends in intake. Household budget surveys are used more widely in Europe than elsewhere. As countries may not produce compatible data the Data Food Networking Project (DAFNE) has developed the methodology to allow the data from 11 European countries to be combined and compared.

Food Account Method

A record is made by a respondent of details of all quantities of food entering the household (purchased, home grown, or received over a period), usually over a period of 7 days. Changes in larder stocks are not estimated as on average some households will gain and some will use up stocks. Estimates of losses and wastage during preparation are made. This method is used for the UK Expenditure and Food Survey (until 2001 the National Food Survey), and has included consumption of food, confectionery, soft drinks, and alcohol outside the home since 1992. As consumption outside the home now accounts for a substantial proportion of dietary intake in the UK the method was modified in 2001 to include the use of till receipts and individual 2-week diaries for each household member aged 7 years or older. This method can be used to measure seasonal variation in intake over 1 year.

Inventory Method

The inventory method is similar to the food account method and respondents record all foods coming into the household. A wastage factor is often applied and a larder inventory is included at the beginning and end of the survey period.

Household Record

Foods available for consumption (either raw or processed) are weighed or estimated. Foods for each meal are recorded separately to give a total for the household. Waste is measured directly or estimated. Interviewers visit the household early in the day to determine the quantity of food used to prepare the first meal and the number of individuals who consumed it. The midday meal may be weighed or recorded using estimated measures. A further interview is required later in the day. This method is appropriate for use in pre-industrial societies where literacy is low and units for buying foods not standardized.

List Recall Methods

The respondent is asked by a trained interviewer to recall the amount and cost of food obtained for household use over a period, usually of 1 week. The method takes into account food use, purchases, and acquired food, but not waste. Quantities consumed are weighed or estimated using household measures. The interview can take up to 2.5 h. Response rates are usually high. Information on the age and sex of people in the household and the number of meals eaten both in and outside the home, income, and other socioeconomic characteristics may be collected. It is helpful to notify the respondent in advance so that records of purchases can be kept prior to the interview. This method was used by the United States Department of Agriculture (USDA) National Food Consumption Survey between 1931 and 1988.

Individual Dietary Intake Methods

Many methods are available for estimating individual dietary intake measures and can be divided into two types: retrospective measures of intake such 24-h recalls (24-HR), dietary history or food frequency questionnaires (FFQs), or current measures of intake such as weighed or estimated food records. Qualitative information is available from all methods but quantitative estimates for nutrient consumption are possible only if data for weighed or estimated portion weights are available. Most methods may be either self-completed or completed by a surrogate. Surrogates may be required if study individuals are too young, old, or infirm but data will be less reliable than when reported directly.

24-HR and FFQs may be self completed or interview administered either face-to-face or by telephone and can be mailed. Data collection costs can be reduced if questionnaires can be self-completed or mailed.

The number of days of report required for adequate measures of nutrients using 24-h recalls, weighed, or estimated records varies depending on the day to day variability of nutrient consumption. The number of days is partly dependent on the variation in nutrient concentration in foodstuffs. The concentration of macronutrients such as protein and carbohydrate in foods varies less than micronutrients such as vitamin C or iron. The number of days required to classify individuals into the correct third of the percentage distribution for usual intake, for 80% of individuals, has been calculated in British and Swedish populations. Up to 7 days of recall would be required for energy, protein, sugars, and calcium. Nutrients with greater variability and requiring between 4 and 14 days of records were alcohol, vitamin C, riboflavin, and iron.

24-Hour Recalls

24-HR determine intake during the preceding 24 h. Interviews can be recorded on paper or using interactive computerized software. Day-to-day variability in nutrient intake is large and a single day will not categorize individuals correctly within a distribution of intake. Therefore, single 24-HR are better used for group assessments than estimates for individuals. However, multiple 24-HR can be used to overcome this problem. The sampling protocol for studies should include an equal proportion of all days of the week and coverage of all four seasons.

Diet History

The diet history consists either of an interview administered 24-HR or establishing usual eating pattern over a 1-week period, followed by a frequency questionnaire to provide additional information. The dietary history provides a representative pattern of usual intake and is interview administered only.

Food Frequency Questionnaires

FFQs consist of a list of specific foods or food types associated with frequency of consumption. They are termed semi-quantitative if portions are included. Most questionnaires specify a frequency response in relation to an average or medium portion but some request records of specific portions. The period

of record is usually the previous month or year. FFQs provide an indication of usual intake and can be used to obtain population estimates of frequency of consumption of food types.

FFQs need to be developed for specific population groups otherwise important foods may be missed. FFQs may become outdated if the supply of foodstuffs changes. FFQs consist of a fixed food list, which may be a disadvantage for prospective studies as hypotheses to be tested are limited by the list. Factors that affect the response to FFQs are the literacy and numeracy of respondents as some mathematical ability is necessary to calculate relative frequencies, the length and complexity of the food list, and the influence of current diet. Not all respondents will relate frequency to portion size accurately.

In the US examples of FFQs are the Block and Willett questionnaires. In Europe FFQs were developed for the European Prospective Investigations into Cancer and Nutrition (EPIC) study in the Netherlands, Germany, Greece, Italy, Denmark, France, and the UK.

Weighed Food Record Inventory and Estimated Food Record

For weighed food records (WRs) all food consumed over a period is weighed and recorded with details of food type and method of preparation, on preprinted forms or booklets, to obtain consumption over a period of days. Portable scales need to be supplied. WRs may include some estimated items eaten out of the home. Leftover food should be weighed and deducted. The recommended time period for records is 4–7 days or more, although the number of days depends on the nutrient of interest, study population, and objectives of the study. As some populations have different eating habits at weekends, weekend days should be included proportionately.

For estimated food records all foods consumed over a period are recorded with details of food type, method of preparation, and estimated portions over a period of days (see **Table 2**). If recorded over 7 days, this may be called a '7-day diary'.

Both these methods have a high respondent burden and need cooperative, literate respondents. Respondents require training in the level of detail needed to describe foods. It is also possible that respondents may change usual eating patterns to simplify the process of the record. It is also beneficial to include a review of weighed records during the period of recording either after the first day or at the end.

Duplicate sample technique

Duplicate samples of all foods consumed are made and the nutrient content analyzed. This method is used for metabolic studies and though providing greater accuracy than other methods, its use is not feasible for most purposes.

Further Information

Although nomenclature for dietary methodology is reasonably consistent, care should be taken when reading the literature as methods with the same name may have been applied differently. The final decision over which method to choose will depend on the aims of the study, the population for study, the potential burden on respondents, and the resources available. Household surveys and food balance sheets provide data for per caput but not individual intake. In general, individual and the more intensive methods are associated with higher costs and respondent burden, whereas household methods are more economical and have a lower respondent burden.

Clinical Practice

Dietary methodology for clinical practice requires rapid assessments of nutritional intake in order to prescribe dietary change or to improve nutritional status. Traditionally, 24HR of 'usual' intake or diet histories have been used for this purpose. Food frequency questionnaires and weighed or estimated food records are not generally used due to the more intensive burden on respondents and on the resources required for coding and processing the data.

There is considerable discussion over the optimum method to use for establishing individual dietary intake and studies designed to measure the validity of methods suggest that those that are more intensive and detailed lead to greater measurement precision, justifying the greater cost. Confirmation of these findings is required. Despite these potential benefits if resources are unavailable less intensive methods tend to be used.

Factors Affecting Individual Ability to Report Intake Accurately

Factors governing individual accuracy and quality of reports are respondent's literacy and numeracy skills; preconceived ideas on the purpose of the enquiry and, for list-based methods, the interpretation and meaning of food names. Individuals may make errors when measuring and recording food weights or estimating weights of foods consumed.

There is also respondent variation in the perception of the size of portions represented by photographs.

Interviewers

The aim of using interviewers with dietary methods is to obtain a complete, accurate, and detailed record of what respondents eat. Therefore, it is important for interviewers to be well trained and have an awareness of food composition and preparation techniques. Ideally, interviewers should be educated in nutrition (dietitians or nutritionists), although nonnutritionists can be trained to standardized techniques, and come from the same cultural or ethnic background as the study population. Interviewer protocols should be developed.

Computerized Interview Procedures

Computerized interview systems can aid interviewers by prompting for specific questions to elicit sufficient and specific detail and reduce the burden on interviewers. Examples are the Minnesota Nutrition Data System and the EPIC-SOFT systems, used in the US and a number of European countries. Although computerized interviews have advantages in improving accuracy and standardization, and in saving time and effort when recording and coding data, interviewers do have to be competent with computers and the resources required to develop systems are high.

Using Dietary Methods in Different Populations

Ethnic subpopulations may consume different food types than a main population and baseline surveys will be required to establish what types of foods and method of preparation are common. This information would be required before list-based methods such as the FFQ could be developed.

Recall of Remote Diet

Investigators may wish to recall diet in the remote past, perhaps of many years. However, interpretation of remotely recalled dietary data is complex as recalled diet is heavily influenced by current dietary habit. Some studies have found that the correlations between recalled past diet and current diet were higher than the correlations between actual past diet and recall of past diet. The onset of diseases such as cancer may affect the appetite and dietary intake of study participants and as recall of remote diet is strongly related to current diet, may affect recall of remote diet. As diet prior to the onset of disease is the measure of interest, it is preferable to collect dietary information prospectively, that is before disease onset. Case–control studies in which the diet of cases with disease is compared with controls may be affected by altered perception of recalled diet, particularly by cases.

Reproducibility of Dietary Methods

The reproducibility of a method may also be referred to as reliability, repeatability, or precision and is a measure of the extent to which the same results can be obtained when repeated under the same conditions. Repeated measures provide an estimate of the within-person variability of intake. However, interpretation of the repeatability of measures is difficult as a lack of consistency may be due to genuine change over a time period or a lack of sensitivity or specificity of the method used to measure intake.

Use of Data and Conversion of Reported Intake to Nutrients and Food Types

Qualitative Analysis

Dietary method data can be used qualitatively, for instance during the process of reviewing nutritional intake for the purpose of dietary treatment as in clinical practice. Data on frequency of consumption may also be collected and analyzed by the FFQ method without conversion to nutrient intakes. However, even for qualitative analyses it is likely that paper-based dietary methods will require conversion to an electronic format. The majority of uses of dietary methods are targeted towards quantitative analyses.

Quantitative Analysis

The data collected by dietary methods are converted into food and nutrient consumption by calculating the amount of food eaten and linking this to a database with values for the nutrient composition of foods.

The databases of nutrient composition of foods are provided by the governments of many countries. They consist of nutrient composition data for the average composition of commonly consumed foodstuffs and are usually available as printed publications, computerized databases, or as part of software packages. Values in nutrient composition databases are expressed as either per 100 g of food or per common household measure. Nutrient databases vary in the coverage and comprehensiveness of the foods and nutrients. They are revised periodically to cover newer foods of different nutrient compositions or to modify or extend the nutrient coverage. Some issues concerning the choice of nutrient databases are shown in **Table 4**. It is important to read the

Table 4 Factors to consider when choosing a nutrient database to calculate nutrient intakes

Comprehensiveness of food item and beverage coverage?
Does the database contain entries for important foods consumed by the population to be studied?
How comprehensive is the coverage of nutrients?
Does the database contain data for mixed or multiple ingredient recipes or dishes?
What analytical techniques were used to derive nutrients in the database? (There can be differences in nutrients measured by different techniques)
Are the data officially evaluated?
What compilation methods were used to construct the database?
Which conversion factors are used to calculate metabolizable energy content of foods for protein, fat, carbohydrate, and alcohol?
What proportion of missing values exists within the database? (Missing values are counted as zero in calculations, resulting in systematic underestimates of intake.)
For international studies or comparisons how do the analytical methods for determining nutrient composition and compilation techniques affect the resulting data?

information distributed with the printed or electronic versions of databases to determine the uses and limitations of the data.

Several steps are involved in calculating nutrient intake (also known as coding or processing). The first is to choose an item in the database, which corresponds most closely with the food consumed. If the food consumed is not in the database a suitable alternative can be chosen by considering food type, general characteristics, and likely nutrient profile. Once the food has been chosen the nutrient composition of the food quoted in the database is multiplied by the amount of food eaten, e.g., for 60 g food the nutrients would be multiplied by 0.6 (where nutrients are expressed per 100 g of food).

To calculate daily intake for an individual the contribution of each food is calculated and all the foods for a day summated. If more than one day's data have been collected it is usual to calculate the average of the number of days recorded. Data from FFQs are usually computed to consumption per day but can also be computed per week.

Although it is possible to compute intake by hand, using a calculator and a printed copy of a nutrient database, this is very labor intensive and in practice for most purposes has been superseded by computerization.

Data Processing and Computing Dietary Intake

The same care as that invested in data collection should be applied to data processing as errors of great magnitude may be introduced.

Estimated Food Quantities

To obtain quantitative information for nutrients or food groups, actual or estimated food weights are used. For methods using estimated food weights, values also need to be found for foods described such as standard units, average portions, or household measures. Sources of data are national publications, surveys of weighed dietary intakes, and food manufacturers. Data may also be included in nutrient calculation programs. Portion weights need to be population specific and, if unavailable, studies to establish values will be needed. Intensive methods used for large-scale surveys will require databases of more than 20 000 values for portion weights.

Data Entry and Nutrient Calculation Systems

A number of computerized data entry systems and nutrient calculation programs exist; factors that need to be considered when choosing a system are given in **Table 5**. The features required depend on the intended use of the data but as a minimum should include a list of foods, weights of portions, and a nutrient composition database. Ideally, systems should enable entry of data in sufficient detail to fulfil hypotheses for investigation and include measures to ensure consistent entry by staff such as defaults for inadequately reported foods, portions, or mixed component foods. They should also include a method for entering newer foods with different nutrient composition from the existing nutrient database. This is particularly important, as the range of new foodstuffs and products with different nutritional characteristics is ever increasing.

Computerized systems and nutrient databases become out-dated and for large-scale prospective studies it is desirable to develop systems with a flexible approach to updating by using database technology.

Data Processing Errors

Errors arising during the coding (data entry) and processing of individual dietary methods (24-HR,

Table 5 Factors to consider when choosing a computerized entry or interviewing program

Speed of the assessment
Requirements of the study for detailed or general data
Food composition database used
Food portion database used
Cost of the system
Facilities for organization of data
Ability to extract nutrients or food groups from the system
How up to date are the nutrient composition databases included in the system?
Commercial availability

diet history, weighed and estimated records) need to be avoided. Misclassification can arise due to human error if incorrect foods are chosen during coding, for instance, if milk was consumed in the full-fat form but was coded for skimmed milk. This may also arise where a food has local or alternative food names, which may be unknown to the coder. It is important to have a qualified nutritionist available to develop a protocol for training staff, answering queries, and dealing with ambiguities. Coders should have knowledge of food composition and food preparation techniques. It is difficult to control entry of incorrectly matched foods but careful checking and staff training are crucial in preventing this. Other potential errors are entry of incorrect quantities or multiplication factors for portion weights and missed items, problems that can occur even with structured computer programs. So, systematic post-entry checks to identify extremes of portion weights or nutrient values and the verification and correction of data are necessary.

Issues Associated with Measurement of Dietary Intake

Measurement Error

There is potential for the occurrence of measurement error with the measurement of any exposure such as when using dietary methods to measure nutritional intake. Errors may arise as a result of flaws in the design of the measurement instrument or during data collection or processing. Measurement error may also occur as a result of individual characteristics of participants in studies. Measurement error can be defined as the difference between the measured exposure (or measure of dietary intake) and the true exposure. All measurement of dietary exposures is subject to some degree of measurement error making it difficult to achieve measurements of true intake.

Efforts to reduce measurement error during data collection and processing should be introduced into the protocol of all studies, however, even if preventative measures are taken it is impossible to eliminate it altogether. It is difficult to identify the type and structure of measurement error associated with dietary intake. Measurement error may occur because of inaccurate reporting by respondents. It may also vary according to dietary method, for instance, food items within record methods may be intentionally or unintentionally omitted and with FFQs frequency of consumption may be inaccurately reported. Systematic bias, interviewer bias, recall bias, and social desirability bias have been identified but there are likely to be other sources of error. (Bias can be defined as the modification of a method of measurement by a factor, which influences the measurement in one or more directions.) Measurement error associated with dietary methods may consist of one or more types of error.

Measurement Error in Data Collection and Processing

Systematic bias Systematic bias is a systematic mismeasurement of data and can occur, for instance, if equipment such as weighing scales under- or overestimates values or if an interviewer consistently fails to use questions to probe for consumption of snacks and additional foods. If systematic bias can be identified solutions can be found, for instance, by calibrating equipment or training and monitoring interviewers.

Interviewer bias The behavior of an interviewer can influence the response of interviewees leading to interviewer bias. The degree of rapport between interviewer and respondent also influences results. Bias may occur if interviewers omit responses or record them incorrectly. Trained interviewers should ask open-ended questions in a neutral or nonleading manner, and not imply that a food or beverage should or should not have been consumed and avoid value judgments.

Social desirability bias Social desirability bias can influence dietary measures as respondents strive to report what they think is required not what was actually consumed, for example, reporting less alcohol consumption than is the case or greater consumption of foods with perceived health benefits such as fish, fruit, or vegetables. This is likely to be the cause of mis-reporting, under-reporting, or low energy reporting, which occurs in certain respondents. It is possible to predict how much energy a respondent should report, as this is the amount required to maintain a stable weight. (Weight will be either gained or lost if more or less energy is consumed than required.) As energy intake should equate to energy expenditure, expenditure effectively measures intake. Techniques for measurement of energy expenditure such as whole body calorimetry and doubly labeled water can be used. Using these techniques those individuals classified as low energy reporters are likely to be older, more overweight, and of lower educational and socioeconomic status than the rest of the population. Low energy reporters tend to have lower consumption of foods in the groups cookies, cakes, puddings, confectionery (candy) and

sugary foods and, in some populations, lower consumption of spreads, cooking fats, and potato chips. Interviewers should be aware of low energy reporting, aim to be entirely nonjudgemental, and also request participants make complete records of food intake.

Impact of Measurement Error

As the proportion of error within a measurement increases, the accuracy of the measurement decreases and the results using the measurement will become less interpretable. Hence, greater measurement error reduces the likelihood that the truth has been measured with accuracy and increases the likelihood that analyses relating diet to disease status will tend towards null results. The effect of measurement error is to mis-classify an individual within a range of intake.

Validation of Dietary Methods

Validation is used to quantify the measurement error that occurs when measuring dietary intake exposures. It requires two measures: a main measurement and a second measurement subject to less measurement error than the first. The errors of the two measurements should be independent. Validation is used to estimate the proportion of measurement error within the main method by modeling the differences between the main and the secondary measurement. It had been considered that dietary methods had errors independent of each other and that record methods such as 24-HR could be used, but it is now known that the errors are not independent as individuals report in the same way with different methods. Therefore, it is better to use biological variables measurable in blood or urine (also known as biomarkers) as the second measure for dietary validation. Examples are vitamins, minerals, and individual fatty acids in blood such as vitamin C and carotenoids or urinary excretion over 24-h of nitrogen, potassium, and sodium. Examples of validation studies are those performed within EPIC-Europe and the Observing Protein and Energy Nutrition Study (OPEN) in the US. Work is ongoing to extend the number of biomarkers available and to define further and elicit the structure of measurement error.

Use of Calibration Methods to Adjust for Measurement Error

In contrast to validation, which attempts to identify the type and scale of measurement error, calibration is designed to adjust for systematic over- or underestimation in dietary intakes within populations. It may also be used at the individual level to attempt to correct for attenuation bias (or dilution) in relative risk due to errors in dietary measurements. Calibration of data has been proposed for large multicentre nutritional studies that have used different dietary methods to capture population-specific diets. Calibration studies require a highly standardized second dietary measure to be used in a representative sub-sample from each cohort to form a common reference measurement across populations. An example of this approach has been used by the European EPIC (European Prospective Investigations into Cancer and Nutrition) Study using a computerized, standardized 24-h recall in ten countries.

Future Developments

Future developments in methodology are likely to use computing, digital, and Internet technology, such as videos of food eaten and online programs for self-reported intake. Use of Dictaphones and combinations of weighing and other recording equipment are also possible.

The number of foodstuffs available, particularly of manufactured foods and ready-made meals, will continue to increase, presenting challenges for those attempting to estimate nutrient intake. Nutrient databases will continue to be expanded and updated to incorporate newer food items and nutrient measurements available using improved analytical techniques.

In some populations more than 40% of individuals have been shown to consume supplements and as very few comprehensive databases of vitamin and mineral supplements exist these need to be developed, as supplements can make a major contribution to nutrient intakes.

Validation

M Nelson, King's College London, London, UK

Although the basic approaches to dietary assessment have changed little in the past 20 years, there has been a growing awareness of the ways in which errors in dietary assessment may undermine an understanding of diet–disease relationships. There have been two stages in this process: (i) acceptance of the fact that every measure of food consumption is likely to be influenced by the reporting process and (ii) the improvements in the methods for estimating the size of the difference between what is observed and the likely true values for countries, households, or individual subjects. This article examines the techniques for coping with the sources of error in the assessment of diet, particularly through the use of biochemical and statistical techniques that are available to evaluate the quality or enhance the interpretation of dietary data.

Reproducibility and Validity of Dietary Intake Measurements

Reproducibility, Repeatability, and Reliability

'Reproducibility' is the extent to which a tool is capable of producing the same result when used repeatedly in the same circumstances. The terms 'repeatability' and 'reliability' are often used synonymously with 'reproducibility.' All of these terms are equivalent to the word 'precision,' often used by biochemists to describe the variation of a measurement based on repetition of a particular assay using a single piece of equipment.

A measurement may have good reproducibility and yet have poor validity, but a measurement that has good validity cannot have poor reproducibility.

In reality, 'the same circumstances' can never exist in relation to dietary measurements because diet (whether of individuals, households, or countries) varies over time, be it on a daily, weekly, seasonal, or annual basis. In epidemiological studies, the aim is usually to assess 'usual' intake. Part of the variation in any dietary measurement will thus relate to genuine variability of diet. The remaining variation will relate to biases associated with the method. Due consideration must be given to these time-related factors when evaluating the reproducibility and validity of dietary measures, and a well-designed validation study will separate the variability associated with reproducibility (the error in the method) from that associated with genuine biological variation over time.

Validity

Validity is an expression of the degree to which a measurement is a true and accurate measure of what it purports to measure. Establishing validity requires an external reference measure against which the 'test' measurement (the one being used in the main survey or research activity) can be compared. In nutrition, there is no absolute reference measure of the truth. Every measurement of dietary intake includes some element of bias. The best that can be managed is to assess relative or congruent validity of measurements, comparing results obtained with the test instrument with what are believed to be more accurate measures of food or nutrient intake obtained, for example, using a biological marker.

There are two main problems arising from inaccurate measurements:

1. Incorrect positioning of a country, household, or person in relation to an external reference measure (e.g., dietary reference values)
2. incorrect ranking of countries, households, or people in relation to one another

The first type of error can result in inappropriate investigations or actions being taken to remedy an apparent dietary deficit or excess that does not really exist. Alternatively, no action may be taken when some is needed (e.g., a true deficit is not detected because diet is overestimated). The second type of error tends to undermine the ability to assess relationships between diet and health. For example, if someone who properly belongs in the top quarter of the distribution of saturated fat intake (associated with an increased risk of heart disease) is classified in the bottom quarter because he or she underreports his or her true fat intake, the relationship between fat intake and outcome (risk of heart disease) will not be shown. Again, this can lead either to inappropriate recommendations for improving health in the population or, more often, to a failure to take action because the true relationship between diet and health is obscured by measurement error.

Table 1 lists some of the sources of measurement error, their principal effects, some ways of taking errors into account in analysis, and ideas for dealing with them in practice. At the national level, errors in reporting of food production, imports, exports, food moving in and out of stocks, and nonfood uses (e.g., sugar used in the brewing industry) tend to produce overreporting of food and nutrient availability in economically developed countries and underreporting in developing countries. The consequences for between-country comparisons will therefore vary nutrient by nutrient. Where true values are higher in developed countries and lower in developing countries (e.g., energy), a tendency in wealthier countries to overstate consumption and in poorer countries to understate consumption will exaggerate the true differences between countries (**Figure 1**). Where true intakes tend to be higher in developing countries and lower in developed countries (e.g., nonstarch polysaccharides), such biases in measurement will minimize any apparent differences between countries. These types of errors do not lend themselves easily to correction or adjustment. The best solution is to try to improve reporting mechanisms that reduce duplication or omission, although this may be particularly problematic in developing countries, in which a high percentage of the population is engaged in subsistence agriculture.

At the household level, information can be obtained from records of food acquisitions (expenditure and/or amounts), often referred to as household budget surveys. Errors associated with the recording process (omission and misrecording) will contribute to the error of estimates of consumption. Keeping a record of purchases can lead householders to alter their usual purchasing patterns or encourage purchasing in excess of true requirements (especially easily storable items such as flour, sugar, oil, and cooking or spreading fats). Some form of cross-check is necessary—either an internal reference measure such as a cross-check list of foods purchased or used at mealtimes or an external reference measure such as an independent assessment of food consumption by all household members. There are problems related to the estimation of waste and the amount of food given to pets. The true amount of food wasted cannot be known, and direct measures of waste are likely to introduce bias into the measurements. Adjustments for waste range from 4 to 10%, and 6% is a typical value for average waste.

In household budget surveys, the amounts of food eaten away from home (or, more correctly, derived from outside the household food supply) are sometimes measured directly by individual household members who keep records of their food and drink consumption away from home. Alternatively, the amount of food eaten from outside the household food supply can be measured indirectly by asking the main household respondent to record which meals have been consumed from the household food supply and the ages and genders of all people present at those meal, including any visitors. The menu records do not usually include information about snacks between meals. Whether based on the direct or indirect method, household surveys tend to underestimate the amount of food eaten away from home and thus to overestimate the proportion of the diet consumed from the household food supply.

The estimate of the nutrient content of the diet in household-level surveys is based on nutrient conversion factors. These differ from food composition data. Food composition data reflect the chemically determined nutrient content of foods. Nutrient conversion factors modify these values to allow for preparation and cooking losses so that the final estimate of the nutrient content of the diet relates the amount of food initially purchased to the amount of food and nutrient likely to be consumed. There are many assumptions in the determination of the nutrient conversion factors (e.g., the proportion of water-soluble vitamins lost in the cooking process). The result may be an over- or underestimate of

Table 1 Sources of error at different levels of dietary assessment, their effects, ways to adjust for measurment error in analysis, and ways to minimize error in data collection

Level of assessment	*Source of error*	*Effect of error*	*Statistical adjustment*	*Ways to minimize*
National: Food balance sheets	Inaccurate values of food production, imports, exports, storage, nonfood uses	Over- or underemphasizes apparent differences between countries	Not possible; error likely to vary nonsystematically between countries	Improve reporting mechanisms and estimates of waste and production losses
Household: Household budget surveys, with or without larder inventories	Omission of food items	Underestimation of consumption, especially for certain foods (e.g., sweets)	Inflate estimate of intake to compensate for known underestimation	Cross-check food purchasing list at final interview
	Misrecording of food items	Misrepresentation of true consumption pattern	Not possible; likely to differ between households for different foodstuffs	Cross-check food purchasing list at final interview
	Distortion due to effect of survey (e.g., selection of items believed to be 'healthy')	Misrepresentation of true consumption pattern	Not possible; likely to differ between households for different foodstuffs	Cross-check food purchasing list at final interview
	Overpurchasing stimulated by measurement process	Overestimation of consumption, especially for certain foods (e.g., flour and sugar)	Deflate estimate of intake to compensate for known overestimation	Validate purchasing against reference measure of actual consumption at individual level (for all household members)
	Estimate of amount wasted or given to pets	If amount is underestimated, leads to overestimation of consumption (and vice versa)	Deflate estimate of intake to compensate for known overestimation (or inflate)	Improve estimates of waste through surveys
	Estimate of amounts of food eaten away from home or consumed by visitors, based on menu records	If amount is underestimated, leads to underestimate of total consumption (if overestimated, leads to overestimation)	Inflate estimate of intake to compensate for known underestimation (or deflate)	Household members keep records of amounts eaten away from home (but see problems with records kept by individuals)
	Use of nutrient conversion factors	Unknown biases introduced into calculation of the nutrient content of the diet	Not possible; errors not systematic between foods	Improve estimates of nutrient content and of preparation and cooking losses
Individual: prospective or retrospective methods	Underreporting	Underestimate of usual intake	Calibrate result against valid measure of intake and adjust accordingly	Use more than one measure of intake, including valid reference measure
	Differential misclassification	The error in measurement not consistent between subgroups, making valid comparisons impossible	Identify likely error according to characteristics on which subgroup comparisons are to be based, and adjust accordingly	Undertake appropriate validation studies within subgroups
	Distortion of usual diet (prospective recording or retrospective recall)	Overestimation of intake of some foods and nutrients and underestimation of others	Not possible unless nature of distortion is known for different foods and for different subgroups	Use biomarkers of intake to confirm dietary measures; use more than one measure of intake, including valid reference measure

Adapted from Nelson M (1998) Methods and validity of dietary assessment. In: Garrow J and James WPT (eds.) *Human Nutrition and Dietetics*, 10th edn. London: Churchill Livingstone.

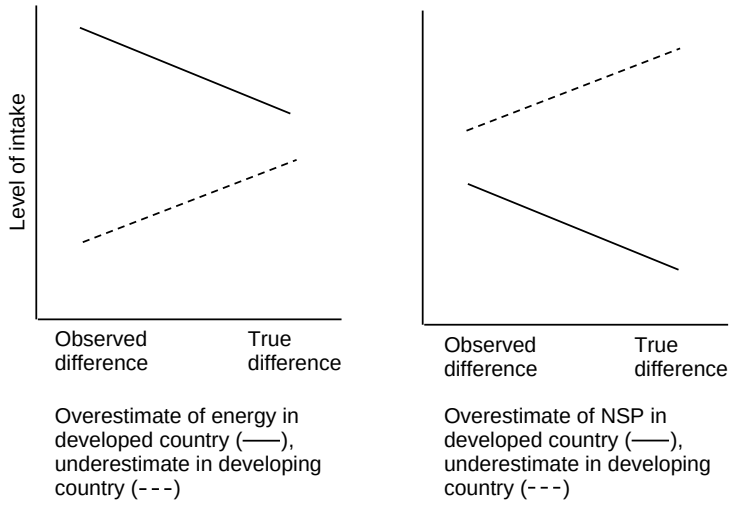

Figure 1 Effects of measurement error on between-country comparisons of nutrient availability.

the actual nutrient content of the diet consumed, depending on the nutrient concerned.

At the individual level, the high reproducibility of results using a given technique led researchers for many years to assume that the observed results were valid. Reproducibility was confused with validity. Researchers argued that the results from their chosen technique were correct, but they were unable to explain adequately why measurements of the same diets using different techniques yielded different results. It is now clear that different techniques introduce different types of errors in assessment. Moreover, one can argue that the main sources of error in the assessment of diet at the individual level (e.g., errors in perception of frequency of consumption and of food portion sizes; the desire to increase the reporting of those foods perceived as being 'healthy' or to reduce the reporting of foods perceived as being 'unhealthy'; and items forgotten, intentionally or unintentionally) are not readily amenable to correction.

The most common error in the assessment of diet at the individual level is underreporting. Thus, the mean estimate of energy intake in a group of subjects that includes people who underreport their true consumption is also likely to be an underestimate. Moreover, any comparison of subgroups that include different proportions of underreporters will yield a false picture of the relationships between subgroups. For example, when comparing energy intake based on 7-day weighed records between normal weight and overweight subjects, it is often observed that the overweight subjects (whose energy requirements are higher) will report energy intakes equal to or less than those of the normal weight subjects. This is because overweight subjects show a strong tendency to underreport their usual consumption levels, particularly of foods with a high proportion of fat. It is worth noting that there is also a small group of subjects who overreport their usual consumption, but their characteristics are less readily defined.

In many validation studies, comparisons are made between methods to establish 'concurrent validity,' often between a new instrument such as a food frequency questionnaire and a more established technique such as a weighed inventory of diet. **Table 2** summarizes the problems associated with the use of specific dietary reference measures. The

Table 2 Limitations of dietary reference methods appropriate for validation of dietary assessment measures

Reference method	*Limitations*
Weighed records and household measures	Underreporting Unrepresentative of 'usual' diet over sufficient number of days Distortion of food habits due to recording process
Diet history	Interviewer bias Inaccuracy of portion size reporting due to conceptualization and memory errors Errors in reporting of frequency, especially overreporting of related foods listed separately (e.g., individual fruits and vegetables) Requires regular eating habits
Repeat 24-h recalls	Under- or overreporting of foods due to reporting process (e.g., alcohol underreported and fruit overreported) Unrepresentative of 'usual' diet over sufficient number of days Inaccuracy of portion size reporting due to conceptualization and memory errors

principal error is likely to be underreporting within certain subgroups, and any validation study needs to address this. Issues regarding distortion of diet are more difficult to identify, however. Work has been carried out to identify some of the errors associated with perception, conceptualization, and memory in relation to assessment of food portion sizes. Agreement between methods is no guarantee of validity. If the two methods are biased in the same way (e.g., using a diet history to validate a short food frequency questionnaire), then the observed level of agreement is likely to overstate the validity of the new method. If the validation is based on repeated measures and the errors in the reference assessment are repeated (e.g., validating a food frequency questionnaire against repeat 24-h recalls), then the level of agreement between the two methods is likely to underestimate the true correlation between the test measure and the truth because the true variance of diet will be underestimated by the reference measure.

Some types of bias may influence reporting in a similar way in all subjects. For example, if a food frequency questionnaire does not ask for sufficient detail about tropical fruit consumption in a survey of West Indian families living in London, then all responses are likely to be biased in the same way. This will result in nondifferential misclassification: Everyone's intake of tropical fruit (and hence vitamin C and carotene intake) is likely to be similarly misclassified. If, on the other hand, the nature of the bias is likely to be related to individual characteristics—for example, West Indian women overreport their tropical fruit consumption compared to West Indian men—then the tropical fruit intake of men and women will be misclassified in different ways in different subgroups. This is known as differential misclassification. If the risks for men and women are being compared in a diet–disease analysis, the errors in the estimates of those risks will not be the same for both groups.

There are many factors in addition to body size or gender that may influence the ability of a dietary measure to estimate accurately the level of food consumption or nutrient intake. **Table 3** lists the potential confounders of good dietary reporting that may affect validation studies. If there is concern about misclassification in one group (e.g., smokers) being different from misclassification in another group (e.g., nonsmokers), then validation must identify the extent of misclassification in the two groups independently so that it can be compensated for in any subsequent analyses. It is therefore important to measure all of the potential confounders that may be a source of misclassification (differential or nondifferential).

Table 3 Factors that may influence the reliability and validity of dietary assessments and that may need to be measured in a validation study

Related to the subject	*Related to the measuring process*
Age	Portion size
Gender	Interviewer
Height, weight, etc.	Learning effects
Region	Recency effects
Social class	Lag time
Education	Number of foods on an FFQ
Language	Nutrient database
Culture and ethnic background	
Smoking	
Social approval	
Social desirability	

The design of a validation study must also reflect the purpose for which the dietary assessment is being carried out. Most dietary assessments measure current or recent consumption. However, if the aim is to estimate past diet related to the induction of cancer 10 years before the time of the assessment (e.g., in a case–control study), then the validation process should in theory address the relevant time period. In practice, this may be very difficult (i.e., if there is no robust reference measure of diet relating to the relevant time period). In such circumstances, the weaknesses of an unvalidated test measure should not be overlooked nor understated.

Use of Biological Markers to Validate Dietary Intake Measurements

Nutritional biomarkers are those elements or compounds in biological samples capable of reflecting relationships between diet, nutritional status, and disease processes. Not all biomarkers are suitable for use in dietary validation studies. One of the key features of a marker should be its ability to reflect intake over a wide range of intakes.

Figure 2 shows the sequence whereby food or drink containing potential biomarkers (nutrients and nonnutrients) may be ingested, absorbed, distributed, and excreted. The stages in the top of **Figure 2** are not usually amenable to sampling (e.g., taking samples of gastric contents), and it is only in the later stages in which compounds are in circulation, present or stored in tissues, or excreted that they are more readily sampled. The complexity of the relationship between intake and the measured levels of biomarkers in these lower stages, however, may limit the usefulness of certain compounds in validation studies. **Figure 3** illustrates for four nutrients the varying relationships between tissue levels

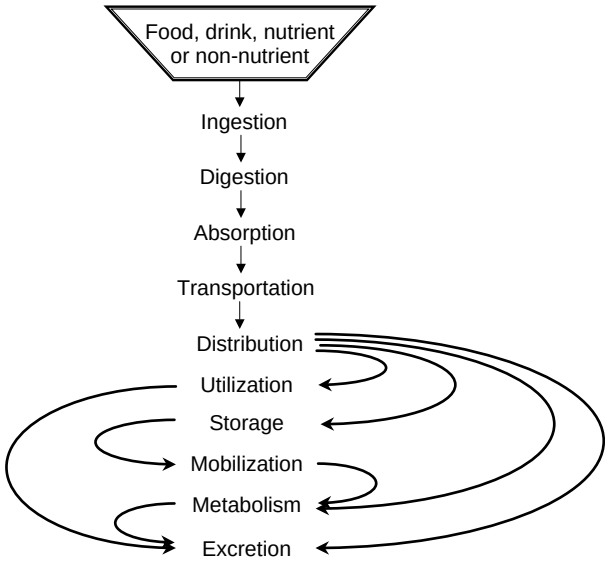

Figure 2 Stages in the pathway between intake and measurement of biomarkers.

and levels in diet. Vitamin E shows a more or less linear relationship between blood and dietary levels across a broad range of intakes. Riboflavin appears in urine only after tissues are saturated and any excess is excreted. An alternative measure to assess riboflavin, erythrocyte glutathione reductase activity coefficient), is a sensitive biomarker of intake only at low levels. Vitamin C in blood is a poor marker at low levels of intake, increases in sensitivity as a marker of intake across the middle range of intakes, and is poor once again at high levels of intake where excess vitamin is excreted in the urine. Retinol is stored in the liver and its level in blood is controlled homeostatically. It is therefore a poor marker above relatively low intakes. A further problem is the point in time or span of intake reflected by the marker. **Figure 4** shows that some markers relate to intakes days or weeks prior to the sampling point (e.g., energy and doubly labeled water), whereas other may reflect intake over months (iron intake reflected by ferritin) or years (calcium intake reflected by bone mass). The influence of other factors relating marker to intake (e.g., hem versus non-hem iron in the diet, and the influence of vitamin C or dietary fiber on absorption) may undermine the ability to conclude that a low measurement of a marker is necessarily a reflection of low dietary intakes. Thus, the value of markers in assessing the validity of intake measurements is often limited to specific ranges of intake in diets of known composition. This may not be sufficient for epidemiological purposes, where the entire range of intake may be of interest in relation to disease risk.

The two most widespread uses of biomarkers for the assessment of the validity of measures of diet are to identify under- or overreporters and to assess the correctness of ranking of individuals according to their nutrient intake.

Techniques for Identifying Under- and Overreporters

Doubly labeled water The scientific basis that underlies the doubly labeled water method for estimating energy expenditure relies on the differential rates of loss of hydrogen and oxygen from the body at different levels of energy expenditure. Hydrogen is lost primarily in water, whereas oxygen is lost in

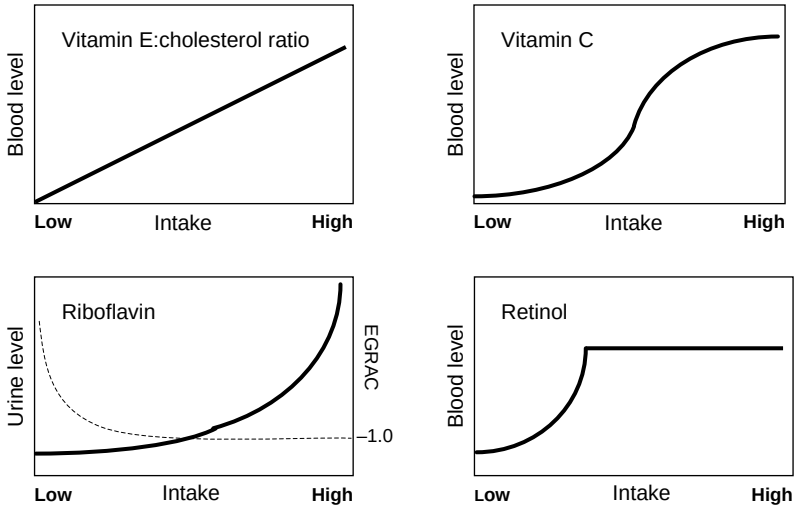

Figure 3 Associations between intake and biomarker over a wide range of intakes: vitamin E:cholesterol ration, vitamin C, riboflavin, and retinol. EGRAC, erythrocyte glutathione reductase activity coefficient. (Adapted from Kohlmeier L (1991) What you should know about your biomarker. Figure 4 Time scale over which different biomarkers may reflect the relationship with intake.

both water and carbon dioxide. The relative rates of loss can be used to estimate energy expenditure in free-living subjects over a period of approximately 2 weeks, thereby providing a reference measure for energy intakes over a similar period. Provided the subject is in energy balance (neither gaining nor losing weight due to changes in body composition), the measures of expenditure and intake should agree. The technique allows for identification of both under- and overreporters. The boundaries of acceptability of the test measures (e.g., to within $\pm 10\%$ of habitual energy intake) need to be chosen according to the needs of the study in which the validity of the test measure is being assessed. The level of agreement between test and reference measure will dictate both the precision of the estimate of mean intake for an individual or subgroup and the extent to which subjects will be misclassified when ranked according to level of intake.

The main disadvantage of the doubly labeled water technique is its high cost. In a large-scale study, it is not feasible to use doubly labeled water with every subject in order to assess the completeness of dietary records. The technique is therefore usually used to assess validity of the test measure in a sample of subjects who are taken to be representative of the sample for the main study.

Another disadvantage is that doubly labeled water provides a marker for energy only. The diet recorded could differ substantially from the subject's usual diet but have an energy content in agreement with the estimate of energy expenditure. In the absence of additional information about usual patterns of food consumption, such a record would be regarded as valid. A further problem is that not all food consumption or nutrient intake correlates strongly with energy intake. For example, fruits and vegetables and their associated nutrients (e.g., vitamin C, beta-carotene, and potassium) may be overreported in a dietary assessment in which energy intake agrees well with energy expenditure, but the overreporting would not be identified. These comments are summarized in **Table 4**.

Urinary nitrogen and potassium excretion A second technique for identifying under- or overreporters is to collect 24-h urine samples and compare the amounts of nitrogen and potassium excreted with the amount ingested. Allowing for incomplete absorption and losses of nitrogen from the gastrointestinal tract (digestive juices and shed epithelial cells), hair, skin, and sweat, the amount of nitrogen excreted should be approximately 81% of the nitrogen ingested. Allowing for daily variations in intake and excretion, if daily recorded intake of nitrogen is less than 70% of the corresponding urinary nitrogen excretion over the following 24 h, the respondent is likely to have underreported his or her usual consumption; anyone whose recorded intake of nitrogen is more than 100% of their excretion is likely to have overreported their consumption. The more days of intake and excretion data that are collected, the better the agreement over the recording period should be for subjects who are in nitrogen balance. If urinary nitrogen is to be used as a marker for the completeness of dietary recording, it is helpful to have at least 4 days' worth of data (diet and urine). For potassium, the expected urinary excretion is 95% of the intake, with limits of 80 and 110% for 'good' reporting.

As with doubly labeled water, it is assumed that the subject is in balance, neither losing nor gaining body nitrogen or potassium.

Table 4 Limitations of biological reference methods appropriate for validation of dietary assessment measures

Reference method	*Limitations*
Doubly labeled water	Energy only
	Assumptions of model regarding water partitioning may not apply in cases of gross obesity, high alcohol intake, or use of diuretics
	Very expensive
	Analysis technically demanding
Urinary nitrogen: completeness of samples confirmed using PABA	Protein only
	PABA analysis affected by paracetamol and related products
Urinary nitrogen only	Protein only
	Danger of incomplete samples
Biochemical measurements of nutrients in blood or other tissues	Complex relationship with intake mediated by digestion, absorption, uptake, utilization, metabolism, excretion, and homeostatic mechanisms
	Cost and precision of assays
	Invasive
Energy intake:BMR ratio	Imprecision of estimate of BMR based on body weight and regression equations
	Single cutoff point (e.g., EI:BMR <1.1) will not identify low-energy reporters with higher habitual energy expenditures
	Higher estimates of cutoff (e.g., EI:BMR <1.2) captures more true low energy reporters but also more good reporters

It is important to ensure that the urine collections are complete. This necessitates the use of an inert metabolic marker (para-amino benzoic acid (PABA)), which is rapidly absorbed and excreted. Subjects take a divided dose of 240 mg PABA throughout the day. At least 85% of the PABA should be recovered in the urine in a 24-h collection. If the amount recovered is less than 85%, the urine sample may be regarded as incomplete and therefore not suitable for analysis of nitrogen in order to check the completeness of the dietary record. Because paracetamol and related compounds interfere with the PABA assay, a measure of excretion over 115% of the administered dose would be suspect.

As with doubly labeled water, the principal weakness of urinary nitrogen as a marker for the completeness of dietary records is that many foods contain low levels of nitrogen but may be important sources of other nutrients. Any check for the completeness of dietary records based on nitrogen will not assess the presence or absence of these other foods. Also, the issue of dietary distortion is not addressed. Potassium is more widespread in foods, although the largest contributors are usually fruits and vegetables. Using urinary nitrogen and potassium in combination gives a better assessment of the completeness of the recording than any single marker.

Ratio of energy intake to basal metabolic rate Doubly labeled water and urinary nitrogen excretion are particularly useful for assessing the validity of prospectively recorded diets because the time frame of the test and reference measures can be made to coincide. A third technique for assessing validity can be used with both prospective records and recalls of diet. It is based on energy and thus has the limitations of a validating marker relating to a single dietary factor. It has the advantage, however, of being able to be applied to all subjects in a dietary survey because no external reference measure is needed. It is a biomarker in the sense that it relies on a biological measure (body weight) and is best applied when measures of physical activity at the individual level are also available. The assumption is that there should be reasonable agreement between estimated requirement and estimated intake.

Schofield equations can be used to estimate basal metabolic rate (BMR) based on age, gender, and body weight. An individual whose reported energy intake is below the level of energy expenditure likely to be needed to carry out day-to-day activities has probably underreported his or her diet. A typical cutoff point for an acceptable ratio of the energy intake to BMR ratio in an individual is 1.2, taking into account daily variations in energy intake over a period of 7 days of dietary recording and allowing for the inaccuracies of the estimate of BMR based on the Schofield equations. A cutoff of 1.2 will identify only those subjects who underreport and whose levels of activity are low. For subjects with higher levels of activity (e.g., estimated from questionnaire responses), proportionately higher cutoff points are appropriate. It is also possible to estimate an upper probable level of energy expenditure (e.g., 2.5 times BMR, depending on habitual level of activity) and subjects with reported levels of intake over this value may be regarded as being overreporters.

Statistical Assessment of Validity

There are two broad approaches to establishing validity between test and reference measures: comparison of mean values and correlation. The use of mean values is appropriate where group intakes are to be determined or where an absolute measure of intake is required. This is especially important where a threshold value of intake will be used to make recommendations (e.g., recommending an increase in potassium intake because of its association with lower blood pressure and reduced risk of myocardial infarction—there would be no point in recommending additional consumption of potassium for individuals who were identified as having intakes already above the levels that were seen to be protective). The correlation technique (plotting the observed measure against the reference measure) is appropriate where it is important to classify subjects according to high or low intakes because differences in intake are associated with different levels of disease risk. In relation to disease risk, a steeper or shallower slope of observed intake in relation to true intake will have a profound effect on the relative risk estimates in relation to disease outcome. Moreover, the correlation coefficient describes only one aspect of agreement. In practice, both ranking and absolute levels are important in establishing correct diet–disease relationships.

Mathematically, disease risk can be modeled by the expression

$$R(D|T) = \alpha_0 + \alpha_1 T$$

where $R(D|T)$ is the risk of disease D, T is the unobservable true long-term habitual intake of a given food or nutrient relevant to disease risk, α_0 is the underlying risk of disease in the population independent of dietary exposure, and α_1 is the log relative risk (RR) that may be positive (for predisposing factors) or negative (for protective factors).

Because we cannot measure the true dietary exposure, we approximate it using the dietary test measure that is the focus of the validation process. The expression for describing disease risk then becomes

$$R(D|Q) = \alpha_0 + \alpha^* Q$$

where Q is the observed intake, and α^* is the observed log relative risk. In most circumstances, it can be argued that $\alpha^* = \lambda\alpha_1$, where λ is known as the 'attenuation' factor and is equal to the slope of the regression line of T plotted against Q. In most dietary studies, the value for λ is between 0 and 1, but in cases of differential misclassification it may also be negative. The consequence is that the estimate of disease risk in relation to diet is likely to be different from the true risk (usually tending toward a relative risk of unity).

For a given individual i, the observed measure Q_i will be given by the expression

$$Q_i = (T_i)B + a + \epsilon_i + e_i$$

where T_i is the true measure, and the attenuation factor λ is a function of B (proportional bias), a (constant bias), ϵ_i (random error within a subject, such that the mean of the random error across all subjects is equal to zero), and e_i (bias in the ith subject, such that the mean of the individual biases across all subjects is not equal to zero—this is the consequence of differential misclassification). In practical terms, the aim of a validation study is to quantify these sources of error (see **Table 3** for the main likely sources) and to estimate the value for λ so that the true relative risk α_1 can be estimated using the expression $\alpha_1 = \alpha^*/\lambda$.

It is probable that both the test measure and the reference measure are positively correlated with the truth. This is represented by r_{QT} and r_{RT} in **Figure 5**. There will also be a relationship between the test and reference measures, r_{QR}, given by the expression

$$r_{QR} = r_{QT} \times r_R$$

The relationship between the test measure and the truth can be estimated by solving for r_{QT}:

$$r_{QT} = r_{QR}/r_{RT}$$

Assuming that the reference measures are unbiased, r_{RT} can be estimated by knowing the relationship between within- and between-subject variance in a group of subjects whose records or measures are assumed to be valid (e.g., from whom

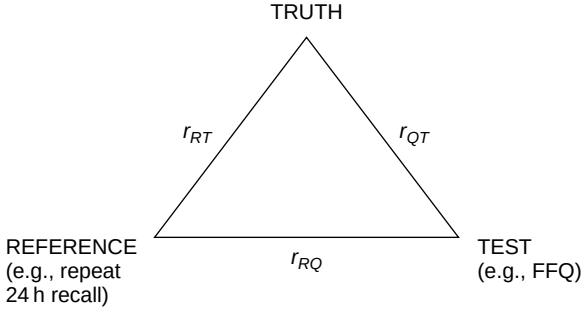

Figure 5 The relationship between test and reference measure and the truth. (Source: Nelson M (1997) The validation of dietary assessments. In: Margetts BM and Nelson M (eds.) *Design Concepts in Nutritional Epidemiology*, 2nd edn. Oxford: Oxford University Press.)

likely under- or overreporters have been excluded) using the expression

$$\sqrt{n/(n + (s_w^2/s_b^2))}$$

where n is the number of repeat observations within one subject, and s_w^2 and s_b^2 are the within- and between-subject variances, respectively. In this way, the likely relationship between the test measure and the truth can be estimated, and the relative risk can be adjusted to account for misclassification of subjects based on the test measure alone.

This approach has two weaknesses. First, if the reference measure is a dietary measure, it does not address the problem of correlation of errors (the tendency for an individual to misreport diet in the same way using the test and reference measures). If errors are correlated between methods, then the observed r_{RQ} is likely to overestimate $r_{RT} \times r_{QT}$; it will appear that the test method is performing better than it actually is performing. If the errors are correlated within methods (e.g., if the same types of within-person bias are occurring from day to day using repeat 24-h recall), then the observed r_{RQ} is likely to underestimate $r_{RT} \times r_{QT}$. The second weakness of this approach is that it does not address the problem of differential misclassification.

A similar technique is the method of triads (**Figure 6**), in which no assumption need be made about the relationships between reference measures and the truth. Instead, the relationships between three measures can be used to estimate values for ρ, which in theory approximate the correlation between each of the measures and the truth. As in the technique described previously, valid estimates of ρ are based on the assumption that the errors in the methods are uncorrelated and that the errors are random and not differentially biased between subjects.

Because the validation process helps to identify subjects who are likely to be misreporting their diet, the temptation may be to exclude from analysis those subjects who have misreported their diet. It may be, however, that the very subjects who are most likely to misreport their food consumption (e.g., people who are overweight) are also those who are at increased risk of disease (e.g., hypertension, heart disease, and colon cancer). In estimating disease risk, therefore, the aim must be to retain all of the subjects in the analysis.

Estimating the components of error and finding appropriate values for λ is the best way to address this issue. A special case is to adjust nutrient intakes to allow for misreporting in some subjects by assuming that true energy intake and true nutrient intake in all subjects are well correlated. Thus, if a subject underreports energy intake, it is assumed that other nutrients will be underreported to a similar extent. By estimating nutrient intake in relation to reported energy intake, subjects can be ranked according to whether, for a given level of energy intake, their nutrient intake was above or below the average. This is known as energy adjustment. To find the energy-adjusted estimate of nutrient intake, the nutrient intakes should be plotted against energy intakes and the regression line and the residual values derived (**Figure 7**). Energy-adjusted nutrient intakes are then computed by adding the residual to the mean nutrient intake. This approach allows all subjects to be included in an analysis, and it provides realistic estimates of intake (unlike computations of nutrient density in which each subject's nutrient intake is divided by his or her energy intake). Like doubly labeled water, however, the

(Source: Ocké M and Kaaks R (1997) Biochemical markers as additional measurements in dietary validity studies: Application of the method of triads with examples from the European Prospective Investigation into Cancer and Nutrition. *American Journal of Clinical Nutrition* **65**:1240S–1245S.)

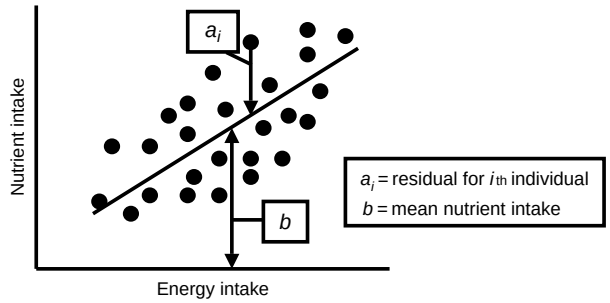

Figure 7 Energy-adjusted nutrient intake for the *i*th individual = $a_i + b$. (Adapted from Willett WD, Howe GR and Kushi LH (1997) Adjustment for total energy intake in epidemiologic studies. *American Journal of Clinical Nutrition* **65**:1220S–1228S.)

weakness of energy adjustment lies in the fact that not all nutrient intakes are well correlated with energy intake. Overreporting of fruits and vegetables consumption leading to an overestimate of vitamin C intake, for example, would not be appropriately compensated for using energy adjustment if the person was at the same time underreporting his or her fat consumption.

Conclusions

The validation of dietary assessment measures is a necessary part of any dietary investigation. The use of unvalidated instruments is likely to lead to misinterpretation of diet–disease relationships. In most circumstances, unvalidated measures of diet will lead to the conclusion that there is no diet–disease relationship when in reality one exists (bias toward the null). In circumstances in which differential misclassification is at play, it may also lead to the conclusion that there is a relationship when in fact none exists. In order not to waste resources, it is vital to ensure either that dietary assessments are valid or that the errors associated with them are clearly identified and taken into account in the interpretation of diet–disease relationships.

In summary,

- Never take dietary measurements at face value.
- Always include an analysis of errors of dietary data in epidemiological studies.
- Ensure that the validation study sample is representative of the population in the main study.
- Quantify all significant sources of error.
- Obtain measures of within-subject reliability.
- Adjustment of estimates of intake is preferable to excluding misreporters from the diet–disease analysis.

Finally, it is worth noting that virtually all of the discussion in this article relates to nutrient intakes. There is an urgent need to improve our understanding of the validity of measurements of the consumption of foods. Advice on healthy eating is given primarily in terms of foods, not nutrients.

DIETARY SURVEYS

K L Tucker, Tufts University, Boston, MA, USA

Purpose and Design

Dietary surveys are used for multiple purposes and range from measurement of food disappearance at the national level, to food use at the household level, to detailed multiple assessments of individual intake for linkage with health outcomes. Each of these methods has strengths and limitations, depending on the survey purpose (see **Table 1**).

Research Questions and Data Needs

At the national level, information on food use and dietary intake is needed for economic and agricultural policy decision making. For policy makers to advise on food production, food imports, pricing of staple foods, and other factors that affect food availability, they require information on the production, inflow, and outflow of food commodities and products at the national level. Most countries use food balance sheets to measure these flows, and total available nutrients are estimated in relation to the size and composition of the population. These surveys measure overall national food production, imports, and available food stocks, and subtract exports, food used for animals rather than humans, and losses that occur during production, storage, and manufacturing. The FAO has compiled food balance sheets for many countries since 1949, thus allowing useful intercountry comparisons of food availability. However, the aggregate information obtained with food balance sheets does not allow consideration of food distribution within a country and does not quantify food intake or needs of subgroups of the population.

Most countries need more information on household level food use to target food nutrition policies toward groups at need. Household food surveys capture the amounts and types of food that enter a household, and *per capita* intake equivalents are calculated by dividing the total nutrients available in the household from the edible portion of entering foods by the numbers of household members, weighted by specific age and sex. With information on the average *per capita* intake of specific households, it is possible to consider groups at risk of inadequate intake of energy or of specific macro- or micronutrients. For example, these surveys may highlight rural–urban differences, inland–coastal differences, differences by socioeconomic strata, and so on. Such surveys provide critical information within countries for the development and targeting of economic, agricultural, and nutritional policies specific to regions or other subgroups of the population.

Table 1 Advantages and disadvantages of different types of dietary survey

Level	*Survey type*	*Advantages*	*Disadvantages*
National	Food balance sheets	Inexpensive	Crude estimate; no consideration of wastage; does not allow disaggregation to sublevels
Household	Food account method	Inexpensive	Does not account for food consumed away from home, inventories or wastage
	Interviewer-administered list-recall	More detail obtained on foods than in the food account method	List may limit responses; Waste usually not accounted for
	Household diet record	Usually covers one week with great detail; most accurate of household methods	High respondent burden; expensive
Individual	24-h Dietary recall	Detailed information on food intake, good estimate of means by subgroup	Misclassifies individuals; not useful for correlative investigation
	Multiple recalls	Average of multiple days can give good quantitative estimate of usual intake	Expensive
	Food frequency questionnaire	Inexpensive, measures usual intake	Semiquantitative, dependence on food list and recipe assumptions may lead to error in estimation of intake in some subgroups

They do not, however, provide information on individual intakes within the household, and are not useful for understanding age- and sex-specific intakes.

For a detailed understanding of food and nutrient intake by age, sex, and physiologic state, data are needed at the individual level. Surveys of individual dietary intake use methods that range from qualitative food checklists to multiple detailed records of food intake, with quantification of preparation methods and portion sizes. Data at the individual level are used for a variety of purposes and the design of the survey and level of detail utilized will depend on the primary data needs. At the national level, a primary objective is to identify subgroups at risk of inadequate intake of energy or specific nutrients. The important advantage of individual level data is that target age and sex groups may be identified in addition to groups identified by region or other household level characteristics. A further objective is to determine the extent of undernutrition in relation to energy or specific nutrients in the total and subpopulations. This requires consideration of the distribution of intakes in specific age, sex, and physiologic status groups. A more ambitious objective of some national or targeted dietary surveys is to associate aspects of individual dietary intake with the existence of health conditions. This objective requires that survey data be valid and reliable at the individual level and requires the estimation of usual intake by individuals.

Issues in Survey Design

National data on food availability is generally collected with food balance sheets. While not a survey in the formal sense, this is a collection of data from the food sector regarding wholesale distribution. After adjusting for expected losses and wastage, these data are compared to nutrient values and then to the size and composition of the population to calculate *per capita* nutrient availability. Because this is a crude assessment, it generally does not account for all losses or waste and therefore tends to overestimate availability.

In order for a household level survey to be nationally representative, one must carefully consider the sampling design. This is generally done by multilevel selection of regions, then sub-regions, then households, in such a way that the resulting data may be generalized to the national level. In cases where results are required at the regional level, coverage of all regions is necessary, although this will usually increase the cost of the survey. When the objective is more specific than national description, target areas may be selected, based on risk status or relevance to the question being addressed.

Similarly, for individual level data to be representative of the greater population of individuals, complex sample design is employed to be sure individuals are selected randomly. Decisions on sampling design will generally be a balance between equal opportunity for subject inclusion against logistic and cost considerations of full randomization. For that reason, multi-level complex sampling design is usually employed. This design may be similar to that of the household level survey, with the added step of randomly selecting individuals within households. Although some surveys do select households and then interview all members of the household, this decreases the generalizability of the individual data due to the lack of independence of the observations. Members in the same family, for example, will consume similar foods and therefore will be more like each other than like others in their community. Although this lack of independence can be adjusted in the analysis design, it will require larger total numbers of interviews to achieve representative stability of data estimates and is therefore not usually the most effective design. While the multistage approach of region, subregion, and community also leads to reduced power, this is corrected by consideration of the 'design effect,' which can be calculated by comparing the variation in intake within versus between sampling units at each level. Although the design effect may demand higher overall numbers of surveyed individuals, this is generally considerably less expensive than expanding coverage to all locations.

In addition to the multistage selection of respondents for representation of the general population, many surveys are concerned with subgroups that will not be well represented unless specifically over-sampled. Examples may include pregnant women, ethnic subgroups, or low-income groups. In these cases, individuals that meet the specified characteristic are identified within the existing sampling design, but are then selected in larger numbers than would be representative of the entire population. This allows sufficient sample size to present valid estimates for these groups. When included in measures of the total population, the extent of over-sampling by subgroups can be adjusted using weights that correct for what would otherwise be an over-representation of these groups.

Another design consideration relevant to accurate representation of dietary intake is the timing of the survey. In many countries, intake may vary

considerably by season, and it is therefore important that all seasons are represented. Although logistic and cost constraints often limit ideal design planning, it is also optimal if data from all seasons is collected in all survey locations, as opposed to certain regions being collected in the summer and others in the winter. If the latter is the case, comparisons across regions may be compromised. Similarly, intakes are known to differ by day of the week, and overall intakes may be misrepresented if certain days of the week are not included in the data collection plan.

Selection of Dietary Assessment Measure

Household Level

There are several alternative methods of dietary assessment that may be selected to assess intake. At the household level, a commonly used approach may be referred to as the food account method. A person in the household who is responsible for the acquisition and/or use of food is selected to keep a daily record of all the food that enters the household for a specified period – often 1 week. This includes household food purchases, food production, and food received as gifts during that period. This provides a general picture of the food that passes through the household in a given week. There are several limitations to this approach, including the assumption of constant food stores, which may not be the case.

In some locations, it is not feasible for many individuals to record this information accurately. In this case, an interviewer-administered list-recall method is often used. The interviewer asks the responsible household member to recall food purchases, production, or other receipt in the household during a specified period of preceding days, following a list of major foods that are relevant for that country or location. Additional information on age and sex of household members and number of meals each consume at home is collected to calculate adult equivalent *per capita* food availability for the household. Although edible portions of foods are generally considered in quantifying availability, most such surveys do not account for wastage, loss, or use by animals and therefore may overestimate household food use and availability. On the other hand, they do not generally account for food consumed away from the home, thereby underestimating food intake. While useful for economic and food commodity flow information, this type of survey is therefore limited with respect to nutritional intake assessment.

For the purpose of better understanding the dietary intake within households, more elaborate methods are needed. One approach is to use a household diet record. In this case the household respondent is asked not only to report inflows of food, but also to record actual use and preparation of foods in the household over a specified period of time. Food consumed outside the home may also be recorded for each household member as well as the number of individuals, including guests, who are present at each meal. While much more demanding for the respondent, this approach provides a better estimation of the total food consumed by the household than do the inventory methods described above. Estimation of waste is included in some but not all such surveys and is a limitation of most. Because of the heavy respondent burden, nonresponse or incomplete response is also a major problem. With high proportions of nonresponders, the generalizability of the survey is threatened.

Individual Level

A wide variety of methods are available for use at the individual level, and their selection depends on the questions to be addressed balanced with cost considerations. As noted above, major uses of individual intake data from dietary surveys include the description of mean intakes by subgroup, description of the proportions of the population with inadequate intake of specific foods or nutrients, and comparison of dietary intake with individual characteristics, including health status.

For the purpose of describing mean intake of groups and subgroups, the most efficient method is the use of a single 24-h dietary recall per selected individual. For estimating group means, it is most effective to include sufficient numbers of individuals per subgroup to be represented as opposed to completing multiple recalls on a smaller number of individuals. This is the methodology that was, until recently, used in the US National Health and Nutrition Examination Survey (NHANES), providing a good description of average intakes of nutrients by age, sex and ethnic groups. As an aggregate measure, this design has worked very well. However, there are limitations to these estimates and validation against quantified energy expenditure measurements has shown that most people tend to under-report intakes with the 24-h dietary recall method. Further research is needed to better understand whether this tendency to under-report is random or, as some investigations have shown, associated with individual characteristics

such as obesity, restrained eating behavior, or social desirability bias in reporting.

The major limitation in the use of single 24-h recalls in a dietary survey is the misclassification of individuals that results from day-to-day variation in individual intake. An individual who on average is a heavy consumer of energy and fat, for example, may on any single day, eat uncharacteristically lightly or vice versa, leading to severe misclassification of individuals in the intake distribution. Although the mean intake is reliable and reasonably valid, the tails of the intake distribution with a single day of intake per person are extended, leading to overestimation of proportions either above or below a specified cut-off point, relative to what is seen when usual intake is assessed as the average of multiple days. The misclassification of individuals relative to their actual usual intake also severely limits the ability to correlate intake data with any individual characteristics, including health status and biomarkers.

Because of the importance of using national or regional survey data to identify the extent of inadequate nutrient intake, there has been considerable discussion on how to assess diet efficiently, yet estimate prevalence of inadequacy. As noted above, the distribution of intake obtained with a single day per individual is extended due to day-to-day variability in intakes. However, with repeated recalls on a representative subset of the population, this day-to-day variability may be quantified and used to adjust the distribution to better represent usual intake. Although they require specialized training to use, statistical methods have been developed to adjust distributions for this purpose. By adjusting the distribution, we are able to pull in the tails and get a more realistic distribution of usual intake and, thereby, a more accurate estimate of the proportion that falls below or above a specified cut-off point.

Because recommended dietary allowances (RDAs) are set as a guideline for nutrient intake that will meet the requirements of most healthy individuals in the population, a cut-off point of two-thirds of the RDA has frequently been used for assessing the proportion with low intake. A more precise way to estimate the relationship between intake and actual requirements was proposed that uses information on the probability that a specific nutrient is inadequate. This method requires information on the requirement distribution for that nutrient, which is then compared with an intake distribution. In actuality, we still have only limited data on the distribution of requirements. In the most current US nutrient intake recommendations, estimated average requirements (EARs) are proposed as well as RDAs. In general, the proportion of individuals who fall below this EAR, using an intake distribution adjusted for day-to-day variability, are a good estimate of the proportion of the population with inadequate intake.

A third important objective of dietary survey data is to gain a better understanding of the correlates of nutrient intake, but with respect to individual characteristics that may be associated with lower versus higher intake and the extent to which intake is associated with indicators of health. For many nutrients, the day-to-day variation in intake is considerable, and multiple days would be required to achieve stable estimates of intake at the individual level. Without this, the misclassification of individuals in the distribution leads to a weakening in the ability to see associations that may truly be there. An extreme example is vitamin A, which tends to be concentrated in a few foods. If one frequently has liver and carrots, but happened not to on the day of the recall, that individual would be classified as having low vitamin A intake when their usual intake is quite large. Conversely, one who almost never eats these foods, but happened to have liver on the day of the recall would be placed at the upper end of the vitamin A distribution despite the fact that this may have been the only time that year they consumed such a high vitamin A source food. The effect of this is to weaken correlations or regression coefficients so that no association may be seen between intake and outcomes such as plasma retinal or eye health.

There are two ways that this major limitation may be handled in dietary surveys. First, with information from multiple recalls on a subset, it is possible to calculate the ratio of the intra-individual variance, or day-to-day intake variation within individuals, to the inter-individual variance, or difference in intake across individuals. To the extent that intra/inter-individual variance ratios are large, as in the case of vitamin A, the ability to see associations will be severely limited. When inter-individual differences exceed day-to-day variation within subjects, the ability to correlate intakes with other factors is stronger. Unfortunately, in most cases, this variance ratio is sufficiently large that a single day of intake will not allow correlational analyses. The collection and averaging of multiple days of intake will greatly improve this situation. For most nutrients 3 or 4 days are acceptable. However, for some nutrients of interest, including vitamin A and vitamin B_{12}, the variability ratios are so high that an unrealistic number of days is needed for stable estimates. For this reason, many researchers choose to use food frequency questionnaires when correlational analysis is a major objective.

The food frequency questionnaire asks respondents to report the frequency of consumption of a prespecified list of specific foods. Additional questions on portion size and on preparation methods are added in differing ways to different questionnaires. Food frequency questionnaires provide a lower cost alternative to multiple recall days, but also have limitations. Because they rely on a food list, their validity is dependent on the representativeness of that list, and of portion size and recipe assumptions. Most food frequencies in wide use have been developed using data that represent the major sources of nutrient intake in a population. However, individuals with divergent eating patterns will not be well represented using this tool.

When single recalls are available along with information on the variance ratios for each nutrient, another approach to improving correlational estimates is to use what is called 'deattenuation' methods to correct for the effect of day-to-day variability. Because the effect of this variability is assumed to be random in the population, the ratios provide a mathematical basis from which to estimate what the 'true' association between the nutrient intake and correlated indicator may have been, after accounting for this variability.

Data Analysis and Limitations

Whatever dietary assessment measure is used, the utility of the data is dependent on the translation of reported food intake to nutrient intake. This requires detailed and accurate nutrient databases. The US Department of Agriculture has the most extensive nutrient database in the world, allowing for good estimation of dietary intakes in the US. Most other countries have not conducted this level of food composition analysis for their own locations. Therefore, most databases used throughout the world have obtained at least some of their values from the US nutrient database, adding information as possible from locally analyzed products. However, because the nutrient composition of many foods, including fruits, vegetables, and even animal products can vary widely by growing conditions and specific subvariety, most available nutrient databases remain inadequate. Many use extrapolated values from similar foods when chemical analysis has not been completed. Furthermore, it is common for many country-specific databases to include information only on macronutrients and a few selected vitamins and minerals. The continual arrival of new manufactured products also complicates the upkeep and management of food composition databases. Consequently, considerable database work remains to expand the utility of worldwide dietary surveys.

Once the nutrient data are calculated, data are generally tabulated to present age, sex and, sometimes, ethnic specific mean intakes and standard deviations. Further disaggregation by region, socioeconomic group, or other group characteristic can by very helpful in understanding the macro-distribution of nutrient intake and for targeting specific groups with nutrition intervention programs. If a complex survey design was used, or if systematic nonparticipation was observed, sampling weights must be applied to adjust the means and standard errors.

Using the methods described above, estimates of the population with low intakes of specific nutrients are also calculated. Beyond these descriptive measures, comparison of nutrient intakes with individual characteristics and health measures generally requires multiple regression analysis with appropriate adjustment for potentially confounding variables. Again, when complex survey designs have been used, the inclusion of sample weights and appropriate adjustment of variances is needed. Specialized statistical software for use with survey data is available. In cases where a single recall has been used, substantial weakening, or attenuation, of associations is likely, but use of 'deattenuation' methods can, at a minimum, provide information on the likely extent of this attenuation. When food frequency data are used, it is important to include some validation methods, preferably with comparison to key biomarkers of nutritional status, but at least to multiple recalls on a subset. This is particularly true when a new questionnaire is being used, but is also important over time as the food supply and food habits change in the population.

DIETETICS

P A Judd, University of Central Lancashire, Preston, UK

This article briefly relates the history of the development of dietetics, discusses the changing roles of the dietitian, and outlines the current involvement of dietitians in some general and specialist areas of practice.

Definition and History of Dietetics

Dietetics is defined as 'the application of the science of nutrition to the human being in health and disease.' However, the term 'dietitian,' used to describe a practitioner of dietetics, was in use long before the science of nutrition had become an accepted discipline. The first use of the title of dietitian was recorded in 1899 in the United States when the dietitian was described as 'a person working in a hospital who provided nutritious meals to patients.' The earliest dietitians were therefore mainly concerned with provision of food and usually trained as home economists. The role of the dietitian has changed markedly in the past 50 years, and the dietitian is now accepted as the expert in the planning and evaluation of nutritional care for patients requiring therapeutic dietary regimens as well as for the population in general.

The profession of dietetics is a relatively young one, first formalized in the United States in 1917 with the foundation of the American Dietetic Association (ADA). In the United Kingdom, the first dietitians were nurses and the first dietetic department opened in the Edinburgh Royal Infirmary in 1924. The British Dietetic Association (BDA) was established in 1936. The profession developed rapidly in other countries, and in 2004 there were 23 dietetic associations registered with the European Federation of the Association of Dietitians and 36 national dietetic associations registered with the International Committee of Dietetic Associations.

The Role of the Dietitian

The first dietitians (with the exception of those concerned mainly with food service provision) worked mainly in hospitals. Clinical dietetics and the acute hospital service still claim a large proportion of the graduates from dietetics but other areas of work are increasingly becoming more important. In the United Kingdom, changes in the emphasis of health care, particularly the change from acute (hospital) care to care in the primary health care setting, has resulted in a marked increase in the number of dietitians based in primary care.

Dietitians also have many other roles outside the health services. Increasingly practitioners work with government agencies, for example, in dietary surveys of the population, in execution and evaluation of nutrition intervention programs, and advising on the practical application of policy. In industry, they may work as advisors to food companies, wholesale and retail suppliers of food, and with companies producing specialized dietary products. In addition, dietitians are increasingly working independently as consultants, for example, in private practice, journalism, and sports nutrition. The scope of the dietitians' work is illustrated by **Table 1**, which lists the special interest groups for dietitians in the United Kingdom.

Whatever aspect of work a dietitian chooses, one of his or her primary roles will be that of an educator, whether this be in assisting individuals to understand and apply a therapeutic regimen; teaching doctors, nurses, or other health professionals about nutrition and dietetics so that they may carry out their own role more effectively; teaching groups of people about aspects of preventative nutrition; or writing an article for the scientific or lay press. The ability to communicate is therefore central to every dietitian's role.

Table 1 Specialist groups and special interest groups in the British Diatetic Association (2004)

Specialist groups	*Special interest groups*
Community Nutrition Group	Burns Interest Group
Diabetes Management and Education Group	D – Liver (Dietitians Working in Liver Disease)
Dietitians in HIV and AIDS	Dietitians in Neurological Therapy
Freelance Dietitians Group	Dietitians in Sport and Exercise Nutrition Group
Mental Health Group	Dietitians Working in Obesity Management (UK)
Multicultural Nutrition Group	Gastroenterology Interest Group
Food Counts	Northern Eating Disorders Dietitians Interest Group
Nutritional Advisory Group for Elderly People	Nutritionists in Industry
National Dietetic Managers Group	Pediatric Renal Interest Group
Oncology Group	UK Dietitians Cystic Fibrosis (CF) Interest Group
Pediatric Group	
Parenteral and Enteral Nutrition Group	
Renal Nutrition Group	
UK Heart and Thoracic Dietitians	

The Dietitian's Role in Food Service

In the United States and countries that follow the US model hospital dietitians work in either administrative or clinical (therapeutic) areas. Administrative dietitians manage the provision of food services for all patients and staff. They are responsible for food production and quality control in the delivery of the hospital meal service as well as ensuring their nutritional adequacy. They are also often responsible for budgeting and staffing of the dietary departments and usually relate to other administrators and managers, having little or no direct contact with patients or medical staff. The clinical dietitian is the person who has direct contact with patients and the medical and paramedical staff involved in their care.

In the United Kingdom, very few dietitians have overall responsibility for food service. However, there is usually close liaison between the dietitians and the catering manager in hospital practice to ensure the provision of nutritionally sound selective menus. The dietetic manager will also be consulted on matters of policy, such as the implications of changes in food preparation systems or the introduction of healthy eating policies. It is accepted now that many patients (especially elderly people) are malnourished when they enter the hospital and that this malnourishment may get worse during the hospital stay. Dietitians are therefore very much involved in attempts to ensure that every patient has a nutritionally adequate diet.

Clinical or Therapeutic Dietetics

The term 'therapeutic dietetics' is used in the United Kingdom to describe the work of the dietitian in his or her direct dealings with patients who require 'special diets' for various reasons. In the United States, the corresponding term is 'medical nutrition therapy' and the importance of this is recognized by its acceptance as allowable treatment by medical insurance companies. Medical nutrition therapy includes nutritional diagnostic, therapeutic, and counselling services provided by a registered dietitian and can

effectively treat and manage disease conditions;
reduce or eliminate the need for prescription drug use;
help reduce complications in patients with disease; and
improve patients' overall health and quality of life.

The role of the clinical dietitian has broadened in the past decade, with respect to both the range of conditions that are encountered and the setting in which the work is done. In the past, the role of the therapeutic dietitian was to calculate, teach, and facilitate compliance to a range of dietary regimens prescribed by medical or surgical practitioners for specific disorders. These functions are still important and are extending as improvements in medicine enable patients who would previously have died in childhood to survive to adulthood with continuing needs for nutritional care. For example, patients with cystic fibrosis require nutritional support as their lungs deteriorate and women with hyperphenylalaninemia need dietary advice in order to help them achieve successful pregnancies. The dietitian is an important member of the multidisciplinary team dealing with many clinical conditions.

In addition to these roles, dietitians are increasingly involved in the assessment and support of patients not traditionally seen as requiring a therapeutic diet. For example, planning and implementing feeding for patients who are nutritionally compromised as a result of aging, trauma, surgery, or chronic illnesses such as cancer or AIDS is now an important part of the workload of the dietitian working in both acute and community settings.

Clinical dietitians are increasingly involved in decisions about the appropriateness of particular dietary

regimens or the type of nutritional support required and in many institutions are responsible for prescribing the patients' diet in consultation with the physician or surgeon, who recognises the dietitian as the expert. In acute care a dietitian is an important member of the nutrition support team, working alongside nurses, pharmacists, and medical staff to advise on the feeding of all patients who need nutritional support.

The dietitian must be aware of advances in clinical practice, and many dietitians are now involved both in research on the development of new treatments and in evaluating current practice. In the past decade, the requirement to demonstrate evidence-based practice and satisfy the demands of clinical governance within acute care has increased the need for understanding and contribution to the development of the evidence base. Dietitians are increasingly obtaining research qualifications and initiating their own projects, working alongside experienced investigators and in multidisciplinary teams.

In the United Kingdom, consultant posts for Allied Health Professionals, who are considered to be 'experts in a specialist clinical field, bringing innovation, personal mastery, and influence to clinical leadership and strategic direction,' have recently been introduced. The consultants are expected to have exceptional skills and advanced levels of clinical judgment, knowledge, and experience and be able to enhance quality in areas of assessment, diagnosis, management, and evaluation, improving patient outcomes and extending the dietitian's role. Although in early 2004 there were only two such dietetic posts (in diabetes and oncology), the number will doubtless increase.

In the United Kingdom a shortage of dietitians and the recognition that many of the tasks carried out by dietitians did not require such highly qualified practitioners have resulted in the recent official recognition of the role of assistant practitioner by the BDA. Dietetic assistants (or community nutrition assistants) are now working under the supervision of registered dietitians, carrying out many of the tasks that do not require specialist input. In the United States and some other countries, diet technicians have been undertaking these roles for some years and the American Dietetic Association has recognized training programs for them; such training programs are being developed in the United Kingdom.

Examples of Specialist Roles in Dietetics

Renal Dietetics

Renal dietitians are usually attached to specialized renal units and are an integral part of the team involved in the treatment of people suffering from varying degrees of renal impairment, whether acute or chronic. In the United States, there is a legal requirement related to funding of patient care that states that a qualified dietitian must be part of the professional team that develops long- and short-term care plans for renal patients. The dietitian, together with the nephrologist, has responsibility for nutritional assessment, the diet prescription, and for monitoring responses to treatment. In addition, he or she must be able to devise appropriate individualised dietary plans, taking into account any other ongoing disease processes or conditions (e.g., diabetes mellitus), and will teach the patient and family how to manipulate the diet. The dietitian will also monitor dietary compliance. A thorough knowledge of physiology and the pathological processes involved in the various kidney diseases and an ability to interpret the patient's biochemical data are therefore essential for the renal dietitian.

Some disorders may resolve with treatment, whereas others may become chronic and result in permanent kidney failure. In progressive renal disease, patients may initially be managed using diet and drugs alone but as the kidneys fail will require replacement therapy, such as peritoneal dialysis, hemodialysis, or transplantation. Each of these stages requires different dietary treatment. The dietitian will deal with a variety of patients with different types of disease and at different stages of progression, with different needs with respect to diet, and will also have to teach the patient how to cope with changes in diet that follow as he or she changes from one treatment to another.

Nutritional Support

Nutritional support of patients who are unable to feed themselves adequately by the normal oral route is an important area of practice. The dietitian's involvement will include the assessment of the nutritional status of the patient, decisions about the most suitable method of nutritional support, and advising on provision of appropriate nutrition. This may range from prescribing oral supplements for the patient who cannot eat enough to designing and advising on complete parenteral nutrition regimens for the unconscious patient in intensive care. Between these two extremes will be the patients who need enteral feeds to provide complete or supplementary nutrition for a variety of reasons and for periods varying from a few days to a lifetime.

Patients requiring nutritional support may be acutely ill or may require long-term feeding, sometimes at home. The dietitian must be able to assess the nutritional requirements of each individual and

design appropriate feeding regimens in all circumstances. Many patients will be sent home while still being tube fed, either enterally or parenterally, and the community dietitian as well as the dietitian in the acute hospital will both be closely involved in the patient's care and in monitoring progress.

Diabetes Care and Education

Traditionally, the dietitian always had an important role in the treatment of patients with diabetes mellitus (DM), and the radical changes in dietary approaches during the past 15–20 years have emphasized this role. In the latter part of the twentieth century there was a move away from the use of diets low in carbohydrate in the treatment of diabetes and the basis for the treatment of all people with DM, whether young and insulin dependent or older and treated by diet alone or diet and hypoglycemic drugs, tended to rely on the supply of an appropriate amount of energy as a low-fat diet with at least 50% of energy from foods rich in complex carbohydrates and nonstarch polysaccharides. In addition, the recognition that similar amounts of carbohydrate from different foods have different effects on blood glucose levels, and that this response may be further effected by other foods eaten with them, has led to less stress on absolute intakes of carbohydrate and more toward a qualitative approach to the diet.

Many established diabetics found the change in dietary treatment confusing and have needed help in switching to the new regimen, and newly diagnosed patients also need help in learning to manipulate and control this lifelong disorder. Many dietitians have also been involved in the research that has underpinned the progression of dietary treatment and are now evaluating its effects.

HIV and AIDS

The dietetic care of patients with HIV and AIDS has become increasingly important in the past decade. Dietitians may work with people who are HIV positive to help them optimize their nutritional status and resist the opportunistic infections that eventually cause death in patients with frank AIDS. Once the person develops AIDS, the dietitian's role becomes both therapeutic and palliative, devising and implementing with the patient regimens that enable him or her to satisfy nutritional requirements when, for example, disease of the gastrointestinal tract results in multiple malabsorption or cancer results in weight loss and anorexia. The advent of new, multidrug regimens that require careful planning of meals to match their absorption characteristics and that have side effects affecting nutritional status has made the dietitian's role even more important.

Pediatric Dietetics

The pediatric dietitian has a unique role in that they have to combine the metabolic requirements of the disease process or condition with the normal requirements for growth and development. With the advances in early diagnosis of many complex metabolic conditions, children may require complicated diets that are very different from those of the rest of their family and peers, need constant modification as the child grows, and may be lifelong. The dietitian is responsible for modifying the diet as necessary to take account of the patient's metabolic requirements, any feeding difficulties, mechanical or physiological, and the patient's food preferences and dislikes as he or she grows. The dietitian is an essential part of the support system for children with inborn errors of metabolism such as phenylketonuria and cystic fibrosis, conditions such as renal or heart disease, food allergies, diabetes, and many others, being able to tailor the diet to the patient's specific needs and having access to information about special foods and products of which the care provider may be unaware or have difficulty locating.

The increase in overweight and obese children and adolescents and the consequent increase in type 2 diabetes in young people is a new challenge for the pediatric dietitian.

The pediatric dietitian has an important role as an educator, often teaching the child's parents initially and later the child how to cope with the constraints of a special diet both at home and at school. As is the case with adult patients, the dietitian will often be able to put the child and family in contact with support groups in which newly diagnosed patients or parents will be helped by others with firsthand experience of the disease and its treatment.

Other Areas of Specialization

There are many other areas of clinical dietetics in which individuals may specialize, including obesity, oncology, liver disease, gastroenterology, eating disorders, gerontology, and care of the mentally ill or mentally handicapped. Many of the activities in these areas and those described in the previous sections are not confined to the hospital but require input from the dietitian in the community.

Dietetics in the Community

Community dietitians fulfill a variety of roles that may range from working mainly in clinical dietetics in the community setting (e.g., advising a variety of

patients in a general practitioner's clinic) to being a public health nutritionist advising the local health or social services on aspects of food policy. In recent years, due to the changing emphasis in health care, the number of community dietitians in the United Kingdom has increased markedly. The main focus of the increase has been in supplying clinical (therapeutic) care to the primary health care setting and approximately 21% of UK community dietitians surveyed in 1997 stated that this was their only role. Approximately half of the respondents to the survey were involved in health promotion activity as well as clinical work, but only 9% worked solely in health promotion.

Many dietitians working in health promotion achieve their objectives by educating other professional groups, such as doctors, nurses, health visitors, and midwives, who will then pass the specific knowledge on to the individual or groups of patients. Prevention of diseases that may be diet related has recently become a much more important issue, and dietitians are working with schools, health education departments, and industry to try to educate the public to consume a healthier diet. Dietitians also work as advisors in government departments and are therefore involved in planning nutrition policies for the country as a whole.

Dietitians in Research and Education

The advances in all areas of nutritional knowledge, both in terms of achieving optimal health and prevention of disease and in therapeutic nutrition, have led to an increasing number of dietitians working in research. The combination of nutritional and medical knowledge and the ability to translate these into terms of foods eaten means that the dietitian has a unique role to play. Dietitians often approach research from a deductive perspective (i.e., in order to understand or solve difficulties observed in practice) and the results of this research will often have practical significance and can be incorporated into treatments. Evaluation of practice can also be considered as part of this deductive process and is essential in the current health care climate, in which increasing reliance is put on measuring effectiveness and the use of evidence-based medicine. In addition, dietitians are increasingly involved in the basic experimental and analytical scientific research that is essential for nutrition and dietetics to advance in both clinical and nonclinical areas. Involvement in research has led to registration for higher degrees and the number of dietitians with masters' degrees or doctorates is now considerable in countries such as the United States, United Kingdom, Canada, and Australia.

Research is also seen as an important part of the role of those dietitians employed in universities and colleges to teach dietetic and other students. In the United Kingdom and other countries, there is a requirement that each dietetic training course has registered dietitians on the staff, and in many cases these people also work in the NHS in order to keep up-to-date with current practice. Dietitians have been involved for many years in the education of other professional groups, including nurses, midwives, and pharmacists. Recently, advances have been made in convincing those in charge of medical education at undergraduate and postgraduate levels of the importance of nutrition in medical education, and this is also seen as an important area in which dietitians should be involved.

Dietetics Education and Training

The following quotation from the introduction of *The Manual of Dietetic Practice* (Thomas, 2001) summarizes some of the skills needed by a dietitian—all of which must be acquired during preregistration and continuing professional development. The emphasis here is on the role of the clinical dietitian; additional skills will be acquired by the dietitian working in public health and policy:

> While principles of care can be standardised, the way in which they are applied has to vary to take account of individual needs, problems, lifestyle, associated health risks, and readiness to change. In order to provide effective care the modern dietitian has to exercise considerable clinical judgement in deciding how a specific set of circumstances may be most appropriately managed. This requires more than just nutritional knowledge. The modern-day dietitian has to make a global risk assessment when setting nutritional goals, have an understanding of human behaviour in order to achieve dietary change, acquire the interviewing and counselling skills necessary for meaningful dialogue between patient and professional, and have the ability to evaluate whether objectives have been achieved.
>
> (page x)

It is now therefore accepted that the practice of dietetics requires a wide range of knowledge and skills that are achieved by both academic study and practice learning. As the scope of dietetic practice has expanded over the years, the preregistration education and training programs have continually adapted to ensure that the practitioner has the current knowledge and skills required. The education and training of a dietitian usually comprises a degree program (either BSc or MSc), based in a university, including or followed by a period of practical

training (or internship) based in recognized hospital dietetic departments.

Preregistration programs include coverage of basic and applied sciences (chemistry, biochemistry, physiology, nutrition, and microbiology) as well as social sciences (psychology and sociology). In addition, because dietetics is concerned with feeding people, a knowledge of the food habits of populations together with detailed knowledge of food composition and food preparation is essential. To this basic foundation is added knowledge of medicine, pathology, and the therapeutic uses of dietary treatment and, increasingly emphasized, the development of skills required to communicate with all types of people whether counselling individuals or teaching groups.

During the practical training or internship, the student dietitian learns to apply the theory learned at university with individuals or groups of people. The training covers all aspects of dietetic practice and the students spend time in different settings, including community care and, in some countries, large-scale catering establishments. In order to become a registered practitioner, the students must demonstrate that they have both good theoretical knowledge and are competent practically.

In the United States, United Kingdom, Canada, Australia, New Zealand, South Africa, The Netherlands, and many other countries training programs are regulated by bodies external to the educational establishments and successful completion of such a regulated training allows registration as a dietitian. In the United States, regulation of courses and training programs is carried out by the ADA and in the United Kingdom by the Health Professions's Council (HPC), in conjunction with the Quality Assurance Agency of the Higher Education Funding Council. In the United Kingdom, only registered dietitians may be employed in the National Health Service. The registration body, in each case, produces a statement of conduct that describes the role and responsibilities of the registered dietitian, and failure to work within this statement of conduct may result in disciplinary action and removal from the register. In the United Kingdom, since 2003 this code of conduct has been presented as 'standards of proficiency' and on registration the registered dietitian must sign a document that involves taking responsibility to work only in areas in which he or she is competent to practice.

Registration in one country does not automatically mean that a dietitian can work elsewhere in the world because levels of education and training are not always comparable from country to country. Within Europe, for example, the education level and skills of dietitians vary widely and there is currently a move within the European Federation of Dietitians to develop benchmarks for dietetic qualifications. The registering body will therefore consider applications from dietitians from other countries and suggest further training if appropriate.

Continuing education and demonstration of continuing competence to practice are increasingly being seen as vital in this rapidly changing profession; in the United States there has long been a requirement to demonstrate continuing education, and continuing registration is dependent on this. In the United Kingdom, it will soon become a requirement to demonstrate continued competence to practice for continued registration with the HPC. The BDA, the professional association for dietitians, has well-developed systems for assisting dietitians in both accessing and recording continuous professional development. The provision of validated specialist courses, the development of a Diploma in Advanced Dietetic Practice, which recognizes CPD over a 5-year period, and most recently the support for a Masters Course in Advanced Dietetic Practice are examples of this. In Australia, continuing professional development is recognized by the status of Accredited Practising Dietitian.

DRUG–NUTRIENT INTERACTIONS

K G Conner, Johns Hopkins Hospital, Baltimore, MD, USA

Introduction

Understanding the interactions between dietary constituents and pharmacological compounds is essential to monitor drug therapy correctly and to assess the potential nutritional impact of medications. Most therapeutic agents exhibit some form of interaction that ultimately affects the nutritional status of the host, by altering absorption or utilization of nutrients. Frequently, these changes are not readily identified or may be obscured by the underlying disease.

The interactions between therapeutic agents and nutrients are part of the large number of interactions occurring between nutritional and non-nutritional constituents of the human diet. These constituents include all substances added to the food chain – incidentally or deliberately – during harvesting, processing, packaging, distribution, and preparation of foods. Some examples are pesticides, food additives, antibiotics, hormones, and environmental toxins.

Drug–nutrient interactions operate in two directions: drugs can have a significant impact on nutrient absorption and utilization, and the nutritional status of the host affects the drug's ability to be absorbed and transported and to exert an effect on the target tissues.

Drug–nutrient interactions can be broadly classified into two categories: direct physicochemical interaction and physiological or functional interaction. Drug–nutrient interactions can also be classified according to their site of occurrence: within the food matrix, in the gastrointestinal (GI) tract, or during transport, metabolism, and excretion. The mechanisms and sites of drug–nutrient interactions are listed in **Table 1**.

Table 1 Mechanisms and sites of drug–nutrient interactions

Site	*Mechanism*	*Effect*
Food matrix	Binding and chelation	Decreases bioavailability
Gastrointestinal tract	Changes in gastrointestinal motility, binding and chelation, bile-acid concentration, and gastric pH	Increase in transit time reduces absorption, decreases bioavailability, and reduces absorption of fat-soluble nutrients
Circulation	Albumin concentration	Affects absorption of iron, vitamin B_{12}, and other substances
	Competitors for albumin binding	Decreases transport of bound substances; displaces albumin-bound nutrients (fatty acids, tryptophan, etc.)
Target tissues	Antagonistic effects	May increase requirements for antagonized nutrients
	Enzyme activities	Reduced concentration of enzyme product
Excretion	Renal function	Increased excretion may lower nutrient levels, increasing requirements
	Sequestration	As above

Physicochemical Interactions

Physicochemical interactions usually involve some form of molecular interaction between the drug and a nutrient, and occur primarily during digestion and absorption. The usual consequence of this interaction is a reduction in the bioavailability of the drug and/or the nutrient. A well-known example of this is the binding of metals by the antibiotic tetracycline.

Functional Interactions

Functional Interactions in the Gastrointestinal Tract

Functional interactions in the GI tract are particularly significant because alterations in GI function are likely to affect the digestion and absorption both of the drug and of a number of nutrients. The most common GI functional effects are as follows.

Changes in GI motility A reduction in transit time may lead to decreased absorption. There are a large number of drugs that affect gut motility, whether this is their primary therapeutic effect or not. Conversely, food composition also affects motility. Dietary fiber not only increases motility but also may trap other nutrients and drugs and reduce their bioavailability.

Changes in gastric-acid output Reduced production of chloride with a subsequent increase in gastric pH retards gastric emptying and may alter the balance between ionized and nonionized forms of therapeutic agents.

Reduction in the concentration of bile acids A reduction in the concentration of bile acids will affect the absorption of most fat-soluble compounds. Lower bile-acid concentration may result from increased binding and excretion or from decreased production. For example, the antibiotic neomycin binds to bile acids and increases their faecal excretion, thus reducing their luminal concentration and, in this fashion, decreasing the absorption of fat-soluble vitamins. This interaction, like many others, can be used therapeutically to reduce bile-acid turnover in patients with certain liver diseases and to lower cholesterol levels by reducing their reabsorption.

Alterations in the GI microflora Alterations in the GI microflora may affect the availability of nutrients produced by the normal gut flora, such as vitamin B_{12}′. Since many drugs are susceptible to bacterial metabolism, changes in the gut flora may also affect drug bioavailability. In certain cases, drug cleavage by intestinal microorganisms is an expected and necessary step for adequate drug action. For example, the anti-inflammatory agent 5-aminosalicylic acid is given as its precursor sulfasalazine, which is converted into the active compound by colonic bacteria. An altered colonic flora will affect the production of the active compound. Drugs can also affect nutrient absorption by directly inhibiting protein synthesis in the enterocyte. Since most transport systems require active protein synthesis and turnover, such inhibition results in a decreased rate of nutrient absorption. Furthermore, certain drugs undergo initial metabolism in the enterocyte, before reaching the bloodstream. Alterations in protein synthesis in the enterocyte, or an impaired turnover of the intestinal epithelia, will also affect this process.

Interactions Affecting Transport, Metabolism, and Excretion

Functional Synergism or Antagonism

The biological actions of nutrients and drugs can be synergistic or antagonistic, occur at different times after exposure, and affect a variety of target tissues. Some of the most common mechanisms are as follows.

Alterations in drug transport Drugs circulate in the bloodstream as free compounds or bound to other constituents, usually proteins. Drugs vary greatly in their propensity to bind to circulating proteins, covering virtually the entire spectrum from 0 to 100%. For a given drug, the bound fraction tends to be relatively constant under physiological conditions, but responds to changes in pH, electrolyte balance, and the presence of competing molecules. The major transport protein in plasma is albumin, and its concentration and the presence of other compounds with an affinity for albumin binding will affect the amount of drug that will ultimately be transported by this protein.

Increase in nutrient catabolism Certain drugs stimulate detoxifying systems, such as the cytochrome P-450 pathway. Activation of this system may result in increased catabolism of certain nutrients. In other cases, drugs directly affect nutrient catabolism, as in the case of anticonvulsant drugs, which stimulate vitamin D catabolism in the liver.

Changes in drug metabolism Certain nutrients (such as those found in grapefruit) can inhibit the activity of cytochrome P-450. Cytochrome P-450-3A is the only isoform affected in a clinically significant way. The mucosal cells of the small intestine are affected to a greater degree than the hepatic cytochrome P-450-3A. Certain HMG-CoA reductase

inhibitors (statins), simavastin, and lovastatin can have a significant interaction with grapefruit juice.

Biological antagonism Biological antagonism occurs when drug and nutrient have opposite biological actions, as is the case, for example, with vitamin K and salicylates in the coagulation process.

Increased nutrient losses Many drugs directly or indirectly enhance the urinary excretion of nutrients. Examples are the increased urinary losses of electrolytes caused by aminoglycoside antibiotics and amphotericin B antifungals, and the increase in urinary ascorbic acid excretion induced by barbiturates.

Host-related Functional Interactions

Nutrients and nutritional status can also affect drug action and disposition. Perhaps the most significant host-related factor affecting drug disposition is protein synthesis. Altered protein synthesis, usually resulting from insufficient dietary protein intake or severe diseases, will affect absorption, transport, metabolism, and excretion, as these are all protein-dependent processes. The role of plasma albumin in drug transport was discussed above and will certainly be affected by impaired albumin synthesis and/or sequestration in the extravascular space, as seen in protein-energy malnutrition. It should be noted, however, that malnutrition affects many aspects of drug metabolism, not all in the same direction. For example, drug delivery may be reduced by impaired albumin concentration, but the drug concentration in the bloodstream may be increased as a result of impaired clearance, which is also affected by malnutrition.

The plasma amino-acid profile may affect the efficacy of drug entry into the central nervous system. At the blood–brain barrier, certain drugs are transported into the brain by the same transport system that carries the large neutral amino-acids; thus they must compete with them for use of the carrier binding sites. Diet composition, by affecting the postprandial amino-acid profile, may significantly affect the clinical efficacy of drugs such as L-dopa, used in the treatment of Parkinson's disease.

Body composition is also a relevant determinant of drug disposition and action. Although most drug dosages are calculated by total body weight, most drugs act only in the fat-free body mass. Thus, at a given body weight, individuals with more body fat will tend to receive a higher effective dose than those with less body fat. The amount of body fat is also important for drugs that are stored in adipose tissue.

Major Drug–Nutrient Interactions of Clinical Relevance

Table 2 provides information on the major drug–nutrient interactions of clinical relevance. The list reflects well-known interactions of drugs that have been on the market for some time. The US Food and Drug Administration (FDA) maintains an on-line database of recently reported interactions and interactions of new drugs. The database can be assessed at http://www.fda.gov.

Table 2 Major drug–nutrient interactions of clinical relevance

Drug	*Class*	*Food/nutrient*	*Effect/mechanism*
Acarbose	Antidiabetic	Food	Delays carbohydrate breakdown and glucose absorption
		Iron	Decreased iron absorption
Acetaminophen	Analgesic	Food	May delay extended release; high-pectin food delays absorption
		Alcohol	Increased risk of hepatotoxicity
Acetohexamide	Antidiabetic	Glucose	Hypoglycaemia
		Alcohol	Flushing, headache, nausea, vomiting, sweating, tachycardia
		Sodium	Hyponatremia, SIADH
Acyclovir	Antiviral	Food	No effect; may take with meals
Aluminum hydroxide	Antacid	Thiamin	Affects bioavailability, owing to pH
		Iron	Decreased iron absorption
		Phosphorus	Inhibits phosphorus absorption
		Vitamin A	Inhibits vitamin A absorption
Amikacin	Antibiotic	Calcium, potassium, magnesium	Causes renal wasting of these nutrients
Amoxicillin	Antibiotic	Food	Decreased absorption owing to delayed gastric emptying
Amphotericin B	Antifungal	Potassium, magnesium	Causes renal wasting of potassium and magnesium
Ampicillin	Antibiotic	Food	Decreased absorption owing to delayed gastric emptying

Continued

Table 2 Continued

Drug	*Class*	*Food/nutrient*	*Effect/mechanism*
		Potassium	High doses increase urinary potassium losses
Antipyrine		Green vegetables, beef protein	Decreased absorption
Aspirin	Analgesic	Food	Decreased rate of absorption
		Folic acid	Increased excretion of folate
		Amino-acids	Decreased intestinal absorption of amino-acids, increased urinary excretion of tryptophan
		Iron	Chronic high dose 3–4 g day^{-1}, iron deficiency possible
		Alcohol	Gastric irritation, leading to possible gastric bleed
		Curry powder, liquorice, teas, raisins, paprika	Potential salicylate accumulation
		Ascorbic acid, fresh fruits, high vitamin	Increased urinary excretion; decreased concentration in serum and platelets
Astemizole	Antihistamine	Grapefruit juice	May result in cardiotoxicity
		Food	Decreased bioavailability
Atenolol	Antihypertensive	Food	Delayed absorption
Atovaquone	Antibiotic	Food	Bioavailability increased, especially in high-fat foods
Atropine	Anticholinergic	Iron	Delayed absorption
Azithromycin	Antibiotic	Food	Decreased rate and delayed absorption
Bacampicillin	Antibiotic (penicillins)	Food	Decreased absorption
Barbiturates	Anticonvulsants	Alcohol	Enhanced CNS depression
		Calcium, vitamin D	Increased vitamin D requirements, owing to increased metabolism
		Cyanocobalamin	Increased bone resorption
		Folic acid	Decreased serum levels, leading to megaloblastic anemia
		Serum lipids	Decreased CSF folate and erythrocyte concentration; may increase cholesterol, HDL triacylglycerols
Benzodiazepines	Anticonvulsants	Nutrient	Enhanced CNS depression
Clonazedam		Calcium	Increased vitamin D requirements secondary to increased metabolism
Clorazepate dipotassium		Vitamin D	Increased bone resorption
Lopazepam		Cyanocobalamin	Decreased serum levels, leading to megaloblastic anemia
Oxazepam		Folic acid	Decreased CSF folate and erythrocyte concentration
		Serum lipids	May increase cholesterol, HDL triacylglycerols
Buprenorphone HCL	Analgesic Narcotic Agonist–antagonist	Alcohol	Enhanced CNS depression
Butorphanol tartate	Analgesic Narcotic Agonist–antagonist	Alcohol	Enhanced CNS depression
Calcium carbonate	Antacid	Iron	Decreased iron absorption
		Fats	May cause steatorrhea
Captopril	Antihypertensive ACE inhibitor	Food	Reduced absorption
Carbamazpine	Anticonvulsants	Sodium	SIADH
		Food	Enhanced absorption, increased bile production
Carbenicillin iandanyl sodium	Antibiotic	Food	Decreased rate of absorption
Cephalosporins	Antibiotic	Alcohol	Flushing, headache, nausea, vomiting, tachycardia

Continued

Table 2 Continued

Drug	*Class*	*Food/nutrient*	*Effect/mechanism*
Cefadroxil		Food	No effect (may take with food)
Cefpodoxime proxetil		Food	Bioavailability increased with food
Cefuroxim axetil		Food	Bioavailability increased with food
Cefixime		Food	Decreased rate of absorption
Cefachlor		Food	Decreased rate of absorption
Cephalexin		Food	Absorption reduced for suspension, delayed for capsules
Cephradine		Food	Rate of absorption delayed
Ceftibuten		Food	Decreased absorption
Cefamandole		Vitamin K	Decreased vitamin K hypoprothrombinemia
Cefoperazone		Vitamin K	Decreased vitamin K hypoprothrombinemia
Cefotetan		Vitamin K	Decreased vitamin K hypoprothrombinemia
Cetrizine	Antihistamine	Food	Delays time to serum peak; no effect on overall absorption
Chlorambucil	Antineoplastic	Food	Reduced absorption
Chloramphenicol	Antibiotic	Iron	Increased serum level iron; increased total iron-binding capacity
		Folic acid	Antagonist to physiological action; increased requirements of folic acid
		Vitamin B_{12}	Increased requirements of vitamin B_{12} can cause peripheral neuropathy
Chlorothiazide	Diuretic	Food	Increased drug absorption owing to delayed gastric emptying
Chloroquine	Antimalarial	Food	Increased bioavailability
Chlorpromazine	Antiemetic	Food	Decreased absorption owing to delayed gastric emptying
Chlorpropamide	Antidiabetic	Glucose	Decreased blood glucose concentration
		Sodium	Hyponatremia, SIADH
		Alcohol	Flushing, headache, nausea, vomiting, tachycardia
Cholchicine	Antigout	Cyanocobalamin	Decreased absorption of cyanocobalamin
Cimetidine	Histamine 2 antagonist	Food	Delays absorption
Ciprofloxacin	Antibiotic (quinolone)	Caffeine	Decreased rate of absorption
		Food	Decreased elimination of caffeine
		Calcium	Calcium can bind quinolones
		Mineral supplement	Absorption of divalent and trivalent cations decreased by binding to quinolones
Cisapride	Motility	Food (grapefruit)	May result in increased cardiotoxicity
Clarithromycin	Antibiotic (macrolide)	Food	Decreased onset of absorption; no change in total amount absorbed
Clonazepam	Anticonvulsants (benzodiazepine)	Nutrient	Enhanced CNS depression
Clorazepate dipotassium		Calcium	Increased vitamin D requirements, owing to increased metabolism
		Vitamin D	Increased bone resorption
		Cyanocobalamin	Decreased serum levels, leading to megaloblastic anemia
		Folic acid	Decreased CSF folate and erythrocyte concentration
		Serum lipid	May increase cholesterol, HDL triacyclglycerols
Clorgyline	Antidepressant (MAO inhibitor)	Tyramine-rich foods (avacado, canned figs, aged cheese, cola beverage, coffee, chocolate, wine, soy sauce, fermented meats, yeast, yoghurts)	May increase blood pressure

Continued

Table 2 Continued

Drug	*Class*	*Food/nutrient*	*Effect/mechanism*
Cloxacillin	Antibiotic (penicillin)	Food	Decreased rate of absorption
Codeine	Narcotic agonist, analgesic	Alcohol	Enhanced CNS effect
		Glucose	Can cause hyperglycemia
Corticosteroids Prednisone Prednisolone Dexamethazone Methylprednisolone Hydrocortisone	Steroids	Calcium, phosphorus, vitamin D	Decreased absorption of calcium and phosphorus; increased urinary excretion; chronic high dose can cause osteomalacia
Corticosteroids	Steroids	Nitrogen	Increased urinary nitrogen losses
		Zinc	Increased urinary excretion and decreased serum levels
		Glucose	Impairs glucose tolerance; increases plasma levels
		Triacylglycerols, cholesterol	Increased serum levels
Co-trimaxazole	Antibiotic	Potassium	Decreased excretion hyperkalemia
		Sodium	Increased excretion hyponatremia
		Folic acid	Potential for folate deficiency
Cyclosporine	Antirejection	Milk, fat, pineapple juice	Increased absorption
Demeclocycline	Antibiotic	Food, calcium, iron	Decreased absorption of dairy products and divalent and trivalent cations
Diazepam Clonazedam Clorazepate dipotassium Lopazepam Oxazepam	Anticonvulsant	Food	Increased absorption with high-fat meals and delayed gastric emptying
Dicumarol	Anticoagulant	Food	Increased absorption with high-fat meals and delayed gastric emptying
Didanosine Tab	Antiviral	Food	Decreased rate and extent of absorption
Oral suspension		Fruit juice or acid liquid	Didanosine unstable in acid
Digoxin	Cardiac	Food	Delayed absorption; adsorbent to high-fiber high-pectin foods
Dirithromycin	Antibiotic (macrocide)	Food	Slightly increased absorption
Divalproex	Anticonvulsant	Food	Decreased rate of absorption; extent of absorption not affected
Doxycycline	Antibiotic	Food	Decreased absorption of food and milk
Erythromycin	Antibiotic (macrocide)	Food	Increased absorption by delayed gastric emptying
Erythromycin stearate		Food	Reduced absorption by delayed gastric emptying
Ethionamide	Antituberculosis	Pyridoxins	Reports of peripheral neuritis and paraesthesia
Etodolac	NSAID	Food (milk)	Decreased total bioavailability of tolmetin; decreased absorption of ibuprofen
		Sodium	Hyponatremia (indomethacin/ketorolac)
		Potassium	Hyperkalemia (indomethacin/ketorolac)
		Food	Increased rate of absorption
Felbamate	Anticonvulsant	Glucose	Hypoglycemia
		Magnesium	Hypomagnesemia
		Phosphorus	Hypophosphatemia
		Potassium	Hypokalemia
		Sodium	Hyponatremia
Fenoprofen	NSAID	Food (milk)	Decreased total bioavailability of tolmetin
Fenoprofen calcium		Sodium	Hyponatremia (indomethacin/ketorolac)
		Potassium	Hyperkalemia (indomethacin/ketorolac)
		Food (milk)	Decreased bioavailability of tolmetin; decreased absorption of ibuprofen

Continued

Table 2 Continued

Drug	*Class*	*Food/nutrient*	*Effect/mechanism*
		Food	Increased rate of absorption
Fluconazole	Antifungal	Potassium	Hypokalemia
Flucytosine	Antifungal	Food	Decreased rate of absorption; no change in extent of absorption
Foscarnet	Antiviral	Calcium	Hypocalcemia; drug chelates; divalent metal ions
		Magnesium	Hypomagnesemia
		Phosphorus	Hypophosphatemia and hyperphosphatemia
		Potassium	Hypokalemia
Furazolidone	Anti-infective	Tyramine-rich foods (avocados, canned figs, aged cheese, cola beverages, coffee, chocolate, wines, soy sauce, fermented meats, yeast preparation, yoghurts)	Prolonged large doses result in increased risk for hypertensive crisis
		Alcohol	Rushing, headache, nausea, vomiting, sweating, tachycardia
Furosemide	Diuretic	Food	Delayed absorption
Ganciclovir	Antiviral	Food	Increased area under curve plasma concentration
Glipizide	Antidiabetic	Food	Delayed absorption
		Alcohol	Flushing, headache, nausea, vomiting, sweating, tachycardia
		Sodium	Hyponatremia, SIADH
Griseofluvin	Antifungal	Alcohol	Can increase alcohol effect, flushing, tachycardia
		High-fat food	Increased drug absorption rate
Hydralazine	Diuretic	Food	Increased absorption
Hydrochlorothiazide	Diuretic	Food	Increased absorption by delayed gastric emptying
HMG-CoA Reductase inhibitors Simvastatin Lovastatin	Antihyperlipidemic	Food (grapefruit)	Increase drug serum concentration; increase area under curve concentration
Ibuprofen	NSAID	Food (milk)	Decreased total bioavailability of tolmetin; decreased absorption of ibuprofen
		Sodium	Hyponatremia (indomethacin/ketorolac)
		Potassium	Hyperkalemia (indomethacin/ketorolac)
		Food	Increased rate of absorption
Indinavir	Antiviral	Food	Decreased absorption of high-calorie, high-fat and protein-rich foods
		Grapefruit juice	Decreased area under curve concentration
Indomethicin	NSAID	Food (milk)	Decreased total bioavailability of tolmetin; decreased absorption of ibuprofen
		Sodium	Hyponatremia (indomethacin/ketorolac)
		Potassium	Hyperkalemia (indomethacin/ketorolac)
		Food	Increased rate of absorption
Iron	Mineral	Ascorbic acid	Increased absorption
		Amino-acids	Increased absorption
		Calcium phosphate	Decreased absorption
		Zinc	Inhibits absorption
		Vitamin A	Vitamin A deficiency inhibits iron utilization and accelerates the development of anemia
		Tea/coffee	Decreased absorption owing to formation of iron tannate

Continued

Table 2 Continued

Drug	*Class*	*Food/nutrient*	*Effect/mechanism*
		Vegetable polyphenols	Binds and insolubilizes iron
Isoniazid	Antituberculosis	Food	Decreased intestinal absorption
		Pyridoxine	Decreased metabolism, antagonism
		Food and histamine, tuna, liver, aubergine, parmesan cheese, tomato, spinach, tyramine-containing foods	Headache, redness, itching of eyes and face, chills, diarrhea, palpitation; potential hypertensive crisis due to monoamine oxidase inhibitor activity
Itraconazole	Antifungal	Food	Increased absorption, increased triacylglycerols
		Potassium	Hypokalemia
Ketoconazole	Antifungal	Alcohol	Flushing, headache, nausea, vomiting, sweating, tachycardia
Lansoprazole	H/K proton-pump inhibitor	Food	Delays absorption
Labetalol	Antihypertensive	Food	Increased absorption
Lamivudone (3TC)	Antiviral	Food	Decreased rate of absorption
Levodopa	Anti-Parkinson's	Food	Decreased absorption; with high-protein meals amino-acids compete for absorption
Lithium	Antimanic	Low-sodium diet	Increased lithium concentrations
		High-sodium diet	Increased lithium clearance
		Food	Increased absorption
Linezolid	Antibiotic	Tyramine-rich foods	May result in blood-pressure changes
Lomefloxacin	Antibiotic (quinolone)	Food	Decreased rate and extent of absorption
Loracarbef	Antibiotic	Food	Decreased rate of absorption
Lovastatin	Antihyperlipidemia	Food	Increased absorption
Mebendazole	Anthelmintic	Food	Increased absorption
Meclofenamate	NSAID	Alcohol	Additive CNS effects; increased prothrombin time
		Food	Decreased bioavailability
Melphalan	Antineoplastic	Food	Reduced absorption
Mercaptopurine	Antineoplastic	Food	Reduced absorption
Methacycline	Antibiotic	Food, calcium, iron	Decreased absorption of dairy products, cereals, divalent and trivalent cations
Methenamine mandelate	Urinary anti-infective	Milk products, citrus fruits	Excessive amounts inhibit drug conversion
Methosuximide	Anticonvulsant	Alcohol, calcium	Additive CNS effects; hypocalcemia
Methotreate	Antineoplastic	Food	Increased absorption
Methyldopa	Antihypertensive	Vitamin B_{12}, folate	In high doses methyldopa can increase vitamin B_{12} and folate losses
		Food	High-protein meals compete for absorption
Metoprolol	Antihypertensive	Food	Increased absorption
Metronidazole	Antibiotic	Alcohol	Flushing, headache, nausea, vomiting, sweating, tachycardia
		Food	Decreased peak serum concentration but total amount of drug absorbed is not affected
Minocycline	Antibiotic	Food, calcium	Decreased absorption
Nafcillin	Antibiotic	Food	Decreased absorption; decreased serum levels due to altered gastric pH
		Potassium	High doses can cause hypokalemia owing to increased urinary losses
Nifedipine	Antihypertensive	Food (grapefruit)	Increases pressor effect of drug
Nitrofurantoin	Antibiotic	Food	Increased absorption by delayed gastric emptying
NSAIDs	NSAID	Food (milk)	Decreased bioavailability of tolmetin
Diclofenl		Sodium	Hyponatremia (indomethacin/ketorolac)
Etodolac

Table 2 Continued

Drug	*Class*	*Food/nutrient*	*Effect/mechanism*
Fenoprofen Ca Ibuprofen Ketoprofen Ketorolac Naproxn Oxapron Piroxican Sulindac Tolmetin NA		Potassium	Hyperkalemia (indomethacin/ketorolac)
		Food	Decreased absorption of ibuprofen
		Food	Increased rate of absorption
Norfloxacin	Antibiotic (quinolone)	Food, dairy products	Decreased rate of absorption
		Multivitamin and mineral supplements	Decreased absorption due to formation of divalent and trivalent cation complexes with quinolones
Nifedepine	Antihypertensive calcium-channel blocker	Grapefruit juice	Increased serum level of nifedepine flavonoids inhibits cytochrome P-450
		Food	Decreased bioavailability, formulation dependent
Ofloxacin	Antibiotic (quinolone)	Dairy products and mineral supplements	Decreased absorption by polyvalent cations
Ondansetron	Antiemetic	Food	Increased extent of absorption
		Potassium	Hypokalemia
Omeprazole	H/K proton-pump inhibitor	Food	Delays absorption
Oral contraceptives		Ascorbic acid	Decreased ascorbic-acid concentration in plasma, platelets, leucocytes
		Vitamin C, folic acid	Decrease in serum levels
		Vitamin B_{12}	Impairs tryptophan metabolism
		Amino-acids, vitamin A, vitamin E, copper	Increase in serum levels
Oxacillin	Antibiotic	Food	Decreased absorption and decreased serum concentration
		Fats	Oxacillin can cause steatorrhea
Paromomycin	Amoebicide	Food	Increased absorption by delayed gastric emptying
		Vitamins A, D, E, K	Malabsorption of fat-soluble vitamins owing to hypocholesterolemia
Penicillamine	Antidote (chelating agent)	Food	Decreased absorption
		Iron, zinc	Decreased absorption 30%–70% of increased zinc absorption; decreased penicillamine absorption
Penicillin G & VK	Antibiotic	Food	Decreased absorption by delayed gastric emptying
		Glucose	Hyperglycemia
Pentamidine	Antibiotic	Calcium, magnesium	Hypomagnesemia, hypocalemia
		Potassium	Hyperkalaemia due to nephrotoxicity
Phenacemide	Anticonvulsant	Fresh fruits and vitamin C	Increased urinary excretion of phenacemide
Phenobarbital	Anticonvulsant (see Barbiturates)	Food	Decreased absorption due to protein binding
		Protein	Low-protein diet increases duration of action of phenobarbitol
		Vitamin D, calcium	Decreased serum vitamin D by cytochrome P-450 hypocalcemia
		Fresh fruits and vitamin C	Increased urinary excretion of phenobarbitol
Phensuximide	Anticonvulsant (succinimides)	Calcium, vitamin D	Decreased serum vitamin D by P-450 cytochrome hypocalcemia

Continued

Table 2 Continued

Drug	*Class*	*Food/nutrient*	*Effect/mechanism*
		Vitamin B_{12}, folic acid	Decreased absorption and serum levels of folates; inhibits vitamin B_{12} transport
		Copper	Increased serum levels
Phenytoin	Anticonvulsant (hydantoins)	Fresh fruits and vitamin C	Increased urinary excretion
		Vitamin D, calcium	Decreased serum vitamin D by cytochrome P-450 hypocalcemia
		Enteral feeds	Decreased absorption
		Food	Increased absorption by delayed gastric emptying
Pimozide	Antineruoleptic	Food (grapefruit)	Increased risk of cardiotoxicity
Piroxicam	NSAID	Food	Delayed absorption
Praziquantel	Anthelmintic	Food	Decreased rate and extent of absorption
Primidone	Anticonvulsant	Fresh fruits and vitamin C	Increased urinary excretion of primidone
		Protein	Low-protein diet increases duration of action of primidone
Propantheline	Anticholinergic	Food	Decreased absorption
Propranolol	Antihypertensive	High-protein foods	Increased absorption
Proxyphene	Analgesic	Food	Increased absorption by delayed gastric emptying
Pyrimethamine	Antimalarial	Folic acid	Decreased serum folate concentrations
Quinidine	Antiarrhythmic	Food	Delayed absorption due to protein binding
Riboflavin	Vitamin	Food	Increased absorption by delayed gastric emptying
Rifampin	Antibiotic	Food	Decreased absorption
Ritonavir	Antiviral	Vitamins	Can cause vitamin deficiency
		Potassium	Hyperkalemia and hypokalemia
		Cholesterol	Hypercholesterolemia
		Triacylglycerols	Hypertriacylglycerolemia
		Food	Delayed absorption
Oral solution		Food	Increased extent of absorption
Capsules			
Salicylates	Analgesics	Iron	Long-term chronic use decreases serum iron
Magnesium salicylate			
Choline salicylate		Vitamin C	Decreases concentration in serum and platelets
Sodium salicylate		Amino-acids	Decreases their intestinal absorption and increases urinary secretion
Saquinavir mesylate	Antiviral	Food	Increased absorption of high-calorie, high-fat foods
		Calcium	Hypercalemia
		Glucose	Hyperglycemia and hypoglycemia
		Phosphorus	Changes in serum phosphorus
		Potassium	Hyperkalaemia and hypokalemia
Spironolactone	Diuretic	Food	Increased absorption by delayed gastric emptying
Sulfonamides	Antibiotic	Food	Delayed with no effect on extent of absorption
Sulfadiazine			
Sulfisoxazole		Folic acid	Decreased intestinal synthesis, absorption, and serum levels
Sulfamethoxazole			
Tetracycline	Antibiotic	Food	Decreased absorption
		Minerals	Inhibits absorption of iron, calcium, zinc, and magnesium; chelation by polyvalent cations
		Fats	Decreases absorption
		Vitamin K	Decreases bioavailability
		Vitamin C	Increases urinary losses; decreases

Continued

Table 2 Continued

Drug	*Class*	*Food/nutrient*	*Effect/mechanism*
Terfenadine	Antihistamine	Food (grapefruit)	Increased risk of cardiotoxicity
Theophylline	Broncodilator	Charbroiled beef	Increased metabolism of theophylline
		High-fat meals	Increased absorption dependent on formulation
Tolazamide	Antidiabetic	Sodium	Hyponatremia and SIADH
Tolbutamide	Antidiabetic	Ethanol	Prolonged hypoglycemia, disulfram reaction
Trimethoprim	Antibiotic	Folic acid	Decreased serum folate levels
Valproic acid Divalproex Sodium valproate Sodium oral solution	Anticonvulsant	Milk, food, carbonated drinks	Delayed absorption but no effect on extent of absorption
Warfarin	Anticoagulant	Alcohol, vitamin K	Inhibits warfarin metabolism; beef liver, pork liver, green tea, leafy green vegetables high in vitamin K inhibit anticoagulant effect
		Vitamin E	Can increase warfarin response
Zalcitabine	Antiviral	Food	Decreases rate and extent of absorption
Zafirlukast	Selective leukotiene antagonist	Food	Delayed absorption
Zidovudine	Antiviral	Food	Decreased rate of absorption

SIADH, Syndrome of inappropriate antidiuretic hormone excretion; CNS, central nervous system; CSF, cerebrospinal fluid; NSAID, nonsteroidal anti-inflammatory drug

Herb–Drug Interactions

Herbal botanicals have been used in many cultures throughout the world for hundreds of years. These products are usually seen as natural; they should not be synonymous with safe.

Possible interactions can involve hepatic cytochrome P-450 and changes in intestinal absorption, distribution, and renal excretion. Herbal interactions with certain drugs are listed in **Table 3**.

Table 3 Herbal–drug interactions

Herbal	*Drugs*	*Effect/mechanism*
Echinacea	Methotrexate, aminodarone, ketoconazole, steroids (anabolic)	Increased hepatotoxicity
Feverfew	NSAIDs	Decreased herbal effect
	Anticoagulants	Additive platelet inhibition
Garlic	Aspirin, anticoagulants	Reduced clotting time
Ginkgo biloba	Aspirin, anticoagulants, NSAIDs, tricyclic antidepressants, anticonvulsants	Decreased seizure threshold; increased risk of bleeding
Ginseng	Monoamine oxidase inhibitors	Headache, tremors, mania
	Corticosteroids	Increased steroid toxicity
	Warfarin	Decreased INR
	Digoxin	Increased digoxin levels
Kava kava	Benzodiazepines	Increased CNS depression
Epherda	Antidepressants, CNS stimulants	Increased herbal effect
St John's wort	Antidepressants, CNS stimulants	Additive effects
	Piroxicam, tetracycline	Increased photosensitivity
	Theophylline	Decreased theophylline levels
Saw palmetto	Oestrogen	Increased effect of herbal
Valerian	CNS depressants	Additive CNS depression

CNS, central nervous system; INR, International Normalization Ratio; NSAIDs, nonsteroidal anti-inflammatory drugs.

A J Buckley and S E Ozanne, University of Cambridge, Cambridge, UK

Introduction

The prevalence of metabolic diseases such as type 2 diabetes and cardiovascular disease is increasing at an alarming rate. Around one in ten people today suffer from type 2 diabetes and it is estimated that by 2010 over 250 million people worldwide will have this condition. Although the etiology of these metabolic diseases is considered to be multifactorial, there is now a substantial body of evidence suggesting that the pathogenic mechanisms underlying these adult-occurring diseases originate from disturbances experienced during *in utero* and early life.

The long-term effect of an insult during a critical period of development has been recognized for many years. As long as 70 years ago it was recognized that the early environment in which a child grows could have long-term effects on its health. This was based on the observations in England, Scotland, and Sweden that suggested that death rates in specific age groups at any time depended upon the year of birth, suggesting that the time of death was more related to the year the person was born in rather than the age of the person. Additional evidence supporting the importance of the early environment came from a study in Norway investigating the geographical variations in current death rates from arteriosclerotic heart disease. Forsdahl and coworkers demonstrated a significant positive correlation between the current death rates and geographical variation in past infant mortality rates.

In utero growth and development is an extremely critical period in one's life. This was first recognized by Barker and Osmond when they demonstrated a striking association between adult mortality from cardiovascular disease and past infant mortality rates earlier in the century in the same geographical regions of England and Wales. As infant mortality was greatest in regions where low birth weight was also present, it was hypothesized that adverse early life nutritional influences could result in low birth weight and lead to an increased predisposition to cardiovascular disease. Subsequent regional studies have also demonstrated associations between low weight both at birth and 1 year of age and high mortality rates from ischemic heart disease. Mounting support for the role that the early life environmental influences play in establishing the risk for disease came when this association was found not to disappear even with an improvement in diet during adult life or with moving to other regions of the country.

It is thus now well established that poor fetal growth confers an amplified risk for the development of diseases such as type 2 diabetes, cardiovascular disease, insulin resistance, and obesity. Metabolic programing, a concept defined as the process whereby exposure to a stimulus or insult during a crucial phase of growth and development results in permanent alterations in the structure or function of an organ or metabolic action, is involved in amplifying this risk. Maternal nutrition and the maternal metabolic milieu during gestation and lactation, as well as the functionality of the placenta, have been widely recognized as major influential factors of adverse fetal and early life metabolic programing.

Birth Weight and Adult Disease

Further evidence for the role that the early life environmental influences play in establishing the risk for disease came in the early 1990s when studies conducted by Barker and colleagues in a large cohort of men and women from Hertfordshire, UK revealed strong correlations between low birth weight and a high prevalence of metabolic diseases in later life (**Table 1**). Although not universally accepted, numerous epidemiological studies completed throughout the world, including other parts of the UK, Europe, US, and India, have found reproducible results in extensive population and ethnic groups and various age ranges.

The Hertfordshire study was a retrospective study that collected the birth records of 15 726 men and women born in Hertfordshire between 1911 and 1930. This study was the first to demonstrate that the incidence of death from coronary heart disease was highest in adults born with a low birth weight. Barker and colleagues replicated this finding in a cohort of 1586 men born in Sheffield, UK between 1907 and 1925. The link between low birth weight and coronary heart disease in adult life again received confirmation from studies involving over 70 000 nurses from the US born between 1921 and 1945. A study in South India demonstrated that in a cohort of 517 men and women born between 1934 and 1954, the prevalence of coronary heart disease rose to 11% when the recorded birth weight was less than 2.5 kg. In those people who had a birth weight of more than 3.1 kg the prevalence of coronary heart disease was only 3%. A Swedish study of over 14 000 men and women born in Uppsala, Sweden between 1915 and 1929 was able to clearly identify that the risk of death from cardiovascular disease was associated with being small for gestational age.

In the Hertfordshire study, Hales and Barker demonstrated a strong inverse relationship between birth weight and type 2 diabetes or impaired glucose tolerance in men aged 64 years. Similar findings have been reported in populations of men and women in other parts of Europe, Australia, and the US. Further support of the association between low birth weight and the development of metabolic disease comes from studies of monozygotic twins. Two studies have demonstrated that impaired glucose tolerance and type 2 diabetes is more prevalent in the twin with the lower birth weight.

Although initial studies focused on the relationship between cardiovascular disease and type 2 diabetes subsequent studies have reported associations with other conditions. From an early age, children born with a low birth weight demonstrate reduced endothelium-dependent dilation and increased arterial stiffness. It has been observed that this endothelial dysfunction persists into adult life. The mechanisms behind the association between low birth weight and impaired vascular function remain to be elucidated. Despite this, it has been suggested that endothelial dysfunction is an early feature and precedes the metabolic disorders that develop in low-birth-weight humans.

Whilst the association between low birth weight and high predisposition to disease has been reported quite substantially, it is important to note that a U-shape relationship does occur when investigating the association between birth weight and the development of metabolic diseases. Babies born large for gestational age are also at an elevated risk of developing diseases such as coronary heart disease and type 2 diabetes.

The etiology of breast cancer has now also been linked to prenatal influences. Investigations in Sweden, Norway, and the US have provided epidemiological data indicating that high birth weight potentially increases the risk of developing breast cancer. The specific biological mechanisms underlying this association still remain unclear. However, it has been suggested that prenatal exposure to the high level of estrogen that occurs during pregnancy may play a significant role. Other maternal hormones and growth factors may also be involved. A U-shape relationship also exists when investigating prenatal influences upon the development of breast cancer. Studies have reported birth weights below 2.5 kg and above 4 kg are significant risk factors for the development of breast cancer in women.

Table 1 Adult health characteristics associated with low birth weight

- Type 2 diabetes
- Coronary heart disease
- Hypertension
- Hypertriglyceridemia
- Impaired glucose tolerance
- Insulin resistance

Underlying Mechanisms

The Fetal Insulin Hypothesis

Hattersley and colleagues have suggested that the relationship between birth weight and type 2

diabetes could be mediated by mutations/polymorphisms in genes that influence insulin secretion or insulin sensitivity. Insulin is an important fetal growth factor, thus any defects in its secretion or action would result in both low birth weight and increased risk of diabetes. This is supported by studies of individuals with maturity onset diabetes of the young 2. These individuals who have mutations in the glucokinase gene have a lower birth weight compared to their unaffected siblings. The fetal insulin hypothesis therefore holds true in this rare monogenic form of diabetes.

The Thrifty Phenotype Hypothesis

An alternative hypothesis, termed the thrifty phenotype hypothesis, was proposed by Hales and Barker in 1992. This proposal focused on the role played by the fetal environment. It suggested that the mechanistic basis underlying the observed relationship between poor fetal growth and the future development of metabolic diseases was related to fetal nutrition.

Central to the thrifty phenotype hypothesis is the suggestion that during times of nutritional deprivation, the growing fetus undergoes metabolic adaptations that are beneficial to survival postnatally in similar conditions of poor nutrition. Such adaptations include the essential preservation of brain growth at the expense of the normal development of organs such as the liver, muscle, and the pancreas. This has no detrimental effect if the fetus is born into conditions of poor nutrition. Hence in sub-Saharan Africa where there is chronic malnutrition, rates of diabetes are very low. Detrimental consequences of fetal programing arise when the fetus is born into conditions that differ from those experienced *in utero*. The imbalance between the early and adult environments may then conflict with the programing that occurred during fetal life and predispose the offspring to the subsequent development of metabolic diseases in adulthood (**Figure 1**).

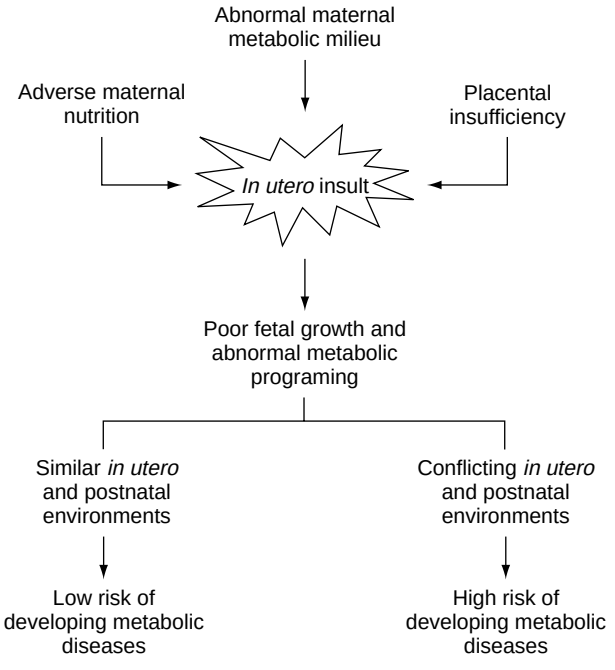

Figure 1 The interactions between *in utero* insults and the subsequent development of metabolic diseases.

Underlying Factors

Glucocorticoids

Maternal glucocorticoids can also influence birth weight of the offspring. Under normal conditions, fetal exposure to glucocorticoids is relatively low due to the presence of placental 11β-hydroxysteroid dehydrogenase 2 (11βHSD2), an enzyme that acts as a placental barrier by inactivating maternal glucocorticoids before they cross into the fetal environment. Maternal glucocorticoid treatment during pregnancy or inhibition of the placental 11βHSD2 can therefore increase the amount of active glucocorticoid crossing the placenta. Excess glucocorticoid exposure has also been implicated in disturbing the normal growth and development of the fetus with consequential effects on the overall health of the adult offspring. There does, however, appear to be a critical window of sensitivity where the developing fetus is particularly sensitive to glucocorticoids. Glucocorticoid overexposure in the 3rd trimester is known to cause reductions in birth weight. Studies in rats have established that glucocorticoid-exposed offspring undergo rapid postnatal catch-up growth, which proves deleterious to their adult health. These studies have demonstrated that excess exposure to glucocorticoids during fetal life is linked to low birth weight, altered functioning of the hypothalamic-pituitary-adrenal (HPA) axis, and the subsequent development of hypertension and impaired glucose tolerance in adulthood.

Increased HPA activity has been demonstrated in low-birth-weight human adult populations. Enhanced responsiveness of plasma cortisol to ACTH and increased urinary cortisol metabolite excretion has been reported in low-birth-weight adult males. Prenatal alteration of the HPA axis may therefore be involved in the subsequent development of cardiovascular disease in low-birth-weight adults.

Leptin

Cord plasma leptin levels have been shown to correlate positively with birth weight and neonatal adiposity. It has been suggested that leptin has a regulatory role in growth and development. Low levels of cord blood leptin have been reported in growth-restricted offspring. These low leptin levels may also predict significant weight gain and catch-up growth, both of which are evident in these growth-restricted offspring. Ong and colleagues hypothesized that there may be a link between *in utero* programing of leptin levels and the predisposition to the development of metabolic diseases.

Maternal Nutrition and Fetal Origins of Adult Metabolic Diseases

Assessing the impact of maternal nutrition on health of the offspring in humans is difficult. However, investigations involving offspring conceived during conditions of famine have provided direct evidence of the effects that maternal nutrition during gestation and lactation has on the overall health of the adult offspring. The Dutch famine, which occurred in the western part of the Netherlands at the end of World War II, only lasted around 5 months from late November 1944 to early May 1945, and was therefore defined as a short period of famine. Prior to the onset of the famine conditions, the affected area of the Netherlands consisted of a reasonably well-nourished population. The occurrence of this abrupt famine therefore granted researchers a unique opportunity to retrospectively study the effect of maternal nutrition during specific stages of gestation on insulin-glucose homeostasis and obesity risk in adult offspring (**Table 2**).

Investigators traced and studied individuals who were born immediately before the famine commenced, those born during the famine, and those born up to 21 months after the famine had ceased. Compared to the offspring not exposed to *in utero* famine conditions, individuals who were *in utero* during the famine had higher plasma glucose levels 2 h after a standard oral glucose tolerance test. These glucose levels were highest in those individuals who had been exposed to the famine during the final trimester of pregnancy and then become obese in adult life. In terms of obesity, individuals who were exposed to the famine during the first half of pregnancy were more obese at age 19 years. In contrast those who were exposed to the famine during the last trimester of pregnancy and in early postnatal life had reduced obesity. This suggests that the critical time windows for increased risk of obesity and type 2 diabetes differ. This study provided direct evidence that poor maternal nutrition leads to increased susceptibility of type 2 diabetes and obesity in offspring. It also supports the hypothesis that the greatest risk of developing metabolic diseases exists when there is a marked conflict between the environmental conditions experienced *in utero* and that experienced in adult life.

Table 2 Effects of famine conditions during the different stages of pregnancy

Maternal exposure to famine during pre-early gestation	*Maternal exposure to famine during mid-late gestation*
Increased birth weight	Reduced birth weight
Increased birth length	Reduced birth length
Increased obesity	Reduced glucose tolerance
Increased risk of coronary heart disease	Increased risk of type 2 diabetes

As nutritional studies in humans are complex and clouded by multiple confounding factors, a number of animal models of maternal nutritional insults have been developed. Investigations involving these models have significantly contributed to elucidating pathogenic mechanisms underlying the fetal origins of adult metabolic diseases.

Maternal Total Food Intake

Animal models replicating human famine conditions have been developed to enable a more in-depth investigation of maternal calorie restriction throughout pregnancy and the long-term health consequences that this nutritional insult imposes on the developing offspring. Various animal species have been utilized whilst studying the fetal origins of adult metabolic disease in response to maternal feed restriction using dietary insults of up to 70% *ad libitum* food restriction.

Maternal total food restriction (50% of normal food intake) in the rat throughout the gestation period can induce intrauterine growth restriction and result in significantly reduced birth weight. This poor fetal growth is then accompanied by numerous metabolic disturbances in later life. Compared to age-matched control rat offspring, the blood pressure of the maternal food-restriction offspring is significantly elevated and endothelial vascular dysfunction is evident. Insulin resistance, as defined by an elevated fasting plasma insulin level, has also been shown in adult rats exposed *in utero* to the adverse effects of severe maternal food restriction (to only 30% of *ad libitum* intake). In guinea pigs, mild to moderate maternal food restriction (70%–85% *ad libitum* intake) during

the pregnancy leads to perturbations in postnatal glucose-insulin homeostasis as well as alterations in the homeostasis of cholesterol metabolism in the male offspring.

Despite the observed significant reduction in birth weight, adult rats exposed to maternal undernutrition (30% of *ad libitum* intake) whilst *in utero* have been shown to develop obesity. Compared to the control offspring, the feed-restricted offspring appear to have been inappropriately programed and display hyperphagia and elevated food consumption as a consequence of *in utero* exposure to an adverse maternal diet. The underlying mechanisms leading to the hyperphagia in these offspring remains to be determined. However, the involvement of leptin resistance has been implied as these offspring also display hyperleptinemia and have significantly elevated fat pad mass as adults.

Even short-term maternal food restriction during the various stages of the gestational period has been demonstrated to provoke perturbations within the metabolic processes of the offspring. Exposure to maternal malnutrition, particularly in the final trimester and during lactation, impairs the programming of β-cell development and induces alterations in the fetal endocrine pancreas that persist into adulthood such that the offspring at 12 months of age display profound insulinopenia and marked glucose intolerance.

Maternal Protein Consumption

In addition to total calorie intake there is also evidence that composition of the maternal diet can have long-term consequences on the metabolism of the offspring. Experimental animal models involving maternal protein restriction have suggested that adequate protein intake is critical in both development of the fetus and its long-term health. They have also provided insight into the possible underlying mechanisms.

Offspring of rat dams fed a low (8%) protein diet throughout the gestational period are consistently smaller at birth than offspring of a control diet containing 20% protein. Initially, the low-protein offspring have significantly improved glucose tolerance than the control offspring. In humans, small-for-gestational-age infants also display increased insulin sensitivity with respect to glucose disposal in early postnatal life. Offspring of dams fed a low-protein diet appear to undergo a greater age-dependent loss of glucose tolerance. By 15 months of age, the male low-protein offspring are considered to have developed glucose intolerance that is associated with insulin resistance and by 17 months of age this has progressed to type 2 diabetes.

Consistent with the thrifty phenotype hypothesis, the growth restriction of the tissues and organs of the low-protein offspring is not uniform. In the growth-restricted rats, brain growth is spared at the expense of the growth of other developing tissues. In addition to the altered structure and growth patterns, the insulin-sensitive tissues (skeletal muscle and adipose tissue) and organs (liver and pancreas) of the low-protein offspring have been metabolically programed to have altered functionality.

Recently, evidence has been provided suggesting that taurine supplementation to the maternal low-protein diet may benefit the health outcomes of the rat offspring. Maternal taurine supplementation was found to restore and normalize the vascularization of the offspring's endocrine pancreas. Despite these findings, there is little evidence to suggest that a maternal high-protein intake has overall beneficial effects on the metabolic health of the offspring. Some human epidemiological studies and human trials involving high-protein dietary supplementation have in fact demonstrated that the consumption of a high-animal-protein, low-carbohydrate diet throughout late pregnancy can lead to metabolic disturbances in the offspring when they reach adulthood. It has been suggested that these high-protein diets stimulate the hypothalamic-pituitary-adrenal axis and cause maternal cortisol levels to increase. As a result, the developing fetus is presented with the metabolic stress of being exposed to excess cortisol levels. This inappropriate exposure to cortisol during fetal life appears to program lifelong hypercortisolemia and elevated blood pressure. It is likely that the type of protein is also important and this may in part explain some of these apparent discrepancies.

Adverse metabolic disturbances in offspring have therefore been demonstrated as consequential effects of both the *in utero* exposure to either maternal protein restriction or maternal high-protein consumption. The role of the carbohydrate level in these diets still needs to be ascertained. Nevertheless, it is essential that the optimal level of protein intake during pregnancy and lactation be clearly established so as to aid in the normal growth and development of the fetus.

Maternal Iron Restriction

Women, especially pregnant women, in today's society are often diagnosed as being anemic or iron deficient. A rodent model of maternal iron restriction has been developed to determine if metabolic health consequences are observed in the offspring of

iron-deficient women. Similar to other restricted maternal diets, iron restriction during pregnancy in rats can lead to disturbances within the events of early life metabolic programing and can induce permanent adaptations of the offspring's physiological and metabolic processes.

Although the mechanisms remain unclear, growth restriction of the offspring of rats fed an iron-deficient diet throughout gestation has been consistently reported. Elevated blood pressure appears to occur in response to maternal iron restriction and persists throughout the life of the offspring. Changes in cardiac size are evident prior to the initiation of hypertension in the offspring of iron-restricted rat dams. Elevated levels of cardiac hypertrophy may therefore contribute to the programed rise in blood pressure documented in these offspring. Renal development is also adversely altered in the offspring of iron-restricted dams. Maternal iron restriction during pregnancy can induce reductions in nephron and glomerular number in the adult rodent offspring. Significant inverse relationships between glomerular number and systolic blood pressure exist in the offspring of iron-restricted dams suggesting that abnormal renal development may also be involved in inducing the hypertensive state in these offspring. The principal mechanisms behind the association of maternal iron restriction during pregnancy with the altered cardiac and renal growth in the offspring and the subsequent induction of permanently elevated blood pressure still need to be further investigated.

Maternal High-Fat Consumption

In today's Western, more affluent society, the *in utero* environment is likely to be influenced by maternal nutritional insults such as excess fat consumption. There is little dispute regarding the deleterious effects of a high-fat diet. It is well documented that a diet high in fat has played a fundamental role in the prevalence of type 2 diabetes, reaching the epidemic proportions that is seen today. Both human epidemiological studies and experimental animal investigations have demonstrated clear associations between the consumption of a high-fat diet and the increasing prevalence of cardiovascular disease, insulin resistance, and type 2 diabetes. In light of this, a high-fat diet can increase the risk of a pregnant woman developing gestational diabetes. As will be discussed later, it is well established that offspring of diabetic mothers are themselves at an increased risk of developing the disease at an early age. Consumption of a high-fat diet may not only therefore cause deleterious effects to the current generation, but may ultimately have profound consequential effects on future generations. Considering this, the negative impact that a maternal high-fat diet has on the offspring is a topical area of research that requires more detailed attention.

Like any maternal nutritional insult, exposure to an abnormal *in utero* environment, induced by the maternal high-fat diet, can lead to subsequent disturbances in metabolic programing of the developing fetus. To date, investigations studying this nutritional insult have mainly concentrated on the effects of a maternal diet high in saturated fat. Such a diet has led to rat weanlings having increased amounts of body fat, increased liver weight, increased liver triglyceride content, higher blood glucose, and higher blood triglyceride levels. Permanent alterations in the structure and function of the pancreas, vascular dysfunction, and reduced insulin sensitivity have also been documented in rat weanlings and young adult offspring of high-saturated-fat-fed rat dams. Recently, it has emerged that feeding pregnant rats with diets containing a high proportion of animal lard can induce severe endothelial dysfunction in the offspring, along with the subsequent development of increased adiposity, hyperglycemia, insulin secretory deficiency, and insulin resistance. Taken together, these investigations demonstrate profound metabolic derangements in the offspring of fat-fed rats. The underlying mechanistic basis for these observations, however, still requires elucidation. It is also important to note that a high-fat diet is concurrently low in carbohydrate content and it cannot be ruled out that a carbohydrate deficiency in the female rats may account for the metabolic perturbations observed in the offspring of high-fat-fed dams.

Maternal Alcohol Consumption

Several laboratories have investigated the effects of sustained maternal alcohol consumption on the offspring's metabolic health. Alcohol consumption during pregnancy can lead to abnormal fetal development and a subsequent reduction in birth weight. Increased offspring morbidity may also be linked to gestational alcohol consumption. It has been previously documented that female rats fed a gestational diet supplemented with alcohol tended to have a higher number of pups die in early postnatal life. Of those alcohol-exposed offspring that survived, the reduced rate of prenatal growth and development has been linked to abnormalities in the offspring's glucose and insulin homeostasis. Both glucose intolerance and insulin resistance are evident in the rat offspring exposed during *in utero* life to maternal alcohol. Phenotypic abnormalities,

commonly associated with insulin resistance and other metabolic diseases, are also evident in the *in utero* alcohol-exposed offspring. The accumulation of triglycerides in nonadipocyte tissue, namely the skeletal muscle and the liver, is commonly observed in both insulin-resistant humans and experimental animal models of insulin resistance. Elevated levels of plasma and nonadipocyte tissue triglycerides have now also been documented in low-birth-weight rats that were exposed to maternal alcohol *in utero*.

Consumption of alcohol is quite common among breast-feeding mothers as studies have shown ethanol to aid in the promotion of lactation. Establishing the harmful effects of alcohol consumption during lactation is therefore important. Newborn rats exposed to maternal alcohol only during the lactation period have also been shown to develop reduced insulin sensitivity despite having normal prenatal growth and development. In early postnatal life some important metabolic processes are still undergoing development. Therefore, it must be considered that early postnatal life is still a vulnerable period of growth and the developing metabolic processes may still be particularly susceptible to adverse effects induced by alcohol consumption by breast-feeding mothers.

Maternal Metabolic Milieu and Fetal Origins of Metabolic Diseases

Over two decades ago it was hypothesized that perturbations in the metabolic milieu of pregnant women can disturb the intrauterine environment and influence long-term health consequences in the offspring. Abnormalities in the maternal metabolic milieu can evoke the adverse transfer of hormones and fuels from the mother to the growing fetus and thereby increase the predisposition to metabolic disease in the offspring's later life.

The effect of a diabetic pregnancy has been thoroughly examined in the Pima Indians of Arizona. The Pima Indian population has the world's highest prevalence and incidence of type 2 diabetes. Metabolic disorders are becoming increasingly common in the younger generation of this population. Consequently, it is possible that these disorders are present in Pima Indian women of childbearing age. In fact, 10–15% of Pima Indian pregnancies are complicated by type 2 diabetes.

Diabetic pregnant women are hyperglycemic, a characteristic of the general diabetic population. Whilst maternal insulin cannot cross the placental barrier, maternal glucose can freely do so. Elevated maternal glucose levels can therefore induce fetal hyperinsulinemia, subsequently promoting excessive growth and adipose tissue accumulation in the offspring. Compared to the offspring of either nondiabetic or prediabetic (those who developed type 2 diabetes after the birth of their offspring) women, the offspring of diabetic females generally have increased birth weights. This obese state then tracks with the offspring throughout life. Interestingly, excessive obesity can also develop in the subset of normal-birth-weight offspring of diabetic women. These findings suggest the offspring of diabetic women are detrimentally programed into developing altered metabolic processes regardless of birth weight.

Exposure to maternal diabetes whilst *in utero* is also largely responsible for the offspring having an increased risk of developing insulin resistance, impaired glucose tolerance, and type 2 diabetes at an early age. These metabolic disorders are significantly more prevalent in the offspring of diabetics than the offspring of nondiabetics and prediabetics. It has been established that more than one-third of Pima Indian children diagnosed with type 2 diabetes in the past decade seem to have developed the disease as a direct programed response to being exposed to an intrauterine diabetic environment.

Metabolic disorders such as type 2 diabetes have been suggested to have a strong genetic component. It has been postulated that diabetes-susceptibility genes are transmitted to the fetus and this then confers an increased risk for the offspring to develop the disease in adulthood. According to this explanation, offspring born either prior to or after the mother's type 2 diabetes diagnosis should carry the same risk of inheriting the diabetes-susceptibility genes. However, it has become evident that this does not appear to be the case. Sibship studies have compared the prevalence of type 2 diabetes and the degree of obesity in Pima Indian siblings either born before or after their mother was diagnosed with type 2 diabetes. Within the same family, offspring born prior to the mother having developed the disease remained relatively unaffected. Conversely, children born after the diagnosis developed obesity at an early age and were at an increased risk for type 2 diabetes. Therefore, these findings confirm that in addition to any genetic effect, direct exposure to the diabetic intrauterine environment is implicated in the offspring having an increased predisposition to the premature development of metabolic disorders.

Placental Insufficiency and Fetal Origins of Metabolic Diseases

Poor fetal growth and development can occur in the offspring of adequately nourished women or women

with normal metabolic milieu. It is believed that placental insufficiency may be largely responsible for the growth restriction observed in this subgroup of offspring. Placental transfer of nutrients and metabolites is pivotal to fetal growth and development. Interference within this transfer process can lead to placental insufficiencies and a disruption to fetal nutrition, hence disturbing the normal growth of the developing fetus.

Placental insufficiency has been artificially produced in both rats by uterine artery ligation and in sheep by placental embolization. Both models have demonstrated intrauterine growth restriction to be a direct consequence of functional disturbances within the placental nutrient transfer process. To date, these studies have mainly focused on the detrimental effects present during fetal and early postnatal life. Further investigations are indeed warranted to establish whether metabolic disturbances persist into adult life.

Summary and Conclusions

Studies investigating the fetal origins of metabolic disease have confirmed a pivotal role for the *in utero* environment mediating the relationship between poor fetal growth and the subsequent increased risk of developing metabolic diseases in adult life. Disturbances within the critical *in utero* environment may be induced by maternal nutritional insults, abnormalities within the maternal metabolic milieu, or by placental insufficiencies. Animal models have been developed in an attempt to elucidate the mechanistic basis of this adverse metabolic programing. However, there is still an urgent need to explore further the pathogenic mechanisms involved in order to allow suitable intervention studies to be initiated.

The escalating epidemic of obesity and type 2 diabetes may be a consequence of a vicious cycle (**Figure 2**). Exposure to an abnormal *in utero* environment may predispose the offspring to the premature development of metabolic diseases. Consequently, the female offspring that are programed to develop the metabolic disease at a young age may, when pregnant, perpetuate this cycle. Generation after generation then has the subsequent risk of also prematurely developing metabolic diseases such as obesity and type 2 diabetes.

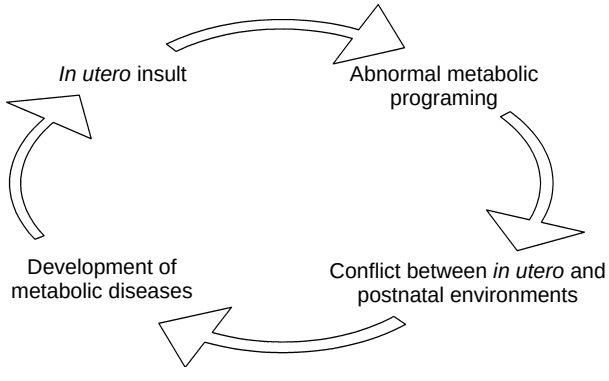

Figure 2 The vicious cycle that may be responsible for the increasing prevalences of metabolic diseases.

The ultimate aim in medical research is to prevent human disease. As maternal nutrition and their metabolic milieu status appears to have such a sizeable influence over the correct functioning of the metabolic processes in the offspring, there is an urgent need to establish ideal nutritional recommendations for pregnant and lactating women. Additionally, ways to treat the occurrence of placental insufficiencies successfully need to be identified. It is of utmost importance to optimize the growth, development, and metabolic programing of the offspring during the critical phase of *in utero* and early life. The development of possible prevention and treatment strategies may therefore aid in combating the epidemic prevalence of metabolic diseases such as obesity, coronary heart disease, and type 2 diabetes.

Non-Fetal

L S Adair, University of North Carolina, Chapel Hill, NC, USA

Introduction

A substantial body of evidence supports the hypothesis that adult chronic diseases have origins in early life. The basic premise of research in this field is that nutritional insufficiency during sensitive developmental periods results in structural changes or programing of metabolic functions. In the short term, such changes may enhance survival and spare brain growth at the expense of other organs. In the long run, the cost of such adaptive responses may be an increased risk of chronic disease. The main focus of research has been on fetal origins of adult disease, but there remains substantial potential for nutritional programing of later disease risk during infancy and childhood. The young infant has high energy and nutrient needs to support rapid growth and development. Birth weight typically doubles in the first 4–6 months of life, and length increases by about 30% between birth and 6 months. Many organ systems continue to mature after birth, notably the immunologic, gastrointestinal, and renal systems. This combination of rapid growth and continued development make the infant highly susceptible to the effects of environmental exposures and suboptimal nutrition, which might affect the development of disease risk. Differentiating postnatal from fetal origins is challenging, however, owing to the inevitable link between pre- and postnatal growth.

Instances of purely postnatal effects relate primarily to infant feeding or exposure to pathogens or toxins. The potential effects of infant feeding relate to nutritional adequacy, and to exposure or lack of exposure to specific substances in human milk or human milk substitutes. Effects of feeding may occur independently of the infant's nutritional status at birth. This topic is discussed further in a separate section below.

There is also a continuum of fetal and postnatal effects. Intrauterine growth-restricted infants may experience optimal or even excess postnatal nutrition, or they may continue to be exposed to nutritional insufficiency. Their responses to postnatal challenges may be conditioned by their fetal nutritional history, such that there is an interaction or synergism of fetal and postnatal effects.

Prenatal nutritional insufficiency may be thought to result in 'downsizing.' It may produce smaller organs, for example, kidneys with a reduced nephron number, a pancreas with fewer islet cells, or a low skeletal muscle mass. Nutritional insufficiency may also alter metabolic or hormonal regulation, for example, hormone secretion or sensitivity of the hypothalamic-pituitary axis. In either case, the effects may be permanent, or subject to compensatory responses once nutritional or other insults are removed. For example, a permanently reduced nephron number is a hypothesized mechanism through which fetal growth restriction affects later blood pressure. Similarly, a reduced skeletal muscle mass may persist and affect insulin sensitivity in later life associated with a reduced number of insulin receptors. In such cases, the physiological capacity to respond to risk factors encountered later in life (e.g., diets high in sodium or excess calories relative to energy needs) may be compromised.

Alternatively, catch-up or compensatory postnatal growth may occur. Many infants who were underweight for length at birth typically undergo a period of rapid postnatal compensatory growth in weight, while those who are relatively short at birth have larger length increments (see **Figure 1** for an example from a Philippines infant cohort). A central finding in many studies is that chronic disease risk is most likely to be elevated in individuals who were growth restricted *in utero* and thus small at birth, but relatively large at the time health outcomes were measured, leading to the conclusion that excess

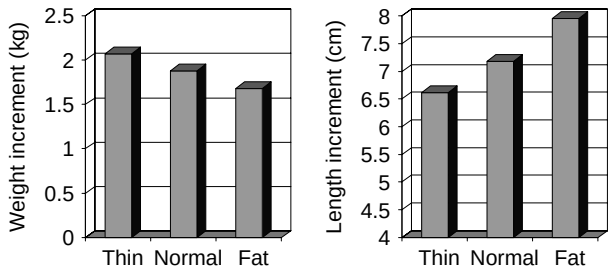

Figure 1 Early growth of Filipino infants is associated with relative weight at birth. Mean growth increments from birth to 2 months of age in children who were relatively thin (BMI $<$ 10th sample percentile) or fat (BMI $>$ 90th sample percentile).

postnatal growth contributes to disease risk. The extent to which rapid postnatal growth itself is a risk factor for the development of chronic disease has been the subject of extensive recent research. The relationship of early growth patterns to later disease risk is discussed in detail in a subsequent section.

Long-Term Effects of Infant Feeding

Much of the literature on the long-term effects of infant feeding is based on comparison of outcomes associated with human milk versus infant formula feeding. Postulated effects relate primarily to the different composition of human milk versus formula and different energy and nutrient intake by infants. The literature does not provide a clear and consistent picture of the long-term effects of feeding. When effects are found, they tend to be modest. Before discussing the results of these studies, it is important to raise several important methodological issues relevant to the interpretation of the literature.

First, breast feeding is a complex behavior chosen by mothers. Women who choose to breast-feed are likely to differ in systematic ways from those who do not. The choice to breast feed and the duration of breast feeding may be related to other short- and long-term health behaviors that affect the ultimate health outcomes of interest. To isolate the effect of infant feeding, it must be assumed that other concurrent and subsequent exposures are not systematically related to feeding history, or such exposures must be taken into account in multivariate analysis. Unfortunately, most studies have insufficient data to adequately control statistically for these other behaviors, particularly since they are often unmeasured or poorly measured.

Second, many studies use historical cohorts in which feeding method is recalled by the mother or based on limited records. While the decision to initiate breast feeding is likely to be accurately recalled, information about breast feeding duration and timing of introduction of other foods may be subject to recall bias.

Third, the composition of proprietary infant formulas has changed since their introduction in the 1920s. For example, sodium levels and fat sources have changed, and new ingredients such as n-3 fatty acids and nucleotides have been added recently. Therefore, results from older versus younger cohorts may differ either because true age-specific effects have emerged or because they were exposed to infant formula of different composition. Furthermore, the effects of breast and formula feeding on infant health are likely to differ depending on the environmental context.

The ideal study design for determining the long-term effects of infant feeding would require randomization to feeding regimens, and frequent follow-up of subjects up to the time when a disease risk factor or outcome is measured. Such designs are rarely ethical or feasible. An exception is a series of studies in the UK conducted by Alan Lucas and colleagues, which assessed long-term outcomes among preterm infants randomized to receive banked human milk or formula, and full-term infants whose mothers chose not to breast-feed randomized to different types of formula. While many of the studies have focused on neurodevelopment, some are now looking at other health outcomes.

Selected Outcomes Related to Infant Feeding

The following are examples of some chronic disease-related outcomes studied in relation to infant feeding. The selected outcomes are intended to be illustrative of a range of effects rather than a comprehensive treatment of all outcomes related to infant feeding.

Serum lipids Based on a systematic review of literature relating infant feeding to blood lipids in infants, adolescents, and adults, total cholesterol was found to be consistently higher in breast-fed infants compared to bottle-fed infants. No consistent differences related to feeding history were found in children and adolescents; and among adults, a majority of studies reported lower mean total cholesterol in those who had been breast-fed. The proposed but unproven mechanism for the protective effect of breast-feeding in adults is downregulation of endogenous cholesterol synthesis.

Blood pressure Differences in the sodium and fat content and composition of breast milk versus formula are thought to be the relevant determinants of

long-term effects of infant feeding on blood pressure. In a recent systematic review, data were compiled to compare exclusive breast feeding to formula feeding, with adjustment for current age, sex, height, and body mass index (BMI). The analysis was based on 26 studies of systolic blood pressure and 24 studies of diastolic blood pressure. On average, subjects who were breast-fed had a modestly lower systolic blood pressure than those who had been formula fed, with an average effect of −1.10 mmHg, and no marked differences by age. However, the analysis suggested publication bias since the effect was significantly larger in small studies than large studies. The studies showed no effects of feeding on diastolic blood pressure.

Taking advantage of a 1980 randomized trial to study the effect of a low or normal sodium diet in Dutch infants, a follow-up study at age 15 years found systolic blood pressure to be 3.6 mmHg lower and diastolic to be 2.2 mmHg lower in the low-sodium group. These results suggest that sodium intake in infancy may affect blood pressure later in life.

Further evidence of the effects of diet composition comes from a long-term follow-up of the Barry Caerphilly Growth study cohort. In this study, mothers and their offspring were randomly assigned to receive a milk supplement or usual care. In young adulthood (age 23–27 years), blood pressure was positively associated with dried formula milk supplement consumed in infancy. The effect was attenuated but remained significant after controlling for current BMI, suggesting an effect of diet composition independent of growth.

Reproductive function The relatively high levels of isoflavones in soy-based infant formula have raised concerns about potential effects on endocrine and reproductive function later in life. A recent retrospective cohort study of young adults who as infants had participated in controlled feeding studies during infancy found no differences associated with soy feeding across a large number of outcomes potentially susceptible to estrogenic or antiestrogenic activity of phytoestrogens, including timing of maturation, sexual development, or fertility in adolescents or adults. Another literature review reported no meaningful differences in child growth related to feeding of soy formula. However, data are limited and further randomized controlled trials are needed to provide definitive evidence.

Growth and body composition Mode of feeding may indirectly affect later disease risk through its effects on energy intake or aspects of metabolic regulation that affect growth and body composition. Numerous studies demonstrate different growth patterns in breast- and formula-fed infants that are hypothesized to reflect differences in nutrient intakes. In fact, evidence of systematic differences in breast- and formula-fed infants has led the World Health Organization to undertake the development of growth charts for breast-fed infants. In one careful study of body composition, total energy intakes and weight velocity from 3 to 6 months of age were higher in formula-fed compared to breast-fed infants. Estimates of fat and fat-free mass also indicate higher adiposity in formula-fed infants, however, none of these differences persisted into the second year of life. Similarly, in a study of nearly 5600 children who participated in the Third National Health and Nutrition Examination Survey, those who had been exclusively breast-fed for 4 months weighed less at 8-11 months than did infants who were fed in other ways, but few other meaningful differences in growth status through age 5 years were associated with early infant feeding.

Longer term effects of infant feeding have been assessed in studies that examined whether breast-feeding protects against later overweight or obesity. A recent review found inconsistent results, with some large cohort studies showing a moderate protective effect, and others showing no effect. The studies were also inconsistent in showing a dose response. An illustrative large study in 3–5-year-old children found that after adjusting for potential confounders, risk of having a BMI > 85th percentile was reduced among exclusively breast-fed children compared with those never breast fed, but there was no reduced risk of having a BMI > 95th percentile.

The findings are typically based on retrospective studies, in which breast-feeding data derive from maternal recall. This makes it difficult, if not impossible, to control for confounding, since a mother's decisions about breast-feeding may relate to subsequent child feeding and other factors associated with overweight. Thus, it is not clear based on the available data whether the effects of infant feeding are causal or whether breast-feeding serves as a marker for other health behaviors that may affect child and adolescent growth. Recent studies among siblings, which allow control for maternal characteristics, show no protective effects of breast-feeding on obesity in adolescents and young adults.

Exposure to antigens and development of autoimmune disease The infant's diet is the main source of exposure to antigens suspected to be related to the development of autoimmune diseases. A likely protective effect of exclusive breast-feeding relates to lack of exposure to food allergens, though some

other protective mechanisms related to specific substances in breast milk have been postulated. Exposure to bovine proteins by milk feeding, and to allergenic plant proteins such as those found in wheat is suspected to increase risk of developing diseases such as type 1 diabetes and celiac disease in genetically susceptible individuals.

Type 1 diabetes is one of the most prevalent chronic diseases with childhood onset. It is characterized by autoimmunity to pancreatic islet cells and is associated with a specific human leucocyte antigen (HLA) genotype. Not all individuals with the genotype develop the disease, suggesting an important role for gene–environment interactions. Hypothesized early exposures include infant feeding and enterovirus infections. Early introduction of cows' milk has received a great deal of attention as a potential risk factor. Numerous case–control studies associate increased risk with cows' milk, but a nearly equal number of studies show no effects. These retrospective studies have been criticized as suffering from recall bias and inappropriate control groups, for example, controls without the susceptible genotype. Recent prospective studies of at-risk infants in Australia and Germany found no association of type 1 diabetes with feeding of cows' milk. However, pilot study data from an international primary prevention trial suggests that eliminating cows' milk proteins in at-risk infants reduces risk of developing islet cell autoantibodies. This study also supports a role for early enterviral infections in the etiology of type 1 diabetes in genetically susceptible individuals. In fact, the research team has suggested that the effect of cows' milk may depend on viral exposures.

Recent studies suggest a role for other food antigens. A study of at-risk German children found that feeding of gluten-containing foods before 3 months of age was associated with risk of having pancreatic islet cell autoantibodies. Another study in the US also found an increased risk of islet cell autoimmunity among at-risk children given cereal before 3 months or after 7 months of age. Furthermore, they found that risks associated with cereal introduction were reduced by breast-feeding.

Other aspects of diet may have immunomodulatory effects. Vitamin D and the n-3 fatty acids EPA and DHA are suggested to be protective against immune-modulated diseases. For example, in a case–control study, Norwegian children given cod liver oil, a rich source of EPA and DHA, in the first year of life had significantly reduced risk of type 1 diabetes.

Type 2 diabetes Few studies have assessed the relationship of infant feeding to later development of Type 2 diabetes. Early feeding may affect patterns of insulin secretion in the newborn period, and thereby program subsequent development of metabolic control. Two studies in native American populations, one in Canada and one among Pima Indians, report a protective effect of breast-feeding on later development of Type 2 diabetes. In the Pima study, exclusive breast-feeding in the first 2 months of life was associated with a lower rate of Type 2 diabetes in children and adults. In the Canadian study, breast-feeding for more than 12 months was associated with decreased risk of Type 2 diabetes. Other studies have examined early risk factors related to subsequent development of Type 2 diabetes. For example, in a study of preterm infants randomized to human milk or formula of different composition, 32-33 split proinsulin, a marker of insulin resistance, was elevated in adolescents who had received a nutrient-enriched diet compared to those with a lower nutrient diet.

In sum, infant feeding, through nutritional adequacy, direct exposure to antigens, and protective substances provided in human milk, has the potential to alter response to subsequent exposures and to directly influence the beginning of disease processes.

Postnatal Growth and Later Risk of Disease

Small body size in childhood may reflect nutritional insufficiency that may program adult disease in ways similar to that observed in the fetal period. Independent of birth weight, low weight at 1 year of age has been associated with increased risk of cardiovascular disease in adult men. Similarly, poor childhood growth manifested as short stature has been linked with insulin resistance.

More attention has recently been paid to the effects of rapid childhood growth in height and weight. The observation in much of the fetal programing literature that effects of birth size emerge or are strengthened when current body size (typically represented as BMI) is taken into account suggests an important role for postnatal growth in the origins of adult disease. Individuals who are born small, but who end up relatively large (taller or heavier than their peers) have clearly experienced more rapid growth at some point between birth and when health outcomes and current size are assessed. Whether rapid growth is an independent risk factor or whether it confers increased risk only in individuals with a history of intrauterine growth restriction is a question requiring further research. Moreover, even when strong associations of growth rate and chronic disease risk are found, it is unclear whether the association is causal

or whether growth serves as a marker for other underlying causal processes.

Postnatal growth is clearly related to prenatal growth. Some metabolic changes associated with prenatal nutritional sufficiency may affect postnatal physiology and behavior that, in turn, affect growth. In addition, there is intriguing evidence from animal studies that prenatal nutritional restriction alters appetite and induces hyperphagia, and also reduces physical activity in adult animals (see **Figure 2**). If true in humans, this would be an important pathway by which disease risk is affected. Suggestive evidence comes from human infants whose cord blood leptin levels at birth were inversely related to weight gain in the first 4 months of life, independent of birth weight. Leptin may relate to subsequent growth by affecting appetite and energy intake.

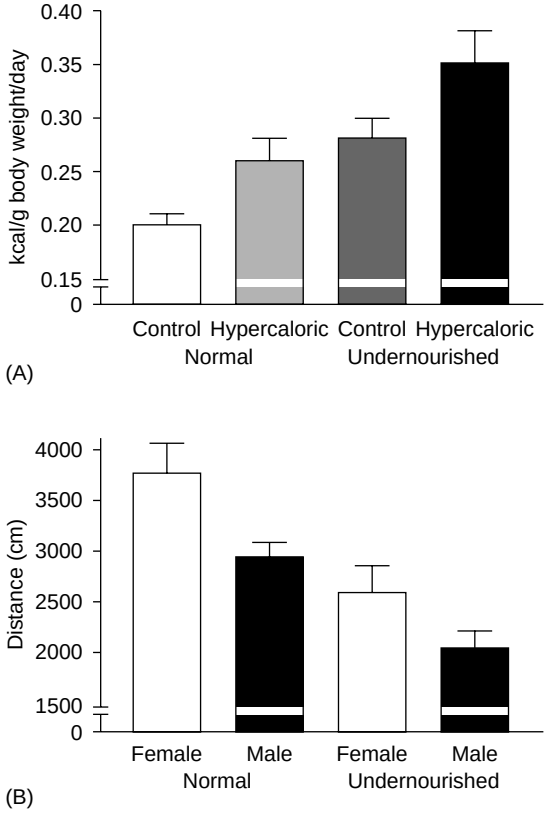

Figure 2 Locomotor behavior and food intake in Wistar rats as a consequence of a normal or adverse fetal environment ($n = 6$–8/group). (A) Food intake (kcal per gram body weight per day over a 5-day period) in females at day 145; $P < 0.005$ for effect of fetal programing, $P < 0.05$ for postnatal hypercaloric diet. (B) Locomotor activity at 14 months in males and females; $P < 0.005$ for effect of fetal programing and gender. Data analyzed by factorial ANOVA, and data are shown as means ±SE. (Reproduced from Vickers MH, Breier BH, McCarthy D, and Gluckman PD (2003) Sedentary behavior during postnatal life is determined by the prenatal environment and exacerbated by postnatal hypercaloric nutrition. *American Journal of Physiology. Regulatory Integrative and Comparative Physiology* **285**(1): R271-273 with permission from the American Physiological Society.)

Depending on the outcome under study, there are differences in whether linear growth or growth in weight, particularly weight relative to height, matters. Most often, more rapid weight gain is the risk factor, owing to the fact that excess adiposity is an important risk factor for many chronic diseases of adulthood. Another key issue concerns the timing of effects. There is controversy about whether early infancy compensatory growth following intrauterine growth restriction confers risk, or whether it is only later growth that matters.

Where many potential adverse outcomes might be affected by postnatal growth, the following sections focus on adiposity, blood pressure and coronary heart disease, insulin resistance and diabetes, and cancer.

Adiposity and Obesity

Early undernutrition followed by later overnutrition as well as early overfeeding independent of prior growth restriction are thought to increase risk of later obesity. Rapid postnatal weight gain occurs in a significant proportion of infants who are born small for gestational age. Prospective studies in US, South African, and British cohorts show that rapid growth in early infancy increases later risk of overweight. Longitudinal data from the US National Perinatal Collaborative study show that, independent of birth weight, one-third of obesity at age 20 is attributable to rapid weight gain in the first 4 months of life. In a Bristol, UK cohort, nearly one-third of children had an increased weight standard deviation (SD) score of more than 0.67 units from birth to age 2 years, and these children remained fatter, having more central fat distribution at age 5 years compared to children with lower early growth rates. Similarly, data from the South Africa Birth to Ten cohort showed that children with rapid weight gain in infancy were significantly lighter at birth and significantly taller, heavier, and fatter throughout childhood.

Early postnatal growth rates may program insulin-like growth factors, IGF-I and IGF-II. **Figure 3** illustrates this point with data on 5-year-old children from Bristol, UK in whom IGF levels were strongly related to current body size, but also that, independent of current size, children who had experienced catch up growth (change in Z-score >0.67 SD) from birth to age 2 had higher IGF levels. Childhood IGF levels are important as determinants of later linear growth and timing of puberty, and are associated with later risk of hormone-dependent cancers.

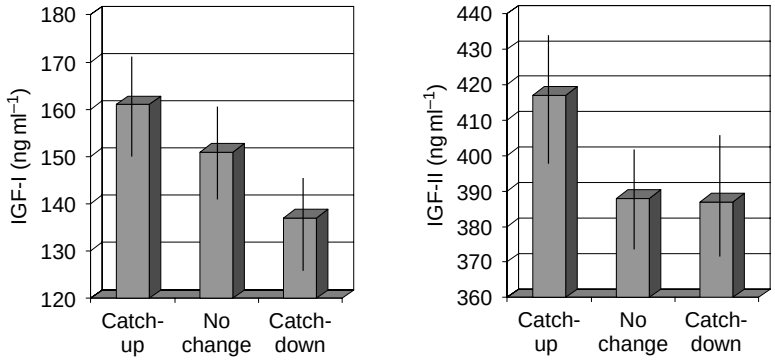

Figure 3 Hormone levels at age 5 years by change in weight Z-score from birth to 2 years of children in the ALSPAC cohort: means and 95% confidence intervals of IGF-I and IGF-II, adjusted for fat mass and fat-free mass. (Drawn from data from Ong K, Kratzsch J, Kiess W, Dunger D, and ALSPAC Study Team (2002) Circulating IGF-I levels in childhood are related to both current body composition and early postnatal growth rate. *Journal of Clinical Endocrinology and Metabolism* **87**(3): 1041–1044.)

Cancer

A large body of literature relates adult height to cancer risk, with the largest volume of evidence on breast, prostate, and colorectal cancers. In each case, risk of disease is increased with taller stature. A role for accelerated childhood growth is inferred, since taller individuals have experienced more linear growth. Possible mechanisms fall into two categories: childhood growth as a marker for other exposures that influence risk (fetal exposures, infections, timing of puberty, and energy intake) or growth as a mediator of risk (effects of growth promoting hormones such as IGF-I and IGF-II).

Few studies have directly addressed the effects of childhood growth, owing to lack of longitudinal data. Based on data from the UK Boyd Orr cohort, a one SD difference in height was associated with a 42% higher risk of overall cancer mortality in later life among males, but no effects were found in females. In another UK birth cohort, risk for breast cancer was elevated among women who were large at birth and tall at age 7. Based on data from the US Nurse's Health Study, rapid adolescent growth was associated with an increased risk of both pre- and postmenopausal breast cancer.

Blood Pressure and Coronary Heart Disease

Blood pressure is the one of the most well-studied outcomes in the context of fetal programing, with fairly consistent findings of a modest inverse relationship of birth weight to adult systolic blood pressure that increases with age. Substantial evidence demonstrates a synergistic relationship of fetal growth restriction with rapid postnatal growth. **Figure 4** presents the classic picture for systolic blood pressure: the highest pressure is found among adolescent males who were relatively thin at birth, but relatively heavy as adolescents. Current BMI is typically the strongest anthropometric predictor of blood pressure, but at the same BMI, those with a history of fetal growth restriction have higher mean blood systolic pressure and increased risk of having high blood pressure.

Owing to the existence of good longitudinal growth data in Scandinavia, child growth trajectories can be traced for individuals with and without hypertension or other adverse outcomes such as coronary heart disease. As shown in **Figure 5**, though initially smaller, adults with hypertension diverged in their BMI trajectory and were relatively heavier after age 7 compared to those without hypertension.

There remains controversy about the age at which higher growth rates pose risk of later disease. Some studies show elevated blood pressure in association with rapid weight gain in infancy, while other studies show no effect, or a protective effect (infants with larger weight increments have lower blood pressure

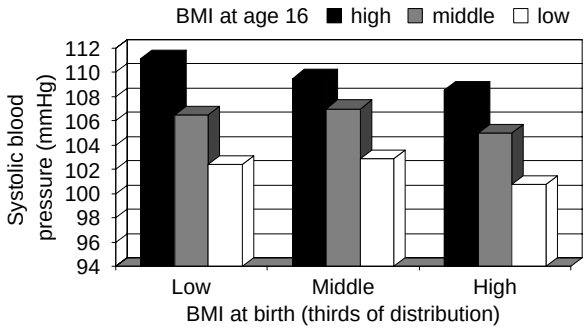

Figure 4 Synergistic effect of BMI at birth and age 16 on systolic blood pressure of Cebu (Philippines) boys: ■ high; ■ middle; and □ low BMI. Data from the Cebu Longitudinal Health and Nutrition Survey.

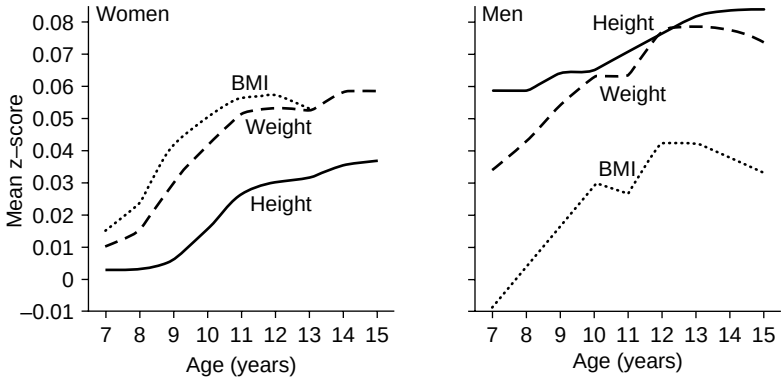

Figure 5 Z-scores for height, weight, and BMI from 7 to 15 years in 975 boys and 983 girls who later developed hypertension. Mean values for all 7086 subjects in cohort are zero. (Reproduced with permission from Eriksson J, Forsen T, Tuomilehto J, Osmond C, and Barker D (2000) Fetal and childhood growth and hypertension in adult life. *Hypertension* **36**(5): 790–794.)

as adults). The degree to which rapid infant growth represents risk may depend on whether it occurs in the context of recovery from fetal growth restriction and results in normalization of body weight versus excess growth leading to infant obesity.

There is more consistent evidence of increased risk associated with rapid weight gain in later childhood. In a Philippines cohort, larger weight increments from age 8 to 15 years increased risk of high blood pressure in boys who were relatively thin at birth. However, higher childhood weight gain in the absence of fetal growth restriction was not a risk factor in this population.

Fetal undernutrition may result in a reduced number of nephrons. Such deficits may not increase disease risk in individuals who remain small, but excess growth may challenge the ability of the kidneys to effectively regulate blood pressure. Catch-up linear growth has not been consistently implicated as a risk factor for later elevated blood pressure. In fact, continued poor linear growth, particularly in association with more rapid weight gain, increases risk of later elevated blood pressure.

Insulin Resistance and Diabetes

Most evidence relates to type 2 diabetes, but one large, population-based case–control study of type 1 diabetes in European populations found that height and weight were higher in cases starting at 1 month after birth, with maximum differences in cases and controls between 1 and 2 years of age. In the case of type 2 diabetes, both continued growth faltering in infancy and more rapid growth are associated with increased risk. Postnatal faltering in length is associated with impaired insulin metabolism.

As was the case for blood pressure, highest risk is associated with the combination of small size at birth and rapid postnatal growth gain. In a well-studied cohort in Finland, men and women who developed type 2 diabetes had lower birth weight, length, and ponderal index, and accelerated growth in weight and height from age 7 to 15 years. Precursors of diabetes such as insulin resistance have been studied. For example, in a follow-up study of British children who were born preterm, fasting split proinsulin and glucose concentration 30 min after a glucose load were highest in children with the greatest increase in weight centile between birth and time of measurement, regardless of early size.

Extensive studies of early origins of type 2 diabetes have been conducted in India, where rates are rising very rapidly. Indian babies who are small at birth have a deficit in skeletal muscle, but not body fat compared to normal size infants. These infants tend to grow into adults that retain a lower skeletal muscle mass, but have increased abdominal obesity. This body composition is strongly related to increased risk of type 2 diabetes. Prospective studies of Indian children show an interaction between birth weight and subsequent growth. For example, children who were born small but were relatively large at age 4 had higher plasma glucose and insulin concentrations 30 min after an oral glucose load, and greater insulin resistance at age 8.

Higher growth rates in previously growth-restricted individuals may pose excessive demands on systems initially adapted to function in the face of limited resources, leading to increased risk of diseases, particularly those associated with the metabolic syndrome. Rapid growth in weight during infancy and childhood, and in particular, rapid growth following prenatal growth restriction, increases risk of developing obesity, especially abdominal obesity. Factors that contribute to early onset of obesity are therefore important to control, since obesity tracks from early life to adulthood, and is a well-recognized risk factor for diseases such as type 2 diabetes, hypertension, and coronary heart disease.

In sum, the continued vulnerability and responsivity of the developing infant and child suggest the importance of a life course perspective on the development of diseases that are typically thought of as 'adult onset.'

EATING DISORDERS

Contents

Anorexia Nervosa

A R Rolla, Harvard Medical School, Boston, MA, USA

The relentless pursuit of thinness and the increasing prevalence of obesity in modern societies are the roots of the present higher prevalence of eating disorders. These eating disorders can be classified according to the interaction between the preoccupation with food and body weight and the self-control of hunger (**Figure 1**).

Classification of Eating Disorders

Obesity

Obesity can be classified as an eating disorder since, primarily or secondarily, obese patients eat

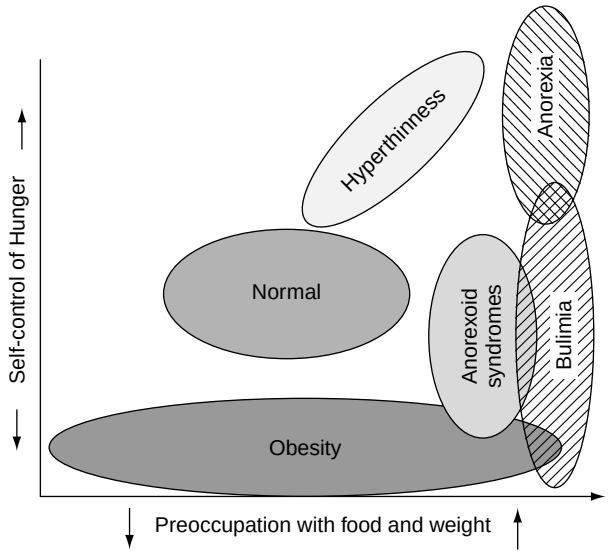

Figure 1 Classification of eating disorders based on the interaction between the preoccupation with food and body weight and the self-control of hunger. © 1999 Academic Press.

inappropriately for their increased weight and because obese individuals tend to suffer also from the other eating disorders.

Anorexia Nervosa

Anorexia nervosa is usually seen in younger women who restrict their food intake and increase exercise, causing a voluntary, stubborn malnutrition.

Bulimia

People who cannot control their hunger over a long period of time tend to have secret binging episodes. This is followed by an overwhelming feeling of guilt and depression, which frequently leads to self-induced vomiting. For this reason, the terms 'bulimia' (which means binge eating) and 'self-induced vomiting' are used interchangeably.

Anorexoid Syndromes

These abnormalities are seen in individuals who can no longer control their weight by dieting and exercising and have to resort to abnormal subterfuges, such as the following:

Self-induced vomiting
Ipecac abuse
Laxative abuse
Diuretic abuse
Anorexic agents abuse
Self-induced glycosuria in patients with insulin-dependent diabetes mellitus
Thyroid hormone abuse
Excessive, compulsive exercising

Professional Hyperthinness

This is a borderline condition, not necessarily pathological, in which individuals, usually with narcissistic tendencies, overvalue personal appearance and thinness as a way of obtaining professional success. It is commonly seen among models, figure skaters, ballerinas, artists, gymnasts, etc. They do not use the 'subterfuges' of the anorexoid patients; they are not socially isolated; their weight loss is not extreme; they have normal psychosexual activity; and they do not see themselves as overweight, unlike people with anorexia nervosa. For them, thinness is a means of obtaining success, not the final goal as in anorexia nervosa.

Anorexia Nervosa

Anorexia nervosa is a serious disease.

Psychological Disturbances

Psychological disturbances are most likely to be the initial event; they result in a complex obsession characterized by the following features:

1. An intrusive body image delusion makes the patients see themselves as being overweight when they are actually severely undernourished. This leads to a pathological fear of fatness (dysmorphophobia), a chronic voluntary starvation, and resistance to any external pressures to gain weight. Anorexic patients hide and dispose of food in the most ingenious ways to avoid eating.
2. An overwhelming sense of personal ineffectiveness makes anorexic patients believe that they cannot control the world around them. They continuously fear that they are going to lose their inner control. They therefore tightly control their world inside and slowly separate themselves from their social surroundings, with growing feelings of alienation and loneliness. There is no psychosexual development or interest, and no dating, unlike patients with bulimia.
3. Depression occurs which may be primary or secondary, obvious or atypical, and may or may not be amenable to treatment with psychotherapy and/or antidepressant medications.
4. Increased physical activity coexists with an apparent lack of hunger and fatigue and is inappropriate for the degree of malnutrition and depression.

Malnutrition

Anorexia nervosa is a self-imposed starvation. The term 'anorexia' is a misnomer since (at least initially) these patients are hungry. Anorexia nervosa is different from other forms of malnutrition because it is voluntary, resistant to nutritional treatments, accompanied by increased physical activity, without an initial organic cause (such as malignancy or surgery), and without associated infections. Because anorexia nervosa is a state of pure malnutrition without associated increased energy expenditure due to fever, immune response, or tissue reconstruction, these patients have a lowered metabolic rate and do not tend to develop opportunistic infections.

The exact mechanism by which these patients are able to control their hunger is unknown. Disturbed brain neurotransmitter activity may be implicated primarily or secondarily.

Endocrine and Metabolic Changes

Amenorrhea, decreased metabolic rate, hypothermia, hypotension, bradycardia, lanugo hair, carotinodermia, leucopenia, osteoporosis, etc. are mostly secondary to the severe malnutrition and are reversible with weight gain.

Other Clinical Characteristics

Anorexia nervosa is more frequent among daughters of white, affluent, achievement-oriented families in developed societies; it is extremely uncommon in areas of the world with poor nutrition. It tends to occur during the last years of high school or at the time of departure to a university or college.

The patients tend to be well-behaved perfectionists with good academic performance. Mothers of anorexic patients have a higher incidence of obsessive–compulsive personalities and preoccupation with diets and weight loss. Anorexic patients have done everything their mothers or families have trained them to do and, when faced with the increasing demands (and choices) of adult life, they exaggerate the only control left in their lives: *hunger*. There is an unconscious wish to revert to childhood, or to a prepubertal state, by means of undernourishing.

The onset of anorexia nervosa is usually subacute, over a period of weeks, not uncommonly after an episode of weight gain or after somebody has made a comment about the patient being overweight. Initially, it appears as an innocent attempt to lose weight, but soon thereafter it starts showing its rebellious and progressive nature. Anorexia nervosa appears in small epidemics in cities and countries, probably owing to social pressures and to imitation behaviors.

In contrast to their poor dietary intake, these patients have a paradoxical enhanced interest in nutrition and cooking. They collect recipes, read nutrition textbooks, plan a career in nutrition or cooking, or find a job in a restaurant (usually waitressing). Anorexic patients enjoy cooking and feeding the rest of the family. They know the precise energy content of all usual food and use their knowledge to select low-energy items.

When forced to eat, anorexic patients will dispose of or hide food. They use their above average intelligence to overcome all efforts to make them gain weight. They can be very resourceful in tampering with scales (adding weights to shoes or clothing, drinking large amounts of water just before weighing, etc.), and they have the most imaginative excuses as to why they are not gaining weight. They are extremely manipulative and master the art of confusing the different members of the treating team and family in their favor and against each other.

As they lose their natural insulation (subcutaneous tissue), it is difficult for anorexic patients to maintain their body temperature. They wear layer upon layer of clothing, which also helps them to hide their malnutrition. Lack of body fat is sensed by the hypothalamus as a sufficiency of stored energy, and therefore the cycling and amplitude of gonadotrophins decrease. This leads to hypothalamic amenorrhea, although approximately 30% of patients stop having menses before there is a significant weight loss. Depression may be another cause of hypothalamic amenorrhea in these patients. Some will remain amenorrheic for several months after regaining normal weight.

In primary or classical anorexia nervosa, patients lose weight by dieting (restrictive) and exercising. These patients tend to be younger, more naive, introverted, and obsessive, and they do not resort to subterfuges to lose weight. Their serum electrolytes, checked at frequent intervals, should be completely normal. Some patients find it impossible to control their hunger and start having binge episodes followed by forced vomiting (bulimia plus anorexia—'bulimarexia'). Others may start abusing laxatives or diuretics as they grow older.

There are patients in whom anorexia is secondary to an underlying, more serious psychiatric disorder, such as depression, schizophrenia, hysteria, or borderline personality disorder. In these cases, the course is longer and depends on the primary condition, as does its treatment. It is very uncommon for men to have anorexia nervosa, in men the condition tends to be associated more often with psychiatric problems and with homosexuality.

Physical Examination

The profound weight loss and cadaveric appearance contrast with the patient's increased physical activity. While hospitalized, if allowed, these patients try to perform some of the nursing chores or even to counsel other patients. Many patients exercise secretly in their rooms and jog or go for long walks when not supervised.

Pubic and axillary hair is preserved, and there is an increase in light, thin hair ('peach fuzz') on the face and neck, back, arms, and thighs (lanugo hair). Patients have low body temperature and poor tolerance to cold exposure because of their malnutrition-induced lowered metabolic rate and the loss of insulation of the diminished subcutaneous tissue. Layers of clothing tend to hide their cachectic appearance. Bradycardia and hypotension are common and secondary to decreased sympathetic drive due to malnutrition.

The skin is dry and has a peculiar bluish erythema over the knuckles and knees. Orange-yellow discoloration of the skin (carotinodermia), seen in palms and soles, is frequently found. It is caused, at least in part, by an increased intake of vegetables, since it may also be seen among vegetarians.

Symptoms

Symptoms are amazingly few. Usually these patients are forced to see a physician by their families. Spontaneous complaints may be amenorrhea, constipation, abdominal pain or distension after eating, 'fluid retention,' and inability to lose weight, for which they may ask to be placed on special diets.

Laboratory Investigations

The following findings are typical:

Mild normochromic, normocytic anemia.

Leucopenia with relative lymphocytosis.

Low sedimentation rates due to low fibrinogen levels.

Serum albumin and transferrin levels are normal, except in severe cases.

Serum carotene and cholesterol levels are normal or slightly elevated, which helps to rule out malabsorption.

Low normal blood glucose levels are found, with low levels of glycohemoglobin.

Electrolyte abnormalities, particularly low serum potassium values, occur only where there is self-induced vomiting or abuse of diuretics or laxatives.

Low serum levels of luteinizing hormone, follicle-stimulating hormone, and estradiol.

Increased growth hormone levels with decreased levels of insulin-like growth factor 1 (somatomedin C) in the serum.

Plasma renin activity and aldosterone levels may be very high in patients who abuse laxatives or diuretics (pseudo-Bartter's syndrome).

Electrocardiography shows sinus bradycardia, flat or inverted T waves, and prolonged QT_c.

Decreased bone density is due to decreased estrogen and progesterone secretion, decreased calcium and vitamin D intake, protein malnutrition, and increased marrow fat content of the bones. The conversion of hematopoietic to fatty marrow is related to the severity of the malnutrition and may be demonstrated with magnetic resonance imaging.

Endocrine Changes

Insulin

Low serum insulin levels occur with increased glucagon concentration. There is a tendency to asymptomatic low blood glucose levels and a low glycohemoglobin concentration. Fasting ketosis may be seen. The number and affinity of insulin receptors in target cells are increased, and abnormal glucose tolerance occurs due to prolonged fasting.

Adipose Tissue Hormones

The adipose tissue secretes different hormones called adipocytokines. Their secretion seems to vary in relation to the amount of adipose tissue accumulated, although the exact mechanism is not known. During profound weight loss, as in anorexia nervosa, there is a marked decrease in the adipose tissue mass with the typical changes in adipocytokines secretion that occur in these circumstances. One of the most studied adipocytokine changes is decreased leptin secretion. Increased fat mass stores are accompanied by an increased leptin secretion; decreased fat mass stores decrease leptin secretion. Low serum levels of leptin reaching the hypothalamus increase the activity of the 'hunger center,' in part by increasing the local activity of neuropeptide Y. Individuals with anorexia nervosa have very low levels of leptin in blood and cerebrospinal fluid, in relation to their decreased adipose tissue. This should cause an increase in hypothalamic neuropeptide Y content and hunger, but this compensatory mechanism to maintain a normal body weight does not seem to be effective in anorexic patients. Another important effect of the serum levels of

leptin on the hypothalamus is the modulation of the gonadal axis. Low levels of leptin are associated with decreased activity of the gonadal axis, and this explains the relationship between starvation and hypogonadism. After nutritional rescue and weight regain, the levels of leptin in the serum become normal.

Gonadal Axis

The female hypothalamus needs to 'sense' the presence of approximately 14–18 kg of body fat in order to allow fertility and menstrual cycles. With lesser amounts of fat, there is a progressive regression to the prepubertal state (low, nonspiking serum gonadotrophin levels). The signal from the fat stores to the gonadal hypothalamus seems to be the level of serum leptin. Very low levels of serum leptin, secondary to the decreased fat mass, seem to result in a decrease in luteinizing hormone-releasing hormone (LHRH) secretion. The hypothalamic, hypogonadal state of anorexia nervosa is due to the combined effects of malnutrition and the psychological disturbances on the hypothalamus. Secretion of LHRH and gonadotrophins improves as weight is regained and leptin levels increase; however, in up to one-third of these patients menses do not return immediately after nutritional rescue and weight restoration are accomplished. The decreased estrogen secretion from the ovaries causes a significant loss of bone mass at a critical time, which will subsequently aggravate postmenopausal osteoporosis.

In males, malnutrition seems to have a less important influence on the gonadal axis. Severe weight loss of long duration decreases serum testosterone and gonadotrophin levels, but to a lesser degree than in women.

Thyroid

Thyroid-stimulating hormone levels are normal but there is a delayed response to thyrotrophin-releasing hormone. Serum thyroxine, both total and free, is normal. The level of serum T_3 is low owing to decreased peripheral conversion (euthyroid sick syndrome), and there is a concomitant increase in reverse T_3. The basal metabolic rate is decreased by 20–30% and not fully corrected with T_3 replacement since it is also due to decreased sympathetic activity.

Sympathetic Nervous System

There is decreased peripheral sympathetic activity, with normal adrenomedullary function. This is due to decreased ingestion of energy, and it explains the tendency to bradycardia, postural hypotension, and low basal metabolic rate.

Adrenal Cortex

Serum cortisol levels are slightly raised, without diurnal variation, and may not suppress with dexamethasone overnight. Urinary 17-hydroxy and 17-keto steroids are decreased by 30–50%, but urinary-free cortisol may be increased. Corticotrophin-releasing factor (CRF) stimulation causes a subnormal corticotrophin rise but a normal or supernormal serum cortisol response. Levels of CRF in the cerebrospinal fluid are elevated. These changes in the hypothalamic–pituitary–adrenal axis are very similar to those seen in untreated depression.

Growth Hormone

Basal and pulsatile secretion of growth hormone (GH) is increased, with a peripheral resistance to its effects. Serum GH levels are elevated in 60% of patients, particularly in the most severe cases. This is due to decreased feedback from lowered serum concentrations of insulin-like growth factor 1 (IGF 1) and to increased serum levels of ghrelin. Growth hormone levels do not rise normally after L-dopa or insulin hypoglycemia, but there may be an unexpected rise in GH blood levels after stimulation with thyrotrophin-releasing hormone.

Ghrelin is a recently discovered polypeptide secreted by the stomach that increases in circulation with weight loss. Ghrelin is an activating ligand for the GH secretagogue receptor in the hypothalamus. With starvation and weight loss, the increased serum levels of ghrelin increase the release of GH and hunger. Individuals with anorexia nervosa have high serum levels of ghrelin that return to normal with normalization of body weight.

Vasopressin

There is decreased capacity to concentrate urine due at least in part to sluggish vasopressin secretion in response to osmotic stimuli. Levels of vasopressin in the cerebrospinal fluid are increased.

Inflammatory Cytokines

Inflammatory cytokines have important endocrinometabolic effects in people with infections and neoplasias, including anorexia and weight loss. In individuals with anorexia nervosa the serum levels of interleukin-1β, interleukin-6, tumor necrosis factor-α, and their soluble receptors are lower than normal, which may be due to decreased adipose production of these cytokines due to the decreased fat mass.

Hypothalamic Control of Hunger in Anorexia Nervosa

In normal individuals fasting and weight loss increase hunger by multiple mechanisms (decreased serum levels of leptin, insulin, and blood glucose and increased levels of ghrelin). At the level of the hypothalamus there is an increase in the potent orexigenic neuropeptide Y and other changes in neurotransmitters secondary to the fasting state. Some of these neurotransmitter changes may be the cause or a mechanism of anorexia nervosa, and for this reason they have received considerable attention in the past several years. It is important to understand that appetite control is a very complex hypothalamic function that involves many local and systemic neuropeptides, amines, and hormones.

Abnormal serotonin activity has been found in the brain of women with anorexia nervosa. An area in the chromosome 1 (p36.3–34.3) that contains genes for the serotonin 1D receptor and for the opioid delta receptor was associated with patients with anorexia nervosa by linkage analysis. One polymorphism in the Agouti related protein (Ala67Thr) has also been found associated with anorexia nervosa. Melanocortin system stimulants in the hypothalamus, such as Agouti related protein, are also involved in appetite and energy regulation. On the other hand, these genetic abnormalities may amount to only a biological tendency and do not explain the relatively short term of the illness during a life time or the changes in prevalence in the past decades.

Bone Density

Decreased estrogen and progesterone secretion; low serum levels of IGF-1; increased levels of serum cortisol; malnutrition with protein, calcium, and vitamin deficiencies; and fatty degeneration of the bone marrow lead to decreased bone density. Increased exercising does not counteract this-osteopenic tendency, which affects mostly young women during the years of skeletal growth. The osteopenia of anorexia nervosa is mostly asymptomatic, but some patients may present with stress fractures (diagnosed only with bone scans) related to their increased exercising. Many of these patients do not achieve their peak bone density even after their nutritional recovery and restoration of menses, and they are left with a propensity to fracture bones for the rest of their lives. Treatment with estrogens, calcium, and vitamin D is mildly effective. IGF-1 and DHEA-S have been used with partial success. Rapid restoration of nutrition seems to be the best management of anorexic osteopenia.

Differential Diagnosis

In the majority of cases the severe and voluntary malnutrition accompanied by the typical delusion of being fat and resistance to gain weight make the diagnosis very clear. Malnutrition due to organic causes in adolescents usually has an obvious reason and the patients want to improve their nutrition. Hypothalamic tumors may rarely present with severe loss of appetite.

The differential diagnosis should include the anorexoid syndromes. In pure anorexia nervosa the weight loss is due only to restrictive eating habits and exercise. Some anorexic patients may start binging and inducing vomiting, in which case their condition is called bulimarexia.

In some cases, anorexia nervosa is secondary to a serious, underlying psychiatric illness, with the weight loss being only an added problem. A particular diagnostic and therapeutic dilemma may occur for young women with personality disorder or chronic schizophrenia and anorexia nervosa.

Treatment

The multifaceted pathogenesis of anorexia nervosa requires an experienced team of psychiatrists, nutritionists, endocrinologists, internists or pediatricians, and nurses. *Each patient should be considered individually* since there are as many variations as there are patients. It is important to maintain communication between the different members of the team in order to present a unified front to the patient. Invariably, the patient will try to find and exploit the most minimal differences of opinion between the members of the team. Ideally, all important decisions should be made by one central team leader. Nurses, aides, and other paramedical personnel should be instructed about how to deal with the patient's behavior and charming search for allies.

There is no specific treatment and the methods reported are, at best, controversial. The etiology of this disorder is unknown, and etiological factors are probably different in each patient. It is therefore important to tailor the therapeutic approach to each patient.

Many cases of established and severe anorexia nervosa require prolonged hospitalization for psychological and nutritional rescue. Separation from parents and home environment is only part of what is to be gained from hospitalization. Administrators

and health insurance companies must understand this need.

Hospitalization is indicated for the following:

Severe and rapid weight loss
Serious metabolic or cardiovascular problems (hypokalemia less than 2.5 mmol l^{-1}) despite oral replacement, blood urea nitrogen more than 10.6 mmol l^{-1} of urea (30 mg dl^{-1}) in the presence of normal renal function, pulse less than 45 min^{-1}, systolic blood pressure less than 70 mmHg, or a body temperature less than 36 °C
Severe depression and suicide risk
Psychosis
Family crisis

Psychiatric Treatment

From the outset, the entire family should be interviewed to gain insight into the patient's previous behavior and to understand the family dynamics and enlist their help in therapy. Clear, simple contracts with the patient are a form of behavior modification that is simple to carry out. Initially, most daily activities and visits are curtailed and the patient is watched, particularly around mealtimes. As the patient improves, restrictions are lessened and privileges increased. Short-term goals are set from the beginning. Weight gains of 250 g daily or 1.3–1.8 kg per week are acceptable limits. Patients who accomplish these goals are rewarded by increasing levels of activity and autonomy within the hospital as a positive reinforcement.

The general attitude of the team should be one of understanding, concern, and firmness. One should try to build a trusting relationship in which the patients feel understood but without giving them a chance to deceive. The nature and course of the illness should be clearly explained to the patient and the family. This includes the serious complications of malnutrition and the fatal outcome of severe cases. Emphasize that the goal of treatment is not to make the patient fat but to make the patient feel better and to improve self-confidence and eating habits. Weight is only a by-product of the improvement, and 'muscle mass and protein recovery,' not fat, is what has to be gained.

This firm understanding should engage the patient in a *treatment alliance* with the team. Remember that many of these patients are very polite and 'out to please you' at least superficially, and many times their initial acceptance hides deeper feelings of isolation and resentment. Psychotherapy is of help for some patients, usually accompanied by behavior modification and family therapy.

Despite the common use of antidepressants, several double-blind trials have been inconclusive or only slightly favorable. Patients with clear manifestations of depression and the more severe cases seem to benefit more from these medications. Tricyclic antidepressants tend to increase appetite and are more suited for patients with pure anorexia nervosa. Selective serotonin reuptake inhibitors may help decrease binging in patients with associated bulimia. Olanzapine, an atypical antipsychotic medication associated with weight gain, has been shown to be useful in some patients with anorexia nervosa in uncontrolled studies.

Nutritional Treatment

The psychiatric treatment is beneficial only as long as the patient's nutrition is improved. The nutritional rescue breaks down the vicious circle of the psychological consequences of starvation and makes the patient more receptive to psychotherapy. The team should be prepared to deal with the most ingenious ways to deceive. The patient should be told that because of the tendency to deceive frequently found in her illness, close supervision will be necessary at least in the beginning of the treatment. Patients should be weighed fasting in the morning, in nightgown without shoes and with the same scale, daily or at regular intervals by a nurse.

Initially, oral intake should be monitored carefully with a nurse sitting through the eating period and for 30 min thereafter to prevent postprandial vomiting. The tray should be checked for any food not consumed. In this way, a careful energy count is obtained daily. If the energy intake is inadequate or if the patient is not gaining weight, the diet should be supplemented with low-residue, high-energy canned formulae dispensed by the nurse during medication rounds. These diet supplements should be consumed in front of the nurse. Many patients with anorexia nervosa have subclinical vitamin deficiencies and they should receive a multivitamin tablet every day.

It is not infrequent for these patients to complain of gastric distress after sudden increases in food intake; smaller and more frequent feedings and/or administration of metoclopramide or cisapride before meals may be of help. Tube feeding is poorly tolerated by most of these patients; it has connotations of a gastrointestinal 'rape.'

If severe malnutrition is present (low serum albumin and transferrin levels, anergic skin testing), parenteral hyperalimentation should be instituted from the beginning. It is recommended to start with small amounts of hyperalimentation fluid to avoid

excessive sodium and water retention (refeeding edema) which is very distressing to patients. The rate of hyperalimentation solution administration should be modified according to the improvement in oral intake and weight. Staff should be continuously aware of the possibility of tampering with the central lines by the patient, with the potential for air embolization, infection, and bleeding. In many patients it is important to curtail all physical activity initially, to the point of confining them to absolute bed rest with only bathroom privileges. As the patient improves, the activities are progressively increased.

Estrogen replacement is indicated to prevent the progressive decrease in bone density but it is poorly tolerated and accepted by these patients. Ideally, a birth control pill with good estrogen content should be administered.

Prognosis

The outcome for patients with anorexia nervosa is variable; a worse outcome is associated with older age of onset, severity and duration of the illness, male sex, and severe associated psychiatric disturbances. In general, 40–60% of patients achieve full nutritional and psychological recovery after 6–12 months. Approximately 20–40% attain a borderline normal weight and existence for the rest of their lives, but with the occurrence of significant stress they may revert to their previous anorexic behavior. There is a mortality rate of 5–30% in the most severe cases due to suicide, electrolyte imbalance, and starvation-induced myocardial damage causing intractable arrhythmias; it is rarely due to infection. Long-term follow-up of these patients has shown an increased later mortality due to alcoholism.

Bulimia Nervosa

A J Hill and S F L Kirk, University of Leeds, Leeds, UK

Episodes of ravenous overeating, referred to as compulsive eating or binge eating, have been recognized clinically since the 1950s. However, the disorder of bulimia nervosa was not formally described until 1979. This relatively recent recognition of the eating disorder has two important implications. First, the clinical picture and understanding of the psychopathology is changing with time. This has led both to a refinement in the diagnostic criteria used to characterize the disorder and to changes in reported prevalence. Second, the research base used to make judgments about development, prevalence, treatment, prognosis, and prevention is smaller than that for anorexia nervosa. Quite simply, there are still many unknowns in the area of bulimia nervosa.

This article focuses on the features used to make a diagnosis of bulimia nervosa, the psychopathology and developmental course of the disorder, and the groups at risk. Specific attention is paid to the nutritional consequences of bulimia nervosa and the ways in which dietary management is used in its treatment. Finally, long-term prognosis is considered.

Diagnostic Criteria

The behavior at the center of the disorder, binge eating, has been progressively redefined. A priority has been to separate binge eating from mere indulgence and everyday overeating. Accordingly, two features of a true binge have been identified: consumption of unusually large amounts of food and an aversive sense of lack of control over eating. The size of binges varies but is typically between 1000–2000 kcal.

Diagnostic schedules (such as DSM-IV and ICD-10) agree on three features that must be present in someone with bulimia nervosa. The first is the presence of binge episodes. Second, the person must use compensatory behavior to control body shape or weight. The most common is self-induced vomiting, but these strategies also include use of laxatives or diuretics, excessive exercise, and extreme dieting or fasting. Third, the person must show overconcern with body weight and shape. Importantly, the person should not be of low body weight, in which case a diagnosis of anorexia nervosa would be made.

The tightening of these formal diagnostic criteria has had the consequence of reducing misdiagnosis and prevalence but has increased the numbers of those with atypical eating disorders. Failing to exhibit one or more of the key diagnostic features, such as an insufficient frequency of binge eating, is classified variously as atypical, partial syndrome or 'eating disorders not otherwise specified' (EDNOS). It is also useful to note that the diagnostic criteria for another eating disorder, binge eating disorder (BED), are included in DSM-IV, albeit for research purposes. The key difference between BED and bulimia nervosa is the absence of the extreme compensatory behaviors that follow the binge. Those with BED are less likely to be restricting their eating but more likely to be overweight and to be older (most presenting between ages 30 and 50).

Psychopathology

The description of body image disturbance that is central to both anorexia and bulimia nervosa has undergone revision. A distinction has been argued for between dissatisfaction with body shape and overvalued ideas about weight and shape. Although body shape dissatisfactions are commonly found in these patients, it is their overvalued ideas about weight and shape that are the necessary diagnostic feature. In other words, concern should go beyond simply feeling fat to a point where a person's life is dominated by their feelings about body weight and shape.

If these overvalued ideas are accepted as the core psychopathology of bulimia nervosa, then the chaotic eating that typifies the condition can be seen as a behavioral consequence. Binges are often interspersed between periods of intense dieting, even fasting, themselves strategies to control weight. Purging always follows a binge and is a way of expelling the food ingested or compensating for the food energy intake. Binges are secretive, planned, often expensive, and emotionally self-destructive. Paired with purging, they are cyclical and self-perpetuating, although their frequency may wax and wane. In addition, this behavior may have a long history before treatment is considered and clinical attention sought.

Bulimic episodes may be triggered by a variety of factors, including anxiety, boredom, tension, or breaking the self-imposed dietary rules necessary to maintain rigid control over eating (see **Figure 1**). Only rarely is hunger identified as precipitating a binge, even though the person may not have eaten for 24 h or more.

Sustained depressive and anxiety symptoms are common and are part of a range of psychological

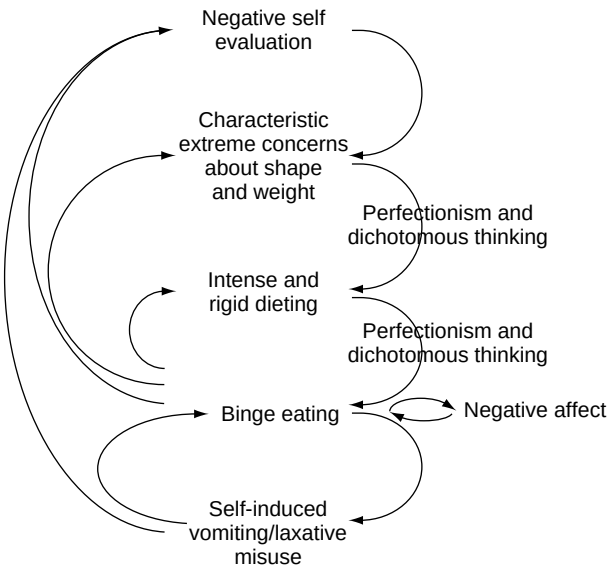

Figure 1 The cognitive behavioral view of the maintenance of bulimia nervosa (adapted from Fairburn & Brownell, 2002).

and social problems characteristic of bulimia nervosa. Impulsivity is also characteristic, with sexual promiscuity, self-harm, drug use, and stealing frequently noted. One suggestion is that impulsivity is a personality trait that favors bingeing over restriction, and so predisposes a person to bulimia nervosa rather than anorexia nervosa.

Etiology

As with anorexia nervosa, the picture of development is complex and multifactorial. There is no single cause of bulimia nervosa. Rather, a variety of psychological, biological, and social factors are involved in the emergence of the disorder. Although etiology is diverse, it has much in common with the forces responsible for anorexia nervosa and is clarified by looking at the groups of people most at risk. Overall, the balance of etiological factors is in favor of psychological and social causes, given that bulimia nervosa is a relatively new condition and has arisen at a time of profound social and cultural change, with little concurrent change in human biology.

The process of the development of eating disorders can be usefully divided into three stages. These conceptually separate the factors that predispose an individual to the disorder, precipitating events that lead to onset, and factors that perpetuate or maintain the disorder once initiated. Any framework drawn up for bulimia nervosa would be very similar to that for anorexia nervosa because the etiology of the two disorders appears to have a lot in common. Indeed, up to a third of patients with bulimia nervosa have a premorbid history of anorexia nervosa.

Although the etiological picture is very similar to that for anorexia nervosa, there are a few clues to differences. Genetic studies suggest the disorder is less heritable than anorexia nervosa, although heritability estimates of 46–71% have been calculated for the key behaviors, binge eating and self-induced vomiting. Evidence from case–control and cohort studies suggests two groupings of factors that contribute independently to the risk of developing bulimia nervosa. First, there is increased exposure to dieting and related risk factors, including parental and childhood obesity, and critical family comments about weight, shape, or eating. Second, a greater number of general risk factors for psychiatric disorder has been observed. These include parental psychiatric disorders such as depression, alcohol and substance abuse during childhood, low parental contact but high parental expectations, neglect, and abuse. Sexual abuse has been reported in 20–25% of patients with bulimia nervosa, a higher level than that found in restricting anorexia nervosa. Although the rate is increased compared to that of matched controls, it is no higher than the rate among young women with other psychiatric disorders. However, women with eating disorders in the context of sexual abuse appear to have higher rates of comorbid psychiatric conditions than other women with eating disorders.

The perspective on the perpetuation of bulimia nervosa is a cognitive one. **Figure 1** shows the vicious circles that maintain binge eating. Four points are emphasized in explaining this to patients. First, although dieting is a response to binge eating, it also maintains binge eating by both biological and psychological mechanisms. Second, compensatory purging encourages bingeing through a belief in its effectiveness at removing food for digestion. In other words, the barriers against overeating are removed since the food will not be absorbed. This is sometimes described as the reason why an individual initiated a binge–purge cycle of behavior. Third, extreme concern about body shape and weight promotes intense and rigid dieting and maintains the eating problem. Fourth, extreme concern about shape and weight is commonly associated with negative self-evaluation such as low self-esteem and longstanding feelings of worthlessness.

Groups at Risk

Like anorexia nervosa, bulimia nervosa is more common in women than in men, with a female:

male ratio around 10:1. The exact prevalence is notoriously difficult to establish for eating disorders, and for bulimia nervosa in particular. Problems in this regard include the recency of the disorder, changing diagnostic criteria, and the secrecy and non-life-threatening nature of the disorder preventing its routine appearance in clinical settings. Studies of US college students in the 1980s revealed up to 20% with bulimic symptoms. However, when such epidemiological studies investigate community samples and use interviews to follow-up questionnaire surveys, the average point prevalence among young women using strict diagnostic criteria is 1000 per 100,000 or 1.0%. In specific groups such as university students, there may be more than twice this level of the disorder. Bulimia nervosa is extremely rare in girls under 14 and the majority of cases are recognized between the ages of 18 and 25. Cases do present clinically in women in their late 20s and 30s, although they may have a long history of disordered eating.

The invisibility of bulimia nervosa is demonstrated by estimates of 1-year-period prevalence rates. These are calculated by adding figures for point prevalence and annual incidence. The 1-year-period prevalence rates for bulimia nervosa per 100,000 young women have been reported as follows:

In the community: 1500
In primary care: 170
In specialist mental health care: 87

These data indicate that only 11% of the community cases of bulimia nervosa are detected, and of these only half are received by specialist services. Since the first clinical description in 1979, there has been a dramatic upsurge in the number of bulimia nervosa cases seen, and much greater than that for anorexia nervosa. Although improved detection may account for some of this increase, there is general agreement that this represents a real increase in the number of women with bulimia nervosa.

Since women are most at risk, it is reasonable to ask why. One reason is that women are far more likely to diet than men. Dieting is itself a behavior that places individuals at risk of developing bulimia nervosa. But the motivations for dieting may be equally important. Women diet more than men for several reasons. These are bound together as a sociocultural perspective on bulimia, an approach that has become a powerful model for explaining who develops bulimia and why. At the heart of this perspective are three issues: the importance of a thin body shape for women, the centrality of appearance in women's gender role, and the importance of appearance for societal success. The arguments and evidence to support this analysis are compelling.

The above information on prevalence indicates that the average age of someone with bulimia nervosa is older than that for anorexia. This may reflect the observation that bulimia nervosa often follows a period of anorexia or at least low weight. Developmental challenges and age-dependent life events are also seen as important. The developmental task of achieving a sense of identity during mid- and late adolescence may be disrupted by relationship problems, peer or family difficulties, or events such as leaving home to go to college. The resultant erosion of self-esteem and perceived control can lead to problems with eating manifest as intensified dieting or periods of overeating and weight gain. The disrupted pattern of eating that follows may be the early stage of the disorder.

Nutritional Findings

A key feature of bulimia nervosa is the extreme dietary restraint that is exhibited in between episodes of binge eating. Such behavior has been described as all or nothing, so that on a good day the sufferer may describe consuming a very low-energy diet, whereas a bad day will consist of several episodes of uncontrolled eating. This will be accompanied by the purging behaviors previously described.

To sustain binge eating episodes, the person with bulimia nervosa may spend hundreds of pounds on food, selecting foods normally avoided during periods of dietary restraint which are easy to eat and subsequently remove from the body. To them, it is this overeating that is seen as the basic problem, not the dietary restraint that precedes it. Yet, it is this dietary restraint that drives the disorder. When not binge eating, it is common for patients to avoid eating for long periods, with 80% reporting consumption of one meal a day or less. While restricting their intake, they will consume reduced energy foods, with a strong tendency to avoid fat and choose energy-reduced foodstuffs.

It is often assumed that people with bulimia nervosa have good nutritional knowledge. Indeed, to the untrained eye, a diet history for a 'good day,' consisting of foods such as wholemeal bread, lots of vegetables and fruit, and skimmed milk, can be interpreted as conforming to healthy eating guidelines. However, this is not the case. Such restrictive behavior may fail to achieve even half the recommended energy intake and consequently may be deficient in micronutrients. The anxiety experienced

through consuming diet-breaking, 'unsafe' foods leads to the individual adopting extremely restricted diets between binges. Such intakes have been found to be lower in fat and higher in protein than the intakes of controls. People with bulimia nervosa also report feeling greater anxiety and guilt after eating foods they believed to be fattening.

Purging behaviors begin as a compensatory mechanism to offset episodes of binge eating. Consequently, it is a widely held belief that they are effective methods of weight control. However, the damage done to the body by these methods far exceeds any benefits in terms of weight. Any weight loss experienced is usually related to disruption of fluid balance rather than a loss of fat tissue. Furthermore, if self-induced vomiting is adopted, binges are likely to become more frequent and severe. If vomiting is prevented, the bulimic will consume significantly less food, thus maintaining the cycle previously described. Research has shown that vomiting fails to rid the body of all the food ingested. It has been estimated that only half the contents of the stomach are removed through vomiting, although this is variable and difficult to determine. Similarly, laxatives work on the system *after* food has been digested. One classic experiment looked at the amount of food energy lost through laxative abuse and found that, despite copious diarrhea, the amount of energy lost from the body was less than that found in the average chocolate bar.

What both laxative abuse and vomiting have in common is the depletion of fluid, leading to dehydration and electrolyte disturbances, particularly hypokalemia (low potassium). In some cases, hypoglycemia may develop as a response to fasting or binge eating and vomiting. In extreme cases, death may occur through cardiac arrest or gastrointestinal complications, such as oesophageal or gastric rupture. Vomiting also leads to erosion of dental enamel, resulting in periodontal disease and an increased incidence of dental caries. Other effects of bulimia nervosa include menstrual irregularities, swelling of the salivary glands secondary to vomiting, and reflex constipation, which occurs as a consequence of laxative abuse and dehydration. Laxative abuse has also been found to cause steatorrhea and protein-losing enteropathy in some cases.

People with bulimia nervosa may have lower energy requirements. Using indirect calorimetry, it has been found that patients have a measured resting energy expenditure below that predicted by standard formulas such as the Harris–Benedict equation. They also report consuming fewer kilocalories per kilogram body weight than control subjects. One explanation for this finding is that bingeing and purging may alter energy efficiency. These findings have implications for nutritional management, particularly in relation to the prescription of energy intakes.

Dietary Management

Dietitians and nutritionists are increasingly involved in the treatment of bulimia nervosa. While this is best utilized within a multidisciplinary team, ideally with some form of psychological intervention available, it is not uncommon for dietitians or nutritionisists to be the only professional involved. Any professional working with eating disorders should be clear about what they can address and be aware of when it is appropriate to enlist other forms of help. Thus, nutritional intervention should aim to separate food from underlying issues, leaving these to be addressed by professionals more experienced in psychological techniques. Research suggests that nutritional intervention, alongside other psychological therapies, most notably cognitive behavior therapy (CBT), is an important part of treatment. In addition, training in CBT techniques is advized for dietitians and nutritionists involved in bulimia nervosa management.

The aim of dietary management of bulimia nervosa is to break the binge–purge cycle previously described. The individual should be informed of the problems of maintaining this cycle through dieting and should be encouraged to stop dieting in an extreme way. They should also be educated about the damaging effects of vomiting and other purging behaviors. In some cases, this is enough to stop such behaviors. In others, this message should consistently be given to encourage them to work toward stopping these behaviors. An important part of breaking this cycle is to get the individual to monitor his or her intake through completing a food diary. In the example shown (**Table 1**), it can be seen how restricting intake earlier in the day can make the person more vulnerable to overeating later in the day. Food diaries are a powerful cognitive tool that enable the individual to understand his or her eating behavior more fully.

Education is essential to ensure that people understand why they are being asked to abandon what are some of the only coping mechanisms they have. They feel anxious that by giving up the pattern of dieting, binge eating, and purging they will gain excessive amounts of weight. These fears are very real and failure to address them with sensitivity can sabotage any attempt to control the disorder. This is

Table 1 Example of a food diary

Time	*Food/drink eaten and amount*	*Binge/vomit/laxatives*	*Comment/feelings*
Breakfast	Nothing	—	Not hungry.
Midmorning	Cup of black coffee × 2	—	Need something to fill my stomach. Really busy at work so no time to eat.
Midday (1.30 pm)	2 crispbreads, dry Small tub of diet cottage cheese 1 tomato, can of diet pop	—	Very hungry, feel as if I could eat more but mustn't.
Midafternoon	Chocolate eclair	Vomited	Someone's birthday in the office so couldn't refuse. Feel really guilty and had to be sick.
Evening meal	2 dishes of blackcurrant cheesecake, a choc ice, 4 bowls of ice cream, 6 snack-size chocolate bars, 5 cheese biscuits with butter and cheese, 5 slices of toast with butter and peanut butter, 2 packets of chocolate biscuits, 2 bowls of cereal, 1 packet of crisps and 1 chocolate and mint biscuit	Binge!! Vomited and took 10 laxatives	Couldn't decide what to have for tea, so started on cheesecake. Could not stop this binge at any cost. I feel terrible.
During evening	6 glasses of water		
Supper	—	—	Feel so terrible and bloated. Will have to cut back tomorrow.

particularly important when an individual has a history of overweight in the past. A detailed weight history should be carried out to include current, highest, lowest, and ideal weights and it should be stressed that recovery cannot be accomplished if the sufferer is trying to maintain a weight below normal. Thus, those with a premorbid history of obesity may have to accept that they will need to reach a weight that is higher than they would like it to be. Weight stabilisation should be an initial emphasis, particularly for those experiencing weight fluctuations. Initially, weight is likely to fluctuate through rehydration and repletion of glycogen stores. This effect should be explained to the individual to reduce unnecessary anxiety. They should also be discouraged from weighing themselves. If they must get weighed, this should be no more than once a week.

An important goal for nutritional management is to establish the individual on a regular pattern of eating. Often, normal cues for hunger and satiety are disrupted through repeated cycles of binge and restrictive eating so encouraging a regular meal pattern also helps the sufferer to begin to identify hunger and fullness again. They should be encouraged to eat regular meals and snacks and to maintain this pattern of eating even after a binge. Each meal or snack should be based around carbohydrate, with moderate amounts of protein foods and vegetables and fruit. They should be encouraged to include non-diet foods and to include foods containing fat. It is also worth getting them to compile a list of foods normally avoided or associated only with binges and to encourage them to include them within their meal pattern, when they feel able to do so. A system of food exchanges may also be useful (see the sample meal plan in **Table 2**). The amount of food required to meet energy needs is greater than that needed to consume sufficient nutrients. Thus, consumption of some energy dense, less nutritious food should be encouraged. A minimum intake of 6.0 MJ (1500 kcal) is usually an appropriate level to begin with, increasing to an intake corresponding to the estimated average requirement for women as recovery proceeds.

If the bulimic is used to keeping his or her stomach empty, even a normal amount of food may seem excessive and may trigger the urge to vomit. They should be informed that stomach distension is a normal consequence of eating and reassured that they will get used to the feeling in time. Similarly, if someone has been abusing laxatives, he or she may suffer from constipation and should be encouraged to have a reasonable fiber intake along with plenty of fluids.

Although it is important to give positive encouragement and feedback when working with individuals with bulimia nervosa, it should also be explained that relapse is a normal occurrence and should not be viewed so negatively that the individual feels a complete failure. Education on relapse prevention should be an important component of any treatment programme.

Table 2 Sample meal plan[a]

Breakfast:	Glass of fruit juice Bowl of cereal with milk Slice of toast, spread with butter/margarine and marmalade/jam if desired
Midmorning:	**Choose from exchange list**
Snack meal:	Sandwiches made with two large slices of bread, spread with butter/margarine, and filled with lean meat, egg, or cheese or beans on toast, etc.
Midafternoon:	**Choose from exchange list**
Main meal:	Average helping of meat, chicken, fish, or vegetarian alternative Potatoes, boiled rice, or pasta equivalent to two exchanges Vegetables or salad
	Option from exchange list
Supper:	1–2 slices of toast or option from exchange list

Exchange list
- 1 large slice of bread or a roll, teacake, or plain bun
- 1 small scone
- 2 plain biscuits or crackers
- 1 chocolate or cream biscuit
- Small bowl of breakfast cereal or porridge
- 2 spoons boiled rice or pasta
- 1 medium potato
- 4 spoons baked beans or tinned spaghetti
- 1 piece of fruit (apple, orange, pear, banana, etc.)
- 1 carton of yoghurt
- 1 glass of milk
- 6–8 tablespoons custard or rice pudding
- 1 packet crisps or nuts and raisins
- 1 average-sized chocolate bar

[a] This plan deliberately does not include specific portion sizes. However, some individuals may need the reassurance of a more detailed plan. The aim is to provide a minimum of 6.25 MJ (1500 kcal). In addition to using the above to exchange foods within the meal plan, some people benefit from having an additional number of exchanges (e.g., five extra) to allow for when they are feeling more hungry and to offset binges. This also ensures an energy intake that conforms to the current EAR for women.

Long-Term Prognosis

Once more, the relative recency of the disorder mitigates against definitive statements. However, the outcome studies conducted so far show that bulimia nervosa is far from being intractable, as was originally suggested. Of the studies with a follow-up of at least 5 years, between a third and a half of those with bulimia nervosa at outset still had an eating disorder, and between 10 and 25% still had bulimia nervosa. There is also considerable flux within samples. For example, in a community sample, each year about a third of patients remitted and a further third relapsed. Studies also report very low rates of spontaneous remission.

In terms of treatment, several psychotherapies have shown their effectiveness in improving the symptoms of bulimia nervosa. Most evidence is available on CBT, and the outcome is generally impressive and replicable. The treatment, usually provided by psychiatrists or clinical psychologists, aims to modify both the disturbed eating habits and the extreme concerns about shape and weight (the core psychopathology). Consequently, it combines psychological and dietetic approaches to patient management. Given a treatment program of around 20 sessions over 5 months, between a half and two-thirds of patients make a full and lasting recovery.

There is still uncertainty regarding prognostic indicators of treatment success. Patients with a less severe form of the disorder appear to do better in treatment. Self-help programs administered on their own or with modest support and encouragement from a nonspecialist therapist (guided self-help) may be of particular assistance to those in whom the disorder is less fully established. Conversely, those with childhood obesity, low self-esteem, or personality disturbance appear to do worse. Importantly, there is no evidence that bulimia nervosa evolves over time into other psychiatric disorders or of any persistent impairment in social functioning.

Binge Eating

M D Marcus, M A Kalarchian and M D Levine, University of Pittsburgh, Pittsburgh, PA, USA

In 1959, Stunkard noted three patterns of eating behavior in obese patients: night eating, binge eating, and eating without satiation. It was not until the 1980s that binge eating began to receive attention as a distinct clinical syndrome. Spitzer and colleagues proposed diagnostic criteria for binge eating disorder (BED) and subsequently evaluated them in two field trials. These initial investigations led to the inclusion of BED in the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (*DSM-IV*), of the American Psychiatric Association as an example of Eating Disorder Not Otherwise Specified (EDNOS) and as a proposed diagnostic category requiring further study. BED is characterized by persistent and recurrent episodes of binge eating without the regular use of inappropriate compensatory behaviors seen in bulimia nervosa (BN). Research on BED is still in an early stage, and the key features of the disorder and its relationship to other eating disorders, especially BN, nonpurging type, continue to be debated in the field.

This article discusses the assessment of BED, prevalence and risk factors, and comorbid conditions associated with BED. In addition, empirically supported treatments are reviewed, including guidelines for choice of treatment approach. Throughout the article, a biopsychosocial framework for understanding aberrant eating behavior is emphasized.

Assessment of Binge Eating

A binge episode is defined as the consumption of a large amount of food within a discrete period of time, accompanied by a sense of loss of control over eating. Researchers and clinicians have agreed that loss of control involves the subjective feeling that one cannot stop eating or control what or how much is being eaten. However, there has been much less agreement about the size and duration of a binge eating episode. Specifically, there is no consensus as to what constitutes a large amount of food, and the duration of binge eating episodes can vary widely, sometimes continuing throughout an entire day. Many individuals have difficulty delineating binges into discrete episodes but can more readily recall whether a binge occurred or not on a given day. Thus, the BED diagnosis is made based on binge 'days' rather than 'episodes.' Similarly, many observers have concluded that the loss of control, rather than the amount of food ingested during a binge (i.e., a 'large' amount), is the hallmark of binge eating. See **Table 1** for the full research criteria for BED.

Several methods can be used to assess BED, including clinical interviews, self-reports such as questionnaires and food diaries, and observation of eating behavior in the laboratory. Currently, a clinical interview by a trained professional is the preferred assessment method. It provides the opportunity to standardize definitions of key concepts such as a 'large amount of food' and 'loss of control.' Although questionnaires are relatively easy to administer, there is high potential for misinterpreting these terms. Interview-based assessments tend to yield ratings of binge eating that are lower, but more precise, than questionnaire-based surveys.

Food diaries involve having individuals keep a daily record of the specifics of eating episodes, including how much food was consumed, whether or not there was loss of control over eating, any use of

Table 1 *DSM-IV-TR* criteria for binge eating disorder

1. Recurrent episodes of binge eating. An episode of binge eating is characterized by both of the following:
   - Eating, in a discrete period of time (e.g., within any 2-h period), an amount of food that is definitely larger than most people would eat in a similar period of time under similar circumstances
   - A sense of lack of control over eating during the episode (e.g., a feeling that one cannot stop eating or control what or how much one is eating)
2. The binge eating episodes are associated with at least three (or more) of the following:
   - Eating much more rapidly than normal
   - Eating until feeling uncomfortably full
   - Eating large amounts of food when not feeling physically hungry
   - Eating alone because of being embarrassed by how much one is eating
   - Feeling disgusted with oneself, depressed, or very guilty after overeating
3. Marked distress regarding binge eating is present.
4. The binge eating occurs, on average, at least 2 days a week for 6 months.
5. The binge eating is not associated with the regular use of inappropriate compensatory behaviors (e.g., purging, fasting, and excessive exercise) and does not occur exclusively during the course of anorexia nervosa or bulimia nervosa.

inappropriate compensatory behavior, and the associated context. Food diaries can provide detailed assessment information without introducing the bias of retrospective self-report; however, self-monitoring also has been shown to affect eating behavior and is frequently employed in clinical treatment. Findings from studies that have utilized food diaries indicate that BED patients report higher calorie intakes than non-binge eaters on both 'binge days' and 'non-binge days.'

Observation of binge eating in the laboratory is a specialized technique that is limited to use in research settings, providing the opportunity to document actual eating behavior and measure consumption. Laboratory studies with relatively small samples have shown that, compared to equally overweight patients who do not binge eat, BED patients ingest more calories, both during binges and at 'regular' meals. This difference in eating behavior in binge compared to non-binge eaters supports the validity of BED as a distinct diagnostic category.

Prevalence and Risk Factors

Available research suggests that the prevalence of BED among the general population is approximately 1 or 2% and thus more common than BN. In addition, preliminary findings suggest that the demographic profile of individuals with BED may be more diverse, affecting relatively more men and minority groups than BN or anorexia nervosa. Furthermore, binge eating is more prevalent among obese individuals in both clinical and community samples. It is estimated that up to one-third of individuals who present for treatment in university-based weight control clinics report significant binge eating.

The most comprehensive risk factor study to date suggests that the risk factors for BED may be weaker and more circumscribed than for BN. Fairburn and colleagues interviewed four groups of subjects matched for age and social class: individuals with BED, BN, another psychiatric disorder, and healthy controls. In comparing the BED group to the controls, negative self-evaluation, parental depression, adverse childhood experience, and exposure to repeated negative comments about shape, weight, or eating emerged as risk factors for BED. Further comparing BED patients to other groups with psychiatric diagnoses, childhood obesity and negative comments from family about eating, shape, and weight emerged as risk factors specific to BED. Thus, BED appears to be associated with two classes of risk factor—those that increase the risk of psychiatric disorder in general and factors that increase risk of obesity.

In order to improve our understanding of how multiple factors interact to determine the onset and maintenance of binge eating, prospective risk factor studies including males and females of different racial groups are needed. As suggested previously, biological (e.g., obesity), psychological (e.g., negative self-evaluation), and social (e.g., exposure to repeated negative comments about shape, weight, or eating) factors have been implicated in the pathogenesis of binge eating. Emergent research also has linked binge eating in a small proportion of individuals to a mutation in *MC4R*, a candidate gene for the control of eating behavior. Thus, future research may further elucidate the genetic influences on aberrant eating patterns.

Comorbidity

Binge eating is strongly associated with both obesity and psychiatric disorder. It is well documented that obesity is linked to adverse medical and psychosocial outcomes. Preliminary findings also suggest that BED may be associated with poor health, independent of the effects of comorbid psychopathology or comorbid obesity.

Severity of binge eating is positively associated with degree of overweight. Additionally, there are important differences between overweight individuals with

and without BED. BED patients report earlier onset of obesity, along with a history of more severe obesity, dieting, and weight fluctuations. When compared with equally overweight individuals without binge eating problems, BED patients report considerably less 'restraint' or control overeating, lower self-esteem, more fear of weight gain, more preoccupation with food, and higher body dissatisfaction.

Individuals with BED endorse high rates of psychiatric symptoms and disorders. For example, when compared to equally overweight individuals without binge eating problems, individuals with BED report significantly higher lifetime rates of major depressive disorder, substance abuse or dependence, and anxiety disorders. Some studies have shown that patients with BED report levels of eating disorder symptomatology, such as eating, shape, and weight concerns, that are comparable to those of normal weight patients with BN. Individuals with BED also have considerably higher rates of personality disorders than overweight individuals without an eating disorder. Thus, among individuals with BED, psychiatric symptomatology appears to be related to the binge eating rather than to the degree of obesity.

Treatment

Among those who seek treatment, BED tends to be a chronic and fluctuating disorder. The clinical picture in BED often involves onset in late adolescence or the early 20s, with numerous periods of relative control over eating, and weight loss during periods of successful calorie restriction, alternating with periods characterized by binge eating and weight gain. Individuals with BED often seek obesity treatment rather than treatment of disordered eating per se.

A variety of psychosocial and pharmacological interventions, as well as behavioral weight loss programs, can help individuals gain control over binge eating. **Figure 1** provides an overview of nonpharmacologic treatments and their postulated mechanisms of action; it should be noted that this list of treatments is not exhaustive. Furthermore, although the postulated treatment mechanisms reflect respective theoretical models of binge eating, the effects of psychosocial treatment usually lack specificity and the treatments often share common elements (e.g., self-monitoring is a central component of cognitive behavior therapy (CBT), dialectical behavior therapy (DBT), and behavioral weight control). Also, effects of psychosocial treatments often extend to areas that are not a focus of treatment (e.g., behavioral weight management programs that target changing eating and exercise also have been shown to improve mood). Thus, some of the treatments do overlap. Finally, it is important to note that a substantial number of patients are not abstinent from binge eating after treatment, suggesting

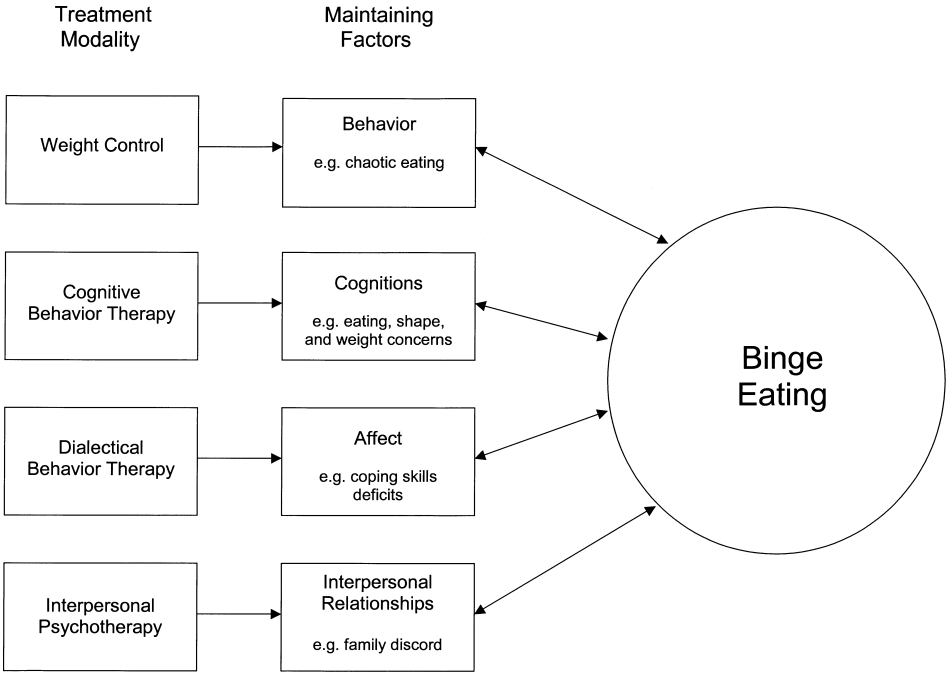

Figure 1 Overview of nonpharmacologic treatments for binge eating.

the need for clinical trials of novel therapeutic approaches as well as combinations and sequencing of treatments.

Psychosocial Treatments

Treatments for binge eating have been adapted from those that have been shown to be effective in reducing binge eating among individuals with BN. The majority of the research on psychosocial treatments has supported two structured, focused, short-term psychotherapies—CBT and interpersonal psychotherapy (IPT)—both of which have been shown to be more effective than no treatment in decreasing the frequency of binge eating and improving the psychopathology associated with binge eating. In addition, the use of DBT shows promise as an alternative treatment for BED.

Cognitive behavioral therapy CBT has been the most extensively studied treatment for individuals with binge eating. CBT for BED is based on the assumption that binge eating is maintained in the context of ongoing dietary restraint, weight concerns, negative emotions, and low self-esteem. Treatment focuses first on normalizing eating and then on the identification and restructuring of maladaptive thoughts and beliefs, particularly those related to eating, shape, and weight.

CBT for BED has been adapted to reflect important differences between individuals with BN and BED. Specifically, cognitions relating to having a large body size are directly targeted in treatment. Overweight individuals with BED may be helped to accept a larger than average body size and to change unrealistic expectations for weight loss. That is, for the majority of BED patients a 5- or 10-kg weight loss does not correspond with their desired weight loss, even though a modest weight loss may relate to improvements in binge eating and overall health. It is therefore important to help patients adopt realistic goals for the body weight and shape they are likely to achieve.

Another adaptation of CBT for BED relates to differences in the role of dieting between individuals with BED and those with BN. Although the treatment of BN stresses the role of dietary restraint in precipitating binge episodes, and treatment focuses on decreasing dietary restraint, patients with BED do not necessarily binge eat in response to restraint or hunger. Indeed, the preponderance of evidence suggests that increasing dietary restraint may help to ameliorate binge eating in obese individuals. Thus, CBT for BED does not stress decreased dietary restraint; rather, treatment encourages the development of a moderate, structured, healthy eating pattern.

Interpersonal psychotherapy Klerman and Weissman's IPT has also received empirical support in the treatment of individuals with BED. IPT for binge eating is based on the idea that dysfunctional eating behavior is maintained in the context of interpersonal difficulties. Treatment focuses on identifying and addressing specific, problematic interpersonal patterns in an effort to ameliorate binge eating. Treatment can focus on role disputes, such as marital or family discord; role transitions, such as the adjustment to motherhood or a new job; grief, such as the loss of a spouse or loved one; and interpersonal deficits, such as loneliness and social isolation.

IPT for BED does not directly target eating behaviors or attitudes about eating, shape, and weight. Although the ways in which CBT and IPT conceptualize and treat binge eating differ, both appear to be equally effective in reducing the frequency of binge eating.

Dialectical behavior therapy Developed by Linehan for the treatment of individuals with borderline personality disorder, DBT has shown promise in the treatment of BED. DBT is a comprehensive treatment program based on cognitive and behavioral principles and complemented by the use of mindfulness strategies derived primarily from Zen Buddhism. In addition to weekly individual outpatient treatment, traditional DBT prescribes a weekly group meeting in which the goal is to increase participants' behavioral skills. A group-only version of DBT for individuals with BED has also been shown to decrease binge eating and maladaptive attitudes about eating, shape, and weight. Additional research is needed to determine the efficacy of DBT relative to CBT and IPT.

Behavioral Weight Control

Because the majority of individuals with BED are also overweight and want to lose weight, and because obesity is associated with significant medical and psychosocial consequences, weight loss is a potentially important outcome in the treatment of BED. Numerous studies have documented that calorie restriction does not exacerbate binge eating in BED patients. Indeed, participation in behavioral weight control programs that focus on calorie restriction, provide education about sound nutritional principles, and promote physical activity may decrease binge eating and improve mood in BED patients. Therefore, concerns about the

potentially deleterious effects of dieting should not deter obese patients who binge eat from attempting behavioral weight management.

Weight lost through dieting is frequently regained, and sustained weight change involves a permanent modification of eating and exercise patterns. However, it is not necessary to achieve large weight losses to improve risk factors for heart disease, diabetes, and other obesity-related comorbidities. There is evidence that sustained weight losses of approximately 10% of initial body weight can lead to significant improvements in modifiable risk factors such as blood pressure, lipids, and blood sugar levels.

Pharmacotherapy

Pharmacologic approaches to the treatment of BED that have empirical support include antidepressant and weight loss medications. Additionally, one study has demonstrated the potential utility of the anticonvulsant agent, topiramate. However, studies to date have not shown that pharmacotherapy increases the effectiveness of psychotherapy for BED.

Antidepressant treatment Because of their efficacy in ameliorating binge eating and purge behaviors in BN, antidepressants have been used in the treatment of BED. Early research comparing tricyclic antidepressants, such as desipramine and imipramine, to placebo showed greater reductions in binge eating among obese binge eaters treated with the drug than with a placebo. Recently, several selective serotonin reuptake inhibitors (e.g., fluoxetine) have been shown to be associated with moderate reductions in binge eating in BED patients. Moreover, the effects of antidepressant treatment on binge eating are independent of any effects on mood.

Antidepressant treatment also may be useful in treating depression associated with BED and has been associated with weight loss among obese binge eaters. Antidepressant treatment also may enhance dietary restraint or improve compliance with a weight loss program. Thus, it seems possible that longer term antidepressant treatment may be useful in breaking the cycle of negative mood, binge eating, and weight gain that characterizes BED.

Anorectic agents The utility of anorectic agents in the treatment of BED has been investigated in a few studies. Early research found that obese binge eaters treated with the serotoneric agent, *d*-fenfluarmine, experienced a significantly greater short-term reduction in binge eating than did those given placebo. However, because of the association between the longer term use of *d*-fenfluramine and the combination of phentermine and fenfluramine with serious pulmonary and cardiac problems, these medications have since been withdrawn from the market. Currently, two anorectic agents, sibutramine and orlistat, have been approved for long-term use in the treatment of obesity. Sibutramine has been investigated in the treatment of BED, with initial findings suggesting decreases in binge eating and body weight among obese women with BED.

Selection of Treatment for Specific Patients

No single treatment approach is effective for all patients. Future research may provide data to guide the selection of treatment for individual patients as well as evaluate alternative treatments. Until such information becomes available, clinicians and patients must decide on a course of treatment based on a careful assessment and thorough consideration of the pros and cons of available options.

Eating disorder and obesity history A history of early onset of binge eating, binge eating in the absence of obesity, or obesity in combination with numerous bouts of weight loss and regain over time ('yo-yo' dieting) suggests a course of psychosocial treatment. Such patients can be reassured that significant improvements in the aberrant eating and eating disorders psychopathology associated with BED can be obtained without weight loss.

On the other hand, clinical experience suggests that patients who report adult onset of binge eating and obesity, and do not have a history of marked weight fluctuations, may be more likely to benefit from a behavioral weight control approach. Behavioral weight control may also be indicated for patients who remain overweight after a trial of eating disorders treatment. Although behavioral weight control appears to be beneficial on average, it is important for each individual to evaluate the likelihood that he or she will be able to sustain lifelong changes in eating and exercise.

Psychiatric status Given the high psychiatric comorbidity in BED, a thorough evaluation is important for all patients who seek treatment. Although mild to moderate depression or anxiety is likely to improve during treatment of binge eating, the presence of marked or severe current illness suggests primary treatment of the mood or anxiety disorder. In addition, the presence of personality

disorders characterized by emotional, dramatic, or impulsive behavior appears to be related to severity of binge eating but does not appear to predict treatment outcome.

Available resources Clinicians trained in the use of psychosocial treatments for eating disorders are likely to be found in most metropolitan areas but may not be available in smaller cities or rural areas. Insurance companies vary in coverage for treatment of eating disorders, and some insurance plans may pay for obesity treatment only if there is a clear medical indication (e.g., hypertension or other cardiovascular risk). Thus, treatment decisions may need to take into account pragmatic factors, such as clinician availability and training or patient insurance plan coverage. Self-help programs may be appropriate for carefully screened, motivated patients with mild to moderate binge eating. However, comorbid psychopathology and high-frequency binge eating may require more intensive clinical intervention.

Conclusion

BED is a chronic and fluctuating disorder that is common among obese individuals who seek treatment, and it is associated with elevated rates of psychopathology. A biopsychosocial model shows most promise in understanding the etiology of aberrant eating. Once established, binge eating is maintained by a complex interplay of eating behaviors, cognitions, affect, and interpersonal factors. Nevertheless, available research indicates that most who binge eat can be helped with either a behavioral weight control program or an eating disorders treatment. Pharmacotherapy may also reduce binge eating but generally does not add to the effectiveness of psychosocial treatment. A careful assessment, review of the benefits and disadvantages of the different therapies, and consideration of the availability of trained clinicians should guide the choice of treatment for an individual with BED. More research is necessary to fully understand this problematic eating pattern and to improve strategies for management and treatment.

EGGS

D J McNamara and H S Thesmar, Egg Nutrition Center, Washington, DC, USA

Introduction

Eggs have been a staple in the human diet for thousands of years. From hunter–gatherers collecting eggs from the nests of wild birds, to the domestication of fowl for more reliable access to a supply of eggs, to today's genetically selected birds and modern production facilities, eggs have long been recognized as a source of high-quality protein and other important nutrients. Over the years, eggs have become an essential ingredient in many cuisines, owing to their many functional properties, such as water holding, emulsifying, and foaming.

An egg is a self-contained and self-sufficient embryonic development chamber. At adequate temperature, the developing embryo uses the extensive range of essential nutrients in the egg for its growth and development. The necessary proteins, lipids, carbohydrates, vitamins, minerals, and functional nutrients are all present in sufficient quantities for the transition from fertilized cell to newborn chick, and the nutrient needs of an avian species are similar enough to human needs to make eggs an ideal source of nutrients for us. (The one essential human nutrient that eggs do not contain is ascorbic acid (vitamin C), because non-passerine birds have active gulonolactone oxidase and synthesize ascorbic acid as needed.) This article summarizes the varied nutrient contributions eggs make to the human diet.

Egg Types

While the majority of eggs consumed today are chicken eggs, a variety of eggs from different species of bird are commercially available in different parts of the world, from the petite quail egg to the very large ostrich egg. The data presented in **Table 1** compare the caloric, protein, lipid, and cholesterol contents per 100 g for eggs from various species. Eggs from commercial chickens differ from those from wild breeds in that they have lower cholesterol and lipid contents. This difference could be the result of many years of genetic selection of breeds with increased feed-to-egg conversion ratios and faster rates of lay.

The commercial hen used in today's egg production has been selected for optimal feed conversion and egg production along with overall health, disease resistance, livability, and temperament. The majority of egg production is carried out using a battery cage system, which offers a high degree of control over environment, feed, water, hygiene, biosecurity, and egg collection. This system also facilitates mechanization. Other production systems include barn and free-range, which offer more freedom to the birds but often lead to higher disease and mortality rates and potentially to increased susceptibility to bacterial contamination of the eggs.

Shifting dietary patterns in the population have resulted in compensatory changes in the egg industry. A major change has been the increased use of eggs in egg products for the pre-prepared packaged-food industry. In the USA over 30% of the total egg production is used to make egg products, and

SFA, saturated fatty acids; MUFA, monounsaturated fatty acids; PUFA, polyunsaturated fatty acids.

egg-product usage has been the most rapidly growing part of the industry, accounting for the majority of the increased per capita egg consumption over the past decade. Another area of growth has been the speciality egg market. As consumers become more health conscious, there has been an emphasis on functional components of foods that contribute to health and well-being. Eggs with enhanced nutrient benefits, especially with increased content of omega-3 fatty acids, are available worldwide.

Egg Macronutrient and Micronutrient Content and Distribution

The levels of many nutrients in an egg are influenced by the age and breed or strain of hen as well as the season of the year and the composition of the feed provided to the hen. While most variations in nutrients are relatively minor, the fatty acid composition of egg lipids can be significantly altered by changes in the hen's diet. The exact quantities of many vitamins and minerals in an egg are determined, in part, by the nutrients provided in the hen's diet.

Hen eggs contain 75.8% water, 12.6% protein, 9.9% lipid, and 1.7% vitamins, minerals, and a small amount of carbohydrates (**Table 2**). Eggs are classified in the protein food group, and egg protein is one of the highest quality proteins available. Virtually all lipids found in eggs are contained in the yolk, along with most of the vitamins and minerals. Of the small amount of carbohydrate (less than 1% by weight), half is found in the form of glycoprotein and the remainder as free glucose.

Egg Protein

Egg proteins, which are distributed in both yolk and white (albumen), are nutritionally complete proteins containing all the essential amino-acids (EAA). Egg protein has a chemical score (EAA level in a protein food divided by the level found in an 'ideal' protein food) of 100, a biological value (a measure of how efficiently dietary protein is turned into body tissue) of 94, and the highest protein efficiency ratio (ratio of weight gain to protein ingested in young rats) of any dietary protein.

The major proteins found in egg yolk include low density lipoprotein (LDL), which constitutes 65%, high density lipoprotein (HDL), phosvitin, and livetin. These proteins exist in a homogeneously emulsified fluid. Egg white is made up of some 40 different kinds of proteins. Ovalbumin is the major protein (54%) along with ovotransferrin (12%) and ovomucoid (11%). Other proteins of interest include flavoprotein, which binds riboflavin, avidin, which can bind and inactivate biotin, and lysozyme, which has lytic action against bacteria.

As shown in **Table 3**, egg protein contains substantial amounts of EAAs and nonessential amino-acids. The first column shows the amount of each amino-acid in one large egg. The second column indicates the amount of each amino-acid per 100 g of whole egg. The third column shows the dietary reference intake (DRI) for all of the EAAs per 50 g of total dietary protein, and the last column indicates the percentage of the DRI for each EAA provided by one large egg. While a large egg provides only 3% of the energy in a 2000 kcal (8394 kJ) diet, it provides 11% of the

[a]Essential amino-acids (EAA) are not synthesized by the body and must be consumed in foods; therefore, only EAA have a dietary reference intake (DRI) value.

USDA National Nutrient Database for Standard Reference, Release 16 (July 2003). Nutrient Data Laboratory Home Page, http://www.nal.usda.gov/fnic/foodcomp

protein needs. The EAAs in an egg contribute between 12% and 31% of the DRI for the various EAAs.

Egg Lipids

A large egg yolk contains 4.5 g of lipid, consisting of triacylglycerides (65%), phospholipids (31%), and cholesterol (4%). Of the total phospholipids, phosphatidylcholine (lecithin) is the largest fraction and accounts for 26%. Phosphatidylethanolamine contributes another 4%. The fatty-acid composition of egg-yolk lipids depends on the fatty-acid profile of the diet. The reported fatty-acid profile of commercial eggs indicates that a large egg contains 1.55 g of saturated fatty acids, 1.91 g of monounsaturated fat, and 0.68 g of polyunsaturated fatty acids. (Total fatty acids (4.14 g) does not equal total lipid (4.5 g) because of the glycerol moiety of triacylglycerides and phospholipids and the phosphorylated moieties of the phospholipids). It has been reported that eggs contain less than 0.05 g of trans-fatty acids. Egg yolks also contain cholesterol (211 mg per large egg) and the xanthophylls lutein and zeaxanthin. The lipid profile of a large egg is presented in **Table 4**.

Egg Vitamins

Eggs contain all the essential vitamins except vitamin C, because the developing chick does not have a dietary requirement for this vitamin. As shown in **Table 5**, the yolk contains the majority of the water-soluble vitamins and 100% of the fat-soluble vitamins. Riboflavin and niacin are concentrated in the albumen. The riboflavin in the egg albumin is bound to flavoprotein in a 1:1 molar ratio. Eggs are one of the few natural sources of vitamins D and B_{12}. Egg vitamin E levels can be increased up to tenfold through dietary changes. While no single vitamin is found in very high quantity relative to its DRI value, it is the wide spectrum of vitamins present that makes eggs nutritionally rich.

Egg Minerals

Eggs contain small amounts of all the minerals essential for life. Of particular importance is the iron found in egg yolks. Research evaluating the plasma iron and transferrin saturation in 6–12-month-old children indicated that infants who ate egg yolks had a better iron status than infants who did not. The study indicated that egg yolks can be a source of iron in a weaning diet for breast-fed and formula-fed infants without increasing blood antibodies to egg-yolk proteins. Dietary iron absorption from a specific food is determined by iron status, heme- and nonheme-iron contents, and amounts of various dietary factors that influence iron absorption present in the whole meal. Limited information is available about the net effect of these factors as related to egg iron bioavailability.

In addition to iron, eggs contain calcium, phosphorus, sodium, potassium, magnesium, zinc, copper, and manganese (**Table 6**). Egg yolks also contain iodine (25 μg per large egg), and this can be increased twofold to threefold by the inclusion of an iodine source in the feed. Egg selenium content can also be increased up to ninefold by dietary manipulations.

Egg Choline

Choline was established as an essential nutrient in 1999 with recommended daily intakes (RDIs) of 550 mg for

Table 6 Egg mineral content per large egg

Mineral	*Whole*	*Albumen*	*Yolk*
Calcium (mg)	26.5	2.3	21.9
Iron (mg)	0.92	0.03	0.46
Magnesium (mg)	6.0	3.63	0.85
Phosphorus (mg)	95.5	4.95	66.3
Potassium (mg)	67.0	53.79	18.53
Sodium (mg)	70.0	54.78	8.16
Zinc (mg)	0.56	0.01	0.39
Copper (mg)	0.05	0.01	0.01
Manganese (mg)	0.02	<0.01	0.01
Selenium (μg)	15.85	6.60	9.52

USDA National Nutrient Database for Standard Reference, Release 16 (July 2003). Nutrient Data Laboratory Home Page, http://www.nal.usda.gov/fnic/foodcomp

men and 450 mg for women. The RDI for choline increases during pregnancy and lactation owing to the high rate of choline transfer from the mother to the fetus and into breast milk. Animal studies indicate that choline plays an essential role in brain development, especially in the development of the memory centers of the fetus and newborn. Egg-yolk lecithin (phosphatidylcholine) is an excellent source of dietary choline, providing 125 mg of choline per large egg.

Egg Carotenes

Egg yolk contains two xanthophylls (carotenes that contain an alcohol group) that have important health benefits – lutein and zeaxanthin. It is estimated that a large egg contains 0.33 mg of lutein and zeaxanthin; however, the content of these xanthophylls is totally dependent on the type of feed provided to the hens. Egg-yolk lutein levels can be increased up to tenfold through modification of the feed with marigold extract or purified lutein. An indicator of the lutein + zeaxanthin content is the color of the yolk; the darker yellow-orange the yolk, the higher the xanthophyll content. Studies have shown that egg-yolk xanthophylls have a higher bioavailablity than those from plant sources, probably because the lipid matrix of the egg yolk facilitates greater absorption. This increased bioavailability results in significant increases in plasma levels of lutein and zeaxanthin as well as increased macular pigment densities with egg feeding.

Egg Cholesterol

Eggs are one of the richest sources of dietary cholesterol, providing 215 mg per large egg. In the 1960s and 1970s the simplistic view that dietary cholesterol equals blood cholesterol resulted in the belief that eggs were a major contributor to hypercholesterolemia and the associated risk of cardiovascular disease. While there remains some controversy regarding the role of dietary cholesterol in determining blood cholesterol levels, the majority of studies have shown that saturated fat, not dietary cholesterol, is the major dietary determinant of plasma cholesterol levels (and eggs contain 1.5 g of saturated fat) and that neither dietary cholesterol nor egg consumption are significantly related to the incidence of cardiovascular disease. Across cultures, those countries with the highest egg consumption actually have the lowest rates of mortality from cardiovascular disease, and within-population studies have not shown a correlation between egg intake and either plasma cholesterol levels or the incidence of heart disease. A 1999 study of over 117 000 men and women followed for 8–14 years showed that the risk of coronary heart disease was the same whether the study subjects consumed less than one egg a week or more than one egg a day.

Clinical studies show that dietary cholesterol does have a small influence on plasma cholesterol levels. Adding one egg per day to the diet would, on average, increase plasma total cholesterol levels by approximately $5\,\mathrm{mg\,dl^{-1}}$(0.13 mmol/L). It is important to note, however, that the increase occurs in both the atherogenic LDL cholesterol fraction ($4\,\mathrm{mg\,dl^{-1}}$(0.10 mmol/L)) and the antiatherogenic HDL cholesterol fraction ($1\,\mathrm{mg\,dl^{-1}}$(0.03 mmol/L)), resulting in virtually no change in the LDL:HDL ratio, a major determinant of cardiovascular disease risk. The plasma lipoprotein cholesterol response to egg feeding, especially any changes in the LDL:HDL ratio, vary according to the individual and the baseline plasma lipoprotein cholesterol profile. As shown in **Table 7**, adding one egg a day to the diets of three hypothetical patients with different plasma lipid profiles results in very different effects on the LDL:HDL ratio. For the individual at low risk there is a greater effect than for the person at high risk, yet in all cases the effect is quantitatively minor and would have little impact on their heart-disease risk profile. Overall, results from clinical studies indicate that egg

Table 7 Changes in plasma lipoprotein cholesterol levels with addition of one large egg per day to the diet

	Cholesterol ($mg\,dl^{-1}$)		*LDL:HDL ratio*
	LDL	*HDL*	*(% change)*
Baseline	125	50	2.50
$+1\,\mathrm{egg\,day^{-1}}$	129	51	2.53 (+1.2%)
Baseline	150	50	3.00
$+1\,\mathrm{egg\,day^{-1}}$	154	51	3.02 (+0.6%)
Baseline	175	50	3.50
$+1\,\mathrm{egg\,day^{-1}}$	179	51	3.51 (+0.3%)

feeding has little if any effect on cardiovascular disease risk. This is consistent with the results from a number of epidemiological studies.

A common consumer misperception is that eggs from some breeds of bird have low or no cholesterol. For example, eggs from Araucana chickens, a South American breed that lays a blue-green egg, have been promoted as low-cholesterol eggs when, in fact, the cholesterol content of these eggs is 25% higher than that of commercial eggs. The amount of cholesterol in an egg is set by the developmental needs of the embryo and has proven very difficult to change substantially without resorting to hypocholesterolemic drug usage.

Undue concerns regarding egg cholesterol content resulted in a steady decline in egg consumption during the 1970s, 1980s, and early 1990s, and restriction of this important and affordable source of high-quality protein and other nutrients could have had negative effects on the well-being of many nutritionally 'at risk' populations. Per capita egg consumption has been increasing over the past decade in North America, Central America, and Asia, has remained relatively steady in South America and Africa, and has been falling in Europe and Oceania. Overall, world per capita egg consumption has been slowly increasing over the past decade, in part owing to the change in attitude regarding dietary cholesterol health concerns.

Allergenic Aspects of Egg Proteins

Eggs are one of the most common causes of food allergies in infants and young children. Although the majority of egg allergies are caused by egg-white protein, proteins in both the egg white and the yolk are associated with allergies. The egg white contains 50% ovalbumin, which is the major allergen. Other egg-white allergenic proteins are ovomucoid, ovotransferrin, and lysozyme. Most egg allergies in young children are outgrown by the age of 5 years following an elimination diet.

Owing to the allergenicity of egg proteins, it is advised not to feed egg yolks to infants younger than 6 months of age and to wait until children are 12 months old to feed them egg whites. When feeding egg yolks to children between the ages of 6 months and 12 months, the eggs should be prepared in such a way that the egg white can be completely removed, as in hardboiled eggs.

Speciality Eggs

There is an increasing interest worldwide in the production and marketing of speciality eggs with enhanced nutrient benefits. The nutrient composition of an egg can be significantly modified by altering the composition of the feed. Commercially available nutrient-enhanced eggs contain increased amounts of omega-3 fatty acids, vitamin E, selenium, and lutein. Other enhancements include increased contents of vitamin D and the B vitamins as well as incorporation of conjugated linoleic acid.

Omega-3 Fatty Acids

The fatty-acid content of eggs is easily and significantly affected by the fatty-acid profile of the hen's feed. The omega-3 fatty-acid content of eggs can be increased by feeding hens a source of omega-3 fatty acids. In some countries, fish meal is used as a source of omega-3 fatty acids, but this can result in eggs with a fishy odour and taste. Marine algae are another source of omega-3 fatty acid and result in higher concentrations of eicosapentanoic acid and docosahexanoic acid (DHA) in egg yolks. Flaxseed oil is also used as a source of omega-3 fatty acids and results in increased levels of α-linolenic acid in egg yolks. The relative proportion of DHA to α-linolenic acid can be controlled by feeding a mixture of flaxseed oil and marine algae. It is possible to attain levels as high as 200 mg of omega-3 fatty acids per large egg.

Although omega-3 fatty-acid levels in eggs are well below levels found in fishes such as salmon and tuna, eggs can still be an important source of omega-3 fatty acids in the diet. For people who cannot eat fish, eggs with higher levels of omega-3 fatty acids can be an important way of including these beneficial fatty acids in the diet.

Other Nutrients in Speciality Eggs

By altering the content in the feed, other nutrients in eggs can be enhanced, for example lutein, vitamin E, and selenium. Vitamin E is usually added to the feed to serve as an antioxidant when the polyunsaturated fatty acids are increased. Vitamin E levels in eggs have been increased as much as 25-fold. The vitamin E in these eggs can provide an additional natural source of this important fat-soluble vitamin. Lutein (a xanthophyll) content can also be increased in eggs by increasing the amount in feed, usually in the form of marigold extract. Lutein is deposited in the egg yolk at levels as high as 2 mg per large egg, and the human body readily absorbs lutein from the egg phospholipid matrix. Nutritional needs for selenium vary widely owing to differences in the selenium content of regional soils. Egg selenium levels can be increased between 5-fold and 8-fold by the addition of an organo-selenium source to the feed.

Egg Food Safety

Eggs pose a unique food-safety problem because they can be contaminated internally with the pathogenic bacteria *Salmonella enterica* Serovar Enteritidis (SE). If SE infects the reproductive tracts of laying hens, it can be deposited in the eggs during formation. In addition to internal egg contamination by SE, eggshells can be contaminated with a number of microorganisms. Caution is required when selecting eggs for consumption. Only clean eggs should be consumed. Vaccinating hens against salmonella, together with temperature control, proper handling, and cooking are important control measures to reduce the incidence of SE illness.

When SE internally contaminates an egg, it is thought to be deposited at the yolk membrane in the egg white. The integrity of the vitelline membrane is very important in preventing SE from entering the yolk, where it could grow very rapidly in the nutrient-rich environment. The egg white has natural antimicrobial compounds, such as lysozyme, that help prevent SE from growing.

In naturally contaminated eggs, scientists have documented that between 10 and 100 cells of SE may be deposited in an egg. The bacterial cell count will remain low unless the egg is exposed to temperatures that would allow rapid growth of SE or the vitelline membrane breaks down. Even when flocks are infected with SE, only a small percentage of the eggs produced will contain SE. Properly cooking eggs to a temperature of 63 °C for 3 min, 65 °C for 1 min, or 70 °C for 1 s will destroy SE if it is present in an egg.

The Role of Eggs in the Diet

The nutritional contribution of eggs to a diet is determined by the per capita consumption profile of a given country. In countries such as Japan, with the highest per capita egg consumption, eggs play an important role as a source of nutrients, while in countries such as India, with very low per capita consumption, their role is minor. Worldwide there are many misperceptions and myths regarding eggs, which influence consumption patterns (**Table 8**).

Eggs are a nutrient-dense source of many EAA, vitamins, and minerals, and, as shown in **Figure 1**, eggs contribute a number of nutrients to the American diet in amounts proportionally greater than their caloric contributions. While providing only 1.3% of the calories, they provide nine different nutrients in amounts ranging from 2% to 6% of the DRI. Such nutrient-dense foods can play an

Table 8 Common myths and misperceptions about eggs

Myth	*Fact*
Brown eggs are healthier than white eggs; fertile eggs have less or no cholesterol; free-range eggs have more nutritional value than commercial eggs	There are no substantive nutritional differences between white eggs, brown eggs, fertile eggs, and free-range eggs; nutritional content is determined by the hen's diet
Eggs contain the hormones they give the hen to force her to lay eggs when there isn't a rooster around	Hens are not given hormones to produce eggs in the absence of a rooster; hens lay eggs with or without a rooster; there are no harmful hormones in eggs
Eggs contain the antibiotics they give hens to increase the number of eggs they'll lay	Antibiotics have no effect on egg production and there is no value in using them unless needed for therapeutic reasons
Eggs in the store are a mixture of fertile and non-fertile eggs; that stringy stuff is the embryo	Commercial eggs are not fertile (can be included in a lactoovo- or ovo-vegetarian diet); that stringy stuff (chalaza) is an egg protein that anchors the yolk in the centre of the egg
Eating eggs can cause liver problems	No study has ever shown that eggs cause liver problems
Eggs with blood or meat spots are fertilized or are bad	The tiny meat or blood spot is caused by the rupture of a blood vessel during egg formation; it has no adverse effect on the egg and can be either removed or eaten
If an egg floats in water, it is bad	As an egg ages the air sac expands and an egg will stand on end in water; this is not a sign that the egg is bad

Additional information and facts can be obtained from the American Egg Board *Eggcyclopedia*. (http://www.aeb.org/).

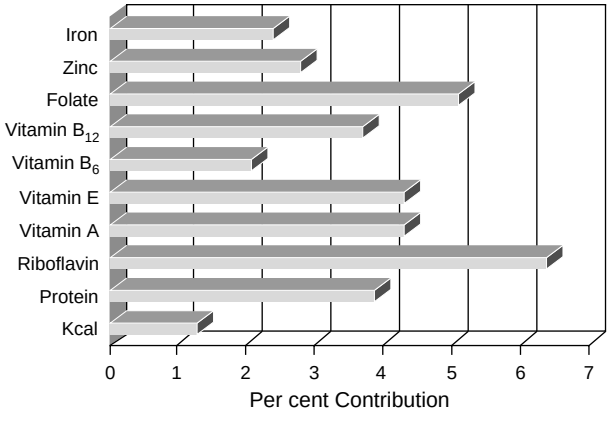

Figure 1 Nutrient contributions of eggs to the American diet.

important role in the diets of seniors who have decreased caloric intakes as well as in weight-reduction and weight-maintenance diets. Studies have shown that egg intake has a significant effect on satiety beyond what would be predicted from its protein and fat contents. Egg intake slows the rate of gastric emptying, resulting in a flatter blood glucose response and a lower insulin response. The effects on gastric emptying appear to be related to the effects of egg yolk (not white) intake on the secretion of cholecystokinin and gastric inhibitory peptide.

Summary

For nutritionally vulnerable populations, including the poor, the very young, the very old, pregnant women, and those suffering from chronic diseases, eggs are an affordable nutrient-dense source of high-quality protein important for maintaining health and facilitating recovery. Pregnancy is an especially important time to optimize the intake of high-quality protein and other essential nutrients to reduce the risk of low birth weight and the associated development of chronic diseases and other health problems during the infant's adult life. Eggs also serve as an important dietary source of choline during pregnancy and lactation, providing the fetus and newborn with choline for brain development. In addition, eggs provide a satiety effect, which, in view of the global problem of obesity, can be a valuable addition to weight-loss and weight-maintenance programs. For various populations, from infants to the aged, there are a multitude of health reasons to include nutrient-dense eggs as part of the diet, and for many of these groups it is economically feasible.

The high-quality protein, many nutritional components, low caloric content, affordability, blandness, ease of digestibility, and satiety response all make eggs ideal for inclusion in the diet at all ages, from very young to very old, and in times of both health and convalescence.

Acid-Base Balance
Water–Electrolyte Balance

Acid-Base Balance

A G Jardine and P B Mark, University of Glasgow, Glasgow, UK

Introduction

Maintenance of cellular and extracellular pH (hydrogen ion concentration) is essential to life, in view of the exquisite pH dependence of processes such as enzyme function. Hydrogen ions (H^+) are generated by cellular metabolism and, to a lesser extent by the ingestion of acids in the diet. Acid-base homeostasis regulates pH between 7.36 and 7.44 (corresponding to a [H+] of 36–44 nmol l^{-1}) in extracellular fluids, such as blood, whereas intracellular pH is more acidic (pH 6.3–7.4) depending on individual organs and circumstances. The pH of subcellular organelles may be more acidic, reflecting their physiological function (e.g., lysosomes). Blood and extracellular fluid pH are tightly regulated by the presence of buffer systems, which attenuate changes as a consequence of acid load. These buffer systems, both extracellular and intracellular, include hemoglobin, other proteins, phosphate, and bicarbonate – the latter being of greatest importance. However, the acid load must ultimately be eliminated by the subsequent excretion of volatile acid by the lungs and fixed acids by the kidney.

Definitions, Acids, Bases, and Buffers

pH

The term pH is an expression of hydrogen ion (H^+) concentration (such that pH and H^+ are inversely related):

$$pH = -\log_{10}[H^+] \qquad [1]$$

Acids and Bases

Acids are substances that dissociate to donate H^+ (eqn [2]); the stronger the acid, the more readily it dissociates. The dissociation constant (p*K*a) is the pH at which 50% of the acid is dissociated. At pH values greater than p*K*a more H^+ will dissociate; the lower the p*K*a, the stronger the acid. A base is a substance that accepts hydrogen ions. In the following text the term 'fixed acid' is used to describe formed acid, and 'volatile acid' is used to describe the potential acid load imposed by carbon dioxide (CO_2). Where 'A' represents an acid, the following applies:

$$AH \leftrightarrow A^- + H^+ \qquad [2]$$

The importance of this relationship in physiological terms is that since the p*K*a of most organic acids is much lower than the pH of extracellular fluids, most organic acids exist in a dissociated state (as acid anion salts) the free H^+ being buffered. In urine, where the minimum achievable pH is around 5, most strong acids (with a p*K*a below this value) will be in a dissociated state, necessitating the excretion of H^+ together with urinary buffers.

Acidosis is the term used to describe conditions where pH is low and those where pH would be low were it not appropriately buffered; similarly, alkalosis is the term used for a high pH and for a potentially elevated pH that has been appropriately buffered. Acidemia and alkalemia reflect low or elevated blood pH. It is common to describe acidosis/alkalosis as respiratory or metabolic depending on their causation.

Buffers

Buffering is the ability of weak acids, present in excess, to accept H^+ donated from strong acids, thus limiting the changes in free H^+ concentrations and pH changes (equation [3]):

$$AH + \text{Buffer} \leftrightarrow \text{Buffer-}H^+ + A^- \qquad [3]$$

The principal buffer system in blood (and other extracellular fluids) is based on bicarbonate (HCO_3^-), accounting for approximately 70% of the buffering capacity of the blood. In blood, CO_2 (the major product of oxidative metabolism) reacts with water in the presence of the enzyme carbonic anhydrase (CA) to form carbonic acid (H_2CO_3). This compound is relatively unstable and tends to dissociate (eqn [4]). The rate of formation of

carbonic acid is dependent on the concentration of carbon dioxide and the rate constant of reaction [i]; the dissociation of carbonic acid to generate H^+ and HCO_3^- is governed by the rate constant of reaction [ii]. In practice, these two reactions can be combined, and the relationship between pH ($[H^+]$), carbon dioxide, and bicarbonate is described by a single equation – the Henderson-Hasselbalch equation [5]:

$$\underset{[i]}{CO_2 + H_2O} \leftrightarrow \underset{[ii]}{H_2CO_3} \leftrightarrow H^+ + HCO_3^- \quad [4]$$

$$pH = 6.1 + \log_{10}([HCO_3^-]/K.S.PCO_2) \quad [5]$$

pH reflects $-\log [H^+]$; 6.1 is the value of $-\log (1/K)$, K being the equilibrium constant describing the overall equation [4]; P_{CO_2} is the partial pressure of carbon dioxide; S is the solubility constant for carbon dioxide. $K.S.$ is constant and equal to 0.225 when P_{CO_2} is measured in kPa, 0.03 when P_{CO_2} is measured in mmHg). **Table 1** shows the normal range for these parameters in humans.

From eqn [5] the principles of acid-base balance can be appreciated. Acidification may occur in two ways: either by the production of CO_2 or by the consumption of bicarbonate (as part of the buffering of fixed acid). The excretion of CO_2 (see below) is controlled by the lungs, and the excretion of fixed acid takes place in the kidney.

The Henderson-Hasselbalch equation allows basic understanding of acid-base physiology, in health and disease, but has limitations. In the presence of either metabolic or respiratory derangement of acid-base homeostasis it does not allow assessment of the severity of the metabolic derangement, analogous to the respiratory component. It also does not assess the influence of other acids other than carbonic acid. For this reason some authors propose analysis of acid-base physiology using a more complex method based on the principles of physical chemistry. This method proposes that all changes pH in plasma can be explained in terms of relative concentrations of CO_2, relative electrolyte, and weak acid. This concept allows more rigorous interrogation of acid-base disorders and may permit greater insight into their pathophysiology and management.

Table 1 Normal ranges

Variable	*Normal range*
pH	7.36–7.44
Hydrogen ion (H^+)	37–44 nmol l^{-1}
Partial pressure CO_2 (P_{CO_2})	34–46 mmHg; 4.5–6.1 kPa
Bicarbonate (HCO_3^-)	24–30 mmol l^{-1}

Maintenance of the pH of the Blood and Extracellular Fluids

Acid and Alkali Load

The sources of acids (and alkalis) are from the diet and metabolism. The major potential source of acid is CO_2 ('volatile acid'; eqn [4]) generated by oxidative metabolism; a total of 12–20 mol of CO_2 are produced daily. Other metabolic products include lactic acid, other organic acids, and urea, the synthesis of which produces H^+. Because of its role in the metabolism of lactic acid and in the synthesis of urea, the liver plays a major role in acid-base homeostasis that is often not appreciated.

Volatile acid (CO_2) is excreted by the lungs, whereas the breakdown of sulfur and phosphorus-containing compounds are 'fixed' acids, requiring excretion by the kidney. For example, cysteine or methionine metabolism leads to the production of sulfuric and phosphoric acid (H_2SO_4, H_3PO_4), while the metabolism of other amino acids (lysine, arginine, and histidine) leads to the production of hydrochloric acid (HCl). In contrast, organic acids (e.g., lactate, fatty acids) may be completely metabolized to CO_2 and H_2O and thus excreted by the lungs. In addition, the absorption of dietary phosphate and the fecal loss of bicarbonate represent an additional acid load. In total, the net acid load of fixed acid is approximately 1 mmol kg^{-1} day^{-1} and may be increased by a high protein intake or reduced by a strict vegetarian diet.

There is surprisingly little information on the direct contributions of individual foods to the acid burden. However, this source of dietary acid is of increasing importance in view of current popular weight reduction diets (e.g., the Atkins diet). The major acids contained in food are citric acid (in fruit, fruit juices), acetic acid (as a preservative, pickles, vinegar), lactic acid (yogurt, fermented foods), malic acid (fruit), oxalic acid (vegetables that contain smaller amounts of citric and malic acids), and tartaric acid (wine). Oxalic acid precipitates in the gut to form calcium salts, which are excreted in the stool and little is absorbed. The other acids are absorbed but quickly metabolized and present an acid burden in the form of CO_2. The largest source of fixed acid comes from the metabolism of amino acids (particularly those from animal proteins – see above). The significance of this source of acid is readily demonstrated in patients consuming a high-protein diet (particularly one rich in animal protein) who have increased urinary acid excretion. Based on studies on the relationship between diet, renal excretion of acid, and urine pH it is theoretically feasible to quantify urinary acid

excretion for individual foods. However, because of daily variation in diet (and therefore absence of a metabolic steady state) and inherent variation in the composition of foodstuffs, it has not been possible to date to estimate accurately the effects of diet on renal acid-base metabolism in circumstances reflective of normal dietary intake.

Alkalis are often prescribed to compensate for metabolic acidosis (see below) and in the past were often used to neutralize gastric acidity. Milk and milk products are also alkaline but seldom cause any disturbance, unless consumed in great excess. Excessive consumption of milk or alkali is now rarely seen.

Regulation

Blood and extracellular fluid pH is regulated at three levels: (1) buffering within the blood and tissues; (2) excretion of volatile acids by the lungs; and (3) excretion of fixed acids by the kidney. Whilst buffering is immediate, respiratory compensation occurs over minutes to hours and renal excretion takes many hours to days (**Table 2**).

Blood/Extracellular Fluid

Immediate buffering of an acid load, for example by the release of lactic acid and CO_2 by anaerobic and aerobic metabolism in exercising muscle, occurs in the blood and other extracellular fluids, which together contain approximately 350 mmol of bicarbonate buffer. Sixty to seventy per cent of the buffering capacity of blood is accounted for by the bicarbonate buffer system; 20–30% is dependent on direct binding to hemoglobin and to other proteins, including plasma proteins. Blood is in equilibrium with extracellular fluid H^+. H^+ ions move across cell membranes depending on concentration and charge; thus, H^+ ions may move into cells in exchange for K^+ (and to a lesser extent Na^+ ions) when extracellular H^+ is increased. Hence, acidosis is often accompanied by increased serum K^+, and alkalosis by low K^+. Large amounts of H^+ may be 'buffered' by direct binding to proteins within cells and tissues, particularly bone where H^+ ions are also buffered by calcium salts, such as apatite.

Table 2 Buffering and acid-base regulation

Mechanism	*Site*	*Role (time)*
Protein (e.g., Hb)	Cell	Rapid binding of H^+ (seconds)
Bicarbonate buffer	ECF	Buffering of H^+ (seconds)
Ventilation	Lungs	Excretion of CO_2, respiratory compensation (hours)
Fixed acid excretion	Kidney	Excretion of H^+, reabsorption and regeneration of bicarbonate, renal compensation (hours to days)

Lungs

The lungs excrete volatile acid (CO_2) by changes in the rate and volume of respiration. This is regulated by respiratory centers in the brainstem that respond to changes in the pH of the cerebrospinal fluid (which is in equilibrium with extracellular fluids elsewhere in the body), and signals from chemoreceptors in the carotid and aortic bodies that are responsive to changes in pH and P_{CO_2} of the arterial blood (increased P_{CO_2} or reduced pH cause an increase in respiration). Thus, acidosis leads to an increase in respiratory rate and ventilatory volume (the pattern in severe acidosis being described as Kussmaul breathing) and alkalosis leads to the opposite effect.

Kidneys

The kidneys have two major roles in acid-base homeostasis: the recovery of filtered bicarbonate and generation of new bicarbonate; and the excretion of fixed acid (**Figures 1** and **2**; eqn [5]). Blood is filtered in the glomeruli and the glomerular filtrate is subsequently modified in the renal tubules so that the final urine volume is less than 1% of the glomerular filtrate volume. Plasma bicarbonate concentration is approximately 25 mmol l^{-1} and glomerular filtration rate (GFR) is 100 ml min^{-1}, thus 3600 mmol of bicarbonate must be reabsorbed daily.

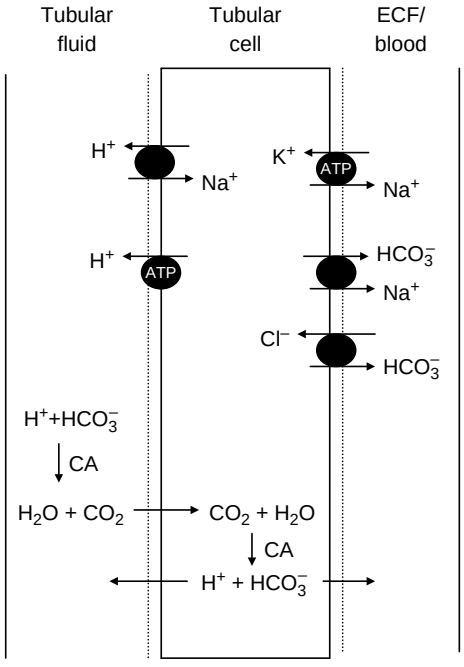

Figure 1 Recovery of filtered bicarbonate in the proximal convoluted tubule. CA, carbonic anhydrase.

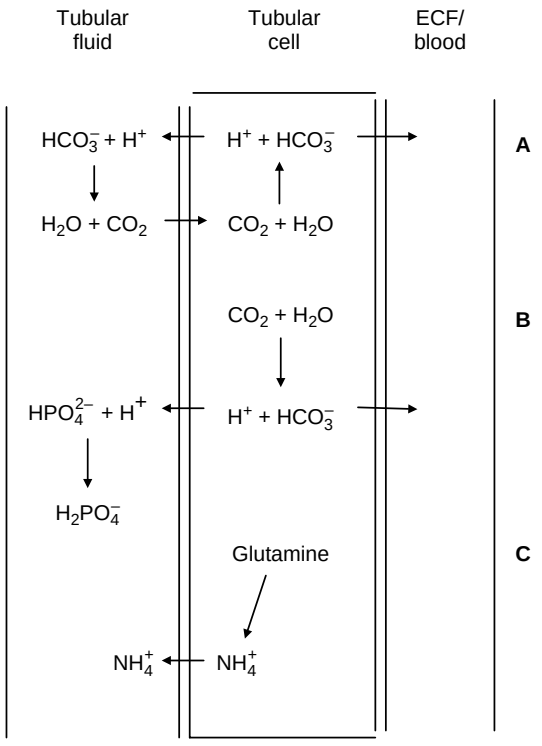

Figure 2 Excretion of acid in the collecting duct.

Bicarbonate reabsorption mainly occurs in the proximal convoluted tubule (PCT, **Figure 1**). Eighty-five per cent of filtered bicarbonate is reabsorbed at this site: 10% in the thick ascending limb of the loop of henle, the remainder being titrated to regulate total acid excretion in the collecting duct (**Figure 2**). As shown in the Figure, different mechanisms are involved at each tubular site. The enzyme carbonic anhydrase, on the luminal brush border of tubular cells, catalyzes the combination of filtered bicarbonate with H^+, secreted by the apical H^+-ATPase and Na^+/H^+ exchangers on tubular cells, to generate CO_2. CO_2 then diffuses into the tubular cells down its concentration gradient. Within the cell, carbonic anhydrase catalyzes the reverse reaction generating the production of H^+ and HCO_3^-. Hydrogen ions are then recycled to the tubular lumen and bicarbonate is secreted into the extracellular fluid (by basolateral anion exchangers or Na^+–HCO_3^- cotransporters) passing into the extracellular fluid and blood. The tubule cells are also exposed to CO_2 in the extracellular fluid and will continue to generate H^+ even in the absence of filtered bicarbonate. This H^+ is then buffered by other buffers in the glomerular filtrate including HPO_4^{2-} and, to a lesser extent, creatinine. Strong acids (e.g., H_2SO_4) with low p*K*a values will dissociate in the urine (pH range 5–8) and are buffered, whereas weaker acids may be excreted intact. In the presence of alkalosis, the function of cellular transporters may be reversed so that H^+ secretion occurs on the basolateral membrane and HCO_3^- secretion on the brush border of tubular cells resulting in alkaline urine.

Classically, the final mechanism by which the kidney can excrete H^+ is by the generation of ammonium (NH_4^+) from the metabolism of glutamine by glutaminase (**Figure 2**), a process that is stimulated by low pH and increased P_{CO_2}. The excretion of H^+ as part of ammonium accounts for around $70\,\text{mmol}\,\text{day}^{-1}$, increasing several-fold (albeit over a period of days) in the face of an acid load. Whether this is truly a urinary buffer is the subject of some debate as ammonium (NH_4^+) is generated directly from glutamine rather than accepting additional protons. There are alternative mechanisms for the role of NH_4^+ in overall acid-base homeostasis that involve the liver. After being pumped into the glomerular filtrate, NH_4^+ may be reabsorbed by the tubule and used by the liver to synthesize urea, generating free H^+ ions. Thus, there is no net loss of H^+ and the overall role of NH_4^+ in acid-base balance is dependent on the balance between tubular reabsorption of NH_4^+ and the hepatic synthesis of urea. The latter function may also be directly influenced by extracellular pH.

Liver and Bone

The liver plays additional roles in acid-base balance that may be underestimated. For example, the liver metabolizes lactate and keto acids; the rate of metabolism is dependent on pH (e.g., ketogenesis is suppressed at low pH) and may be exceeded at higher concentrations of lactate or in liver disease. The synthesis of urea from ammonium and carbon dioxide (above) results in the genesis of two protons, and is reduced in the presence of acidosis. Some buffering also occurs in bone due to the slow exchange of bone calcium carbonate for extracellular phosphate.

Measurement of Urinary Acid Excretion

Urinary pH can be measured by commercially available 'dipstix' or by using a pH meter on a fresh sample of urine. The loss of CO_2 or the production of NH_4^+ from urea-splitting organisms in infected urine will alter the pH with time. The excretion of fixed acid can be determined by the chemical titration of urine to pH 7.4, and is commonly termed 'titratable' acidity. The amount of NH_4^+ is usually estimated from the difference between the most abundant cation (Na^+, K^+) and anion (Cl^-) concentrations in the urine.

Effects of Acid-Base Disturbance

In addition to the adaptive changes occurring in acidosis, a range of metabolic and pathophysiological changes occur; alkalosis tends to produce opposite but milder effects. The metabolism of carbohydrate is altered: both glycolysis and gluconeogenesis are inhibited in the liver. Delivery of oxygen to the tissues is increased by the reduced ability of hemoglobin to retain oxygen in an acid environment (the Bohr effect). Consciousness is impaired, leading to coma in severe cases. However, the most important effects from a clinical perspective are cardiovascular: vasodilatation occurs in peripheral tissues, cardiac contractility is impaired resulting in reduced blood pressure, and, when severe, in reduced tissue perfusion. It is these effects that contribute to the adverse effects of acidosis in, for example, septic shock and contribute to the high mortality in these conditions.

Abnormalities in Acid-Base Balance

Disturbances in acid-base balance are classified as either 'acidosis,' indicating an excess of H^+ ions in the blood (reduced pH) or alkalosis, indicating the opposite. In practice, acidosis is the more common, varied, and serious problem. Disturbances in acid-base balance are usually labeled according to their origin. For example, respiratory acidosis reflects a primary problem in gas exchange with impaired excretion of CO_2, whereas metabolic acidosis reflects the over-production of fixed acid or loss of bicarbonate. Compensation refers to the body's ability to offset the primary problem. Thus, the response to a primary metabolic acidosis is to increase the excretion of CO_2 – respiratory compensation. If the pH returns to normal the problem is said to be 'fully compensated' whereas most disturbances tend to be only partially compensated (**Table 3**).

Table 3 Changes in blood and ECF during acid-base disturbance, the mechanism and degree of compensation

Problem	*$[H^+]$*	*$[HCO_3^-]$*	*P_{CO_2}*	*Compensation*
Metabolic				
Acidosis	↑	1°↓	2°↓	Partial respiratory
Alkalosis	↓	1°↑	2°↑	Partial respiratory
Respiratory				
Acidosis	↑	2°↑	1°↑	Complete renal
Alkalosis	↓	2°↓	1°↓	Complete renal

↑, Increase; ↓, decrease; 1°, primary; 2°, secondary.

Metabolic Acidosis

The main causes of metabolic acidosis are excessive acid production, inappropriate urinary loss of bicarbonate, or failure of the kidney to excrete fixed acid. Although the Henderson-Hasselbalch equation provides mathematical information concerning the equilibrium of bicarbonate species, in practice it provides little information regarding the nature of the underlying cause of the acid-base disorder and the concept of 'anion gap' is useful in assessing the cause of metabolic acidosis. This is derived from the principle of electroneutrality and is calculated thus:

$$([NA^+] + [K^+]) - ([Cl^-] + [HCO_3^-]) \qquad [6]$$

The anion gap represents an artificial disparity between the concentrations of these cations and anions routinely measured in clinical practice, therefore signifying the concentration of unmeasured anions such as proteins (the most important in healthy subjects), sulfate, phosphate, and others. The normal anion gap is 10–18 mmol l^{-1} although recent calculations using more sensitive measurements estimate this to be 6–12 mmol l^{-1}. This concept has limitations but is useful for dividing metabolic acidoses into those characterized by an increased anion gap as a marker of excess generation of organic acids and those with a normal anion gap due to decreased excretion of acid or external losses of bicarbonate. There are exceptions to this rule, e.g., the acidosis of chronic renal failure, but, nonetheless, it remains a useful concept in clinical practice. Classification of the causes of metabolic acidoses according to the presence of an increased or normal anion gap is shown in **Table 4**.

Diabetic Ketoacidosis

The absence of pancreatic insulin secretion in insulin-dependent diabetes results in increased plasma glucose and reduced tissue uptake and utilization of glucose. In the place of glucose, there is increased utilization of nonesterified fatty acid (NEFA) as an alternative source of energy that is metabolized to acetyl coenzyme A (acetyl-CoA). Under normal circumstances this substance is further metabolized in the liver via the tricarboxylic acid (TCA) cycle to CO_2 and water. In diabetic crises this cycle cannot accommodate the excess acetyl-CoA that is, instead, converted to acetoacetic acid, which can be further reduced to β-hydroxybutyric acid or decarboxylated to acetone. These three metabolites are known as 'ketone bodies' and their accumulation results in metabolic acidosis. In diabetic ketoacidosis, the homeostatic compensation is to increase ventilation

Table 4 Causes of metabolic acidoses according to the presence of an increased or normal anion gap

Increased anion gap	*Normal anion gap*
Ketoacidosis	Decreased renal acid excretion
Diabetic	Distal renal tubular acidosis
Starvation	
Alcoholic	
Inborn enzyme defects of metabolism	
Lactic acidosis	Loss of alkali
	Diarrhea
	Ureterosigmoidostomy (urinary conduit)
Renal failure	Increased renal bicarbonate loss
	Proximal renal tubular acidosis
	Azetazolamide
	Renal tubular damage
Intoxication	Increased HCl production
Salicylates	Ammonium chloride ingestion
Methanol	Increased catabolism of lysine, arginine
Ethylene glycol	
Paraldehyde	

and CO_2 excretion, leading to the characteristic pattern of ventilation known as Kussmaul respiration.

Lactic Acidosis

Reduced tissue perfusion, or perfusion that is inadequate to meet the metabolic demands of the tissues (such as exercising muscle), results in an inadequate supply of oxygen and a change from oxidative metabolism (the end products of which are CO_2 and H_2O) to anaerobic metabolism. The end product of anaerobic glycolysis is lactic acid, which is normally metabolized (to CO_2 and H_2O) by the liver or used in the synthesis of glucose (gluconeogenesis). The normal plasma [lactate] is less than $1\,mmol\,l^{-1}$ but may increase 10-fold in extreme exercise. When the ability to metabolize lactate is exceeded, either by increased production, or reduced delivery to the liver (in, for example, circulatory shock) or in the presence of impaired liver function, accumulation results in metabolic acidosis. Thus, lactic acidosis may occur in a variety of conditions, including circulatory shock, severe diabetic ketoacidosis, as a consequence of drugs (for example, the oral hypoglycemic agent metformin that inhibits gluconeogenesis and lactate transport), chronic liver disease, and poisoning (including ethanol and methanol).

Excess Bicarbonate Loss

The secretion of acid into the stomach is neutralized by alkaline secretions in the intestine. It follows that excessive loss of pure intestinal secretions (for example, in the presence of an enteric fistula) may lead to acidosis. A more common circumstance is the presence of an ileal conduit where the ureters are implanted into an isolated loop of intestine, which is then externalized (a 'urinary conduit'). The delivery of urine rich in chloride to the isolated intestine leads to exchange of Cl^- for HCO_3^-, and thence to excessive loss of HCO_3^- in the conduit, resulting in metabolic acidosis.

There are also a group of conditions known as renal tubular acidosis (RTA). These are mostly inherited but may be acquired, for example, as a consequence of recurrent infection. There are two major forms – proximal and distal – reflecting the site of the tubular defect in the nephron. In distal tubular RTA (type I) H^+ secretion is impaired resulting in impaired H^+ excretion, whereas in proximal RTA (type I) HCO_3^- reabsorption is impaired (usually as part of multiple tubular abnormalities) leading to net loss of bicarbonate. Both cause acidosis, the features of which are low pH and hypokalemia as a result of increased distal tubular H^+/K^+ exchange. The precise causes of these conditions is not known but is likely to reflect genetic defects on individual transporter subtypes, for example, those of the Na^+/H^+ exchanger (**Figure 2**).

Renal Failure

In progressive renal failure, renal clearance of all substances is impaired, reflecting the progressive loss of individual nephron function. Reduced excretion of fixed acid leads to bicarbonate consumption in the extracellular fluids and to acidosis. Tubular recovery of HCO_3^- may also be impaired (see RTA), as may the production of tubular NH_4^+, and may be associated with overproduction of urea in the liver.

Drugs and Other Causes

Many drugs can cause metabolic acidosis, generally in overdose. A classic example is aspirin (acetylacetic acid). Lactic acidosis is also associated with oral hypoglycemic agents (specifically metformin, used in the treatment of noninsulin-dependent diabetes), paracetamol, alcohol, and ethylene glycol (antifreeze) poisoning.

Compensation

The body's response to metabolic acidosis is a compensatory increase in ventilation to excrete excessive CO_2, restoring the equilibrium in the Henderson-Hasselbalch equation (eqn [5]). This respiratory compensation is usually incomplete, resulting in pH values or H^+ concentrations at, or marginally outside, the limits of 'normal' (**Table 3**). Complete

compensation depends on renal excretion of excess H^+, or resolution of the underlying condition.

Treatment

Treatment of metabolic acidosis is essentially that of the underlying condition: correction of tissue hypoxia in lactic acidosis; correction of fluid depletion and insulin therapy in diabetic ketoacidosis; and dialysis in renal failure. Rapid correction of pH can be achieved by the administration of intravenous sodium bicarbonate if necessary; treatment of chronic metabolic acidosis (e.g., in chronic renal failure or RTA) may be achieved by the administration of oral sodium bicarbonate. In uremia the prescription of a low-protein diet will also reduce acid load.

Metabolic Alkalosis

Metabolic alkalosis may be caused either by the excessive loss of acid or intake of alkali. The latter may be iatrogenic or factitious, with the excessive intake of prescribed antacids (such as sodium bicarbonate for heartburn or peptic ulcer disease) – the 'milk-alkali' syndrome. The loss of acid-rich gastric secretions in severe vomiting, for example, in cases of gastric outlet obstruction (due to pyloric stenosis, or a consequence of peptic ulcer disease), also leads to alkalosis. Compensation is by reducing ventilation to promote retention of CO_2 and thus balance the Henderson-Hasselbalch equation. Treatment is of the underlying condition rather than by administration of acid.

Respiratory Acidosis

Impaired ventilation reduces CO_2 excretion, increases Pa_{CO_2}, and thus lowers pH. This may occur acutely or chronically. Causes of respiratory acidosis include factors that interfere with the neurological 'drive' for respiration (e.g., head injury, cardiac arrest, opiate and anesthetic drugs), diseases of the respiratory muscles (e.g., poliomyelitis, Guillain-Barré syndrome), or primary lung diseases (acute pulmonary edema or pneumonia, chronic bronchitis or emphysema). In acute conditions, pH may fall dramatically, whereas in chronic conditions, such as chronic lung disease, the pH is generally nearer normal. In chronic conditions complete compensation occurs in the kidney where elevated $PaCO_2$ levels are offset by the increased generation of bicarbonate and excretion of fixed acid by the kidney, to balance the Henderson-Hasselbalch equation.

Respiratory Alkalosis

Respiratory alkalosis occurs as a result of inappropriately increased ventilation and increased excretion of CO_2. This may occur as a transient response to pain or hysteria. Such stimuli tend to be short lived and can be offset by analgesia, sedation, or short-term re-breathing of expired air. Additional causes include the early phases of aspirin poisoning (where the respiratory centers are activated), hypoxia, stroke, and other conditions affecting the brainstem respiratory control centers. Most causes of respiratory alkalosis are short term and, although adaptive responses would be expected to require excretion of bicarbonate to balance the Henderson-Hasselbalch equation, resolution usually occurs by resolution of the underlying condition.

Transporter Mechanisms: Physiology and Pathophysiology

Developments in molecular biology have led to major improvements in our understanding of the physiology and pathophysiology of renal tubular function. It is now possible to subdivide the various types of renal tubular acidosis, for example, by the precise biochemical defect rather than simply the tubular location. Thus, distal (or type 1) RTA may be a consequence of impaired distal tubular H^+ excretion, either due to increased permeability to H^+ or to impaired secretion, the latter, in turn, being a consequence of a variety of defects that include carbonic anhydrase type 2 deficiency, mutations in anion transport protein AE1, or deficiency of collecting duct proton transport ATPase. Whilst specific knowledge of the molecular defect is not necessary to either diagnose or manage these disorders, it is likely that future classification of acid-base disorders will change to recognize the underlying defect.

Water–Electrolyte Balance

S M Shirreffs and R J Maughan, Loughborough University, Loughborough, UK

Body Water and Electrolytes

Man is dependent on ready access to water for survival. Water is the largest component of the human body and the total body water content varies from approximately 45 to 70% of the total body mass; this therefore corresponds to about 33–53 l for a 75 kg man. The water content of the various tissues is maintained relatively constant; as adipose tissue has a low water content (**Table 1**) the fraction of water in the body is determined largely by the fat content. The body's water can be divided into two components—the intracellular fluid and the extracellular fluid. The intracellular fluid is the major component and comprises approximately two-thirds of total body water. The extracellular fluid can be further divided into the interstitial fluid (that between the cells) and the plasma; the plasma volume represents approximately one-quarter of the extracellular fluid volume (**Table 2**).

Numerous electrolytes and solutes are dissolved within the body water compartments: an electrolyte can be defined as a compound which dissociates into ions when in solution. The major cations (positively charged electrolytes) in the body water are sodium and potassium, with smaller amounts of calcium and magnesium; the major anion (negatively charged electrolytes) is chloride, with smaller amounts of bicarbonate and protein. Sodium is the major electrolyte present in the extracellular fluid, while potassium is present in a much lower concentration (**Table 3**). Within the intracellular fluid the situation is reversed, and the major electrolyte present is potassium, while sodium is found in much lower concentrations. Maintenance of the transmembrane electrical and chemical gradients is of

Table 1 Water content of various body tissues for an average 75 kg man

paramount importance for maintaining the integrity of the body's cells and allowing electrical communication throughout the body.

Daily Regulation of Body Water

The body's total body water content is normally maintained within a small window of fluctuation on a daily basis by intake of food and drink to balance the excretion of urine and other losses. Hyperhydration is corrected by an increase in urine production and hypohydration by an increase in water intake via food or drink consumption initiated by thirst. Most of our water intake is related to habit rather than thirst, but the thirst mechanism is effective at driving intake after periods of deprivation. There are also water losses via the respiratory tract, the gastrointestinal tract, and the skin. The extent of these losses will vary from individual to individual and will be strongly influenced by environmental conditions and physical activity levels, but for a sedentary individual in a cool environment these generally represent only a small proportion of the total body water loss.

All the major textbooks of nutrition and physiology include data on the various components of water intake and output, although it is difficult to find the original data on which the various mean values and ranges are based. The Geigy Scientific Tables suggest that the minimum daily water intake for adults is on the order of 1.5 l, but others indicate that the minimum intake should be 2 l per day. Body size has a major influence on water turnover, but the total body water content will also be markedly affected by the body composition. Water turnover should therefore be more closely related to lean body mass than to body mass itself. It is expected, therefore, that there will be differences between men and women and between adults and children.

Environmental conditions will affect the basal water requirement by altering the losses that occur by the various routes (i.e., respiration, sweat, and urine). Water requirements for sedentary individuals living in the heat may be two or threefold higher than the requirement when living in a temperate climate, even when not accompanied by pronounced sweating. Transcutaneous and respiratory losses will be markedly influenced by the humidity of the ambient air, and this may be a more important factor than the ambient temperature. Respiratory water losses are incurred because of the humidification of the inspired air with fluid from the lungs. These losses are relatively small in the resting individual in a warm, moist environment (amounting to about 200 ml per day) but will be increased approximately 2-fold in regions of low humidity, and may be as high as 1500 ml per day during periods of hard work in the cold, dry air at altitude. To these losses must be added insensible water loss through the skin (about 600 ml per day) and urine loss, which will not usually be less than about 800 ml per day.

Variations in the amount and type of food eaten have some effect on water requirements because of the resulting demand for excretion of excess electrolytes and the nonvolatile products of metabolism. An intake of electrolytes in excess of the amounts lost (primarily in sweat and feces) must be corrected by excretion in the urine, with a corresponding increase in the volume and osmolality of urine formed. The daily intake of electrolytes is subject to wide variation among individuals, with strong trends for differences among different geographical regions. Daily dietary sodium chloride intakes for 95% of the young male UK population fall between 3.8 and 14.3 g, with a mean of 8.4 g; the corresponding values for young women are 2.8–9.4 g, with a mean value of 6.0 g. For the same population, mean urinary sodium losses were reported to account for about 175 mmol per day, which is equivalent to about 10.2 g of sodium chloride.

There are also large differences among countries in the recommended intake of salt. The British health authorities advise a maximum of 6 g per day, but in Germany a maximum of 10 g per day is recommended. In contrast, Sweden recommends a maximum of 2 g per day, and Poland recommends a minimum of 1.4 g per day. The differences among countries reflect in part different interpretations with regard to the evidence linking salt intake and health, but also reflect regional consumption patterns dictated by food choices.

A high-protein diet requires a greater urine output to allow for excretion of water-soluble nitrogenous waste; this effect is relatively small compared with other routes of water loss but becomes meaningful when water availability is limited. The water content of the food ingested will also be influenced greatly by the nature of the diet, and water associated with food may make a major contribution to the total fluid intake in some individuals. Some water is also obtained from the oxidation of nutrients, and the total amount of water produced will depend on the total metabolic rate and is also influenced by the substrate being oxidized. An energy expenditure of 3000 kcal (12.6 MJ) per day, based upon a diet composed of 50% carbohydrate, 35% fat, and 15% protein, will yield about 400 ml of water per day. Reducing the daily energy

expenditure to 2000 kcal (8.4 MJ), but keeping the same diet composition, will yield about 275 ml of water. The contribution of this water-of-oxidation to total water requirements is thus appreciable when water turnover is low but becomes rather insignificant when water losses are high.

Thirst and the Control of Intake

In man, daily fluid intake in the form of food and drink (plus that formed from substrate oxidation) is usually in excess of the obligatory water loss (transcutaneous, pulmonary, and renal output), with renal excretion being the main mechanism regulating body water content. However, conservation of water or electrolytes by the kidneys can only reduce the rate of loss; it cannot restore a deficit. The sensation of thirst, which underpins drinking behavior, indicates the need to drink and hence is critical in the control of fluid intake and water balance. While thirst appears to be a poor indicator of acute hydration status in man, the overall stability of the total water volume of an individual indicates that the desire to drink is a powerful regulatory factor over the long term.

The act of drinking may not be a direct consequence of a physiological need for water intake but can be initiated by habit, ritual, taste, or desire for nutrients, stimulants, or a warm or cooling effect. A number of the sensations associated with thirst are learned, with signals such as dryness of the mouth or throat inducing drinking, while distention of the stomach can stop ingestion before a fluid deficit has been restored. However, the underlying regulation of thirst is controlled separately by the osmotic pressure and volume of the body fluids and as such is governed by the same mechanisms that affect water and solute reabsorption in the kidneys and control central blood pressure.

Regulatory Mechanisms

Areas of the hypothalamus and forebrain, that are collectively termed the thirst control centers, appear to be central to the regulation of both thirst and diuresis. Receptors in the thirst control centers respond directly to changes in osmolality, volume, and blood pressure, while others are stimulated by the fluid-balance hormones that also regulate renal excretion. These regions of the brain also receive afferent input from systemic receptors monitoring osmolality, circulating sodium concentration, and alterations in blood volume and pressure. Changes in the balance of neural activity in the thirst control centers regulated by the different monitoring inputs determine the relative sensations of thirst and satiety, and influence the degree of diuresis. Input from the higher centers of the brain, however, can override the basic biological need for water to some extent and cause inappropriate drinking responses. Cases of water intoxication (hyponatremia) during endurance sports events lasting more than about 6–8 h have been reported in which the major cause of the illness is due to overhydration as a result of overdrinking.

A rise of between 2 and 3% in circulating osmolality (i.e., about 6–8 mosm kg^{-1} H_2O) is sufficient to evoke a profound sensation of thirst coupled with an increase in the circulating concentration of antidiuretic hormone, also known as vasopressin. The mechanisms that respond to changes in intravascular volume and pressure appear to be less sensitive than those that monitor plasma osmolality, with hypovolemic thirst being evident only following a 10% decrease in blood volume. As fairly large variations in blood volume and pressure occur during normal daily activity, primarily in response to postural changes, this lack of sensitivity presumably prevents overactivity of the volume-control mechanisms. Prolonged exercise, especially in the heat, is associated with a decrease in plasma volume and a tendency for an increase in osmolality, but fluid intake during and immediately following exercise is often less than that required to restore normal hydration status. This appears to be due to a premature termination of the drinking response rather than to a lack of initiation of that response. Also, the composition of the beverage consumed has an effect on the volume of fluid ingested, with water prematurely abolishing the osmotic drive to drink, while sodium-containing drinks help maintain the osmotic drive to drink and increase voluntary intake.

When a water deficit is present and free access to fluid is allowed, the drinking response in man usually consists of a period of rapid ingestion, during which more than 50% of the total intake is consumed, followed by intermittent consumption of relatively small volumes of drink over a longer period. The initial alleviation of thirst occurs before significant amounts of the beverage have been absorbed and entered the body water. Therefore, although decreasing osmolality and increasing extracellular volume promote a reduction in the perception of thirst, other preabsorptive factors also affect the volume of fluid ingested. Receptors in the mouth, oesophagus, and stomach are thought to meter the volume of fluid ingested, while distension of the stomach tends to reduce the perception of thirst. These preabsorptive signals appear to be

behavioural, learned responses and may be subject to disruption in situations which are novel to the individual. This may partly explain the inappropriate voluntary fluid intake in individuals exposed to an acute increase in environmental temperature or to exercise-induced dehydration.

Renal Function

As well as acting to regulate body water levels by an increase or decrease in the amount of urine produced, the kidneys are also responsible for the elimination of waste products from the body. This, therefore, also affects the daily urine volume. For example, a healthy individual eating a normal diet excretes approximately 600–800 mosmol of solute per square metre of body surface area per day, amounting to a total of about 1000–1500 mosmol day^{-1}. The kidneys can dilute urine to at least as low as 100 mosmol kg^{-1} and can concentrate it to 1200 mosmol kg^{-1}. Therefore, the daily solute load to be excreted can be accommodated in a volume ranging between approximately 500 ml and more than 13 l. To allow for waste product excretion, an obligatory minimum amount of urine must always be excreted, and this is generally in the region of 20–50 ml per hour. However, in the majority of healthy individuals in most situations, the volume of urine produced and excreted is in excess of these basal levels.

Hormonal Control of Urine Production

The volume of urine produced in a healthy individual is largely determined by circulating hormone levels, and in particular by levels of vasopressin. Vasopressin is a cyclic, nine-amino acid peptide. It is released from the posterior pituitary after having been transported there along the axons of neurons whose cell bodies are located in the paraventricular and supraoptic nuclei of the hypothalamus, the site of vasopressin synthesis. An increase in the rate of secretion of vasopressin results in a reduced urine production. Vasopressin acts on the renal distal tubules and collecting ducts to cause an increased permeability to water and hence an increased reabsorption of water from the filtrate. Therefore, a hyperosmotic urine can be formed and the solute load to be excreted can be accommodated in a small volume of water. A decrease in vasopressin secretion results in an increase in the volume of urine produced by causing a reduction in the permeability of the renal distal tubule and collecting ducts to water. Vasopressin secretion is largely influenced by changes in plasma osmolality. An increase in plasma osmolality results in a increased vasopressin secretion and vice versa. The vasopressin is released rapidly in response to the stimuli and begins to act within minutes. When the secretion is inhibited, the half-life of clearance from the circulation is approximately 10 minutes. Therefore, changes in body fluid tonicity are rapidly translated into changes in water excretion by this tightly regulated feedback system.

In addition to the influence of plasma osmolality on vasopressin secretion, other (nonosmotic) factors with an influence are baroregulation, nausea, and pharyngeal stimuli. A fall in blood pressure or blood volume will stimulate vasopressin release; vasopressin secretion is, however, less sensitive to these changes than to changes in osmolality. Nausea is an extremely potent stimulus to vasopressin secretion in man; vasopressin levels can increase 100- to 1000-fold in response to nausea induced by various chemical agents. After a period of water deprivation followed by access to drink, vasopressin levels fall before there is any change in plasma tonicity, suggesting activation of neuronal pathways from the oropharynx.

Aldosterone, a steroid hormone, is released into the circulation after synthesis by the zona glomerulosa cells of the adrenal cortex. Its primary role, in terms of renal function, is to increase renal tubular reabsorption of sodium and in doing so will bring about an increased excretion of potassium and, in association with vasopressin, increase water reabsorption in the distal segments of the nephron. Aldosterone causes this response by increasing the activity of the peritubular sodium/potassium pump and by increasing the permeability of the luminal membrane to both sodium and potassium. The increased luminal permeability allows potassium to move down its concentration gradient from the inside of the membrane cells into the tubule lumen. The majority of the sodium present is reabsorbed into the cell down the concentration gradient. The sodium absorption and potassium excretion are closely correlated with a 3 sodium:2 potassium ratio. Chloride follows the sodium to maintain the electrical neutrality of the urine.

The release of aldosterone is determined by a number of factors including the renin–angiotensin system: A fall in blood or extracellular fluid volume increases renin production and, via angiotensin II, results in an increase in aldosterone secretion.

The presence in the renal filtrate of ions such as bicarbonate and sulphate, which are not reabsorbed, promotes secretion of potassium into the distal tubule of the nephron and will also result in an increased urinary loss of potassium.

Sweat

Exercise, particularly in a warm environment, and diarrheal illness are two situations which will increase the requirement for salt to substantially greater levels. Sweating, therefore, is an important consideration in the area of water and electrolyte balance as this is the one route where there can be extensive losses of water and electrolytes from the body in a healthy individual. If these losses are not replaced, serious consequences can ensue.

Eccrine sweat is a clear, watery, odourless substance whose primary function is to promote heat loss by evaporation from the skin surface. When sweat is produced, the daily water losses increase and the intake must be increased or urine production decreased accordingly if euhydration is to be maintained.

Sweat Evaporation

There is a daily loss on the order of approximately 500 ml of water through the skin. However, when the body is exposed to a heat stress and behavioral and vasomotor mechanisms are insufficient to prevent a rise in temperature, the physiological responses generally include an increase in sweat production in an attempt to prevent hyperthermia; the high latent heat of vaporization of water makes the evaporation of sweat an effective heat loss mechanism (evaporation of 1 l of water from the skin surface will remove 2.4 MJ (580 kcal) of heat from the body). The heat stress may be of external origin (i.e., from the environmental conditions), of internal origin due to muscular work or fever, or from a combination of these factors.

In many individuals sweat rates can be in excess of 2 l per hour, especially in situations of exercise undertaken in a warm, humid environment, and these high sweat rates can be maintained for a number of hours. For example, body mass losses in marathon runners have been reported to range from about 1–6% (0.7–4.2 kg) at low (10 °C) ambient temperatures to more than 8% (5.6 kg) in warmer conditions. However, when sweat rates are high, a significant fraction of the sweat secreted onto the skin may drip from the body and is therefore ineffective at removing heat.

Mechanism of Sweat Secretion

The human body has approximately 2 million sweat glands. The eccrine sweat gland consists of a single tubule, opening onto the epidermis at one end and closed at the other. The proximal half of the tubule is the secretory coil and the distal half the reabsorptive duct. The sweat secreted onto the skin is the original tubular secretion minus the substances which are, further up the tubule, reabsorbed; from the isoosmotic fluid secreted by the coil most of the major electrolytes (Na^+, Cl^-, HCO_3^+, and lactate) are transported out of the duct back into the extracellular fluid in excess of water. The final sweat secreted onto the skin is therefore hypotonic with respect to body fluids.

Sweat Composition

The composition of human sweat is highly variable, both between individuals and within an individual over time. However, sodium and chloride are the major electrolytes lost in sweat, with other ions being present in smaller amounts relative to the whole body status. The sweat electrolyte composition of an individual seems to be related primarily to sweat rate but can be influenced by training status, extent of heat acclimation, and diet. However, the range of values for sweat electrolyte composition reported in the literature probably reflects not only the interindividual differences but also differences in the methodology used for collection of the sweat. This last factor may be the result of errors caused by contamination or incomplete collection of the sample, or it may reflect a real difference induced by the collection procedure.

Due to the secretion and reabsorption process involved in sweat production within the sweat gland and duct, sweat composition is influenced by sweat rate, at least within single ducts, such that a reduction in rate allows for greater reabsorption of certain electrolytes (Na^+, Cl^-, but not K^+) from the duct resulting in a lower concentration in the final sweat produced. There also appear to be regional variations in sweat composition, as evidenced by the different values obtained when the composition of sweat obtained from different parts of the body is compared, and the values obtained by regional collection also differ from those obtained by the whole body washdown technique. Reported values for sweat electrolyte composition are summarized in **Table 3**.

Restitution of Water and Electrolyte Balance

When substantial sweat losses have been incurred, restitution of water balance requires both volume repletion and replacement of electrolyte losses. This can be achieved by ingestion of electrolyte-containing drinks or by ingestion of water and consumption of electrolyte-containing foods. Problems may occur

when large sweat losses are replaced with electrolyte-free drinks. Hyponatremia and blood volume expansion ensue and will promote a diuresis that will prevent effective recovery.

Conclusions

In healthy individuals, water is the largest single component of the body. Although water balance is regulated around a range of volumes rather than a finite set point, its homeostasis is critical for virtually all physiological functions. To further ensure proper regulation of physiological and metabolic functions, the composition of the individual body water compartments must also be regulated.

Humans continually lose water through the renal system, gastrointestinal system, skin, and respiratory tract, and this water must be replaced. Thirst is implicated in our water intake, but behavioral habits also have an important influence on drinking.

When exercise is undertaken or when an individual is exposed to a warm environment, the additional heat load is lost largely due to sweating and this can increase greatly the individual's daily water loss and therefore the amount that must be consumed. Sweat rates on the order of 2 to 3 l per hour can be reached and maintained by some individuals for a number of hours and it is not impossible for total losses to be as much as 10 l in a day. These losses must of course be replaced and when they are so extreme, the majority must be met from fluid consumption rather than food ingestion. A variety of drink types and flavors are likely to be favored by individuals who have extreme losses to replace. Sports drinks have an importance role in this recovery when no food is ingested by their contribution to sweat electrolyte loss replacement which is crucial for retention of the ingested water.

Metabolism

S Cox, London School of Hygiene and Tropical Medicine, London, UK

The energy required for the growth and maintenance of living organisms is acquired through the cellular respiration of organic compounds. In man and other nonphotosynthetic organisms, these metabolic fuels are obtained from food and consist of carbohydrates, fats, and proteins.

Metabolism

Metabolism is defined as the sum of anabolic or synthetic chemical reactions that require energy and the catabolic chemical reactions that break down large organic molecules into smaller molecules, thereby releasing energy for anabolic reactions.

Cellular Respiration and Adenosine Triphosphate

Cellular respiration can be defined generally as the process by which chemical energy is released during the oxidation of organic molecules. If it requires oxygen, it is called aerobic respiration, whereas if it takes place in the absence of oxygen it is anaerobic respiration.

Organic molecules, usually carbohydrate or fat, are broken down by a series of enzyme-catalyzed reactions. Many of these reactions release a small amount of energy that is channeled into molecules of a chemical nucleotide called adenosine triphosphate (ATP) (**Figure 1**).

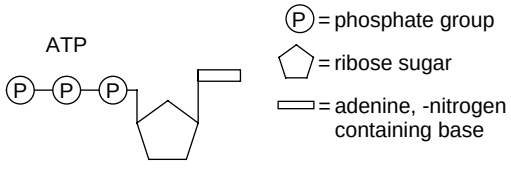

Figure 1 Structure of adenosine triphosphate (ATP).

ATP is the standard unit in which the energy released during respiration is stored. ATP is an instant source of energy within the cell. It is mobile and transports energy to wherever energy-consuming processes are occurring within the cell. The energy is released by the dephosphorylation of ATP to ADP, which can then be rephosphorylated to ATP by being coupled to the processes of respiration. ATP is found in all living cells and can be thought of as a universal energy transducer.

The principal metabolic fuel is glucose, and there are three stages in its oxidation to carbon dioxide, water, and energy, captured as ATP. This process can be summarized very simply by the following equation:

$$C_6H_{12}O_6 + 6O_2 \rightarrow 6CO_2 + 6H_2O + \text{energy (ATP)}$$

In the first stages, glucose and other metabolic fuels are oxidized, linked to the chemical reduction of coenzymes (nicotinamide adenine dinucelotide (NAD^+), flavin adenine dinucleotide (FAD), and flavin mononucleotide (FMN)). In the final stage, ATP is synthesized from ADP and phosphate via a common pathway using energy released from the oxidation and recycling of the reduced coenzymes (**Table 1**). Thus, the oxidation of metabolic fuels is tightly coupled to energy consumption and the production of ADP from ATP in energy-consuming processes (**Figure 2**).

Glycolysis

The main substrate for glycolysis is glucose. Glycolysis does not require oxygen and is important for the direct production of ATP when oxygen is limiting (i.e., in rapidly contracting muscle). Glycolysis results in the splitting of glucose, a six-carbon (6C) compound, into two molecules of pyruvic acid (3C), which in the cytoplasmic solution becomes pyruvate (**Figure 3**). Pyruvate can enter the mitochondrion and be metabolized by oxidative decarboxylation to CO_2, or if oxygen is unavailable it can be further metabolized to lactic acid resulting in the

Table 1 The three principal stages in the production of ATP from one molecule of glucose

Metabolic pathway	*Location*	*O_2 required?*	*Net ATP or reduced coenzymes/glucose*	*Products*
Glycolysis	Cytoplasm	Anaerobic	Net gain 2 ATP 2 $NADH + H^+$	Glucose → 2 pyruvate
Pyruvate → acetyl-CoA	Mitochondrial matrix	Aerobic	2 $NADH + H^+$	
TCA cycle	Mitochondrial matrix	Aerobic	2 GTP → 2 ATP 8 $NADH + H^+$ 2 $FADH_2$	2 Pyruvate → $6CO_2$
Electron transfer chain (oxidative phosphorylation)	Mitochondrial crista and primary particles	Aerobic	12 $NAD^+ + 2$ FAD → 38 ATP[a]	$12H_2 + 6O_2 \rightarrow 6H_2O$

[a]The exact net gain in the number of ATP produced from the oxidation of the reduced coenzymes $NADH + H^+$ and $FADH_2$ varies depending on the mechanism used to transport them across the crista membrane in the mitochondria, the site of oxidative phosphorylation.

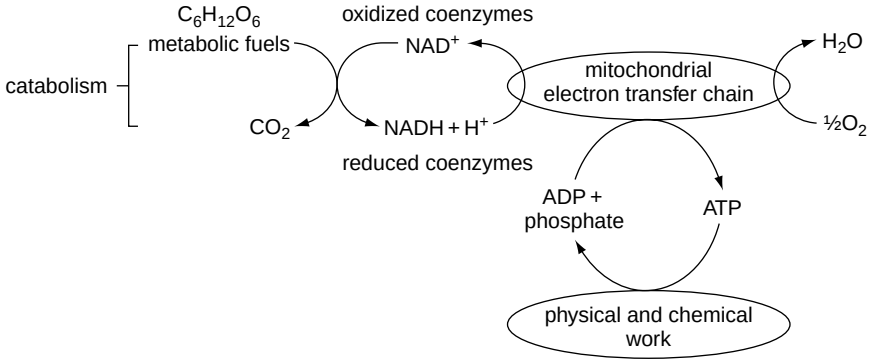

Figure 2 Linkage between ATP utilization in physical and chemical work and the oxidation of metabolic fuels. (Adapted with permission from Bender DA (2002) *Introduction to Nutrition and Metabolism*, 3rd edn. London: Taylor & Francis.)

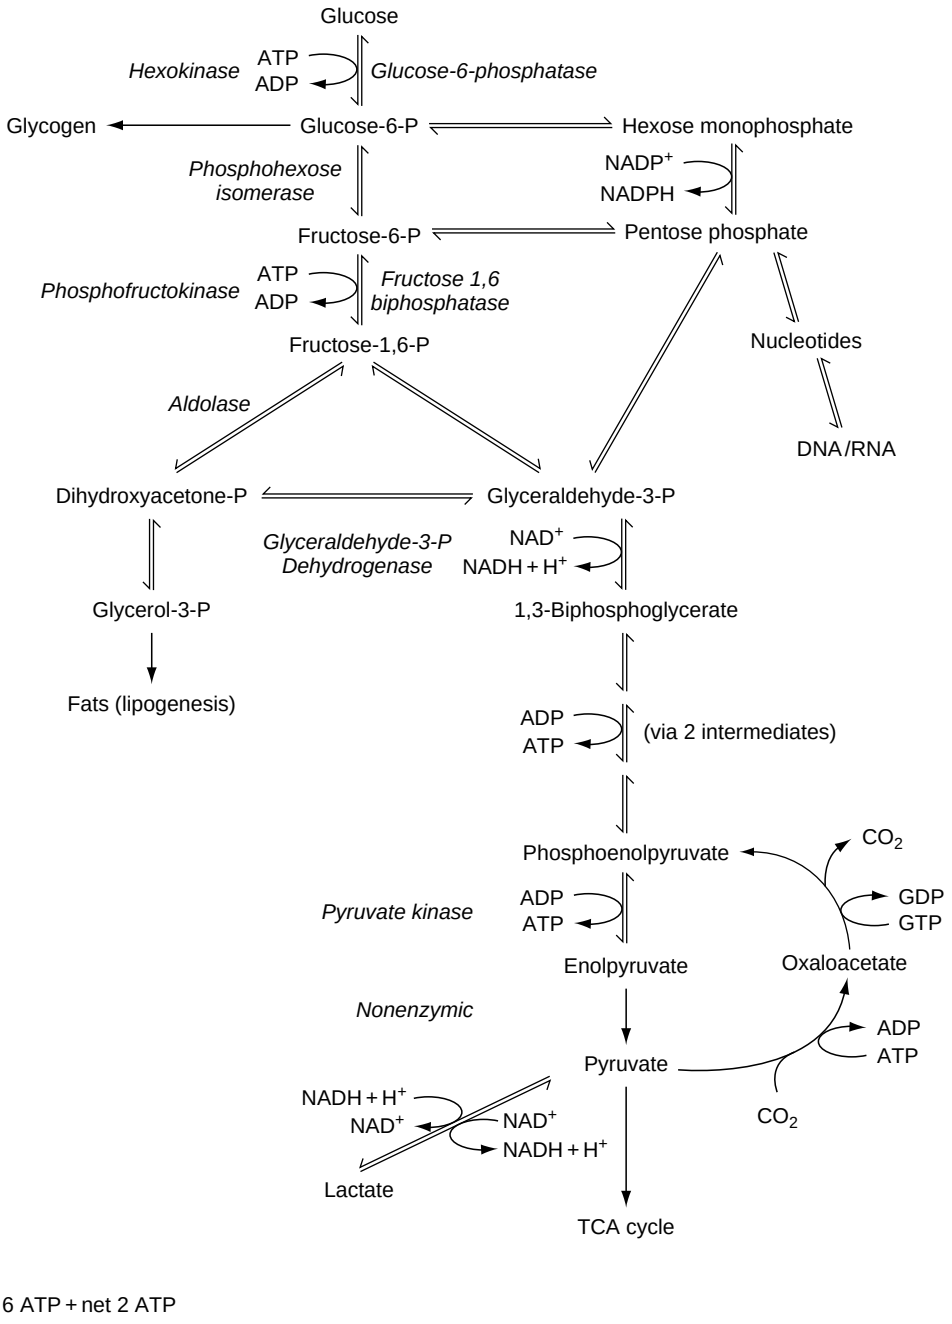
regeneration of NAD^+ from $NADH + H^+$, thus allowing glycolysis to continue in the absence of oxygen. Red blood cells lack mitochondria and therefore glycolysis is the only source of energy metabolism. Thus, red cells can only metabolize glucose or other simple sugars and not fats or proteins. Red cells produce lactate that is excreted into the blood. Lactate is primarily metabolized back to pyruvate in the liver, where it is mostly used for the synthesis of glucose (gluconeogenesis), which is essentially the reverse of glycolysis except for the irreversible reaction of phosphoenolpyruvate (PEP) to pyruvate. Hence, in the liver pyruvate is converted back to PEP via oxaloacetate (**Figure 3**). This cycling of lactate and pyruvate is known as the Cori cycle.

Other sugars, such as fructose and galactose, can be fed into glycolysis at different points and then metabolized in the same way as glucose to pyruvic acid.

The pentose–phosphate shunt (sometimes also known as the hexose–monophosphate pathway) occurs when glucose-6-phosphate is metabolized via an alternative route to glycolysis to generate pentose phosphates to be used as components in DNA and RNA nucleotides. Alternatively, pentose phosphates can be returned into the glycolytic pathway by conversion back to fructose-6-phosphate or glyceraldehyde-3-phosphate. Another purpose of this shunt is the production of $NADPH + H^+$ from $NADP^+$, which is the required coenzyme for fat synthesis (lipogenesis). Reduced $NADP^+$ is also required for the reduction and recycling of oxidized glutathione, an important intermediate in antioxidant defence and in the generation of the respiratory burst, used to kill parasites ingested by macrophages, a type of white blood cell.

Tricarboxylic Acid Cycle

The tricarboxylic acid (TCA) cycle (also known as the citric acid cycle) is located in the mitochondrial matrix and is a common metabolic pathway for all fuels. It is responsible for the production of the majority of the reduced coenzymes used for the generation of ATP in the electron transfer chain. It also plays a central role in the interconversion of



net = 2 NADH = 6 ATP + net 2 ATP

Figure 3 Glycolysis and its interactions with other metabolic pathways.

fuels and metabolites. The TCA cycle participates in gluconeogenesis from amino acids and lactate during fasting between meals and longer term in starvation. TCA cycle intermediates are the source of most of the nonessential amino acids, such as aspartate and glutamate. It is also involved in the conversion of carbohydrates to fat for storage after a carbohydrate-rich meal.

Pyruvate (3C) from glycolysis is oxidatively decarboxylated to acetyl-CoA (2C) in the mitochondria, catalyzed by the multienzyme complex pyruvate dehydrogenase and the coenzyme A (Co-ASH):

$$\text{Pyruvate} + \text{Co-ASH} + \text{NAD}^+ \rightarrow \text{acetyl-CoA} + \text{Co}_2 + \text{NADH} + \text{H}^+$$

Pyruvate dehydrogenase requires several coenzymes derived from vitamins, including vitamin B_1 or thiamine, niacin (NAD), riboflavin (FAD), and pantothenic acid (a component of CoA). Deficiencies in any of these vitamins can affect energy metabolism, as

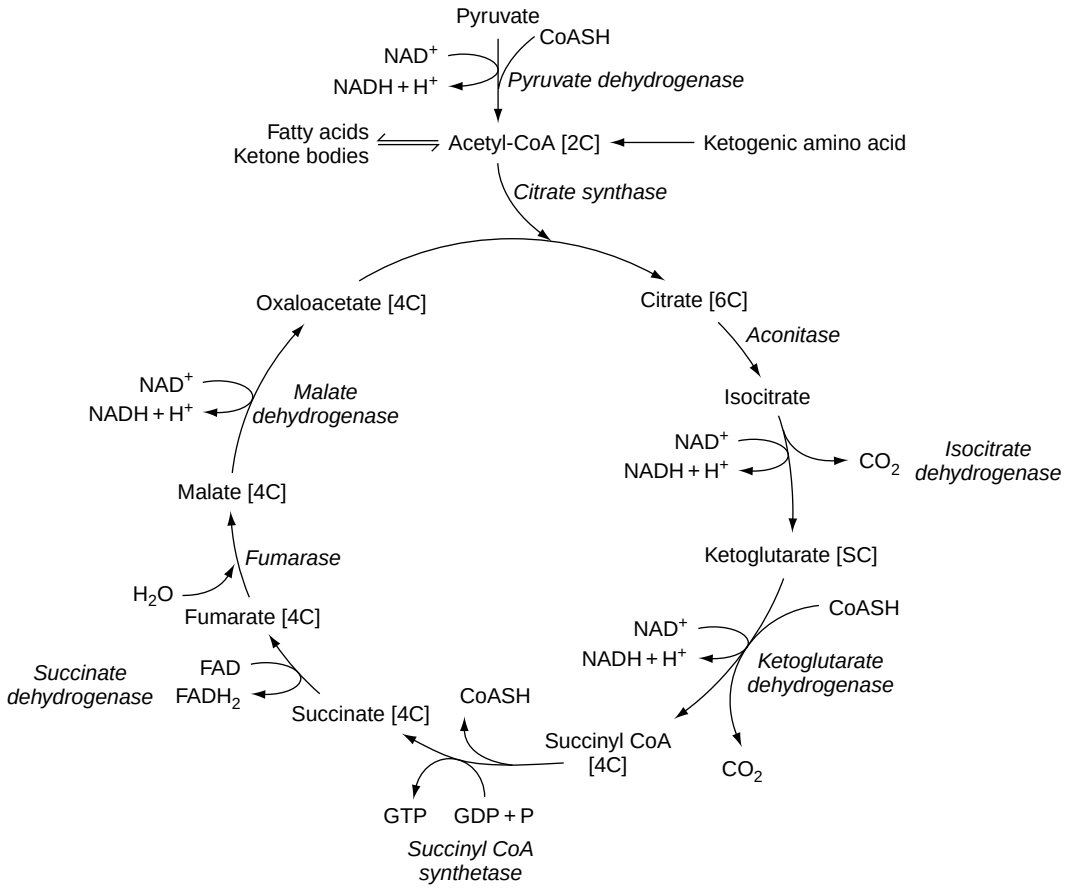


Figure 4 The oxidative decarboxylation of pyruvate and the tricarboxylic acid cycle.

evidenced by the increased cellular pyruvate and cardiac and skeletal muscle weakness in beriberi caused by thiamine deficiency. Pyruvate dehydrogenase catalyzes a central reaction in carbohydrate metabolism, and therefore its activity is regulated by both allosteric and covalent mechanisms.

Acetyl-CoA can be produced from pyruvate but also from fatty acids released from fat stores and from amino acids released from proteolysis of protein tissue, which can be converted to acetyl-CoA or cycle intermediates. In the first of the eight enzymatic reactions, acetyl-CoA (2C) combines with oxaloacetate (4C), forming citrate (6C) and releasing the CoA for further reactions with pyruvate to acetyl-CoA. A cycle of reactions follows in which two molecules of CO_2 are released and three molecules of $NADH + H^+$ and one of $FADH_2$ are produced along with one molecule of GTP (equivalent to ATP). At the end of the cycle, oxaloacetate is regenerated and able to react again with another molecule of acetyl-CoA, and so the cycle continues (**Figure 4**).

In the electron transfer chain, each $NADH + H^+$ yields approximately 3 ATP and $FADH_2$ yields 2 ATP. Thus, each rotation of the TCA cycle produces approximately 12 ATP ($3\ NADH + H^+ \approx 9\ ATP + 1\ FADH_2 \approx 2\ ATP + 1\ GTP$). Because two molecules of acetyl-CoA are formed from one glucose molecule, the TCA cycle rotates twice for each molecule of glucose respired, producing a net of 24 ATP (**Table 1**).

Electron Transfer Chain (Oxidative Phosphorylation)

Oxidative phosphorylation occurs in the crista of mitochondria, formed by invaginations of the inner mitochondrial membrane (**Figure 5**). The hydrogen accepted by NAD^+ and FAD during glycolysis and the TCA cycle is oxidized to water by molecular oxygen with accompanying phosphorylation of $ADP \rightarrow ATP$. This is achieved by phosphorylation of ADP coupled with a series of redox reactions whereby the hydrogen ions (H^+) and their electrons (e^-) are passed along a chain of intermediate carriers in the crista membrane of the mitochondria

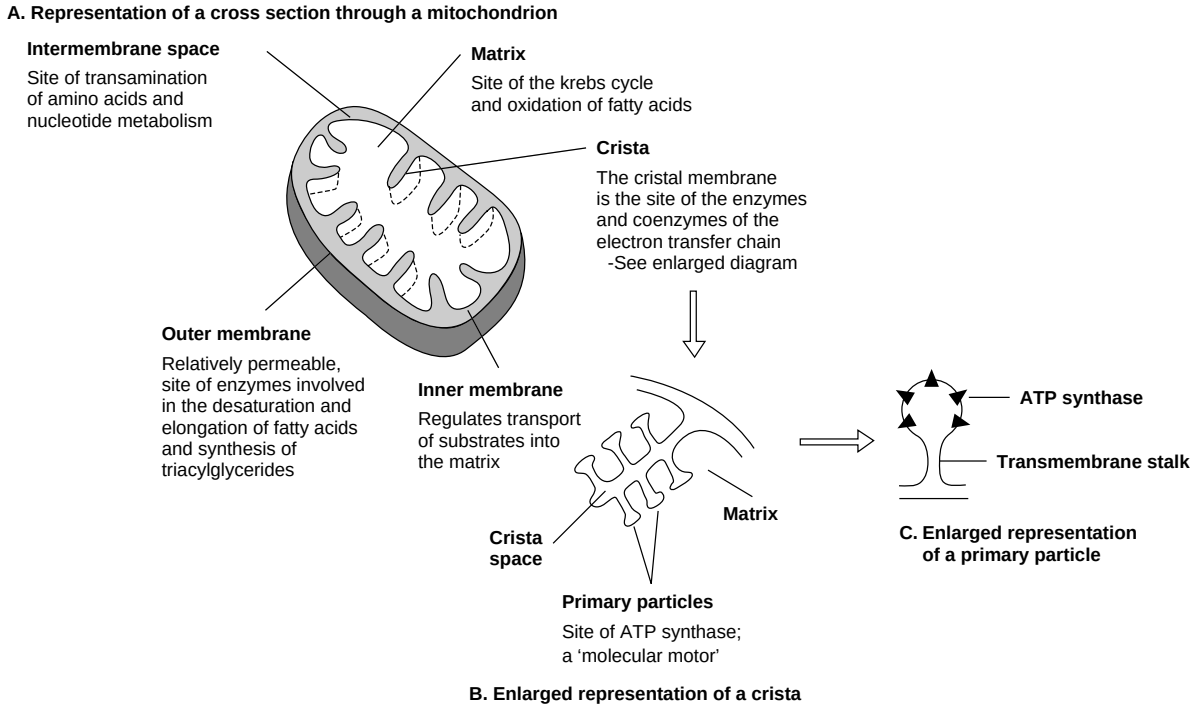

Figure 5 Structure and related functions of a mitochondrion.

(**Figure 6**), with each intermediate being reduced by the proceeding one and in turn reducing the next one and hence itself being oxidized. The chain consists of a flavoprotein and ubiquinone (coenzyme Q), both hydrogen carriers, followed by a series of cytochromes that are carriers of electrons only. Finally, at the end of the chain is cytochrome oxidase, which catalyzes the formation of water from hydrogen ions, electrons, and molecular oxygen. Unlike the other cytochromes, cytochrome oxidase contains copper (Cu^{2+}) in a prosthetic group instead of Fe^{3+} (in the form of a heme molecule), and this final stage can be inhibited by the irreversible binding of cyanide to Cu^{2+} preventing it from accepting electrons and therefore terminating the entire hydrogen electron transfer chain and hence all aerobic respiration. This is the basis of the toxicity of cyanide and also several other substances.

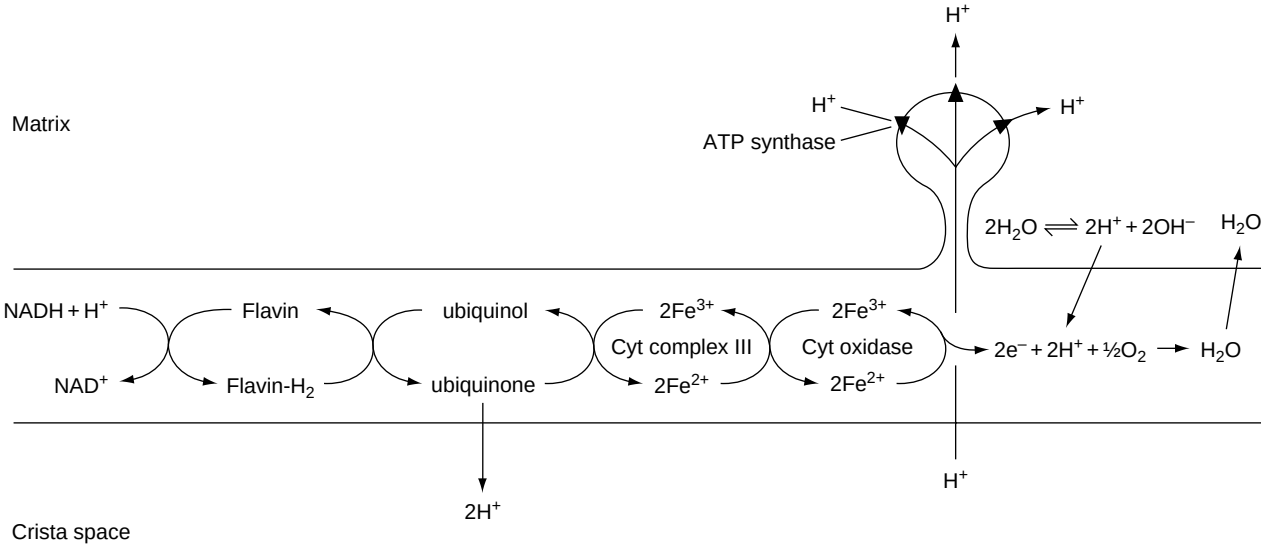

Figure 6 Overview of the electron transfer chain.

When the hydrogen from $NADH + H^+$ or $FADH_2$ is passed from ubiquinone to the first cytochrome, the hydrogen dissociates into a hydrogen ion (proton) and an electron. The proton is excreted into the crista space, whereas the electron carries on down the chain of cytochromes. This creates a proton gradient across the crista membrane. In the last step, the reduction of molecular oxygen to water, the hydrogen protons are obtained not from the hydrogen excreted into the crista space but from the mitochondrial matrix from the dissociation of water ($H_2O \leftrightarrow H^+ + OH^-$), thus maintaining a proton gradient across the crista membrane. The resulting movement of protons from the crista space to the matrix through the transmembrane stalk of the primary particle drives the multienzyme complex of ATP synthase. It is the energy of the flow of the protons that provides the energy required for the synthesis of ATP in a manner analogous to a water mill, where the flow of water can be used to turn a motor, grind wheat, or generate electricity.

The oxidation of $FADH_2$ and $NADH + H^+$ is normally tightly coupled to the phosphorylation of $ADP \rightarrow ATP$ because the phosphorylation of ADP cannot occur unless there is a proton gradient across the crista membrane of the mitochondria, resulting from the processes in the hydrogen electron transfer chain. Metabolic fuels can only be oxidized if there is NAD^+ and FAD available to be reduced. If there is no ADP because it has all been phosphorylated to ATP, protons cannot move down the concentration gradient across the crista membrane and through the 'water mill' of ATP synthase because it will not turn if there is no ADP to bind to it. Once a critical concentration of protons is reached in the crista space, it is no longer possible to extrude any more protons from the oxidation of FADH or $NAD + H^+$ during the transfer of hydrogen from ubiquinone to the first cytochrome. Hence, the whole chain stops and no more oxidized NAD^+/FAD is available for glycolysis or the TCA cycle.

The uncoupling of the electron transfer chain from the production of ATP can only occur if protons move down the concentration gradient across the crista membrane and through routes independent of ATP synthase. In some circumstances tissues, uncoupling proteins can be expressed in the crista membrane, which allow protons to flow down the concentration gradient into the mitochondrial matrix without passing through the ATP synthase and therefore not generating ATP but resulting in the generation of a large amount of heat energy. This is the basis of nonshivering thermogenesis, which is thought to occur mostly in brown adipose tissue in infants by the uncoupling protein thermogenin. In adults, the importance of brown adipose tissue compared with other uncoupling proteins in muscle and other tissues is unclear. In addition to maintenance of body temperature, uncoupling proteins may also be important in overall energy balance and body weight. Leptin, a hormone secreted from white adipose tissue, increases the expression of uncoupling proteins in muscle and adipose tissue, thus increasing energy expenditure and utilisation of adipose tissue fat reserves.

Energy Metabolism of Other Nutrients

The TCA cycle and pyruvate are central in the metabolism of carbohydrate, fat, and protein in the fed and fasting state. Pyruvate can have three main fates depending on the metabolic circumstances. It can be a substrate for gluconeogenesis, or it can undergo oxidative decarboxylation to acetyl-CoA and either enter the TCA cycle or be used for fatty acid synthesis.

Acetyl-CoA can be made from carbohydrates via pyruvate, from fatty acids via β-oxidation in the mitochondrial matrix, or from the proteolysis of proteins to amino acids, some of which are converted to acetyl-CoA.

There are three main stores of metabolic fuels: triacylglycerols in adipose tissue, glycogen as a carbohydrate reserve in liver and muscle, and protein as a source of amino acids that can be oxidized via the TCA cycle or used as a substrate for gluconeogenesis.

Overview of Fat Metabolism

β-Oxidation of Fatty Acids and Ketogenesis

Fats (triacylglycerides) are stored mainly in adipose tissue. Lipolysis breaks down fats into the constituent fatty acids and glycerol. Fatty acids can be oxidized via the β-oxidation pathway in the mitochondrial matrix. In this process, a cyclical series of reactions removes the last two carbon atoms from the carboxyl end of the fatty acyl-CoA, with the addition of another CoA to form a new fatty acyl-CoA that is two carbon atoms shorter plus acetyl-CoA. In muscle, the acetyl-CoA is metabolized via the TCA cycle to produce reduced coenzymes for the production of ATP. In the liver, it is shunted largely to the synthesis of ketone bodies (ketogenesis), which, like glucose, are exported for use in other tissues.

On the outer face of the mitochondrial membrane, fatty acids are esterified to CoA to form

fatty acyl-CoA, which cannot enter the matrix of the mitochondria, the site of the enzymes for β-oxidation. This function is performed by the carnitine shuttle. On the outer mitochondria membrane, fatty acyl is transferred onto carnitine to form fatty acyl-carnitine that is transported across the inner and outer mitochondrial membranes on a countercurrent transporter system, in exchange for transporting free carnitine into the intermembrane space. Once in the matrix, the fatty acyl is esterified to CoA, thus releasing free carnitine. There is no dietary requirement for carnitine because it is readily synthesized from the amino acids lysine and methionine.

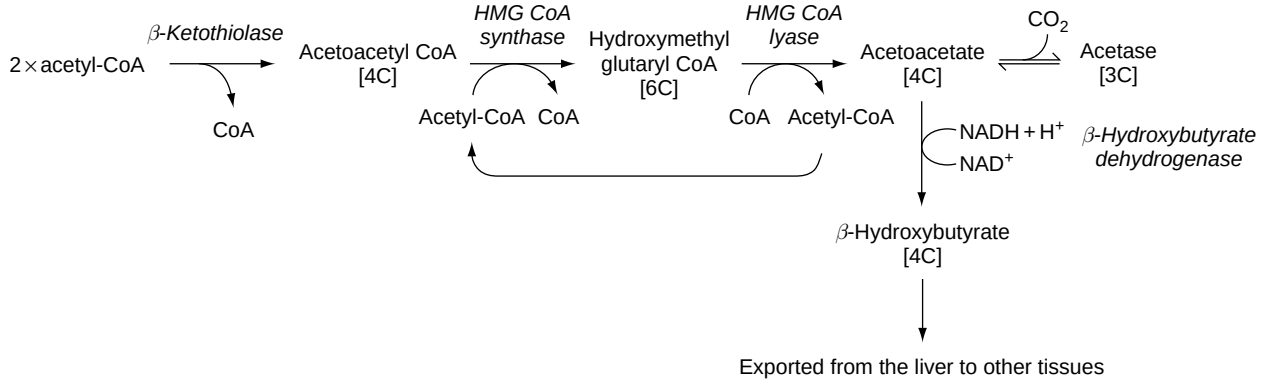
Most tissues have a limited capacity for β-oxidation. However, the liver can produce large amounts of acetyl-CoA by β-oxidation and can then convert some of this into four-carbon ketone bodies that can be easily transported to other tissues for use as a metabolic fuel. Acetoacetate is formed by the combination of 2 acetyl-CoA and the removal of the CoA molecules. This is unstable and undergoes a nonenzymic reaction to acetone, which is poorly metabolized, most of it being excreted in urine and exhaled air. Hence, most of the acetoacetate is reduced to β-hydroxybutyrate before being released from the liver. β-Hydroxybutyrate is metabolized by extrahepatic tissues by adding a CoA via succinate-CoA to form succinate and acetoacetyl-CoA that is then broken down into 2 acetyl-CoA by β-ketothiolase and CoA (**Figure 7**).

Synthesis of Fatty Acids and Triacylglycerides

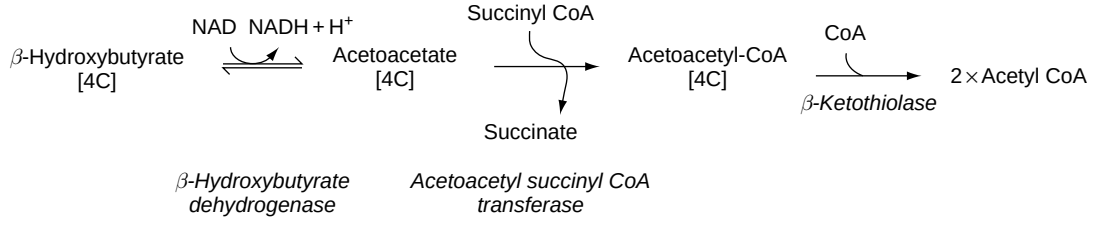
The majority of fatty acids are supplied by the diet, but many tissues are capable of *de novo* synthesis, including the liver, brain, kidney, mammary glands, and adipose tissue. The *de novo* synthesis of fatty acids occurs in conditions of excess energy intake.

Fatty acid synthesis occurs in the cytosol but is essentially the reverse of β-oxidation of fatty acids (although it employs a separate set of enzymes), whereby fatty acids are synthesized from the successive additions of 2C acetyl-CoA followed by reduction.

Acetyl-CoA is formed in the mitochondrial matrix, but it cannot pass across the mitochondrial inner membrane. Hence, the source of acetyl-CoA for fatty acid synthesis is citrate, which can pass out of the mitochondria, where, with CoA, it is cleaved to produce acetyl-CoA and oxaloacetate. The oxaloacetate is returned indirectly to the mitochondrial matrix via its oxidation to pyruvate, which is linked to the generation of reduced NADP, required for fatty acid synthesis. Once in the mitochondrial matrix, the pyruvate is converted back to oxaloacetate and thus returned into the TCA cycle.



(A) Ketogenesis in the liver from acetyl-CoA



(B) Extrahepatic metabolism of β-hydroxybutyrate (Ketone bodies) to acetyl-CoA

Figure 7 The production (A) and metabolism (B) of ketones produced from acetyl-CoA.

The first step in fatty acid synthesis is the carboxylation of acetyl-CoA to malonyl-CoA, followed by the addition of a series of malonyl-CoA units by a complex series of reactions via the multienzyme complex fatty acid synthase. The carboxylation of acetyl-CoA to malonyl-CoA is regulated by the hormones insulin and glucagon, which affect the activity of the enzyme catalyzing this reaction. Hence, in the fed state insulin increases the activity of the enzyme, whereas in the fasting state glucagon decreases its activity. Also, malonyl-CoA inhibits the uptake of fatty acids into the mitochondria via acetyl carnitine-CoA so that when fatty acid synthesis is occurring, β-oxidation is inhibited by limiting the supply of substrate into the mitochondria.

Storage of fatty acids in adipose tissue can only occur when glycolysis is activated in the fed state because the source of glycerol in adipose tissue is blood glucose entering glycolysis and DHA-P removed to be converted to glycerol-3-P.

During fatty acid synthesis, desaturase enzymes can introduce double bonds to make mono- and polyunsaturated fatty acids. However, these enzymes cannot introduce double bonds after C10; this is why there is a requirement for the essential fatty acids linoleic acid (n-6) and linolenic acid (n-3), which can then be converted to the long-chain polyunsaturated fatty acids, arachidonic acid and eicosapentaenoic acid, which are important metabolic precursors.

Protein Metabolism

After a meal there is an increase in the synthesis of tissue protein from absorbed amino acids and the increased availability of metabolic fuel to provide ATP for protein synthesis. During fasting some of the relatively labile protein laid down in response to a meal can be mobilized and the amino acids used both as a metabolic fuel and as a source of TCA cycle intermediates for gluconeogenesis.

After removal of the nitrogen-containing amino group of amino acids, their carbon skeletons can undergo gluconeogenesis (gluconeogenic amino acids only), be converted into ketone bodies via acetyl-CoA (ketogenic amino acids), be fully oxidized to CO_2 and H_2O, be converted into fat or glycogen for storage, or be used as a precursor for a wide range of important biomolecules (**Figure 8**).

Gluconeogenesis

The brain can normally only metabolize glucose as an energy source. Therefore, it is very important to maintain relatively constant levels of circulating glucose. In normal circumstances, glycogen serves as a source of blood glucose as free fatty acids from adipose tissue and ketone bodies from the liver are used preferentially as metabolic fuels by muscle and some other tissues. However, this still leads to the exhaustion of glycogen reserves within 12–18 h.

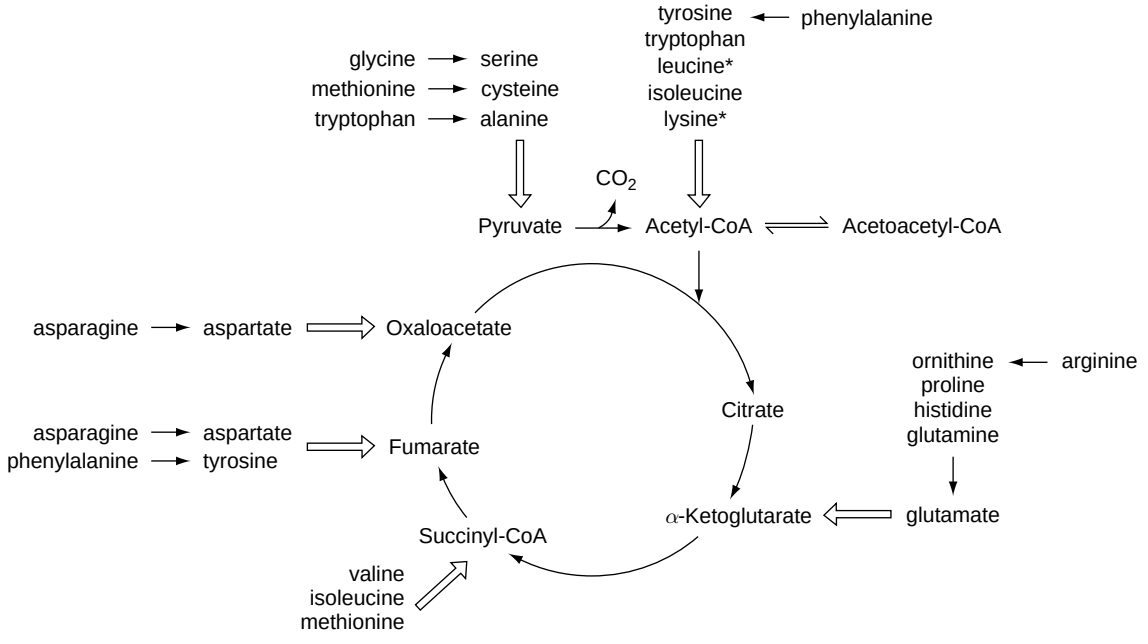


Figure 8 Entry of amino acid carbon skeletons into the tricarboxylic acid cycle. *These amino acids are ketogenic only. (Adapted with permission from Bender DA (2002) *Introduction to Nutrition and Metabolism*, 3rd edn. London: Taylor & Francis.)

Hence, the formation of glucose from noncarbohydrate sources (gluconeogenesis) is important.

Glucose can be formed from the gluconeogenic amino acids and from glycerol released from the lipolysis of TAGs in adipose tissue. Amino acids can enter the TCA cycle as intermediates and be converted to oxaloacetate, the excess of which can then be removed and metabolized to phophoenolpyruvate and then, by a process that is the reverse of glycolysis, be converted to glucose. Glycerol can be converted to an intermediate on the glycolytic pathway and therefore undergo gluconeogenesis if required.

Amino acids that can only be metabolized to acetyl-CoA cannot undergo gluconeogenesis because acetyl-CoA cannot be converted back to pyruvate and the inclusion of more acetyl-CoA will not generate a net increase in oxaloacetate, which can be removed from the cycle. Hence, fatty acids and ketones that are broken down into acetyl-CoA also cannot be used for gluconeogenesis.

There are three enzymes in gluconeogenesis that are different from those in glycolysis, and the relative activity of these compared to the equivalent glycolytic enzymes is tightly controlled by hormones, hence controlling whether glycolysis or gluconeogenesis is the dominant pathway.

Table 2 Summary of relative importance of different metabolic pathways in intermediary metabolism in different tissues

Tissue	*Principal catabolic and anabolic pathways*
Brain	25% basal O_2 consumption
	Metabolizes glucose only, except after prolonged starvation when it can adapt to uptake and metabolize ketones
Blood	Mature red blood cells have no mitochondria ∴ energy from anaerobic glycolysis: glucose → lactate
Muscle	Preferentially metabolize fatty acids and ketones produced from the liver
	Anaerobic glycolysis of glucose from glycogen stores
	Aerobic respiration of glucose from glycogen or fatty acids/ketones
Liver	Mostly amino acid oxidation for generation of ATP
	Most important tissue for maintaining blood glucose by gluconeogenesis from amino acids and lactate (via Cori cycle) and glycerol and also from breakdown of glycogen stores
	Fatty acid synthesis and synthesis of lipoproteins for transport
	Production of ketones into circulation
	Site of the pentose–phosphate pathway for generation of $NADPH + H^+$
Adipose tissue	Designed for the storage of fat
	Can synthesize fat from glucose
Kidneys	Gluconeogenesis
	Amino acid oxidation for ATP generation

Glycogen Metabolism

The red blood cells and the brain have an absolute requirement for glucose for energy metabolism. Glucose is absorbed from the intestines only for 2 or 3 h after a meal; therefore, there must be another source of glucose to maintain a constant blood glucose level. When blood glucose levels increase after a meal, the liver can uptake large amounts of glucose, where it is converted to glucose-6-phosphate that can be used to synthesize glycogen (glycogenesis). When glycogen stores are full, glucose-6-phosphate can enter glycolysis or be used to synthesize glycerol for the formation of fat. When blood glucose levels decrease, during fasting between meals, glycogen is broken down in the liver and glucose is released (glycogenolysis). In the fasting state, glycogen is broken down by the removal of glucose units as glucose-1-phosphate from the many ends of the molecule. This is then isomerised to glucose-6-phosphate. Only the liver can release free glucose because muscle tissue lacks glucose-6-phosphatase. The free glucose released by the liver is used by the brain and red blood cells.

Glucose-6-phosphate released in the muscle tissue from glycogen can enter directly into glycolysis for energy production by the muscle. Alternatively, it can be metabolized to pyruvate and then transaminated to alanine that is exported from the muscle to the liver, where it can be used as a substrate for gluconeogenesis. **Table 2** shows the relative importance of energy metabolic pathways in different tissues of the body.

Balance

Y Schutz, University of Lausanne, Lausanne, Switzerland

Introduction

To maintain physiologic functions, the human body continuously expends energy by oxidative metabolism. This energy is used to maintain chemical and electrochemical gradients across cellular membranes for the biosynthesis of macromolecules such as proteins, glycogen, and triglycerides, and for muscular contraction. Another part of the energy is lost as heat because of the inefficiency of metabolic transformations. Ultimately all the energy produced by the organism is dissipated as heat.

The energy expended by an individual can be assessed by two different techniques: indirect and direct calorimetry. The term indirect calorimetry stems from the fact that the heat released by chemical processes within the body can be indirectly calculated from the rate of oxygen consumption ($\dot{V}O_2$). The main reason for the close relation between energy metabolism and $\dot{V}O_2$ is that the oxidative phosphorylation at the respiratory chain level allows a continuous synthesis of adenosine triphosphate (ATP). The energy expended within the body to maintain electrochemical gradients, support biosynthetic processes, and generate muscular contraction cannot be directly provided from nutrient oxidation. Almost all chemical processes requiring energy depend on ATP hydrolysis. It is the rate of ATP utilization that determines the overall rate of substrate oxidation and therefore $\dot{V}O_2$. With the exception of anaerobic glycolysis, ATP synthesis is coupled with substrate oxidation. The biochemical theory of oxidative phosphorylation considers that 3 mol of ATP are generated per gram-atom of oxygen consumed (i.e., a P:O ratio of 3:1). The energy expenditure per mole of ATP formed should be calculated from the heat of combustion of 1 mol of substrate, divided by the total number of moles of ATP generated in its oxidation. It is interesting to note that each mole of ATP generated is accompanied by the release of about the same amount of heat (~75 kJ/mol ATP) during the oxidation of carbohydrates, fats, or proteins. Because there is a proportionality between $\dot{V}O_2$ and ATP synthesis, and because each mole of ATP synthetized is accompanied by the production of a given amount of heat, one understands the rationale of using $\dot{V}O_2$ measurement to calculate heat production within the body.

Since indirect calorimetry measures the heat released by the oxidative processes and direct calorimetry assesses the heat dissipated by the body, a relationship exists between the two: for a subject in resting conditions, the difference between metabolic heat production and heat dissipation represents the body heat balance (**Figure 1**). The heat production from oxidative processes is equal to the sum of

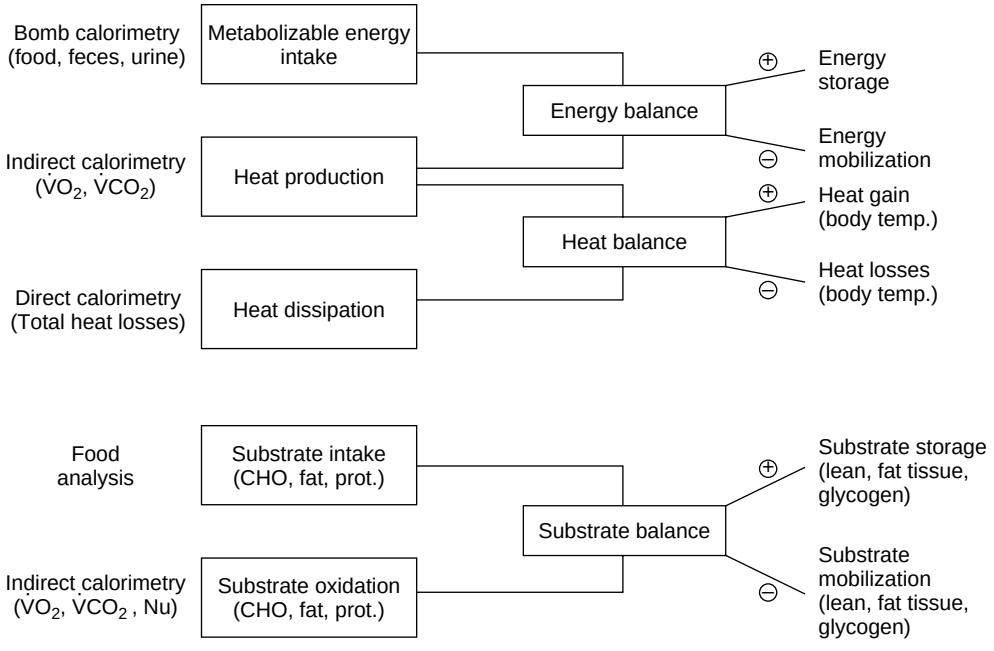

Figure 1 Heat balance, energy balance, and substrate balance: three different concepts.

the nonevaporative components (radiant heat exchange + convective + conductive heat transfer) plus the evaporative heat transfer. In order to assure the equality of the equation an additional term representing the rate of storage of body heat must be included:

$$\text{Heat production} = \text{Heat losses} \pm \text{Heat storage}$$

Heat storage can be positive when excess heat is gained, resulting in a rise in internal body temperature. Heat storage can be negative when excess heat is lost, resulting in a cooling of the body. The rate of heat storage can be estimated from the body weight, the specific heat capacity of the body (which depends upon body composition), and the rate of change in internal body temperature. In practice, this calculation remains somewhat uncertain since the changes in temperature within the body are not uniformly distributed within each tissue.

Under most environmental conditions, heat is lost by all channels (i.e., radiative + convective + conductive + evaporative). However, except during immersion in water, the rate of heat gain or loss by conduction constitutes a small proportion of the total heat loss (typically 3%). Heat can be lost by convection (air currents) but it can also be gained in very hot conditions such as in a desert characterized by high movement of hot air.

Energy Balance: Definition

Overall energy balance is given by the following equation:

$$\text{energy intake} = \text{energy expenditure} + \Delta \text{ energy stores}$$

Thus, if the total energy contained in the body (as fat, protein, and glycogen) is not altered (i.e., Δ energy stores = 0), then energy expenditure must be equal to energy intake. In this case, the individual is said to be in a state of energy balance.

If the intake and expenditure of energy are not equal, then a change in body energy content will occur, with negative energy balance resulting in the utilization of the body's energy stores (glycogen, fat, and protein) or positive energy balance resulting in an increase in body energy stores, primarily as fat.

The difference between the concepts of energy balance and heat balance is presented in **Figure 1**.

Model of Energy Balance: A Dynamic State

There are multiple reciprocal direct and indirect influences of energy intake on energy expenditure and vice versa: for example, energy intake influences resting energy expenditure by increasing postprandial and dietary-induced thermogenesis, whereas changes in energy expenditure via a modification of physical activity is susceptible to influence energy intake to maintain energy balance. In order to assure an accurate regulation of body stores, a double control is essential (see below). Body weight and body composition are not invariant with time but small corrections of both input and output from day-to-day or week-to-week, assure energy homeostasis (**Figure 2**). When attempting to explain the actual responses in energy balance and weight regulation in real life, we need to recognize that several factors may be operating at once on both sides of the energy balance equation. Compensatory adjustments occur in both intake and output, so unravelling the importance of one or other adjustment is not easy in man.

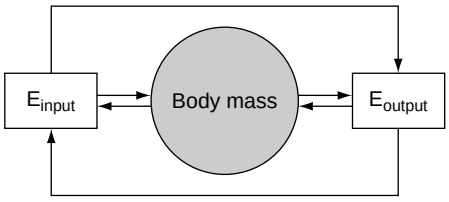

Figure 2 Simple model of energy (E) balance. Long-term constancy of body weight through the regulation of energy balance is achieved through a highly complex network of regulatory systems operating through changes in food intake, in energy expenditure, and body energy content (i.e., change in body composition).

Gross and Metabolizable Energy

The traditional way of measuring the energy content of foostuffs is to use a 'bomb calorimeter' in which the heat produced when a sample of food is combusted (under high pressure of oxygen) is measured. When the food is combusted, it is completely oxidized to water, carbon dioxide, and other incompletely burned elements. The total heat liberated (expressed in kilocalories or kilojoules) represents the gross energy value or heat of combustion of the food. The heat of combustion differs between carbohydrates, proteins, and fats. There are also important differences within each category of macronutrient. The gross energy yield of sucrose, for example, is $16.5\,\text{kJ}\,\text{g}^{-1}$, whereas starch yields $17.5\,\text{kJ}\,\text{g}^{-1}$. The energy yield of butterfat is $38.5\,\text{kJ}\,\text{g}^{-1}$ and of lard $39.6\,\text{kJ}\,\text{g}^{-1}$. These values have been rounded off to give $17.3\,\text{kJ}\,\text{g}^{-1}$ for carbohydrates rich in starch and poor in sugar, $39.3\,\text{kJ}\,\text{g}^{-1}$ for average fat, and $23.6\,\text{kJ}\,\text{g}^{-1}$ for mixtures of animal and vegetable proteins.

The gross energy value of foodstuffs (**Table 1**), however, does not represent the energy actually

Table 1 Metabolizable energy (ME) and Atwater's factors

Nutrient	*Gross energy in kJ g^{-1}(kcal g^{-1})*	*% Absorbed (Atwater's values)*	*Digestible energy in kJ g^{-1}(kcal g^{-1})*	*Urinary loss in kJ g^{-1}(kcal g^{-1})*	*Metabolizable energy in kJ g^{-1}(kcal g^{-1})*	*Atwater's factor[1] (kcal g^{-1})*
Starch	17.5 (4.2)	99	17.3 (4.15)	–	17.3 (4.15)	4
Glucose	15.6 (3.75)	99	15.4 (3.7)	–	15.4 (3.7)	4
Fat	39.1 (9.35)	95	37.1 (8.88)	–	37.1 (8.88)	9
Protein	22.9 (5.47)	92	21.1 (5.04)	5.2 (1.25)	15.9 (3.8)	4
Alcohol	29.8 (7.1)	100	29.8 (7.1)	Trace	29.8	7

[1]Values are rounded off.

available to the body, since no potentially oxidizable substrate can be considered available until it is presented to the cell for oxidation. None of the foodstuffs are completely absorbed; therefore, some energy never enters the body and is excreted in feces. Digestibility of the major foodstuffs, however, is high; on the average, 97% of ingested carbohydrates, 95% of fats, and 92% of proteins are absorbed from the intestinal lumen.

In the body, the tissues are able to oxidize carbohydrate and fat completely to carbon dioxide and water, but the oxidation of protein is incomplete, and results in the formation of urea and other nitrogenous compounds, which are excreted in the urine. Determination of both the heat of combustion and the nitrogen content of urine indicates that approximately 33.0 kJ g^{-1} of urine nitrogen is equivalent to 5.2 kJ g^{-1} of protein since 1 g urinary nitrogen arises from ~6.25 g protein. This energy represents metabolic loss and must be subtracted from the 'digestible' energy of protein to obtain metabolizable energy.

With a mixed diet, rich in carbohydrates and fibers, the metabolizable energy of food is approximately 90% of the gross energy (heat of combustion) (**Figure 3**). The remaining 10% is mainly due to unabsorbed energy (fecal energy losses) and urinary excretion of metabolites.

The collection of representative samples of all food eaten combined with the collection of urine and feces for a week (i.e., complete nutritional balance) is technically difficult and cumbersome in practice. The pioneer investigator Atwater developed in the early 20th century a practical approach for calculating, rather than measuring, the metabolizable energy (ME) of a diet based on its composition of carbohydrates, fat, and proteins. A specific calorimetric factor was developed according to the digestibility and absorption of each macronutrient and the loss of energy in urine (measured by nutrition balance technique). These are the so-called 'Atwater factors.' The ME values for the three substrates and their derivation are shown in **Table 1**.

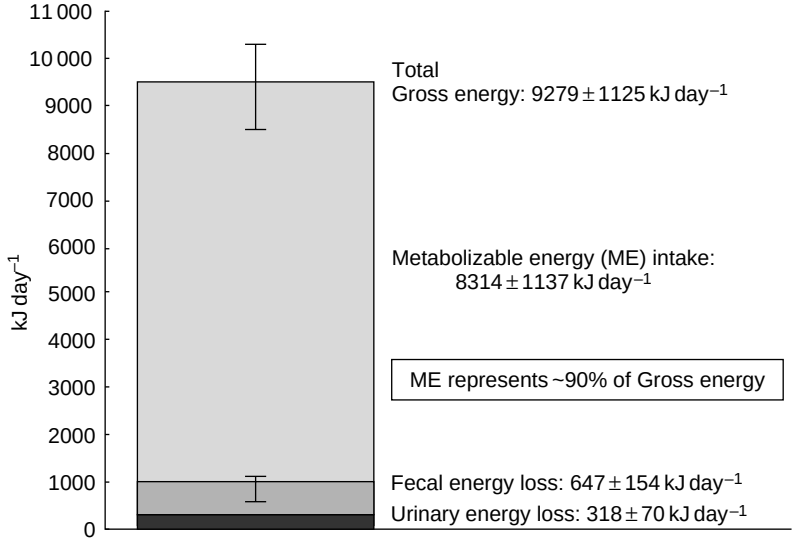

Figure 3 Gross and metabolizable energy intakes of a mixed, high-carbohydrate diet (data from McNeil (2000)). Calculation of metabolizable energy for 10 women on a high-carbohydrate, high-nonstarch polysaccharide (NSP) diet for a period of 7 days.

Assessment of Energy Expenditure

The study of energy metabolism in humans has recently raised a great interest in the regulation of these processes thanks to advances in the construction of open-circuit ventilated hood indirect calorimeters and comfortable respiration chambers.

With the only measurement of $\dot{V}O_2$ (in liters of O_2 STPD (standard temperature (0 °C), pressure (760 mm Hg), and dry) per min), metabolic rate (M), which corresponds to energy expenditure, can be calculated (in kilojoules per min) as follows:

$$\dot{M} = 20.3 \times \dot{V}O_2 \qquad [1]$$

The number 20.3 is a mean value (in $kJ\,l^{-1}$) of the energy equivalent for the consumption of 1 l (STPD) of oxygen. The value of the energy equivalent of oxygen depends on the composition of the fuel mixture oxidized. However, the error in using equation 1 instead of an equation that takes into account the type of fuels oxidized (equations 2 and 3, see below) is no greater than ±1 to 2%.

To take into account the heat released by the oxidation of the three macronutrients (carbohydrates, fats, and proteins), three measurements must be carried out: oxygen consumption ($\dot{V}O_2$), carbon dioxide production ($\dot{V}CO_2$), and urinary nitrogen excretion (N).

Simple equations for computing metabolic rate (or energy expenditure) from these three determinations are written under the following form:

$$\dot{M} = a\dot{V}O_2 + b\dot{V}CO_2 - cN \qquad [2]$$

The factors a, b, and c depend on the respective constants for the amount of O_2 used and the amount of CO_2 produced during oxidation of the three classes of nutrients. An example of such a formula is given below:

$$\dot{M} = 16.18\dot{V}O_2 + 5.02\dot{V}CO_2 - 5.99N \qquad [3]$$

where $\dot{M}$ is in kilojoules per unit of time, $\dot{V}O_2$ and $\dot{V}CO_2$ are in liters STPD per unit of time, and N is in grams per unit of time. As an example, if $\dot{V}O_2 = 600\,l\,day^{-1}$, $\dot{V}CO_2 = 500\,l\,day^{-1}$ (respiratory quotient, or RQ = 0.83), and $N = 25\,g\,day^{-1}$, then $\dot{M} = 12\,068\,kJ\,day^{-1}$. With the simpler equation (1) the results give a value of 12 180 kJ per day.

Slightly different factors for the amounts of O_2 used and of CO_2 produced during oxidation of the nutrients are used by other authors, and the values for the factors a, b, and c are modified accordingly. The difference in energy expenditure calculated by the various formulae is not greater than 3%.

Total Energy Expenditure and its Components

It is customary to consider energy expenditure as being made up of three components: the energy spent for basal metabolism (or basal metabolic rate), the energy spent on physical activity, and the increase in resting energy expenditure in response to a variety of stimuli (in particular food, cold, stress, and drugs). These three components are depicted in **Figure 4**.

Basal Metabolic Rate (BMR) or Resting Metabolic Rate (RMR)

This is the largest component of energy expenditure accounting for between half to three-quarters of daily energy expenditure. It is measured under standardized conditions, i.e., in an awake subject lying in the supine position, in a state of physical and mental rest in a comfortable warm environment, and in the morning in the postabsorptive state, usually 10–12 h after the last meal. There is an arbitrary distinction between RMR and BMR in the literature. RMR may be considered equivalent to BMR if the measurements are made in postabsorptive conditions. It seems difficult to partition RMR into various subcomponents since the metabolic rates of individual organs and tissues are hard to assess in humans under noninvasive experimental conditions. BMR can vary up to ±10% between individuals of the same age, gender, body weight, and fat-free mass (FFM), suggesting that genetic factors are also important. Day-to-day intraindividual variability in BMR is low in men (coefficient of variation of 1–3%) but is greater in women because the menstrual cycle affects BMR. In both women and men, sleeping metabolic rate is lower than BMR by

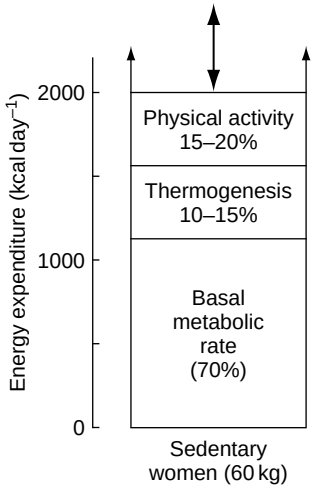

Figure 4 The three classical components of total energy expenditure. (Inactive person).

5–10%, the difference being explained by the effect of arousal. BMR is known to be depressed during starvation.

The major part of the whole-body RMR stems from organs with high metabolic activity such as the liver, kidneys, brain, and heart, although these account for a small proportion of the total body weight (5%). Per unit body weight, the kidneys and heart have a metabolic rate more than twice as high as the liver and the brain. In contrast, the metabolic rate of muscle per unit body weight is nearly 35 times lower than that of the heart and kidneys. Since the proportion of muscle to nonmuscle changes with age from birth to adulthood, the RMR per unit body weight is not constant with age. The tissue with the lowest metabolic activity per unit body weight is adipose tissue, which accounts for only 4% of the whole-body RMR in nonobese subjects. Calculations show that this value can increase up to 10% or more in obese subjects with a large excess in body fat. Skin and intestines (which have a relatively large protein mass and protein turnover), as well as bones and lungs, also contribute significantly to RMR.

Numerous studies have demonstrated that major factor explaining the variation in RMR between individuals is FFM. FFM is a heterogeneous component that can be partitioned into muscle mass and nonmuscle mass. Unfortunately, there is no simple and accurate way to assess these two subcomponents. Owing to the larger variation between individuals in fat mass, as compared to FFM, and because in grossly obese women fat mass can represent a nonnegligible component of total RMR, the prediction models for RMR that include both FFM and fat mass explain significantly more variance in RMR than FFM alone. In addition, age, sex, and family membership are additional factors that should be taken into account.

The effects of gender on resting metabolic rate are explained by differences in body composition. Caution should be used when comparing resting metabolic rate expressed per kilogram FFM in men and women, because the composition of FFM is influenced by gender. The muscle mass of men is greater than that is greater of women and this tends to give a lower value of RMR per kilogram FFM in men when compared to that of women. This is explained by a greater component of tissue with a low metabolic rate (resting muscle) in men than in women.

In clinical work, where body composition is difficult to assess, body weight, gender, and age can be used to estimate BMR and RMR (**Table 2**), bearing in mind that many important determinant of RMR, in addition to body size, have been tracked (**Table 3**).

Table 2 Simple formulae for the prediction of resting metabolic rate in men and women of different ages (equations for predicting basal metabolic rate from body weight alone)

Age range (years)	*kcal per day*	*MJ per day*
Males		
0–3	60.9 W − 54	0.255 W − 0.226
3–10	22.7 W + 495	0.0949 W + 2.07
10–18	17.5 W + 651	0.0732 W + 2.72
18–30	15.3 W + 679	0.0640 W + 2.84
30–60	11.6 W + 879	0.0485 W + 3.67
>60	13.5 W + 487	0.0565 W + 2.04
Females		
0–3	61.0 W − 51	0.255 W − 0.214
3–10	22.5 W + 499	0.0941 W + 2.09
10–18	12.2 W + 746	0.0510 W + 3.12
18–30	14.7 W + 496	0.0615 W + 2.08
30–60	8.7 W + 829	0.0364 W + 3.47
>60	10.5 W + 596	0.0439 W + 2.49

W, body weight expressed in kilograms; MJ, megajoules.

Thermic Effect of Food or Postprandial Thermogenesis

The energy expenditure increases significantly after a meal. The thermic effect of food is mainly due to the energy cost of nutrient absorption and storage. The total thermic effect of food over 24 h represents ~10% of the total energy expenditure in sedentary subjects. The thermic effect of nutrients mainly depends on the energy costs of processing and/or storing the nutrient. Expressed in per cent of the energy content of the nutrient, values of 8%, 2%, 20–30%, and 22% have been reported for glucose, fat, protein, and ethanol, respectively.

Glucose-induced thermogenesis mainly results from the cost of glycogen synthesis and substrate cycling. Glucose storage as glycogen requires 2 mol ATP/mol. In comparison with the 38 mol ATP produced on complete oxidation of glucose, the energy cost of glucose storage as glycogen corresponds to

Table 3 Determinants of resting (basal) metabolic rate

- Body size
- Body composition (lean vs. obese)
- Gender
- Age
- Physiological status (growth, pregnancy, and lactation)
- Genetic make-up
- Hormonal status (e.g., Follicular ve luteal phase)
  - Temperature (body internal and environment)
  - Pharmacological agents (e.g., nicotine and caffeine)
  - Disease (fever, tumors, burns, etc.)

5% (or 2/38) of the energy content of glucose stored. Cycling of glucose to glucose-6-phosphate and back to glucose, to fructose-1,6-diphosphate and back to glucose-6-phosphate, or to lactate and back to glucose, is occurring at variable rates and is an energy-requiring process that may increase the thermic effect of carbohydrates.

The thermic effect of dietary fat is very small; an increase of 2% of its energy content has been described during infusion of an emulsion of triglyceride. This slight increase in energy expenditure is explained by the ATP consumption in the process of free fatty acid reesterification to triglyceride. As a consequence, the dietary energy of fat is used very efficiently.

The thermic effect of proteins is the highest of all nutrients (20–30% of the energy content of proteins). Ingested proteins are degraded in the gut into amino acids. After absorption, amino acids are deaminated, their amino group transferred to urea, and their carbon skeleton converted to glucose. These biochemical processes require the consumption of energy amounting to ~25% of the energy content of amino acids. The second pathway of amino acid metabolism is protein synthesis. The energy expended for the synthesis of the peptide bonds also represents ~25% of the energy content of amino acids. Therefore, irrespective of their metabolic pathway, the thermogenesis induced after absorption of amino acids represents ~25% of their energy content.

Energy Expenditure Due to Physical Activity

The energy spent on physical activity depends on the type and intensity of the physical activity and on the time spent in different activities. Physical activity is often considered to be synonymous with 'muscular work', which has a strict definition in physics (force × distance) when external work is performed in the environment. During muscular work (muscle contraction), the muscle produces 3–4 times more heat than mechanical energy, so that useful work costs more than muscle work. There is a wide variation in the energy cost of any activity both within and between individuals. The latter variation is due to differences in body size and in the speed and dexterity with which an activity is performed. In order to adjust for differences in body size, the energy cost of physical activities are expressed as multiples of BMR. These generally range from 1 to 5 for most activities, but can reach values between 10 and 14 during intense exercise. In terms of daily energy expenditure, physical activity accounts for 15–40% of total energy expenditure but it can represent up to 70% of daily energy expenditure in an individual involved in heavy manual work or competition athletics. For most people in industrialized societies, however, the contribution of physical activity to daily energy expenditure is relatively small. The numerous factors influencing the 3 components of energy expenditure are outlined in **Table 4**.

Table 4 Exogenous and endogenous factors influencing the three components of energy expenditure

Components	*Endogenous*	*Exogenous*
• Basal metabolic rate	• Fat-free mass • Thyroid hormones • Protein turnover	
• Thermogenesis	• Nutritional status • Sympathetic nervous system activity • Insulin resistance (obesity)	• Macronutrient intake (+alcohol) • Cold exposure • Stress • Thermogenic stimuli (coffee, tobacco) • Thermogenic drugs
• Physical activity	• 'Fidgeting' • Muscular mass • Work efficiency • Fitness level ($\dot{V}O_2$max)	• Duration intensity, and frequency of physical activity

The effect of body weight in average women (~60 kg) on energy expenditure is illustrated in **Figure 5**. The relationship is slightly curvilinear because of differences in body composition in terms of leanness and fatness. Resting metabolic rate is shown as a baseline value.

Just as described above for a specific activity, it has been customary to express total energy expenditure

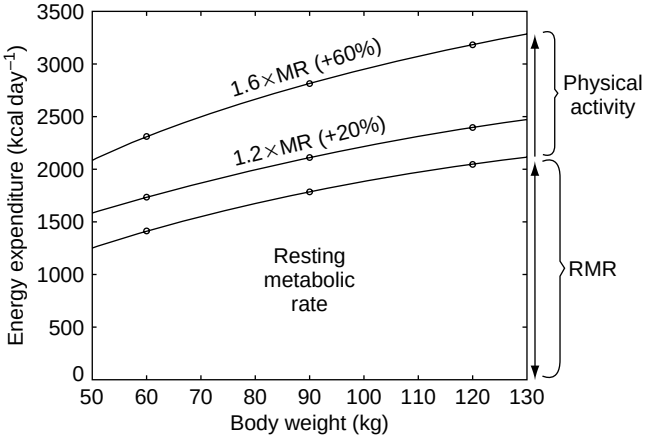

Figure 5 Effect of body weight on total energy expenditure at two levels of physical activity in young women. A physical activity level (PAL) of 1.2 represents minimal physical activity compatible with health, whereas a value of 1.6 represents a 'medium' level of physical activity.

(TEE) relative to RMR (TEE/RMR or TEE/BMR) to offset the large variation in RMR among subjects of difference body weight & body composition. This quotient is called physical activity level (PAL) and reflects multiples of RMR. A PAL of 1.5 indicates that TEE is 50% greater than RMR over 24 h.

Macronutrient Balance, Energy Balance, and Storage

Since macronutrients (carbohydrate, fat, protein, and alcohol) are the sources of energy, it is logical to consider energy balance and macronutrient balance together as the opposite side of the same coin.

There is a direct relationship between energy balance and macronutrient balance, and the sum of individual substrate balance (expressed as energy) must be equivalent to the overall energy balance. Thus:

$$\text{carbohydrate balance} = \text{exogenous carbohydrate} - \text{carbohydrate oxidation}$$

$$\text{protein balance} = \text{exogenous protein} - \text{protein oxidation}$$

$$\text{lipid balance} = \text{exogenous lipid} - \text{lipid oxidation}$$

It follows that Δ substrate balance $\equiv \Delta$E balance. Fat balance is closely related to energy balance (**Figure 6**).

Indirect calorimetry also allows computation of the nutrient oxidation rates in the whole body. An index of protein oxidation is obtained from the total amount of nitrogen excreted in the urine during the test period. One approach to calculate the nutrient oxidation rate is based on the oxygen consumption and CO_2 production due to the oxidation rates of the three nutrients carbohydrate, fat, and protein **Figure 6** respectively. In a subject oxidizing c grams per min of carbohydrate (as glucose), f grams per min of fat, and excreting n grams per min of urinary nitrogen, the following equations, can be used:

$$\dot{V}O_2 = 0.746c + 2.02f + 6.31n \quad [4]$$

and

$$\dot{V}CO_2 = 0.746c + 1.43f + 5.27n \quad [5]$$

We can solve equations 4 and 5 for the unknown c and f this way:

$$c = 4.59\dot{V}CO_2 - 3.25\dot{V}O_2 - 3.68n \quad [6]$$

$$f = 1.69\dot{V}O_2 - 1.69\dot{V}CO_2 - 1.72n \quad [7]$$

Because 1 g urinary nitrogen arises from approximately 6.25 g protein, the protein oxidation rate (p in grams per min) is given by the equation

$$p = 6.25n \quad [8]$$

Energy stores (constituted mainly of fat stores) are big as a proportion of the food intake (2000 kcal day^{-1}, mixed diet in a 60-kg nonobese woman with 25% body fat). The total energy stored is about 90 times total daily energy intake: typically fat stores are 175 times daily fat intake, protein 133 times daily protein intake, and carbohydrate only 1.3 times daily carbohydrate intake (**Figure 7**).

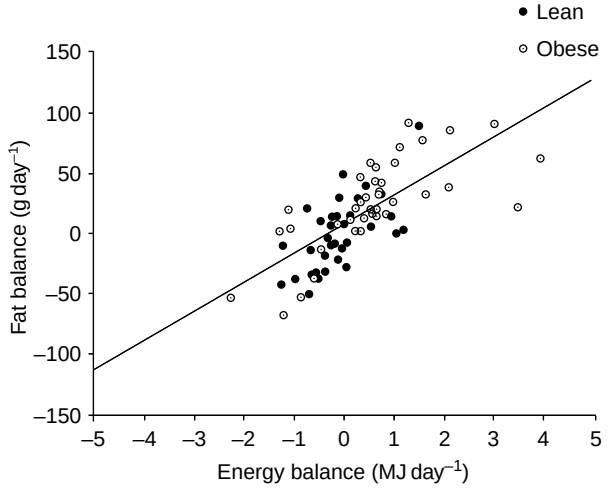

Figure 6 Relationship between energy balance and fat balance in lean and obese individuals. Note that at zero energy balance fat balance is zero. At an excess or deficit of 4.2 MJ day^{-1} (1000 kcal) the fat imbalance (about 100 g day^{-1} = 900 kcal day^{-1}) accounts for more than 90% of the magnitude of energy balance. (Reproduced from Schrauwen P, Lichtenbelt WD, Saris WH, Westerterp KR (1998) Fat balance in obese subjects: role of glycogen stores. *AM J Physiol.* **274**: E1027–33.)

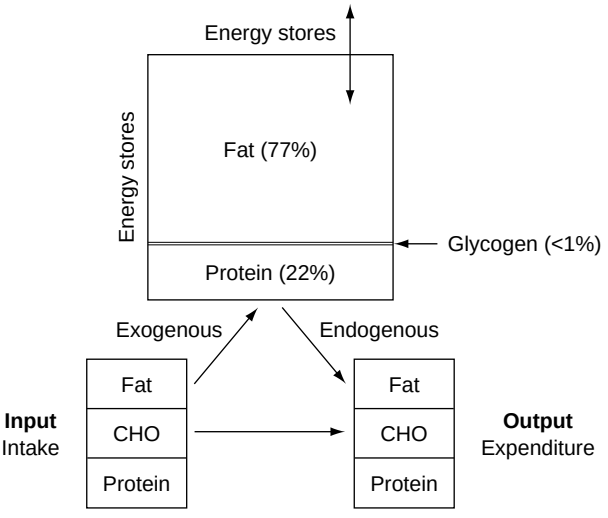

Figure 7 Macronutrient (substrate) stores versus macronutrient intake.

Energy Imbalance and Body Weight

Positive energy balance leads to body weight gain and negative energy leads to body weight loss. There is no fixed relationship between these two variables so that relatively small energy retention can be accompanied by large body weight gain and vice versa. The confounding factor is the associated water storage.

Long-term fluctuations in fat stores will be reflected in body weight. There is a difference in the energy value of fat mass and fat-free mass, the latter including the glycogen–water pool and the protein–water pool (**Table 5**).

Energy density of the tissue stored (or the substrate pool stored) represents an indicator of the composition of tissue stored or mobilized. It is defined as the total calorie per gram of substance. It is about $8\,kcal\,g^{-1}$ for adipose tissue compared to the fat value (triglyceride) of $9\,kcal\,g^{-1}$. This lower former value is due to the fact that fat is diluted out by the small amount of water (5–10%) and proteins the adipose tissue contains. As explained previously, the energy density of the glycogen–water pool is low, about $1\,kcal\,g^{-1}$, since glycogen ($4.2\,kcal\,g^{-1}$) is associated with approximately 3 times its weight of water.

Let us take an energy imbalance of say 1000 kcal. The body weight change will be approximately 8 times lower (i.e., ≈125 g) if fat is stored in adipose tissue, as compared to glycogen stored (under the form of glycogen-water pool) in liver and muscles (≈1000 g). In other words, rapid weight gain (or weight loss) means little fat storage despite what the layman thinks. Day-to-day energy imbalance is generally accommodated by water retention due to changes in carbohydrate storage and sodium intake.

In real life, it is more reasonable to consider that the reserve is composed of a mixture in different proportions of fat and glycogen. If about half of the energy imbalance is accounted for by fat and half by glycogen storage, the energy density will be $4–5\,kcal\,g^{-1}$. With the imbalance value described above, it will generate a body weight change of 400–500 g.

The energy balance varies from day to day. The changes in daily energy intake and expenditure are not necessarily synchronized. Positive energy balance on one day may not be spontaneously compensated by negative energy balance on the subsequent day, so that it is important to consider the overall energy balance regulation over a prolonged period of time. Short-term day-to-day energy imbalance is mostly accommodated by rapid changes in carbohydrate balance, whereas over a prolonged period of time, positive energy balance is mostly expressed as fat storage since carbohydrate stores are small (**Figure 6**).

To what extent do alterations in energy output contribute to the regulation of energy balance and stability of body weight? To understand the regulation of a system, it must be subjected to perturbation. Excess food intake during overfeeding or deficit in food intake during underfeeding disrupts the balance system.

Overfeeding Studies (Figure 8)

In a perfectly regulated system, any increase in energy intake should be offset by a change in energy expenditure of the same magnitude and direction. However, a 100% efficient adaptive process would obviously be counter productive, since this would signify that an increase in energy storage (required during nutritional rehabilitation) or an increase in energy mobilization (required for decreasing body weight) would be very limited. Adaptation to energy imbalance only occurs at the cost of increasing (or decreasing) body weight. In fact, excess energy intakes result in an increased metabolic turnover and energy flux through the mechanism of adaptive thermogenesis. The efficiency of energy storage is not constant and depends upon several factors including the magnitude of energy imbalance and the composition of the surfeit energy fed, as well as endogenous factors. As shown in **Figure 8**, the energy expenditure increases during acute overfeeding, an evidence of the 'flexibility' of the metabolism.

Table 5 Body stores of energy as different macronutrients

Substrate	*Form of storage*	*Pool size*	*Tissues*	*% Water in tissues*	*Daily imbalance*	*Energy density (kcal/g^{-1})*	*Postprandial thermogenesis*
Carbohydrate	Glycogen	Small (limited)	Liver + muscles	70–80	Large	≃4	Average
Fat	Triglycerides	Moderate–large (unlimited)	Adipose tissue	5–10	Small	≃8	Low
Protein	Protein	Moderate (limited)	Lean tissue (muscle)	70–75	Small	≃4	High

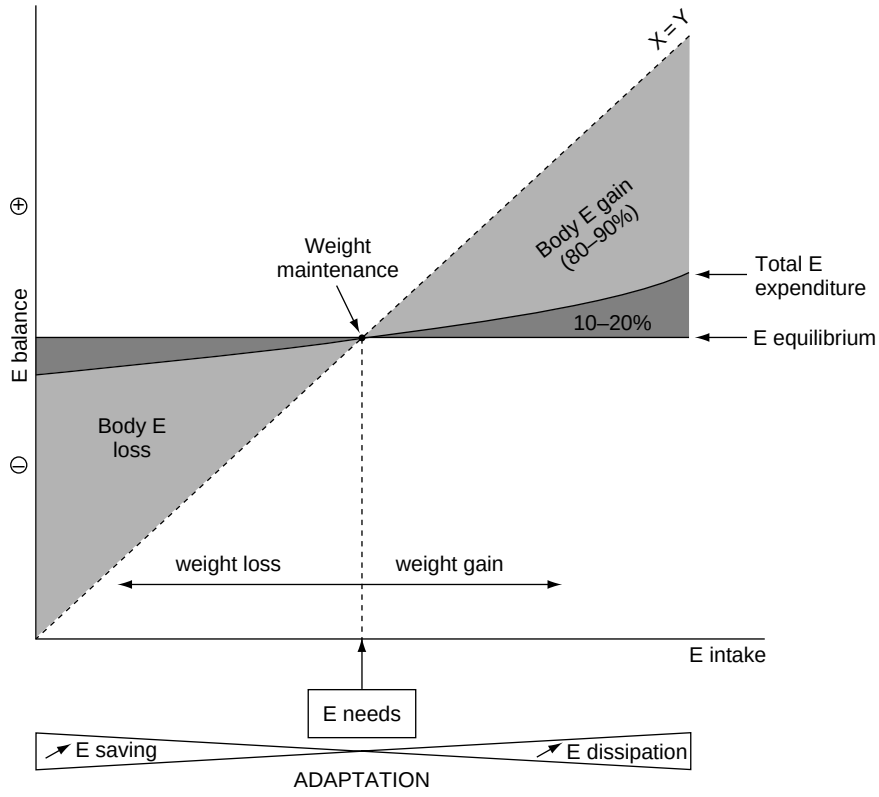

Figure 8 Energy balance in underfeeding (below maintenance) and overfeeding (above maintenance) conditions. E, energy.

Underfeeding Studies (Figure 8)

Analysis of underfeeding experiments shows that the decrease in energy expenditure has three components. First, if energy intake is decreased the thermic effect of feeding (about 10% of energy intake) is similarly decreased. Second, there is an adaptive decrease in metabolic rate during the first week, related in part to a decrease in sympathetic activity. The magnitude of this decrease is significantly related to the initial metabolic rate, and is usually about 5–8%. Third, there is a decrease in metabolic rate related to the weight lost: most investigators find a decrease of 10–12 kcal per day per kg weight loss. The effect of all three processes is that a person who lost weight from, say, 100 kg to 70 kg (a 30% reduction in weight) would experience about a 15% reduction in energy requirements for weight maintenance. Thus, a decrease in energy intake causes a reduction in body weight but, provided the decrease is not too great, a new equilibrium will be reached at which the reduced requirement will be satisfied by the reduced intake, and body weight will stabilize. Taken together we can conclude that the efficiency of energy utilization is lower in overfeeding than in underfeeding conditions because, substrate storage in tissues is energetically costly (ATP needs), whereas the process of energy mobilization requires little energy. In the former situation excess energy must be dissipated.

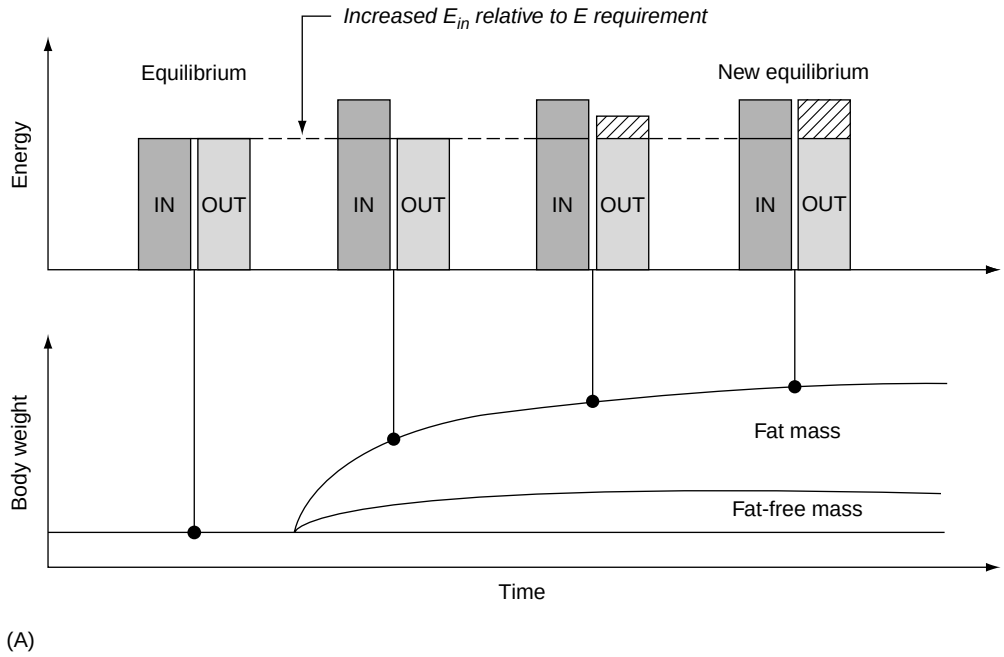
Adaptive changes in thermogenesis do attenuate the impact on energy balance of excessive or insufficient food consumption (as compared to requirement). The magnitude of adaptive thermogeneis varies as a function of the nature of excess substrates fed (protein is higher than carbohydrate and fat).

Energy Expenditure is Less Effective than Food Intake as a Control Mechanism of Energy Balance

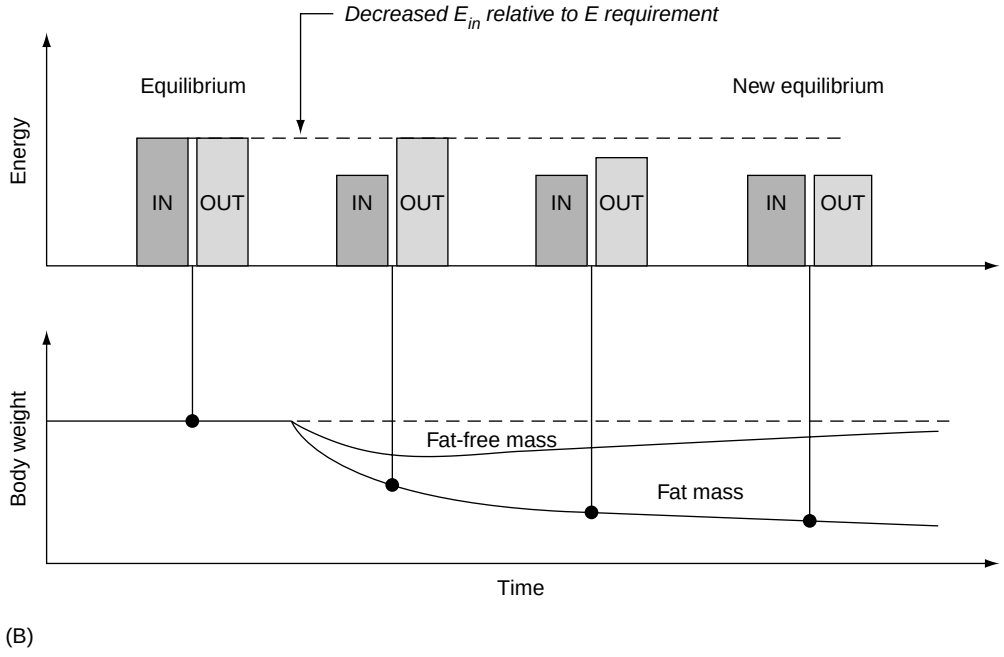
It should be stressed that the relationship between the change in energy intake below and above energy equilibrium and energy storage is not quite linear, indicating an increased net efficiency of energy utilization below energy maintenance and a decreased net efficiency of energy utilization above energy equilibrium (**Figure 8**).

Dynamics of Energy Balance with Overfeeding and Underfeeding (Figure 9)

To understand the dynamic aspect of energy balance while overfeeding is of the utmost important, since as mentioned previously the system is not invariant.



(A)



(B)

Figure 9 Dynamic change in energy balance following a step steady increase (A) overfeeding (or decrease) (B) underfeeding in energy intake. The time required to reach a new equilibrium in energy balance is very long (years) and depends upon the initial energy imbalance, the magnitude of adaptation of energy expenditure in response to change in energy intake, and on the factors related to the subject (obesity versus leanness). The figure shows that the static energy balance as such tells us nothing about the absolute level of energy intake and expenditure (see initial and final balance).

Continuous increase in energy intake above energy requirement will lead to a gradual gain in body weight. The size of the energy imbalance will progressively diminish with time as weight is gained. The reason for this is that the expansion of fat-free mass and fat mass (adipose tissue) will be accompanied by a rise in energy metabolism. A new equilibrium in weight is eventually reached after adaptation of each component of total energy expenditure, i.e., resting metabolic rate, diet-induced thermogenesis, and the increasing energy cost of supporting a heavier body weight. Note that each

kg of excess body weight increases total energy expenditure by about 20–25 kcal day^{-1}, and 10–12 kg day^{-1} when RMR is considered (**Figure 5**).

Let us take the following practical example: small increase in daily intake, e.g., of 100–200 kcal, will induce small increases in body weight with its associated rise in energy expenditure as the mass of lean tissue increases. If these changes occur on a daily basis, month by month, and if after 3–5 years the adult is still eating 200 kcal day^{-1} more than at baseline, they will now be heavier, and have a higher energy expenditure, and will come into energy balance; therefore, they cease to gain more weight.

Summary

- Energy balance is the difference between metabolizable energy intake and total energy expenditure. It is strongly related to macronutrient balances, and the sum of the individual substrate balances, expressed as energy, must be equivalent to the overall energy balance.
- Energy in foods is furnished by carbohydrate, proteins, fats, and alcohol; only 5–10% is lost through the feces and urine.
- The energy available to the body, called 'metabolizable energy', is on average 17 kJ g^{-1} of carbohydrate, 17 kJ g^{-1} of protein, 37 kJ g^{-1} of fat, and 29 kJ g^{-1} of alcohol. These figures vary slightly according to the type of carbohydrate, protein, or fat in the diet.
- The energy used in the body, or energy expenditure, is classically assessed by indirect calorimetry. It involves measuring the oxygen consumption and carbon dioxide production by an individual.
- Short-term regulation of energy balance is poor, but (in most people) long-term regulation is accurate. The mechanism is unknown, but must include conscious alterations in lifestyle to correct unwanted changes in body weight.
- During long periods of energy imbalance the weight gained (or lost) is initially glycogen plus water with an energy density of ~1.0 kcal g^{-1}. If the imbalance continues, after a week the tissue gained (or lost) is a mixture of mostly fat, water, and protein with an energy density of ~7 kcal g^{-1}.
- Undernutrition leads to a decrease in energy expenditure. Part of the decrease in metabolic rate is related to weight loss.
- In overfeeding, although some of the excess energy intake will be stored in adipose tissue, there are compensatory increases in energy expenditure.
- The changes in modern affluent society can be considered in terms of energy balance. The increasing prevalence of overweight in industrialized society can be attributed to a profound change in the pattern of physical activity due to increased mechanization, robotics, and computerization, which have substantially reduced the need for even modest physical activity. Today, the demand for heavy labor is rare. In developed countries increased car ownership and heavy road traffic result in fewer opportunities to travel on foot. Television-watching now fills a large proportion of leisure time and numerous gadgets minimize housework.

Requirements

W P T James, International Association for the Study of Obesity/International Obesity Task Force Offices, London, UK

The metabolic rate of the body is the overall rate of tissue oxidation of fuels by all the body's organs. The dietary fuels are the carbohydrate, fat, protein, alcohol, and minor dietary components that are oxidized in the tissues, with oxygen being taken up by the lungs and the combusted end products (carbon dioxide, water, and urea) being excreted by the lungs, urine, and skin. The total rate of body metabolism is assessed by monitoring the rate of oxygen uptake by the lungs. The sources of fuel can then be estimated from the proportion of carbon dioxide produced and the rate of urea production.

The energy equivalence of oxygen varies depending on the precise nature of the fuels being oxidized, but a value of 20 kJ per liter of oxygen is taken as an appropriate average.

Factors Affecting Metabolic Rate

The process of oxidation involves a series of enzymatically controlled biochemical reactions leading eventually to the combination of oxygen with the carbon and hydrogen components of the body's fuels to yield the carbon dioxide and metabolically derived water. The incompletely oxidized nitrogen is excreted as urea, which is synthesized by the liver and excreted by the kidneys. The intermediate steps in the metabolism of the body's fuels are linked biochemically to drive the generation of phosphate-containing organic molecules, such as adenosine triphosphate (ATP), which in turn serve as the direct energy sources for all the body's cell activities, including the synthesis of complex molecules, the maintenance of tightly controlled ionic gradients in the cell, and the excretion of ions and molecules outside the cell. Thus, the oxygen being taken up by the lungs reflects the tissue metabolism of the fuels needed to regenerate the ATP used up in either biochemical 'internal' work or mechanical external work undertaken by the body's muscles. The rate at which the body burns its own stored fuels in the fasted, resting, and relaxed state (i.e., in the basal state in a warm room) is called the basal metabolic rate (BMR). This varies with the age of the individual, mainly because of the varying sizes of metabolically very different organs at different ages. Thus, a child has a relatively large brain, liver, and intestine, with a higher metabolic rate per kilogram of body weight than a more muscular adult. Body fat cells are metabolically active but contain a substantial amount of inert fat so that the larger fat mass of a woman means she has a lower BMR per unit body weight than a man. However, if the oxygen uptake is calculated in terms of the metabolically active fat-free mass, then her metabolic rate is the same. As men and women age, they tend to lose lean tissue and store extra fat, so the BMR on a weight basis decreases with age.

Equations can be used to estimate a group's BMR from their sex, age, and body weight (**Table 1**), but there is a range of BMR amounting to $\pm 20\%$ of the mean value at each weight. Thus, in a 25-year-old woman who weighs 55 kg, the anticipated mean BMR is 5460 kJ (1305 kcal) per day but may vary under normal conditions from 4448 to 6473 kJ per day. The kilojoule is the standard measure, and 4.184 kJ corresponds to 1 kcal, which was originally defined in energy terms as that required to increase the temperature of 1 g of pure water by 1 °C from 14.5 to 15.5 °C. The variation in BMR at a constant weight in part reflects differences in the fat content of individuals of the same weight. Thus, the BMR per unit fat-free mass varies by 12–15% rather than by $\pm 20\%$ as for weight. Approximately 40% of the BMR variation may be explained by differences in the size of the body's organs (e.g., liver, intestine, and muscle), but there is a residual difference between individuals that seems to be explicable only in terms of differences in the rate at which every organ of the body metabolizes its fuel. This in turn is controlled principally by the circulating concentration of thyroid hormones. Adults with a normal but above average level of thyroid hormones in their blood tend to have a BMR in the upper normal range. Smokers also have a BMR that is approximately 5% above normal, but whether this relates to changes in thyroid hormones is unknown. Young women who have normal menstrual cycles show a change in BMR that is at its lowest in the late follicular phase, just before ovulation. On ovulation, the basal body temperature rises rapidly by approximately 0.5 °C. The BMR is also increased but rises further to a peak in the later luteal phase, immediately before menstruation. This metabolic cycle with changes of $\pm 5\%$ of the mean is independent of changes in food intake, but the recognized 5–10% decrease in intake during the follicular phase with a similar increase in the luteal phase may accentuate the hormonally dependent change in metabolism. The effects of contraceptives that inhibit ovulation and the subsequent increase in basal temperature are unknown. The previous day's food intake does not affect the BMR unless there has been substantial overeating. However, the mixture of fuels combusted during fasting is influenced by the proportion of the previous 3 or 4 days' intake, which is derived from carbohydrate, with much of the glucose from glycogen being metabolized in the fasting state if carbohydrate intake was previously high. When the carbohydrate store of glycogen in the liver is nearing exhaustion, the body's output of carbon dioxide declines as the

Table 1 Equations for estimating basal metabolic rate (BMR) from body weight (kg)[a]

Age (years)	*Males (MJ/day)*	*Females (MJ/day)*
<3	BMR = 0.255 kg − 0.226	BMR = 0.244 kg − 0.130
3–9.9	BMR = 0.0949 kg + 2.07	BMR = 0.085 kg + 2.033
10–17.9	BMR = 0.74 kg + 2.754	BMR = 0.056 kg + 2.898
18–29.9	BMR = 0.063 kg + 2.896	BMR = 0.062 kg + 2.036
30–59.9	BMR = 0.048 kg + 3.653	BMR = 0.034 kg + 3.538
60–74	BMR = 0.0499 kg + 2.930	BMR = 0.0386 kg + 2.875
75+	BMR = 0.035 kg + 3.434	BMR = 0.0410 kg + 2.610

[a]The BMR values for infants and children are no longer used to calculate energy requirements but provide an indication of the likely values. The adult data are those from the original Schofield *et al.* analyses, with the data for 60-year-old and older adults derived from both the Schofield data and information provided to the UK Department of Health (1991).

body switches to using body stores of fat. The oxygen uptake for combusting the fatty acids continues since the demand for regenerating ATP is unaffected by the change in fuel supply, but a carbohydrate-rich diet tends to induce a slightly higher fasting metabolic rate than an energy-equivalent, fat-enriched diet, probably because of a slight induction of thyroid metabolism by dietary carbohydrates.

The BMR decreases 2–5% when individuals move to a tropical, warm environment, and in uninsulated houses seasonal changes in the BMR have been readily seen, with a 5–10% increase from summer to winter observed in the Japanese before World War II. The BMR formulas shown in **Table 1** ignore any temperature effects. The BMR of some people living in the tropics may be as much as 10% below the values shown, but these studies have been conducted on children and adults who are, or were, undernourished. Poor nutrition may have both an immediate and a long-term effect in lowering the BMR. Semistarvation leads to a decrease in BMR beginning on approximately day 4, and within 2 weeks the BMR can decrease by 15% as thyroid metabolism changes and the body's organs become more efficient. More prolonged or severe semistarvation leads to a progressive loss of the body lean tissues as well as fat, and the BMR therefore continues to decline in proportion to the loss of lean tissues. Body weight can eventually stabilize at a new low level, and if physical activity is also reduced, semistarved volunteers can return to energy balance on 50% of their initial intake. However, this requires a 40% loss of weight and marked lethargy if energy balance is to be preserved on such a low intake.

Components of Metabolic Rate

Traditionally, the metabolic rate is divided into three components: BMR, postprandial thermogenesis, and physical activity. The BMR usually comprises 50–60% of an individual's total energy expenditure and postprandial thermogenesis comprises 10%, which is used for the metabolic cost of processing (i.e., eating, absorbing, transporting, and storing food). The remaining energy is used for physical activity.

Postprandial Thermogenesis

The surge in oxygen uptake after a meal, known as postprandial thermogenesis, has been variously described as the specific dynamic action of food, dietary-induced thermogenesis, or the thermic effect of feeding. The last term is particularly favored by animal nutritionists. It is difficult to measure it accurately because after ingesting food with minimum physical effort, an individual has to lie at complete rest while oxygen uptake and carbon dioxide production are monitored for many hours until the metabolic rate has returned to the basal rate. This may take more than 10 h, which explains why BMR is measured after a 14-h fast. Separate feeding of different fuels shows that the maximum effect on oxygen uptake occurs after protein intake. This response is equivalent to approximately 30% of the protein's energy: Glucose induces a 5–10% effect; fat only a 2–5% effect, consistent with its slow absorption by the lymphatic tissue; and alcohol a 0–8% effect. Certain dietary components also increase metabolic rate; for example, a caffeine equivalent to two cups of tea increases metabolic rate by 1–3%, and spices, such as those found in an Indian curry, may increase it by 25% compared with a nonspiced meal. Moderate exercise amplifies the metabolic response to a standard meal so that the combined effect of exercise and food is greater than the sum of the response to each stimulus given separately. The effect, however, is small, amounting to 2% of the total energy expenditure.

Differences in postprandial energy expenditure have been sought as an explanation for the propensity of some individuals and animals to obesity. Results are often conflicting because in any person, the response tends to vary from day to day and is readily influenced by changes in gastric emptying. A proportion of obese subjects have a reduced metabolic response to a meal; this effect may depend on the degree of abdominal insulation since the response is reduced if volunteers are swathed in insulation to reduce abdominal heat loss, thereby increasing the temperature of the blood entering and leaving the liver. This seems to reduce the stimulus to body metabolism. Lactating mothers (and pregnant women) have a lower postprandial thermogenesis that returns to normal after they have stopped breast-feeding. Smoking and postprandial thermogenesis interact synergistically so the thermic output after a meal is enhanced. The small postprandial response during lactation is consistent with that observed in many species of animals in which brown adipose tissue is used as the organ for modulating heat production as a mechanism to maintain body temperature. However, this organ is not very active in humans.

Prolonged underfeeding and overfeeding lead to changes not only in postprandial thermogenesis but also in BMR. The effects of semistarvation when expressed per unit of tissue mass are modest, but overfeeding can produce a much greater response, provided that the intensity of overfeeding (especially

with carbohydrate) is high. Thus, progressive overconsumption of 6.3 MJ (1500 cal) per day leads to a 33% increase in daily energy expenditure. This composite response to more prolonged overfeeding is usually classified as dietary-induced thermogenesis. Nevertheless, this apparent mechanism for dissipating excess energy is limited because, at most, 27% of the excess intake is metabolised, and the remaining 73% is stored—two-thirds as fat and approximately one-third as lean tissue. The majority of the excess response in metabolism is accounted for by the theoretical cost of fat synthesis from carbohydrate, although the human capacity to transform carbohydrate into fat is limited, with preference being given to the selective storage of the fat component of the ingested energy.

Physical Activity

The energy cost of physical activity is predictable, but in order to obtain a reasonable estimate of energy expenditure on a daily basis, an analysis of activity patterns on a minute-by-minute basis is required. Children can be very active, making a detailed analysis difficult because the type of activity needs to be specified if an energy cost is to be assigned to each type of activity. Weight-bearing movement and antigravitational moves (e.g., walking up a hill with a load) are particularly expensive. The simplest way to estimate individual costs is to use the extensive tables on the energy cost of different movements in children and adults. For simplicity, these can be expressed as a ratio of the BMR since, in this way, differences between the sexes and individuals of varying size are removed. **Table 2** illustrates how this is achieved for adults with a moderately active lifestyle. The physical activity ratios (PARs) (i.e., energy costs in relation to BMR) can be assigned on the basis of extensive measures of similar activities. Those involved in sports medicine also call this unit cost a metabolic equivalent (MET), where 1 MET is equal to the resting metabolic rate of approximately 4.2 kJ (1 kcal) per minute. If the average energy requirement of the individual is to be estimated, account must be taken of the different types of work involved throughout the year. Each day is compartmentalized on a minute-by-minute basis, with a division often being made for convenience between occupational and other work. Maintenance of the individual's household varies depending on the day of the week and the season. Integrating all these activities, the ratio of the total daily energy expenditure to the BMR is designated the physical activity level (PAL). Physical activity is of general health benefit, so it is desirable that the overall PAL of individuals should be 1.75 or higher, which requires at least 60 minutes of moderately vigorous activity daily. In sedentary societies, however, 30 minutes of moderately vigorous exercise three times a week benefits muscular tone and physical fitness. This improves cardiovascular health and insulin sensitivity and therefore is likely to limit the development of type 2 diabetes in susceptible individuals. **Table 3** provides a listing of PAL values for adults of all ages according to their activity patterns. Thus, by knowing the sex, age, and body weight of individuals, it is possible to estimate their BMR (see **Table 1**). Given this BMR figure in millijoules per day, multiply by the PAL value shown in **Table 3**, and the energy needs can be estimated. Note that individuals vary in their energy needs by 10% at equivalent weights and activity levels, so an individual's needs cannot be predicted very accurately

Table 2 Calculating the appropriate energy requirements as physical activity levels (PALs) for adults with an active or moderately active lifestyle[a]

Main daily activities	*Time allocation (h)*	*Energy cost (physical activity ratio)*	*Time (h) × Energy cost*	*Mean PAL (multiple of 24-h BMR)*
Sleeping	8	1	8.0	
Personal care (dressing, showering)	1	2.3	2.3	
Eating	1	1.5	1.5	
Standing, carrying light loads[b] (waiting on tables, arranging merchandise)	8	2.2	17.6	
Commuting to/from work on the bus	1	1.2	1.2	
Walking at varying paces without a load	1	3.2	3.2	
Low-intensity aerobic exercise	1	4.2	4.2	
Light leisure activities (watching TV, chatting)	3	1.4	4.2	
Total	**24**		**42.2**	**42.2/24 = 1.76**

[a]If this PAL was from a female population, 20–25 years old, with mean weight of 57 kg and mean BMR of 5.60 MJ/day (1338 kcal/day), TEE = 1.76 × 5.60 = 9.86 MJ (2355 kcal), or 173 kJ (41 kcal)/kg/day.
[b]Composite of the energy cost of standing, walking slowly, and serving meals or carrying a light load.

Table 3 Classification of lifestyles in relation to the intensity of habitual physical activity or physical activity level (PAL)

Category	*PAL value*[a]
Sedentary or light activity lifestyle	1.40–1.69
Active or moderately active lifestyle	1.70–1.99
Vigorous or vigorously active lifestyle	2.00–2.40

[a]PAL ranges apply to both men and women.

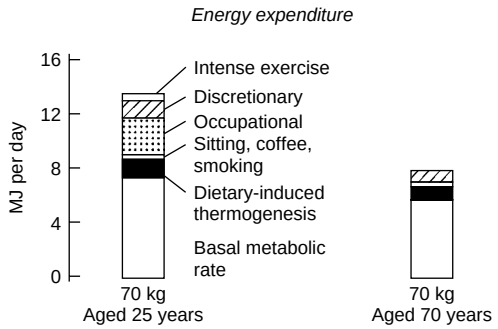

Figure 1 Different components of energy expenditure in a young man and the impact of ageing. Note that the energy expenditure decreases mainly because of a decline in physical activity. There is also a decrease in the basal metabolic rate, but this predominantly reflects a reduction in the lean tissues (i.e., fat-free mass) in the elderly.

unless his or her BMR is measured and account taken of his or her personal lifestyle (i.e., activity pattern). Nevertheless, the total energy expenditure of an individual child or adult is remarkably consistent from day to day, varying by only 1 or 2% provided that food intake and physical activity are meticulously standardized and account is taken in women of the stage of the menstrual cycle. The factors modulating BMR or the metabolic response to food are many, but their effect is small, so it is not surprising that energy expenditure is very predictable; the human body is thus a finely tuned and well-regulated machine. Abnormalities of regulation (e.g., in obesity) only arise because of a consistent discrepancy between the physiological controlled intake and expenditure, which, if discrepant by 1 or 2%, produces a 2- to 5-kg weight change in a year.

New measures of total energy expenditure estimated over 2 or 3 weeks can be obtained by using the double-labeled water technique, which relies on the difference in labeling of urine or saliva with the two heavy isotopes of water, deuterium and ^{18}O. The differential dilution of ^{2}H and ^{18}O in urinary water is monitored over a 2- or 3-week period following a single oral dose of $^{2}H_2\,^{18}O$. The ^{18}O content is diluted more rapidly than the ^{2}H because the oxygen in water exchanges rapidly with the body's bicarbonate pool, which turns over rapidly as carbon dioxide is produced by tissue metabolism. Thus, the difference in dilution rates of ^{18}O and deuterium provides a measure of the rate of carbon dioxide production. The technique is expensive and difficult to perform analytically but very convenient for the subject being studied since only single daily or occasional urine or saliva specimens are needed during the period of observation.

This method is increasingly used, and together in children with a heart rate monitoring system, has been used to revise the estimates of population energy requirements. These are accurate for groups of people but not for individuals, who vary not only in their physical activity patterns but also in their metabolic rate at rest. PAL estimates are less useful in infants because their energy requirement includes not only their total energy expenditure but also their cost of growth; BMRs are also difficult to measure at this age, so the $^{2}H_2\,^{18}O$ method together with estimates of growth costs have been used to compile new lower estimates of energy needs than were originally estimated by the old factorial method.

Age-related changes in energy needs are important not only in children but also in adults for different reasons. **Figure 1** gives an indication of the decline in energy needs during adult life. This results from the atrophy of the lean tissues, which may be related to a decline in physical activity. Lack of exercise is therefore a handicap because it directly reduces energy expenditure, and it may also lead to a slow shrinkage of tissues, such as muscle, thereby producing a long-term decline in metabolism at rest. There may also be up to an additional 5% decrease in the rate of tissue metabolism. Thus, unless people adapt their intake extraordinarily well to this progressive decline in energy output, energy storage, weight gain, and obesity are inevitable.

Extra Energy Costs

The cost of growth amounts to 10–25 kJ/g of new tissue deposited; the value is higher if fat with little lean tissue is laid down. A newborn has a high energy requirement of approximately 460 kJ/kg, with a cost of weight gain amounting to 26 kJ/g; however, by 1 year of age the total daily requirement decreases to approximately 335 kJ/kg as growth slows, with growth now costing 10 kJ/g. Breast-fed infants have an energy requirement approximately 10% lower than that of bottle-fed infants (**Table 4**).

Table 4 Average energy requirements of infants (breast and bottle fed) and of children up to age 18 years

Infants (months)	*Energy requirement (kJ/kg/day)*			*Children (years)*	*Weight (kg)*	*PAL*	*Energy requirement (kJ/kg/day)*	*Weight (kg)*	*PAL*	*Energy requirement (kJ/kg/day)*
	Boys	*Girls*	*Mean*		*Boys*			*Girls*

12	335	330	335	12.1–13	42.3	1.79	252	43.8	1.76	217
				13.1–14	47.8	1.82	242	48.3	1.76	206
				14.1–15	53.8	1.84	233	52.1	1.75	197
				15.1–16	59.5	1.84	224	55.0	1.73	189
				16.1–17	64.4	1.84	216	56.4	1.73	186
				17.1–18	67.8	1.83	210	56.7	1.72	185

The energy requirements of infants were derived from double-labeled water measurements of total energy expenditure to which was added the age-specific energy deposited during growth, taking into account the different proportions of lean and fat tissue laid down during infancy. The children's requirements were estimated from quadratic equations relating body weight to total energy expenditure of girls and boys measured separately or from estimates of total energy expenditure based on calibrated heart rate recordings. Again, the energy deposited as growth was added to give a requirement expressed on a weight basis to allow adjustments for children of different weights at each age.PAL, physical activity level.

Without sufficient energy, a child will fail to grow, but the causes of growth failure usually relate to a deficiency of other nutrients or to infection rather than to a lack of dietary energy. Adolescents, particularly boys, who are physically very active may have a high demand for energy. However, the actual cost of even rapid growth rates at this age is modest.

Traditionally, pregnancy is considered, incorrectly, a time of great demand for food. Good nutrition is extremely important, and a weight gain in pregnancy of approximately 12 kg is desirable for reducing the risk of maternal and fetal complications and preterm and low-birth-weight infants and increasing the probability of delivering a 3.3-kg infant. With a weight gain of 12 kg, increases in maternal BMR are 5, 10, and 25% in the first, second, and third trimester of pregnancy, respectively. In practice, the intensity of physical activity often declines, particularly in late pregnancy, and some enhanced metabolic efficiency seems to occur. Thus, the increase in total energy expenditure amounts to only 1, 6, and 17% in the three trimesters, respectively. Therefore, the need for additional energy is small, amounting to 85, 350, and 1300 kJ/day (20, 85, and 310 kcal/day) for sequential trimesters, and in practice this means that a pregnant women needs to increase her food intake by 1.5 MJ/day (360 kcal/day) in the second trimester and 2.0 MJ/day (475 kcal/day) in the third trimester.

Lactation imposes a greater demand on mothers since their milk contains 1.9 MJ/day after birth, increasing to approximately 2.3 MJ/day on exclusive breast-feeding at 3 months. Extra energy is involved in making this milk, and the total extra energy demand is 2.6 MJ/day. Part of this additional energy derives from the extra fat stored by the mother during pregnancy, with the average, well-nourished women losing 0.8 kg/month, so the mother needs to eat approximately 1.9 MJ/day (450 kcal/day). This explains why mothers are more hungry when nursing their child than when pregnant. During lactation, there are no significant changes in BMR, efficiency of work performance, or total energy expenditure, and in most societies women resume their usual level of physical activity in the first month postpartum or soon thereafter.

Convalescent patients who need to gain weight require extra food, but the cost of this weight gain is 20–40 MJ/kg. If 1 kg is gained per month, the extra food needed amounts to approximately 1 MJ/day.

Adaptation

A G Dulloo, University of Fribourg, Fribourg, Switzerland
J Jacquet, University of Geneva, Geneva, Switzerland

Throughout much of evolutionary history, the mammalian species have been faced with periodic food shortages, specific nutrient deficiencies, and, sometimes, food abundance. Within such a lifestyle of famine and feast, it is conceivable that adaptive mechanisms—operating through adjustments in energy expenditure and in management of the body's main energy-containing compartments (fat and protein)—have evolved to the extent that they constitute key control systems in the regulation of body weight and body composition. These control systems and how they operate to enable the human body to adapt to nutritional stresses and to achieve body weight homeostasis are the focus of this article.

Beyond Adaptation through Mass Action

There is in fact a built-in stabilizing mechanism in the overall homeostatic system for body weight. Any imbalance between energy intake and energy requirements will result in a change in body weight that, in turn, will alter the maintenance energy requirements in a direction that will tend to counter the original imbalance and hence be stabilizing. The system thus exhibits 'dynamic equilibrium.' For example, an increase in body weight will be predicted to increase metabolic rate (on the basis of the extra energy cost for synthesis and subsequent maintenance of extra lean and fat tissues), which will tend to produce a negative energy balance and hence a subsequent decline in body weight toward its set or preferred value. Similarly, a reduction in body weight will result in a reduction in metabolic rate due to the loss in lean and fat tissues, which will tend to produce a positive balance and hence a subsequent return toward the 'set' or 'preferred' weight. In reality, however, the homeostatic system is much more complex than this simple effect of mass action since the efficiency of metabolism (or metabolic efficiency) may also alter in response to the alterations in body weight. Indeed, subjects forced to maintain body weight at a level 10% above their initial body weight showed an increase in daily energy expenditure even after adjusting for changes in body weight and body composition. Conversely, in subjects maintaining weight at a level 10% below the initial body weight, daily energy expenditure was also lower after adjusting for losses in weight and lean tissues. These compensatory changes in energy expenditure (~15% above or below predicted values) reflect changes in metabolic efficiency that oppose the maintenance of a body weight that is above or below the set or preferred body weight.

Interindividual Variability in Metabolic Adaptation

The experiments on forced changes in body weight have also revealed that there is a large interindividual variability in the ability to readjust energy expenditure, with some individuals showing little or no evidence for altered metabolic efficiency and others a marked capacity to decrease or increase energy expenditure through alterations in metabolic efficiency. Indeed, the most striking feature of virtually all experiments of human overfeeding (lasting from a few weeks to a few months) is the wide range of individual variability in the amount of weight gain per unit of excess energy consumed. Some of

these differences in the efficiency of weight gain could be attributed to interindividual variability in the gain of lean tissue relative to fat tissue (i.e., variability in the composition of weight gain), but most are in the ability to convert excess calories to heat—that is, in the large interindividual capacity for diet-induced thermogenesis (DIT). A detailed reanalysis of data from approximately 150 humans participating in the various overeating experiments conducted between 1965 and 1999 suggested that at least 40% of these overfed subjects must have exhibited an increase in DIT, albeit to varying degrees. Part of this variation in DIT could be explained by differences in the dietary protein content of the diet, with DIT being more pronounced in unbalanced diets that are low or high in percentage protein. As shown in **Figure 1**, in a subgroup of volunteers who were overfed on two occasions—once on a normal protein diet and once on a low-protein diet—

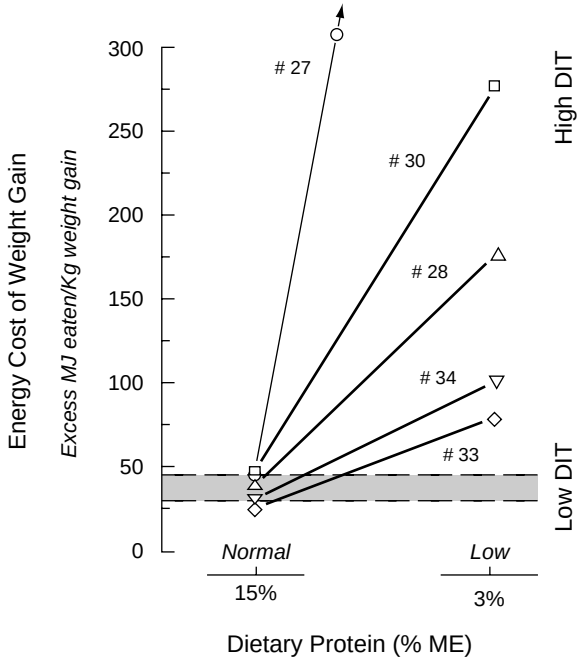

Figure 1 Interindividual variability in thermogenesis by low-protein overfeeding in humans. The data represent the energy cost of weight gain (excess MJ consumed per kilogram weight gained) during 3 or 4 weeks of overfeeding in the five human volunteers who participated in both the normal protein and low-protein overfeeding in the gluttony experiments of Miller and Mumford (1967). The horizontal broken lines (enclosing the shaded area) correspond to predicted energy cost of weight gain on the assumption that weight gain is either 100% fat (45 MJ/kg) or 60% fat (30 MJ/kg), the latter value including the cost of fat-free mass gain. The greater the deviation from the predicted values, the greater the likelihood that the excess calories were dissipated via enhanced diet-induced thermogenesis (DIT). Adapted from Dulloo AG and Jacquet J (1999) Low-protein overfeeding: A tool to unmask susceptibility to obesity in humans. *International Journal of Obesity* **23**: 1118–1121.

relatively small individual differences in DIT on balanced normal protein diet were amplified on the protein-deficient diet. That genes play an important role in variability in metabolism that underlies such susceptibility to weight gain and obesity has in fact been established from overfeeding experiments in identical twins. Conversely, a role for genotype in human variability in both the composition of weight loss (i.e., ratio of lean to fat tissue) and the enhanced metabolic efficiency (i.e., adaptive reduction in thermogenesis) during weight loss has been suggested from studies in which identical twins underwent slimming therapy on a very low-calorie diet. Taken together, it is evident that in addition to the control of food intake, changes in the composition of weight changes (via partitioning between lean and fat tissues) and in metabolic efficiency (via adaptive thermogenesis) also play an important role in the regulation of body weight and body composition, and the magnitude of these adaptive changes is strongly influenced by the genetic makeup of the individual.

What Constitutes Adaptive Thermogenesis?

The quantitative assessment of adaptive thermogenesis in the regulation of body weight and body composition is hampered by difficulties in determining which component(s) of energy expenditure may be contributing importantly to the changes in metabolic efficiency. As depicted in **Figure 2**, energy expenditure in the resting state is measured as basal metabolic rate (BMR) or as thermic effect of food (classically known as the specific dynamic action). Changes in the thermic effect of food (as percentage of calories ingested) or resting energy expenditure (after adjusting for changes in fat-free mass and fat mass) can be quantified, and they reflect changes in metabolic efficiency and hence in adaptive changes in thermogenesis. In contrast, any change in heat production from what is generally labeled nonresting energy expenditure is more difficult to quantify. The efficiency of muscular contraction during exercise is low (~25%), but that of spontaneous physical activity (SPA)—including fidgeting, muscle tone and posture maintenance, and other low-level physical activities of everyday life—is even lower since these essentially involuntary activities comprise a larger proportion of isometric work that is simply thermogenic. Since actual work done on the environment during SPA is very small compared to the total energy spent on such activities, the energy cost associated with SPA

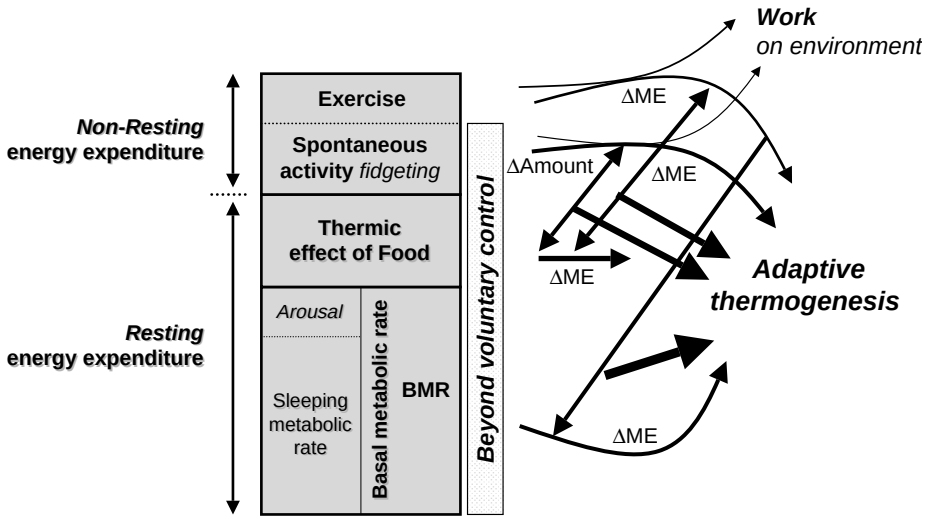

Figure 2 Schematic diagram showing the various compartments of human energy expenditure and how changes in metabolic efficiency (ΔME) both within and across these compartments can lead to adaptive changes in thermogenesis. The diagonal arrows depict possible *interactions* – between compartments of energy expenditure – that also constitute adaptive changes in thermogenesis; see text for details.

has been referred to as movement-associated thermogenesis or SPA-associated thermogenesis. It has also been argued that since SPA is essentially subconscious and hence beyond voluntary control, a change in the level or amount of SPA in a direction that defends body weight also constitutes autoregulatory changes in energy expenditure. In this context, an increase in the amount of SPA in response to overfeeding or a decrease during starvation also constitute adaptive changes in thermogenesis.

Spontaneous Physical Activity

The most direct evidence that changes in SPA contribute to autoregulatory changes in energy expenditure in humans derives from data obtained from the eight men and women who participated in the Biosphere 2 experiment. Biosphere 2 was a self-contained ecologic 'miniworld' and prototype planetary habitat built in Arizona. As a result of an unexpected shortage of food, their loss in body weight (8–25%) over a 2-year period was accompanied by a major reduction in SPA, which, like their reduced energy expenditure, persisted several months after the onset of weight recovery and disproportionate recovery of fat mass. Whether interindividual variability in the amount of SPA during overfeeding contributes to variability in resistance or susceptibility to obesity has also been the focus of a few human studies of energy expenditure. The importance of SPA-associated thermogenesis in human weight regulation was in fact underscored by the finding that even under conditions in which subjects were confined to a metabolic chamber, the 24-h energy expenditure attributed to SPA (as assessed by radar systems) was found to vary between 100 and 700 kcal/day and to be a predictor of subsequent weight gain. In fact, a main conclusion of early overfeeding experiments conducted in the late 1960s was that most of the extra heat dissipation in some individuals resisting obesity by increased DIT could not be accounted for by an increase in resting metabolic rate but could be due to an increased energy expenditure associated with simple (low-level) activities of everyday life. This notion has recently gained support from the findings that more than 60% of the increase in total daily energy expenditure in response to an 8-week overfeeding period could be attributed to SPA, and that interindividual variability in energy expenditure associated with SPA, referred to as nonexercise activity thermogenesis (NEAT), was the most significant predictor of resistance or susceptibility to obesity.

Efficiency of Muscle Work

In addition to changes in SPA, there is also evidence that changes in the efficiency of muscle work also contribute to adaptive changes in energy expenditure. Indeed in experiments of forced changes in weight in which subjects maintained body weight at 10% above or 10% below their habitual body weight, changes in muscle work efficiency could account for a-third of the change in daily energy expended in physical activity. These findings are

consistent with other reports of an increase in skeletal muscle work efficiency (i.e., decreased thermogenesis) after experimentally-induced weight reduction or in chronically undernourished subjects. Instead, changes in muscle work efficiency could account for one-third of the change in daily energy expended performing physical activity. These findings are consistent with other reports of an increase in skeletal muscle work efficiency (i.e., decreased thermogenesis) after experimentally induced weight reduction or in chronically undernourished subjects.

Interactions between Resting and Nonresting Energy Expenditure

It must be emphasized that the separation of adaptive thermogenesis between resting and nonresting is artificial, given the possibilities of their interactions illustrated in **Figure 2**. For example, energy expenditure during sleep, which is generally nested under resting energy expenditure, also comprises a nonresting component due to spontaneous movement (or SPA) occurring during sleep, the frequency of which seems to be highly variable between individuals. Furthermore, nonresting energy expenditure or NEAT may also include heat production resulting from the impact of physical activity (exercise or SPA) on postabsorptive metabolic rate or postprandial thermogenesis. There is evidence that relatively low-intensity exercise can lead to potentiation of the thermic effect of food, and that the effect of physical activity on energy expenditure can persist well after the period of physical activity (postexercise or post-SPA stimulation of thermogenesis). Reduction in postexercise stimulation of metabolic rate has also been proposed as a mechanism for energy conservation in individuals who are considered to be chronically energy deficient since childhood. Thus, any changes in metabolic efficiency in the resting or nonresting state that would tend to attenuate energy imbalance or to restore body weight and body composition toward its set or preferred value constitute adaptive changes in thermogenesis

Autoregulation of Body Weight and Body Composition

From a system physiology standpoint, the available evidence, based on classic longitudinal studies of starvation, refeeding, and overfeeding, suggests the adaptive mechanisms for optimal survival in an environment of famine and feast are embodied in three distinct autoregulatory control systems: the control of partitioning between protein and fat (the two main energy-containing compartments in the body) and two distinct control systems underlying adaptive changes in thermogenesis, as depicted in **Figure 3**. One control system is a direct function of changes in the food energy supply and responds relatively rapidly to the energy deficit. Its effector mechanisms are suppressed early during the course of starvation, and upon refeeding they are restored relatively rapidly as a function of energy reavailability and are activated further if hyperphagia occurs during refeeding, which may account for increased DIT. Because the efferent limb of this control system, which is primarily under the control of the sympathetic nervous system (SNS), is dictated not only by the dietary energy supply but also by a variety of other environmental factors, such as diet composition, specific nutrient deficiencies, ambient temperature, and psychological stress, it is referred to as the nonspecific control of thermogenesis. In contrast, the other control system has a much slower time constant by virtue of its response only to signals arising from the state of depletion/repletion of body fat stores; it is therefore referred to as the control system operating through an adipose-specific control of thermogenesis. The definitions of these two control systems underlying adaptive

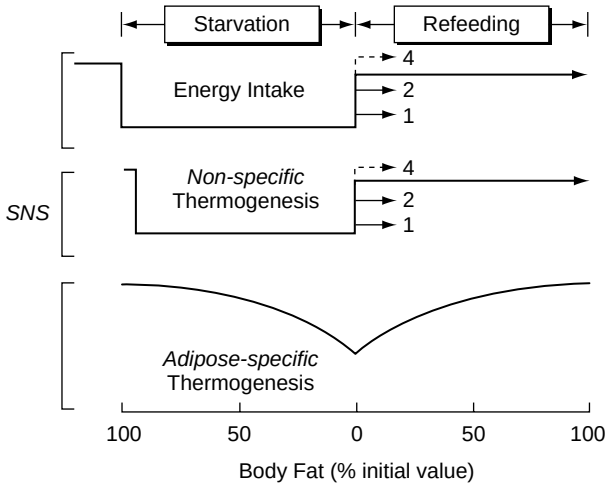

Figure 3 Schematic representation of the concept of two distinct control systems underlying adaptive thermogenesis during prolonged starvation and subsequent refeeding, showing *(i)* the *non-specific* control of thermogenesis, which is mediated primarily by the sympathetic nervous system (SNS) and which is a direct function of food energy supply, and *(ii)* the *adipose-specific* control of thermogenesis which is independent of the functional state of the SNS and which is a direct function of the state of depletion/repletion of the fat stores. Note that the different caloric loads during refeeding correspond to levels 1–4 of energy reavailability, with energy intake at level 1–2 below and level 4 above that prior to starvation, respectively. Adapted from Dulloo AG and Jacquet J (2001) An adipose-specific control of thermogenesis in body weight regulation. *International Journal of Obesity* **25**: (Supplement 5) S22–29.

thermogenesis are thus made on the basis of their differential commands—either deriving solely from the state of adipose tissue fat stores or not.

A Compartmental Model

An overall integration of these autoregulatory control systems in the regulation of body weight and body composition during a cycle of weight loss and weight recovery is discussed with the help of a schematic diagram presented in **Figure 4**. This diagram embodies the finding that the control of body energy partitioning between protein and fat is an individual characteristic—that is, individuals vary in their partitioning characteristic (Pc) during weight loss and weight recovery—and takes into account the two distinct control systems for adaptive thermogenesis that can operate independently of each other.

During starvation, the control of partitioning determines the relative proportion of protein and fat to be mobilized from the body as fuel—the individual's Pc being dictated primarily by the initial body composition. The functional role of the control of partitioning is to meet the fuel needs of the individual in such a way that the energy reserve component in both the fat and the protein compartments (i.e., the part that can be lost without death or irreversible damage) would reach complete depletion simultaneously—a strategy that ensures the maximum duration of survival for a given individual during long-term food scarcity. Furthermore, the energy conserved resulting from suppressed thermogenesis is directed at reducing the energy imbalance, with the net result that there is a slowing down in the rate of protein and fat mobilization in the same proportion as defined by the Pc of the individual. Indeed, the fact that the fraction of fuel energy derived from protein (i.e., the *P* ratio) remains relatively constant during the course of prolonged starvation, albeit in normal-weight humans, implies that neither control system underlying suppressed thermogenesis is directed at sparing specifically protein nor specifically fat but, rather, at sparing both protein and fat compartments simultaneously. Therefore, during starvation the functional role of both control systems underlying suppressed thermogenesis is to reduce the overall rate of fuel utilization (i.e., for energy conservation directed at sparing both lean and fat tissues).

During refeeding, the control of partitioning operates in such a way that protein and fat are deposited in the same relative proportion as determined by the Pc of the individual during starvation, and this serves to reestablish the individual's prestarvation capacity for survival during long-term food scarcity. Furthermore, the increased availability of food leads to the rapid removal of suppression upon the nonspecific (SNS-mediated) control of thermogenesis. In contrast, the suppression of thermogenesis under

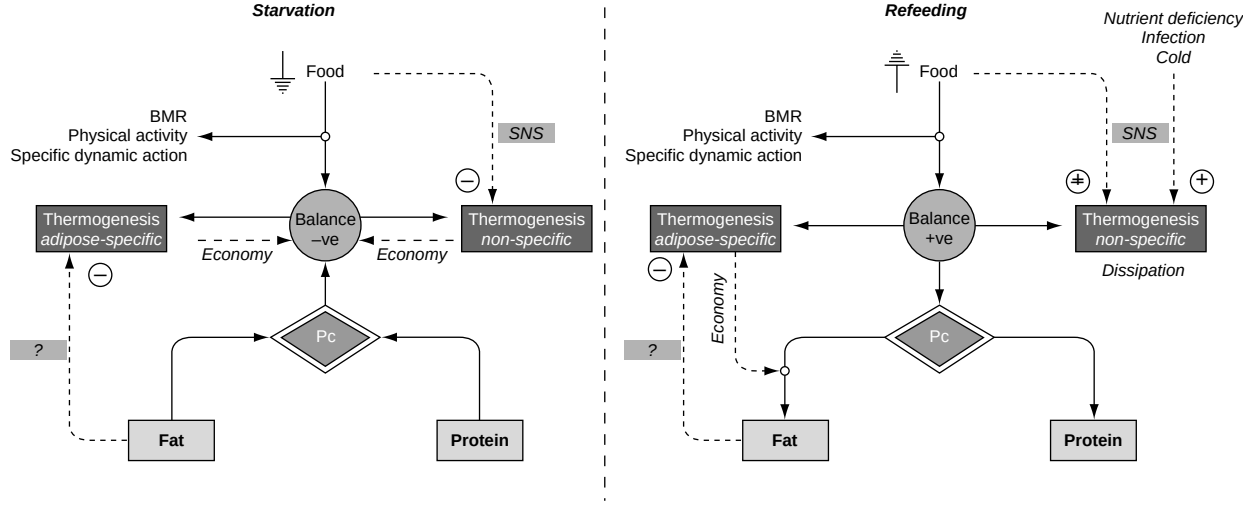

Figure 4 Schematic representation of a compartmental model for the regulation of body weight and body composition during a cycle of weight loss (prolonged starvation) and weight recovery (refeeding). In this model, the two distinct control systems underlying adaptive thermogenesis—the nonspecific control and the adipose-specific control—are integrated with the more 'basal' control of partitioning between the body fat and protein compartments as determined by the partitioning characteristic (Pc) of the individual. Adapted from Dulloo AG and Jacquet J (2001) An adipose-specific control of thermogenesis in body weight regulation. *International Journal of Obesity* **25**(supplement 5): S22–S29.

adipose-specific control is only slowly relieved as a function of fat recovery, such that the energy that continues to be spared is directed specifically at the replenishment of the fat stores. The net effect is that fat is deposited in excess of that determined by the Pc of the individual, thereby contributing to the disproportionate rate of fat relative to lean tissue recovery. This phenomenon of catch-up of fat (rather than catch-up of lean tissue) is often observed, both in adults after severe weight loss due to food unavailability and disease and in infants and children recovering from protein energy malnutrition and growth arrest.

Biological Significance

Such an adaptive phenomenon that accelerates the restitution of fat stores rather than diverting the energy saved toward compensatory increases in body protein synthesis (an energetically costly process) would have survival value in ancestral famine-and-feast lifestyle. This is because by virtue of the fact that body fat has a greater energy density and a lower energy cost of synthesis/maintenance than protein, it would provide the organism with a greater capacity to rapidly rebuild an efficient energy reserve and hence to cope with recurrent food shortage. Thus, the functional role of the adipose-specific control of thermogenesis during weight recovery is to accelerate specifically the replenishment of the fat stores whenever food availability is increased after a long period of food deficit and severe depletion of body fat stores. It provides an alternative mechanism to recover survival capacity in the absence of hyperphagia. However, equally important for the survival of mammals during weight loss and weight recovery is the need to retain the capacity to increase heat production (i.e., to activate thermogenesis) in response to a number of other environmental stresses, namely (i) for increased thermoregulatory needs in cold environments, (ii) for the generation of fever during exposure to infections, or (iii) for increased heat production as an adaptation to nutrient-deficient diets. The necessity to increase DIT in the face of nutrient-deficient diets probably had evolutionary survival advantage of 'homeostatic waste' because it enables individuals to overeat relatively large quantities of poor-quality food in order to obtain essential nutrients without the deposition of excess, nonessential energy as fat. Excessive weight gain would be a hindrance to optimal locomotion, hunting capabilities, and the ability to fight or flee. It has been proposed that DIT may have evolved as a means of regulating the metabolic supply of essential nutrients (protein, minerals, and vitamins) with only a secondary role in regulating energy balance and body weight. Whatever the exact functional significance of DIT, however, it is clear that in the context of weight recovery an elevated efficiency for catch-up fat can be shown to persist even under conditions of hypermetabolism (a net increase in thermogenesis) induced by hyperphagia or nutrient-deficient diets. To explain this apparent paradox, the model presented in **Figure 4** provides a structural framework that illustrates how suppressed adipose-specific thermogenesis that results in enhanced fat deposition during refeeding, and that is postulated to occur in the skeletal muscle, persists under conditions when the nonspecific control of thermogenesis is activated in organs/tissues recruited by the SNS (liver, kidneys, heart, and brown adipose tissue). Such differentially regulated control systems for thermogenesis may thus have arisen during the course of mammalian evolution as dual-adaptive processes that can satisfy the need for energy conservation during weight loss or for catch-up fat during weight recovery, even under environmental stresses when SNS-mediated activation of heat production has equally important survival values.

Energy Adaptation during a Longitudinal Human Study of Weight Fluctuations

The existence and operation of this dual-control system for adaptive thermogenesis are consistent with the temporal changes of BMR and body composition during the unique longitudinal study of semistarvation, refeeding, and subsequent overfeeding in men participating in a Minnesota experiment. The pattern of changes in food intake and body weight, together with kinetics of altered thermogenesis (assessed as changes in BMR adjusted for fat-free mass (FFM) and fat mass and expressed as a percentage of baseline BMR value) are presented in **Figure 5**.

During the phase of weight loss, the operation of the two control systems for adaptive thermogenesis is suggested by the fact that reduction in thermogenesis is biphasic in nature, with an initial rapid reduction in adjusted BMR at week 4, corresponding to 10% of baseline BMR, followed by a slower reduction in adjusted BMR, corresponding to 20 and 25% of baseline BMR at weeks 20 and 24, respectively. At the latter time points during starvation (at S20 and S24), the magnitude of reduced adjusted BMR was found to be associated with the reduction in fat mass (i.e., the greater the degree of depletion of the fat stores, the greater the suppression of thermogenesis).

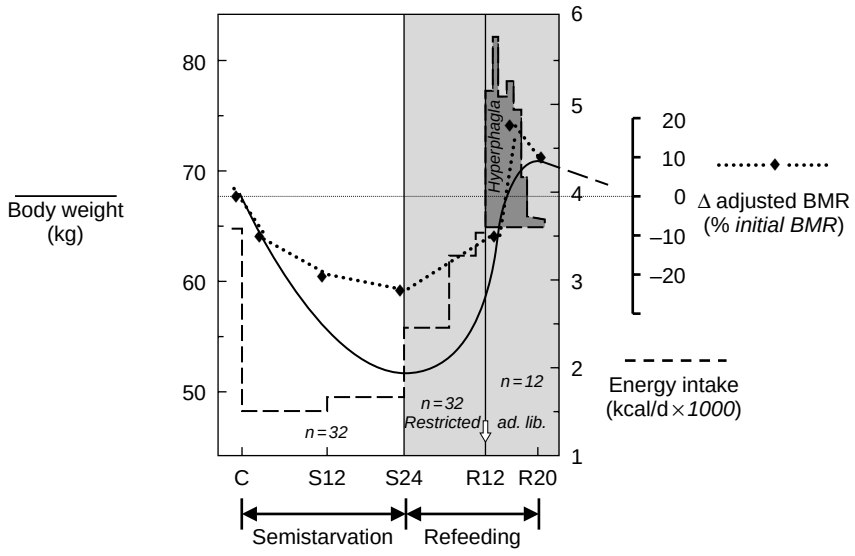

Figure 5 Pattern of changes in body weight, food intake, and adaptive thermogenesis during the various phases of the longitudinal 'Minnesota experiment' of human semistarvation and refeeding. The changes in adaptive thermogenesis at the various time points are assessed as changes in basal metabolic rate (BMR) after adjusting for changes in fat-free mass and fat mass and are expressed as a percentage of the baseline (control) BMR level. C, end of control (baseline) period; S12 and S24, week 12 and week 24 of semistarvation, respectively; R12 and R20, week 12 and week 20 after onset of refeeding, respectively. Data from Keys A, Brozek J, Henschel A, Mickelson O and Taylor HL (1950) *The Biology of Human Starvation*. Minneapolis: University of Minnesota Press; and Dulloo AG and Jacquet J (1998) Adaptive reduction in basal metabolic rate in response to food deprivation in humans: A role for feedback signals from fat stores. *American Journal of Clinical Nutrition* **68**: 599–606.

During the phase of weight recovery, the operation of the two control systems for thermogenesis is also suggested by the following:

1. The relation between the degree of depletion of fat stores and suppressed (adipose-specific) thermogenesis persists at week 12 of restricted refeeding, at which time point (R12) the mean adjusted BMR is still approximately 10% below baseline BMR level, the body fat is 80% recovered, and body weight and FFM recoveries are less than 50%.
2. After withdrawal of the dietary restriction during the subsequent period of ad libitum refeeding, the development of hyperphagia is accompanied by a prompt (perhaps SNS-mediated nonspecific) increase in thermogenesis, as judged by increases in adjusted BMR corresponding to approximately 20% of baseline BMR at week 14 of refeeding.

It is also noticeable that by week 20 after the onset of refeeding (R20), when FFM has been almost 100% recovered and body fat has overshot baseline (prestarvation) level by >70%—a phenomenon referred to as 'poststarvation obesity'—the adjusted BMR remains significantly higher (by approximately 10%) above baseline BMR despite the fact that hyperphagia is no longer present. This post-overfeeding sustained elevation of thermogenesis is consistent with a feedback mechanism existing between thermogenesis and body fat (i.e., the result of an activated adipose-specific control of thermogenesis), which may well have contributed to the subsequent slow return of body weight toward the baseline level after the phase of fat overshooting. Body fat was still higher than pre-starvation values when examined 33 weeks after the end of starvation, but was no longer significantly higher than pre-starvation values when examined 58 weeks after the end of starvation.

It should be noted that this study only enabled analysis of adaptive changes in thermogenesis in the BMR compartment since no measurements were performed pertaining to the thermic effect of food or to the energy cost of physical activity. The authors nonetheless observed that there was a profound decrease in SPA of the subjects, particularly during weeks S12 and S24 of semistarvation, thereby suggesting that adjustments in energy expenditure occurred in both resting and nonresting energy expenditure.

Energy Adaptation and Susceptibility to Leanness and Fatness

In addressing the issue of energy adaptation in human susceptibility to leanness and fatness, it must be noted that even in individuals who maintain a relatively stable lean body weight over decades, there is no 'absolute' constancy of body weight over

days, weeks, and years. Instead, body weight tends to fluctuate or oscillate around a mean constant value, with deviations from a set or preferred value being triggered by events that are cultural (e.g., weekend parties and holiday seasons), psychological (e.g., stress, anxiety, or emotions), and pathophysiological (ranging from minor health perturbations to more serious disease states). Very short-term day-to-day changes in body weight have a standard deviation of approximately 0.5% of body weight, whereas longitudinal observations over periods of between 10 and 30 years indicate that individuals experience slow trends and reversal of body weight amounting to between 7 and 20% of mean weight. In such a dynamic state within which weight homeostasis occurs, it is likely that long-term constancy of body weight is achieved through a network of regulatory systems and subsystems through which autoregulatory changes in food intake, body composition, and energy expenditure are interlinked.

The autoregulatory control systems—operating through adjustments in energy partitioning and through the two distinct control systems underlying thermogenesis—can play a crucial role in attenuating and correcting deviations of body weight from its set or preferred value. The extent to which these adjustments are brought about is dependent on the environment (e.g., diet composition) and is highly variable from one individual to another, largely because of the previous nutritional status of the individual and because of genetic variations. They probably conferred varying capacities to defend the body's protein and fat stores in an ancestral hunter–gatherer lifestyle of famine and feast, but they now underlie varying metabolic susceptibilities to fatness in societies in which palatable foods are abundant year-round. The resultant subtle variations between individuals in energy partitioning and in adaptive thermogenesis can, over the long term, be important in determining constancy of body weight in some and in provoking drift toward obesity in others.

Furthermore, the adaptive responses to starvation, so far discussed in the context of experimentation in normal weight (lean) individuals, also persist in individuals in whom obesity has developed spontaneously and contribute the defense of the obese state once acquired. In fact, longitudinal studies in obese humans losing weight in response to therapeutic slimming also indicate that they show a reduction in BMR (even after adjustments for losses of lean and fat tissues) as well as in SPA during both the dynamic phase of weight loss and subsequent weight maintenance. These findings support the notion that suppressed thermogenesis in response to food deprivation is a factor that reduces the efficacy of therapeutic regimens and contributes to obesity relapse. Furthermore, since the initial body composition (percentage of fat) is the most important determinant of energy partitioning between lean and fat tissue (i.e., Pc of the individual) during weight loss and weight recovery, the higher percentage body fat (i.e., the more obese the individual), the lower the fraction of energy mobilized as protein and hence the greater the propensity to mobilize fat during weight loss and to subsequently deposit fat during recovery. The low partitioning characteristic of the obese, coupled with sustained (adipose-specific) suppression of thermogenesis in response to their relative state of body fat depletion, will contribute to the relapse of obesity.

Indirect Calorimetry

A Raman and D A Schoeller, University of Wisconsin–Madison, Madison, WI, USA

All living organisms require a source of energy for survival. Among animals, this energy is provided in the form of chemical energy in the nutrients they consume, which are converted to other forms of energy through respiration. This conversion is subject to the same laws of thermodynamics that govern all energy systems. The first law of thermodynamics states that energy can neither be created nor destroyed; it can only be exchanged from one system to another. Hence, the chemical energy consumed in the form of food is converted into mechanical energy for work performed by the body, thermic energy for maintenance of body temperature, or stored as chemical energy in tissues as fat, protein, or a small fraction as carbohydrates. This conservation of energy can be stated mathematically as

$$\text{Energy}_{\text{in}} = \text{Energy}_{\text{work}} + \text{Energy}_{\text{heat}} \pm \text{Energy}_{\text{stored}}$$

The sum of energy converted to work and heat is defined as metabolism. Although metabolism constitutes thousands of chemical reactions occurring at the same time throughout the body that cannot be individually measured, their sum can be measured as either the sum of work and heat energy or, in the absence of any measurable work, the rate of heat production by the body. This is based on the assumption that all the cellular events ultimately result in heat.

The process of measuring heat produced by the body during combustion of substances or nutrients in animals or humans is called calorimetry. The term 'direct calorimetry' is used when the rate of heat production is directly measured by placing a person in a thermally isolated chamber. The term 'indirect calorimetry' is used when heat production is not measured directly but is instead calculated from the measurement of the rates of oxygen consumption (V_{O_2}) and carbon dioxide production (V_{CO_2}). In both measurements, the rate of metabolism is commonly referred to as the rate of energy expenditure, which in the absence of work output is the rate at which chemical energy in food is converted to heat. The nutrients in food that provide this chemical energy are the macronutrients: carbohydrates, fat, protein, and alcohol. The chemical process that releases the chemical energy is respiration, in which each of these macronutrients is combined with oxygen to produce carbon dioxide and water. These chemical reactions are chemically equivalent to those that would be observed if the nutrient were combusted in a flame, except the reaction in the body is an enzymatic process that does not produce a flame.

For example, one molecule of sugar (glucose) breaks down as follows:

$$C_6H_{10}O_6 + 6O_2 \rightarrow 6CO_2 + 6H_2O$$

It should be noted that during this reaction, six molecules of CO_2 are produced and six molecules of O_2 are consumed. Thus, the ratio of CO_2 to O_2 has a value of 1.0. This ratio is commonly called the respiratory quotient (RQ), although many investigators prefer the term respiratory exchange ratio (RER) when it is applied to a whole body measurement. Similarly, when one molecule of fat (tripalmitin) is broken down completely, the chemical reaction is

$$C_{57}H_{104}O_6 + 80O_2 \rightarrow 57CO_2 + 52H_2O$$

In the instance of fat oxidation, 57 molecules of CO_2 are produced while 80 molecules of O_2 are consumed when 1 molecule of fat is oxidized. This yields an RER of 0.71. When only carbohydrate and fat are being used to support energy expenditure, this difference in RER makes it possible to calculate what percentage of energy expenditure is being supported by each of the two energy substrates.

There is, however, a third macronutrient that is oxidized to produce energy. The third macronutrient, protein, is more difficult to describe on a chemical basis because a protein is made from a mixture of amino acids, and for each dietary protein the number and composition of amino acids differ.

The breakdown of the average dietary protein, however, can be described by the chemical reaction

$$C_{100}H_{159}N_{26}O_{32}S_{0.7} + 105.3O_2 \rightarrow 13CON_2H_4 + 87CO_2 + 52.8H_2SO_4$$

In the instance of protein oxidation, 87 molecules of CO_2 are produced while 105.3 molecules of O_2 are consumed when 1 molecule of protein is oxidized. This yields an RER of 0.83. Although this RER value is intermediate between carbohydrate and fat, protein is unique among the three energy substrates because it is the only one to contain nitrogen. As such, urinary nitrogen can be assayed to obtain an estimate of protein oxidized by an individual. Combining this with the knowledge that the average protein is 16% nitrogen by weight, it is possible to use the previous chemical relationship to calculate the O_2 consumption and CO_2 production that result from the oxidation of the protein represented by the urinary nitrogen. Subtracting these from the total respiratory gas exchange yields a nonprotein O_2 consumption, CO_2 production, and nonprotein RER. This is used to calculate the nonprotein metabolic rate and eventually the carbohydrate and fat oxidation rates. Because urinary nitrogen is often not measured, results from indirect calorimetry often use the Weir equation to calculate the energy expenditure. This equation was derived assuming that protein oxidation supports 12% of total energy expenditure (**Table 1**).

Over the years, different instrumental methods of indirect calorimetry have been developed to accurately measure V_{O_2} and V_{CO_2} rates. Despite being a precise and accurate method of measurement of macronutrient oxidation and hence energy expenditure, constraints such as expense, portability, gas collection issues, samplers, and applicability of measurements to habitual expenditure prevented it from being available to different types of research. Hence, the quest to develop new instrumental techniques is driven by the desire to make it a more generally applicable and easier to use technique.

Table 1 Formulas for calculation of energy expenditure

Variable	*Formula*
Oxygen consumption (ml/min)	= (Volume of inspired air per minute × fraction of inspired O_2) − (volume of expired air per minute × fraction of expired O_2)
Carbon dioxide production (ml/min)	= (Volume of expired air per minute × fraction of expired CO_2) − (volume of inspired air per minute × fraction of inspired CO_2)
Respiratory exchange ratio (RER or RQ)	$= V_{CO_2}/V_{O_2}$
Weir Equation (TEE, kcal/min)	$= (0.0039 \times V_{O_2}) + (0.0011 \times V_{CO_2})$ − (2.2 × urinary nitrogen, g/min)

Laboratory Methods

Whole Body Indirect Calorimetry

The advent of indirect calorimetry was a significant event in the history of animal and human nutrition. In whole body indirect calorimetry, the subject is kept in a sealed room or chamber, which is ventilated with a constant, measured supply of air. 'It is a setting similar to his habitual living and hence a more applicable measurement of energy expenditure.' The respiratory gas exchange of the subject is measured by the change in composition of the air going into the chamber and that of the air expelled from the chamber. Well-mixed samples of the chamber air are drawn to be analyzed for chamber air composition. The difference in O_2 and CO_2 composition of the incoming and outgoing chamber air is used to calculate the energy expenditure and macronutrient oxidation of the subject. Two main types of indirect calorimetry systems exist.

Closed-circuit indirect calorimetry involves the recirculation of the same air through the chamber. This can be performed by placing the subject in a sealed chamber. The recirculated air is kept breathable by removing the CO_2 produced by the subject and replacing the O_2 consumed by the subject. The replacement of O_2 is controlled by continuously monitoring the change in the volume of the gas in the closed breathing circuit. As the subject consumes O_2, a sensor detects the decrease in volume and a signal is sent to an external source to release constant calibrated pulses of O_2 back into the system to restore the original values. The rate of O_2 consumption is measured by recording the amount of O_2 that is added to the air during recirculation. The CO_2 produced by the subject is removed from the recirculated air by an absorber attached to the system and the CO_2 production is measured from the increased weight of the absorber (**Figure 1**).

Open-circuit indirect calorimetry involves a system in which both ends of the breathing system are open to the atmosphere. The inspired and expired air are kept separate by means of a three-way respiratory valve or non-rebreathing mask. The expired gases are collected into an air-tight bag or are frequently sampled or continuously analyzed for O_2 and CO_2 content.

These two terms are also used to describe some of the many other forms of smaller indirect calorimeters that have been developed over the years.

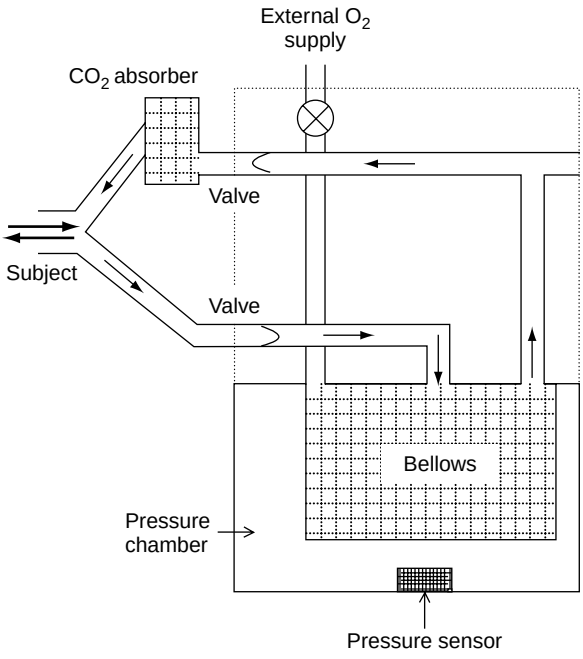

Figure 1 Closed-circuit metabolic chamber in which the subject's oxygen consumption is measured to calculate the corresponding energy expenditure. The change in volume of air in the system is constantly monitored by the sensors and a measured quantity of oxygen is added back to the system. Carbon dioxide is taken out of the recirculated air by a CO_2 absorber.

These can be categorized as laboratory or field techniques based on their portability. The instrumentation used for each varies in complexity and the degree to which they restrict the subject's movement.

Metabolic Carts

Metabolic cart is a common name for a semiportable respiratory gas analyzer that has been made small enough to be placed on a cart with wheels so that it can be rolled to different locations within a building. Two designs are generally available: the ventilated hood and the mouthpiece system.

The ventilatory hood system is an open-circuit indirect calorimeter that usually consists of a pliable plastic or rigid Perspex hood placed over the subject's head with a latex or thin plastic apron providing a rough seal around the neck or chest. These allow air to be drawn across a subject's face while in a reclining or lying position. For longer term measurements, ventilated plastic tents are available that cover all or part of the patient's bed. Since these hoods operate on a suction principle, a tight seal of the hood is not required. For field measurements, whole body transparent plastic ventilated boxes have been used successfully in infants. Many of the ventilatory hoods are constructed by researchers from the components according to the requirements of their study. The components include a pump, a flow meter, and a means of regulating the airflow. Samples of the air drawn from the hood can be directed to gas analyzers, which are usually connected in series to the hood. Respiratory gas exchange is calculated from the difference in O_2 and CO_2 concentration between the air entering and exiting the hood and the controlled rate of airflow (**Figure 2**).

Instruments have been developed to operate in adult and pediatric applications and differ with respect to flow rates and internal volume because of the smaller metabolic rate of children. The expired air enters a mixing chamber within the instrument to eliminate concentration variation resulting from inspiration and expiration before the sample enters O_2 and CO_2 sensor analyzers, which measure the concentration differences between the expired and inspired air. For state-of-the-art instruments, the data are input into a microprocessor providing minute-by-minute calculation of the O_2 consumption, CO_2 production, RER, and energy

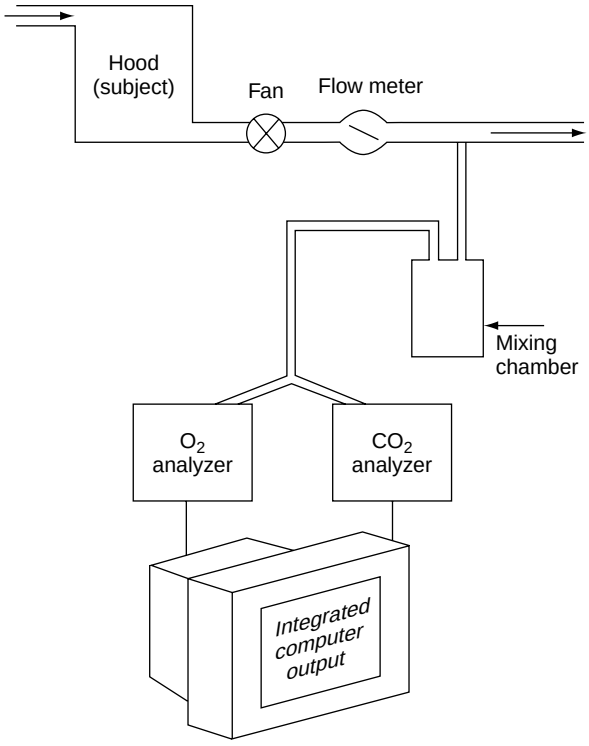

Figure 2 Ventilatory hood system showing a hood that is placed on the subject's head, a mixing chamber, and O_2 and CO_2 analyzers. A fan maintains a slight negative pressure in the hood to pull air into the chamber and also to prevent the escape of the expired air from the system. The air is mixed in the mixing chamber and is analyzed for oxygen and carbon dioxide by the respective analyzers. Results are calculated by the computer.

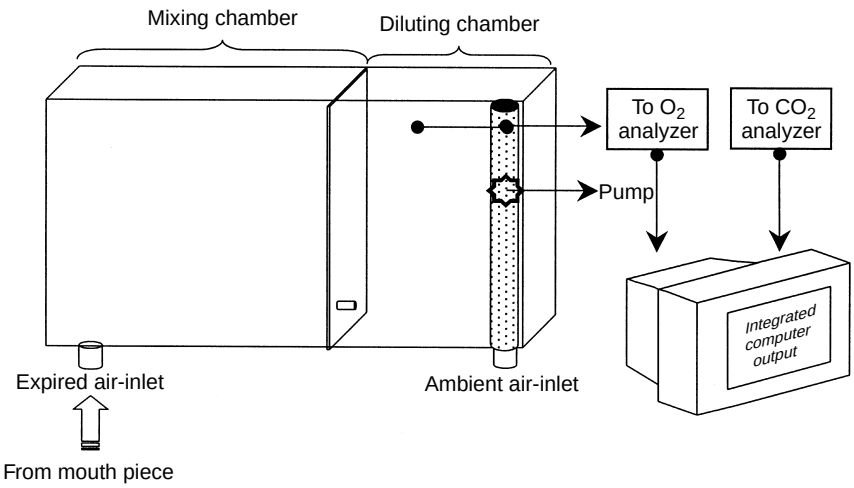

Figure 3 Metabolic unit measuring both O_2 consumption and CO_2 production rates during rest and exercise. In this type of system, expired air is diluted using ambient air before being analyzed by the respective analyzers.

expenditure. These instruments are generally used for measurements of subjects at rest as part of nutritional studies of energy expenditure and macronutrient utilization. These units can also be connected to mechanical ventilators for use in hospitalized patients.

Mouthpiece systems are similar to ventilated hood systems in principle, but instead of placing a hood over the subject's head, the subject wears a mouthpiece connected to the analyzer and nose clips to prevent breathing through the nose. The mouthpiece is connected to a valve system that allows the subject to breath in atmospheric air while directing the exhaled air to the gas analysis system. The expired breath is again subjected to analysis of O_2 and CO_2 concentration, but rather than passing the breath through a mixing chamber to smooth out the changes in concentration gradient of these gases from the start to end of an exhalation, the concentration profile is measured in real time along with the rate of gas flow from the exhalation. Again, the data are fed into a microprocessor for calculation of O_2 consumption and CO_2 production, but in this case the calculation is performed on a breath-by-breath basis. Results are averaged over time, usually provided as minute-by-minute averages of O_2 consumption, CO_2 output, and the rate of energy expenditure. The mouthpiece systems are generally used for studies of gas exchange and energy metabolism during exercise and provide a shorter measurement response time than the ventilated hood systems. The mouthpiece and nose clip used with some of the instruments make long time measurements highly cumbersome. Also, breathing through the mouthpiece often causes untrained subjects to involuntarily hyperventilate leading to inappropriate O_2 and CO_2 rates. It is also often difficult with mask systems to obtain an airtight seal without excessive pressure at the site of contact with the mask and face.

Different types of metabolic carts or monitors are available that are designed for various applications ranging from nutrition to exercise science. Most have built-in gas analyzers and data processing computers, making them highly user-friendly, handy tools for measurement of energy metabolism. They generally provide accurate and reliable data but do require periodic calibration. Ventilated hood systems often use a combination of gases with known concentrations and weighed ethanol or methanol burns for such calibration, whereas breath-by-breath systems use a combination of large volumetric syringes and gases of known O_2 and CO_2 concentration (**Figure 3**).

Field Methods

As for whole body indirect calorimetry, ambulatory and portable systems measure the respiratory gas exchange with the V_{O_2} and V_{CO_2} measurements. Ambulatory methods and less refined laboratory methods often dispense with the measurement of CO_2 to avoid the need for two gas analyzers. The error incurred by assuming a CO_2 production rate is several percentage points, which researchers are prepared to compromise on. When only O_2 consumption is measured, however, it is not possible to compute macronutrient-specific oxidation rates. The accuracy of ambulatory and portable methods is generally between +4 and −2%. Field methods involve the collection of expired air over a fixed period of time as in the Douglas bag or small on-line analysis systems that sample inspired and expired air through a mouthpiece.

Douglas Bag/Tissot Tank

The Douglas bag method is a classical example of collection of expired air to measure energy expenditure in the field during both rest and physical activity. It consists of a gas-impermeable bag with a capacity of ~100 l or a Tissot tank suspended over water, which is used to store the subject's expired air over a fixed, short time interval. A classic Douglas bag is made up of either a rubber sheeting cemented by two layers of canvas or plastic material lined by PVC or aluminum with welded seams. The rubber bags have leakage of CO_2 by diffusion, which is unavoidable, but PVC and metalized bags hold better. If the bags are filled to capacity and analyzed with 20 min of collection, the effects of diffusion can be minimized. The subject wears a nose clip and mouthpiece or a face mask. Outside air or its equivalent is inhaled through the mouthpiece or mask containing a one-way valve and exhaled into a Douglas bag or Tissot tank for a precise period of time. It is important that the mouthpiece and connecting tubing provide minimal resistance to airflow, or the cost of breathing will increase the energy expenditure. Ambient temperature, barometric pressure, and relative humidity are recorded for converting values under conditions of standard temperature and pressure. The volume of air collected in the bag or tank is measured and a sample of exhaled air is obtained to measure the O_2 and CO_2 concentrations using gas analyzers. The volume of oxygen consumed and carbon dioxide exhaled are calculated by analyzing the gas from the Douglas bag for the precise time period during which it was collected. This method is relatively simple and inexpensive yet gives reliable results. It is suitable only for short durations of field measurement, and wearing the mask and nose clip for the whole duration of the study may be cumbersome, interfere with daily activities, and is socially undesirable to the subject.

Spirometers were used in the past for measurement of the volume of the respired air. With the advent of continuous flow electronic analyzers and superior gas flowmeters, spirometers are now rarely used. Ambulatory methods also consist of a mouthpiece incorporating light action-sensitive but robust one-way gas valves, corrugated tubes, and three-way taps. The volume of air respired and the relative concentrations of O_2 and CO_2 in the expired air are measured using O_2 and CO_2 gas analyzers. These small analyzers have replaced the Haldane system or micro-Scholander chemical gas analyzers, which used reagents to absorb the CO_2 and O_2, with the weight of absorbents measured before and after the gases were absorbed.

Max Plank/Kofranyi–Michaels Respirometer

A Max Plank respiration gas meter is a small, compact, and lightweight backpack-mounted respirometer. It combines a gas volume meter and a sampling device for continuous sampling of each breath of expired air. The Max Plank respirometer consists of a dry, bellow-type gas meter for measuring the total volume of expired air during activity. The subject breathes through a low-resistance valve and the expired volume is monitored. A measured quantity of expired air is removed continuously (0.3 or 0.6%) by an aliquoting device to be sent to a small butyl rubber bag. This rubber sampling bag can be connected directly to the oxygen analyzer, eliminating the need for transfer of samples to gas-tight syringes for analysis. The respirometer is suitable for flow rates between 15 and 50 l/min or for periods of 110 min on a slow flow rate and 55 min on a faster rate. It is smaller, more compact, and lighter than the Douglas bag apparatus and can be used in studies involving light to moderate physical activity. Although the system has a low resistance, at higher ventilation rates the resistance increases substantially and hence cannot be used in higher flow rate scenarios. Also, this can be used in studies of shorter duration only. Due to the use of mouthpiece and nose clip, prolonged usage may cause discomfort to the subjects.

Telemetry Systems

The K2 system was the first of a series of portable systems that consists of a soft face mask with a turbine flowmeter attached to it. A transmitter and battery are attached to a chest harness, which transmits signals to a receiver unit. The flowmeter measures the rate of airflow, calculates the volume of expired air per minute, and counts the number of expirations per minute. A small capillary tube passes through to the transmitter unit, which contains an electrochemical gas analyzer used to measure the concentration of oxygen in expired air. The signals from this analyzer are transmitted to the receiver unit by the portable transmitter unit. The receiver unit processes the data and prints it in a desired format. The electrochemical gas analyzer is a polarographic electrode. It has a membrane through which oxygen permeates into an electrolyte solution generating an electrical impulse proportional to the rate of oxygen permeation through the membrane.

Since these systems are portable and easy to use, they have many potential uses in exercise science studies and rehabilitation medicine. They allow a breath-by-breath pulmonary gas exchange

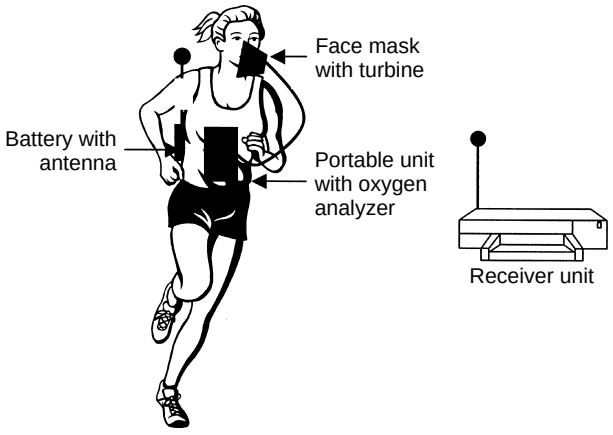

Figure 4 Telemetry system with a face mask attached to a turbine flowmeter, a transmitter, and a receiver unit. The flowmeter measures the rate and volume of airflow and the expiratory cycles per minute. The expired air is analyzed for oxygen concentration by an oxygen analyzer in the transmitter unit. The transmitter then transmits the signals to the receiver unit, which integrates the data and prints the results.

measurement while still being very light and portable, enabling a direct field assessment of human performance and cardiopulmonary limitations. The low-resistance flowmeter allows a wide range of oxygen flow rates to be measured, through these systems face the issue of air leakage from the face masks when subjects are made to exercise at high intensities. The measurement durations usually are limited to 1–5 h. The polarographic electrode membrane is known to have a short life span and hence monitoring of the usage of the instrument is essential. If CO_2 concentrations are essential for a study, this is not a good instrument to use (**Figure 4**).

Tracer Methods of Indirect Calorimetry

These are a third category of techniques that have gained popularity among investigators during the past two decades. These techniques provide a measure of CO_2 production through the use of dilution techniques using isotopic tracers.

Labeled Bicarbonate

A constant infusion-labeled bicarbonate method is useful in estimating the net CO_2 production and hence energy expenditure in animals and humans. This method is based on an isotopic dilution technique whereby the administered label is diluted by the CO_2 produced endogenously by the body. The extent of this isotope dilution is used to measure the rate of CO_2 production and is used to estimate the energy expenditure of the individual. A microinfusion of ^{13}C- or ^{14}C-labeled bicarbonate is given to an individual and the specific activity or enrichment of his or her physiological fluids, especially breath or urine, are measured to estimate the rate of label elimination and hence the rate of endogenous CO_2. Thus, variation in the endogenous CO_2 production rate will be reflected in the dilution of the body pool and consequently in the breath samples.

These measurements are accurate when energy expenditures are measured over a longer duration of time (>1 day) but are subject to effects of label sequestration over shorter periods. Sequestration refers to trapping, or fixation, of the label in tissues that utilize bicarbonate/CO_2 for their metabolic functions. Shorter duration of collection of breath samples requires a correction for the fraction of label that is sequestered. This is based on the assumption that similar amounts of label are sequestered in various individuals. When breath samples are collected over longer durations, the sequestration is often assumed to be negligible.

Some investigators have used a bolus bicarbonate administration rather than the continuous infusion. These investigators measured the rate at which the label concentration decreases with time as a measure of CO_2 turnover and the initial concentration as a measure of the body's bicarbonate pool size. Taken together, these provided a measure of energy expenditure during a short period of constant physical activity.

Doubly Labeled Water

This is an isotope dilution technique wherein deuterium and heavy oxygen-labeled water (doubly labeled water, DLW) are given to individuals and timed urine samples are collected to measure the elimination rates of ^{2}H and ^{18}O in the urine. ^{2}H label from DLW mixes with the body water and is eliminated as water in the urine. Similarly, ^{18}O label from DLW is eliminated as water, but it is also utilized in bicarbonate synthesis and hence is also eliminated in the breath as CO_2. The difference in turnover rates of isotopic ^{2}H-H and ^{18}O-labeled water is proportional to CO_2 production. Energy expenditure, oxygen consumption, water intake, and metabolic water production can be calculated using standard indirect calorimetry equations with an estimated RER (**Figure 5**).

In practice, a measured dose of DLW is given to the subject whose energy expenditure is to be measured. Body water samples, such as blood, urine, saliva, or breath water, are collected before dosing and after equilibrium is attained. The isotopic disappearance rates of ^{18}O and ^{2}H as CO_2 in breath or

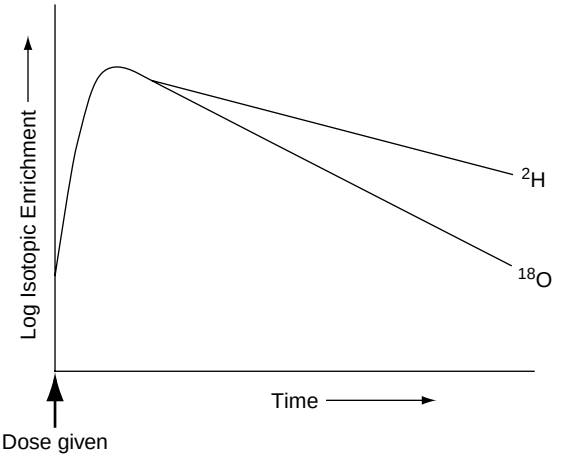

Figure 5 Time course on log scale for the enrichments of the stable isotopes 18-oxygen and deuterium when administered to the subject. Both the tracer enrichments increase rapidly in the body water pool until they reach distribution equilibrium (2–4 h). The enrichments then start to decline as the body water turns over during metabolism. 18-Oxygen is eliminated at a faster rate because it is excreted as water and CO_2 in breath, whereas deuterium is eliminated as water only. The difference in elimination rates of these two tracers is proportional to the rate of CO_2 production by the subject.

H_2O in urine, saliva, or breath water, respectively, are determined from the change in isotopic enrichments of the before dosing and after equilibrium samples.

The doubly labeled water method is both simple and noninvasive. It has been validated in various animals and humans, with the CO_2 production rate showing a mean measurement error of less than 5%. Unlike the majority of the other methods, the doubly labeled water method provides a measure of average energy expended over a period of 3–21 days without restricting the subject's movement and thus provides a better estimate of habitual energy expenditure than the other methods. The doubly labeled water method, however, does not provide any information on the pattern or intensity of any one activity during that time but the overall average energy expenditure. This method is also expensive due to the cost of the ^{18}O and it does require sophisticated mass spectrometric analyses.

Summary

Indirect calorimetry is a noninvasive, reliable, and valuable tool in assessing energy expenditure, evaluating fuel utilization by the body. It has been used extensively for both scientific investigation and medical evaluation and care. Scientists from various fields have used it effectively to measure energy expenditure, establish nutrient requirements, measure physical fitness, and evaluate macronutrient utilization during exercise and rest. Clinicians have used indirect calorimetry to optimize the nutritional support in metabolic disorders as in parenterally fed patients and to quantify the energy expenditure in mechanically ventilated patients. Indirect calorimetry is a reliable, convenient, and accurate diagnostic and prognostic tool in experimental and clinical settings. Indirect calorimetry has such universal appeal because animals and humans derive their energy for sustenance by transforming the chemical energy from the nutrients they consume to heat through respiration, and their existence depends on their ability to balance energy intake and expenditure.

Doubly Labeled Water

W A Coward, MRC Human Nutrition Research, Cambridge, UK

Like methods for the measurement of energy expenditure by respiratory gas analysis, the doubly labeled water (DLW) method is indirect. The disappearance

of stable isotope tracers, given orally, is used to model water and water plus carbon dioxide turnover. Carbon dioxide production rate is then estimated by difference and energy expenditure calculated from it. In practice, this means that subjects merely drink labeled water, samples of body water (e.g., urine, saliva, or blood) are collected over a few days, and these are then passed to the laboratory for tracer analysis and calculation. The method is thus uniquely objective; it is noninvasive and nonrestrictive in that its application does not interfere with normal lifestyles and comparable results can in principle be obtained in any circumstances without subject or observer influence. Complex measurement techniques do not need to be exported to the site where the subjects are located. However, underlying the apparent simplicity are concepts and techniques that are not commonly tools of trade for many potential users of the methodology. In a complete review, these, as well as method practice and results, need to be explained.

Method Fundamentals

Stable Isotopes as Tracers

Although radioactive tracers are familiar tools, the use of tracer elements and compounds to measure metabolic processes was developed first with stable isotopes in the late 1930s by Schoenheimer and Rittenberg soon after ^{2}H and ^{15}N (both stable isotopes) became available. Unlike radioactive isotopes, which are largely man-made, unstable, and decay to other elements, stable isotopes do not decay and are ubiquitous. Virtually all elements exist in nature in at least two stable isotopic forms with the same numbers of electrons and protons but with differing numbers of neutrons in the nucleus. The level of a specific isotopic form in nature is called its natural abundance. For tracer experiments, an element or a simple compound containing it, enriched with one of the isotopes, is prepared by mass-dependent separation on an industrial scale. This is then incorporated into the substrate of interest for biological experiments. In the current context, $^{2}H_2O$ (deuterium oxide, heavy water) is readily available from the electrolysis of water. Water enriched with ^{18}O is prepared directly by fractional distillation or from nitric oxide after its cryogenic distillation.

No radioactivity is involved in the use of stable isotopes in human experiments; thus, the only effects that have to be considered in relation to risk to the subject are related to the physical properties of the isotopic labeled compound. There is inevitably some degree of isotopic discrimination in physical and enzymatic processes, but because stable isotopes are normally present in all biological material at natural abundance levels, the relevant consideration is only by how much and for how long amounts are changed in experimental procedures. Because highly precise measurement techniques are used, it is necessary only to increase isotopic enrichments in body water from natural abundance by very small amounts. In a typical experiment, ^{2}H enrichment might be increased from 150 to 300 parts per million (ppm) and ^{18}O from 2000 to 2400 ppm, and a return to natural abundance levels will occur with a biological half-life of 5–7 days. There is no evidence that amounts many times larger than these have any harmful effects.

Measuring Isotopic Enrichment

Mass spectrometry is a generic name for a family of methodologies in which compounds are ionised and separated on the basis of mass:charge ratio. The method of choice for the measurement of isotopic enrichment with sufficient precision for DLW experiments is isotope ratio mass spectrometry. This technique is applicable only to relatively simple molecules. It separates ions such as $[^{2}H-^{1}H]^{+}$ and $[^{1}H-^{1}H]^{+}$ (mass 3 and 2) or $[^{12}C^{16}O^{18}O]^{+}$ and $[^{12}C^{16}O^{16}O]^{+}$ (mass 46 and 44) and measures isotopic ratios (R) relative to an international standard, such as Vienna Standard Mean Ocean Water (V-SMOW; **Table 1**). For the DLW method, therefore, the isotopic enrichment in water from biological samples has to be measured as hydrogen or carbon dioxide. For hydrogen isotope analysis, a variety of methods have been used for the conversion including reduction by reaction with hot uranium or zinc, but these methods are difficult to automate. Currently favoured methods are the exchange of hydrogen in the water sample with gaseous hydrogen by equilibration in the presence of a platinum catalyst or reduction with hot chromium. Both of these techniques are automated in commercially available equipment. For oxygen isotopes, samples are usually equilibrated

Table 1 Typical isotopic ratios and equivalent enrichments measured in DLW experiments[a]

Sample	*^{2}H isotope ratio (ppm)*	*^{2}H enrichment (‰)*	*^{18}O isotope ratio (ppm)*	*^{18}O enrichment (‰)*
V-SMOW	155.76	0	2005.2	0
Background	152.28	−22.34	1995.74	−4.72
Postdose	342.67	1200	2305.98	150

[a]Enrichment $= 10^{3}\left(\frac{R_{sample}}{R_{V-SMOW}} - 1\right)$.

V-SMOW, Vienna Standard Mean Ocean Water.

with carbon dioxide with exchange of oxygen between the water and carbon dioxide. This procedure is also automated.

Single Pool Kinetics

Considering only hydrogen, **Figure 1** represents a subject, in water balance, with a total body water of N mol with water (tracee) input and output rates of F mol/day containing ^2H at a naturally abundant molar concentration, C_b. A fractional output or rate constant is defined as $K = F/N$.

If a small quantity (D mol) of water labeled with ^2H tracer is added to the pool, it will be removed from it according to the monoexponential relationship

$$q_t - q_b = De^{-Kt}$$

where D is the amount of tracer given, q_t is the total amount (mol) in the body pool at time t (days), and q_b is the amount always present due to inflow at natural abundance. K is a fractional rate constant, sometimes defined in terms of the biological half-life $T_{1/2}$. This can be calculated as $T_{1/2} = \ln 2/K = 0.693/K$.

Since input and output rates are the same and the amount of tracer added is small relative to the pool size, we can write

$$\frac{q_t - q_b}{N} = \left(\frac{D}{N}\right)e^{-Kt} \text{ or } C_t - C_b = (C_0 - C_b)e^{-Kt}$$

where $C_0 - C_b$ is the increment in isotopic concentration resulting from the administration of the dose, and N can be calculated as $N = D/(C_0 - C_b)$.

The foregoing equations have been written in terms of isotopic concentration (e.g., $C = {}^2H/({}^2H + {}^1H)$), but mass spectrometry measurements are in terms of ratio (e.g., $R = {}^2H/{}^1H$) and in practice, for DLW calculations R or enrichment relative to a standard is invariably substituted for C with no effect on results at the low levels of enrichment applied in this methodology.

Principles of the Method

When Lifson first began his physiological experiments with newly available ^{18}O in the mid-1950s, it was already well-known that oral dosing with ^2H_2O and its dilution in body water was a way of measuring body water mass and turnover. Lifson showed that the oxygen in carbon dioxide, the waste product of energy metabolism, was in equilibrium in the body with body water:

$$H_2O + CO_2 \Longleftrightarrow H_2CO_3$$

He realized, therefore, that the greater apparent turnover of body water measured with $H_2{}^{18}O$ in comparison to turnover measured with ^2H_2O (**Figure 2**) was a consequence of carbon dioxide production, as shown in **Figure 3**. Thus, there was potential for a method that would permit the measurement of total CO_2 output and hence energy expenditure over long periods merely by isotopic analysis of samples of body fluids. Initially, the method was applied only to small animals because

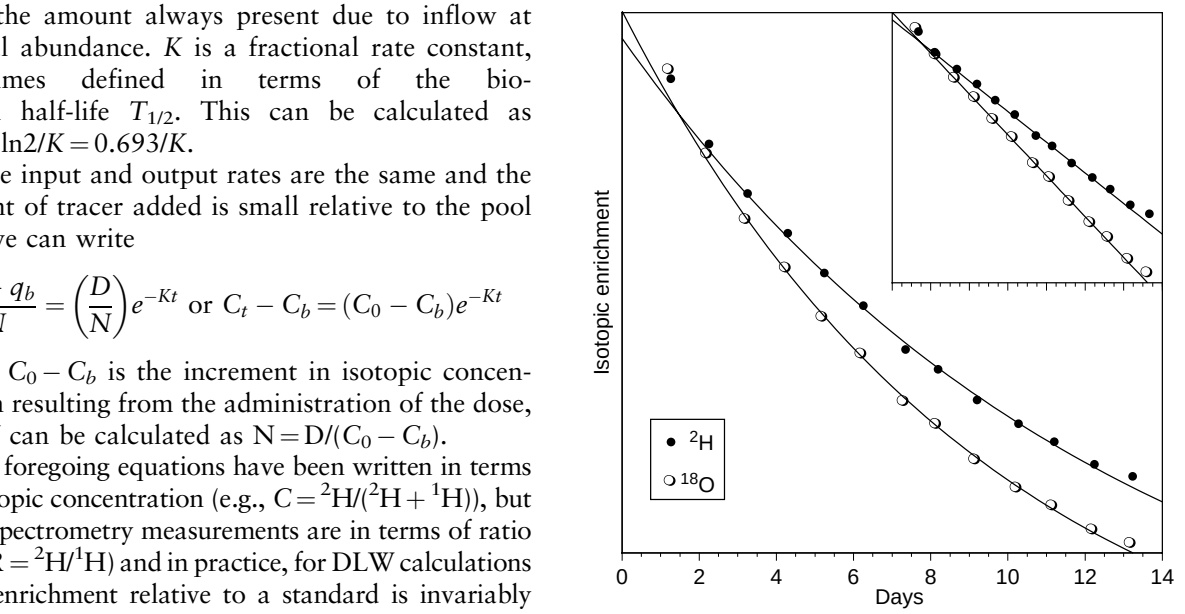

Figure 1 A simple one-compartment model of water turnover.

Figure 2 Exponential loss of ^2H and ^{18}O from body water. The insert shows the data on a log scale.

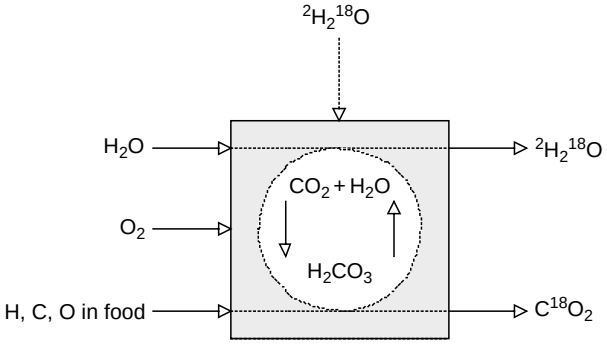

Figure 3 The fate of an oral bolus dose of ^2H and ^{18}O given as water (DLW).

the ^{18}O isotope was (and still is) expensive and instrumental limitations meant that relatively large doses had to be given to achieve adequate measurement precision. However, in the 1980s human studies, which are the focus of this article, became possible and in 1998 a basic unified methodological approach was established as a result of a meeting of the experts in the field (International Dietary Energy Consultancy Group). The publication derived from this meeting remains a valuable tool.

The following are the underlying assumptions of the method:

1. Body water is a single compartment that the isotopes label and from which they are lost.
2. ^{2}H is lost only as water.
3. ^{18}O is lost as water and carbon dioxide.
4. Total body water and output rates of water and carbon dioxide are constant.
5. Water and carbon dioxide loss occurs with the same enrichment as that coexisting in body water.
6. Background isotope intakes are constant.

Taking these in turn, assumption 1 is not correct. Evidence from many studies shows that the single compartments labelled by the isotopes are not the same size; ^{2}H space is approximately 3% larger than ^{18}O space. However, there is no evidence that isotope sequestration is a significant factor in human studies (assumptions 2 and 3). Water and carbon dioxide production rates are unlikely to be constant during a measurement period (assumption 4), but provided variations are random and not unidirectional during the measurement period, justifying the use of mean values for a period in any case, the method will not produce biased results.

Allowing assumptions 1–4, simple equations can be formulated (values of F and N are in mol and K in days^{-1}). F_{H_2O} is measured as

$$F_{H_2O} = K_D N_D$$

and the water plus carbon dioxide output (expressed in mol water equivalents) is

$$F_{H_2O+CO_2} = K_O N_O$$

Carbon dioxide production is then

$$F_{CO_2} = \frac{K_O N_O - K_D N_D}{2}$$

The factor of 2 arises because 2 mol of water is equivalent to 1 mol of carbon dioxide.

These simple relationships are in practice modified to correct for isotopic fractionation that, contrary to assumption 5, does occur. Where evaporative water losses occur, relatively less ^{2}H and ^{18}O leave the body in water vapour compared with liquid water. Fractionation factors are defined as

$$f_1 = \frac{\left(^{2}H/^{1}H\right)_{vapour}}{\left(^{2}H/^{1}H\right)_{liqiud}} = 0.941,$$

$$f_2 = \frac{\left(^{18}O/^{16}O\right)_{vapour}}{\left(^{18}O/^{16}O\right)_{liqiud}} = 0.991,$$

$$f_3 = \frac{\left(^{18}O/^{16}O\right)_{CO_2}}{\left(^{18}O/^{16}O\right)_{H_2O}} = 1.037$$

Thus, water vapour is isotopically depleted in ^{2}H and ^{18}O and carbon dioxide is relatively more enriched in ^{18}O compared to liquid water.

If it is assumed that a constant proportion (x) of water losses is fractionated, carbon dioxide production rate becomes

$$F_{CO_2} = \frac{K_O N_O}{2f_3} - \frac{K_D N_D (xf_2 + 1 - x)}{2f_3 (xf_1 + 1 - x)}$$

This procedure is most frequently used for infants and young children, in whom values of x are assumed to be 0.15–0.20.

For adults, fractionated water losses (F_f) are often defined in terms of F_{CO_2} ($F_f = 2.1F_{CO_2}$), in which case

$$F_{CO_2} = \frac{K_O N_O - K_D N_D}{2f_3 + 2.1(f_2 - f_1)}$$

Assumption 6 relates to the requirement that a predose sample should represent the effect of normal natural abundance isotope input. In most cases, background isotopic enrichment is likely to vary only randomly during a measurement period and so the issues are about the relationship between the background sample measured, the mean background and its random variation during the experimental period, the extent to which background variations in ^{2}H and ^{18}O are covariant, and the size of isotope doses and postdose enrichments in relation to these variations. In most experimental situations investigated with affordable isotopic doses, background variation contributes to the internal errors of the method and limits the extent to which better analytical precision improves results. In some circumstances (e.g., subjects moving from one place to another and use of large amounts of rehydration fluids in hospitalised patients), it is possible that a predose sample taken to represent isotopic background is not at all meaningful and the best advice may be to avoid these circumstances rather than try to correct for them.

Finally, F_{CO_2} values have to be converted into values for energy expenditure based on a fixed relationship between these quantities that depends on metabolic fuels used, expressed as a respiratory quotient (RQ). We can write

$$\text{Energy expenditure (kJ)} = F_{CO_2}\left(\frac{346.7}{RQ} + 124.3\right)$$

where F_{CO_2} is mol. RQ is calculated from dietary information or assumed to have a particular population value, such as 0.85.

Insertion of typical Western adult values ($N_O = 2000$, $N_D = 2066$, $K_O = 0.12$, *and* $K_D = 0.10$) into the relevant equations and 'what if' experimentation will allow the reader to test the effect of making changes to the assumptions and values. **Table 2** provides examples that show that serious errors or bias, for groups or individuals, are unlikely unless the applied population means for assumed values are grossly incorrect or the coefficient of variation (CV) is large.

Experimentation with the data, however, will also show that the magnitude of the difference between $K_O N_O$ and $K_D N_D$ is crucial. The method depends on precisely determining a relatively small difference between these two experimentally measured, larger values. This difference is approximately 20% in the example but can be much less when water turnover is high relative to carbon dioxide production (e.g., very young infants or subjects living in the tropics).

For the slopes (K_O and K_D) a minimum of two time points are required sufficiently far apart in time (two or three biological half-lives) to allow good precision on the slope determination with doses of sufficient magnitude to avoid detrimental effects of natural abundance variations and the limitations of analytical precision, especially at the end of the measurement period. In some protocols, more than two samples are measured, and this permits error calculations based on the goodness of fit of the data. Isotope distribution spaces are calculated from samples taken soon after dose administration (the 'plateau method') or by extrapolation of the disappearance curves to $t = 0$. Distribution spaces may be normalized to population-based estimates (N'_D and N'_O) of their relation to total body water (TBW):

$$TBW = \frac{\frac{N_O}{1.007} + \frac{N_D}{1.041}}{2}$$

$$N'_O = 1.007(TBW)\ N'_D = 1.041(TBW)$$

Figure 4 illustrates some aspects of total imprecision and the origins of the variance for a typical subject defined in **Table 3** when different dosing regimes are applied, with ^{18}O enrichment being varied at a constant initial ^{2}H:^{18}O ratio of 8.

The following are general considerations:

1. Naturally occurring covariance in ^{2}H and ^{18}O enrichment in baseline samples can be used to mitigate errors resulting from physiological variation in these values if dose sizes are suitably tailored to the slope of the variation. Optimum doses in this respect are predicted by

$$\left(\frac{^{2}H}{^{18}O}\right)_{optimal} = S\frac{2^n - 1}{2^{pn} - 1}$$

where $(^{2}H/^{18}O)_{optimal}$ is the ratio of immediate post-dose - background enrichments (rel V-SMOW) for

Table 2 'What if' calculations for a typical subject ($N_O = 2000$, $N_D = 2066$, $K_O = 0.12$, $K_D = 0.10$)

^{18}O analytical error for enriched samples (SD)	0.5% of value + 0.15‰
^2H analytical error for enriched samples (SD)	0.5% of value + 1.5‰
^{18}O background variation (SD)	0.15‰
^2H background variation (SD)	1.2‰
Variance in background ^2H accounted for by variance in ^{18}O (excluding analytical errors)	100%
Slope of background ^2H enrichment on background ^{18}O enrichment	8

^2H and ^{18}O, S is the slope of background ^2H enrichment on background ^{18}O enrichment, n is the experiment duration in terms of the number of biological half-lives for the ^2H isotope, and p is K_O/K_D.

2. Much of the deviation of the ^2H and ^{18}O data from the model for the postdose samples is covariant because it relates to inconstancy of water turnover. Errors thus tend to cancel, and this considerably reduces the potential impact of variance from this source.
3. Although the analytical errors applied in this case are not the lowest reported, they are probably typical and it can be seen that they always account for much of the variance.
4. Errors consequent on background uncertainty become very important when amounts of dose are reduced, but in practice, cost always limits the amount of ^{18}O that can be given. For this example, adequate precision in the total energy expenditure(TEE) measurement is predicted for ^{18}O doses producing initial enrichment in the range of 100–150‰ rel V-SMOW.

Protocols

There are, of course, variations depending on the type of subjects to be investigated, and either exclusively urine or saliva samples can be collected. Typically, for adult subjects, after the collection of a predose sample of urine or saliva, they are asked to drink an accurately weighed mixture of the isotopes to give the required enrichment in body water. A small sample of the dose should be retained for isotope analysis. The dose bottle is then rinsed with a further amount of water (≈50 ml) and this is also drunk. Most investigators fast their subjects for at least 6 h and may restrict food and water intake during the time when the isotopes are equilibrating in body water. If a plateau method is used for the determination of dilution spaces, the requirement is to collect a sample after equilibration is complete but before turnover begins to reduce enrichment. This will usually require a series of three samples collected at successive hourly intervals between 4 and 8 h. If urine samples are used, the first one should be discarded. A further two samples are collected two or three biological half-lives apart. In most adult cases, experiments will last 14 days; however, for both the timing of the plateau samples and the length of time of the study, it is advisable to establish specific times for the population under investigation. If dilution spaces are to be calculated from the intercept of isotope disappearance curves, postdose samples should begin to be collected on day 1 postdose and on subsequent days during the measurement period. Minimally, samples should be collected at the beginning and end of the measurement period (e.g., days 1, 2, 13, and 14). If a plateau method is used, samples are best collected in the presence of the investigation team, but when the intercept method is used subjects can be instructed to collect, label, and store their own samples. A few ml of urine, or saliva are sufficient for analyses, and should be collected and capped immediately to avoid evaporation and possible contamination. For long-term storage, samples should be stored frozen but may be refrigerated in the short term and need not be frozen for shipping.

Experience suggests that often it is the dose administration and sample collection that cause method failures. A good technique and high precision are needed for enrichment measurements but samples can always be reanalysed. Failures consequent on poor technique in subject-related procedures cannot be rectified and can be costly, especially if they are repeated through a whole investigation. New users of the methodology are advised to test all procedures in pilot work before full-scale application in a study.

Enrichment of samples is best calculated in terms of fraction of the dose given; that is,

$$\left(\frac{18.02d}{TD}\right)\left(\frac{E_S - E_P}{E_D - E_T}\right)$$

where E is isotopic enrichment, d is a weight (g) of dose diluted in T (g) tap water, and D is the weight (g) of dose given. Subscripts S, P, D, and T refer to postdose sample, predose sample, diluted dose, and tap water, respectively. The reciprocal of plateau values is the isotope dilution space (N_D or N_O). The reciprocal of the value at the time zero intercept of a plot of its log value vs time provides alternative dilution space estimates. The slope is the rate constant (K_D or K_O).

Validations and Reproducibility

Comparisons between DLW and calorimetry suggest a precision of 4 or 5%, but it should be remembered that studies of this type are highly controlled and may not properly reflect the real-life situation to which the method is intended to apply. The closest useful estimates are therefore perhaps those provided by an analysis of test/retest situations in which the same subjects were measured in more or less the same physiological conditions. **Figure 5** shows a compilation of such data. Apart from the labourers studied in the tropics, where the precision of the estimates may have been limited by known high water turnover rates, the data are quite consistent, with a mean of 8%. Subtraction of a likely contribution of 4% from total measurement error suggests a within-subject variation of 7%.

Applications of DLW in Nutrition

DLW and Energy Intake

Examination of the history of DLW in man suggests that there was an expectation that much would be learned in relation to the development of obesity as an outcome of identified long-term positive energy balance. Certainly in the initial phases of its use in human studies in the late 1980s, experimental protocols were most often designed to measure as accurately as possible the differences between energy intake and energy expenditure, but the findings from these experiments invariably exposed the limitations of energy intake measurements. Probably because the DLW concepts were then somewhat alien to conventional nutrition, the notion that intake measurements were more often than not inaccurate and underestimates was not at first easily accepted, but the most recent of several reviews records a very convincing body of evidence (**Figure 6**). However, although exposing a problem, most of these observations by themselves do nothing

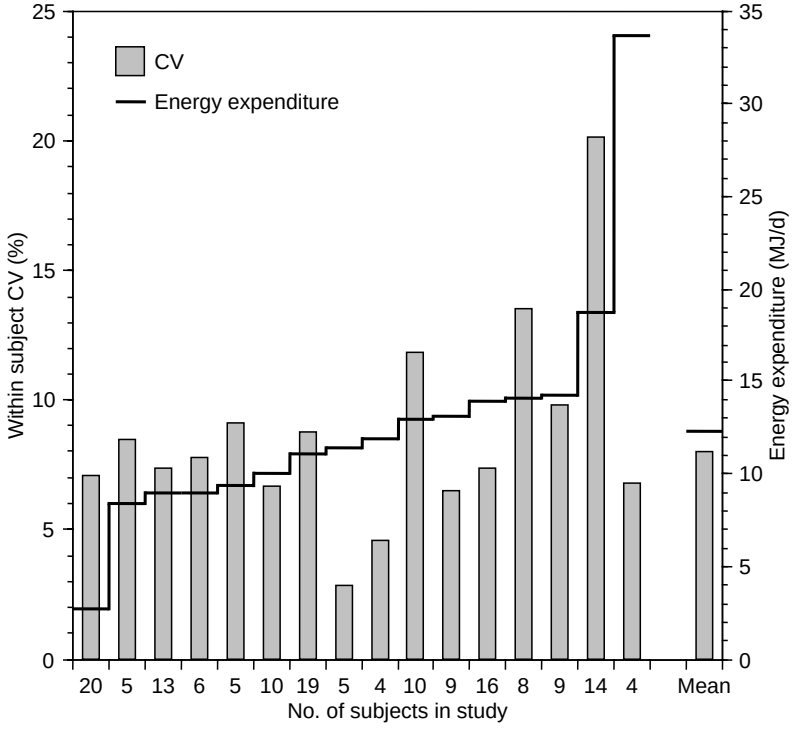

Figure 5 Reproducibility of the DLW method. (Data from Schoeller DA and Hnilicka JM (1996) Reliability of the doubly labeled water method for the measurement of total daily energy expenditure in free-living subjects. *Journal of Nutrition* **126**: 348S–354S.)

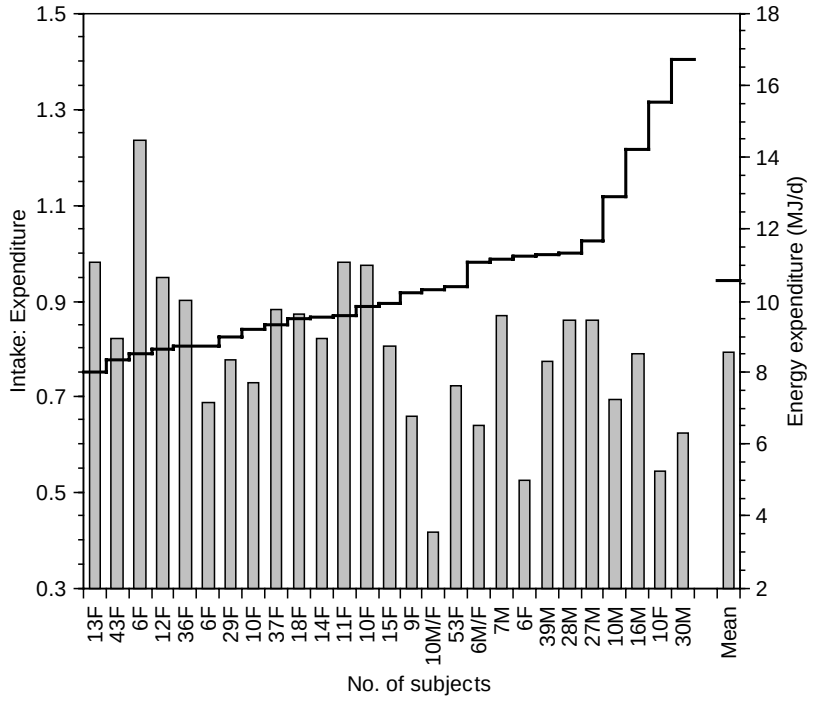
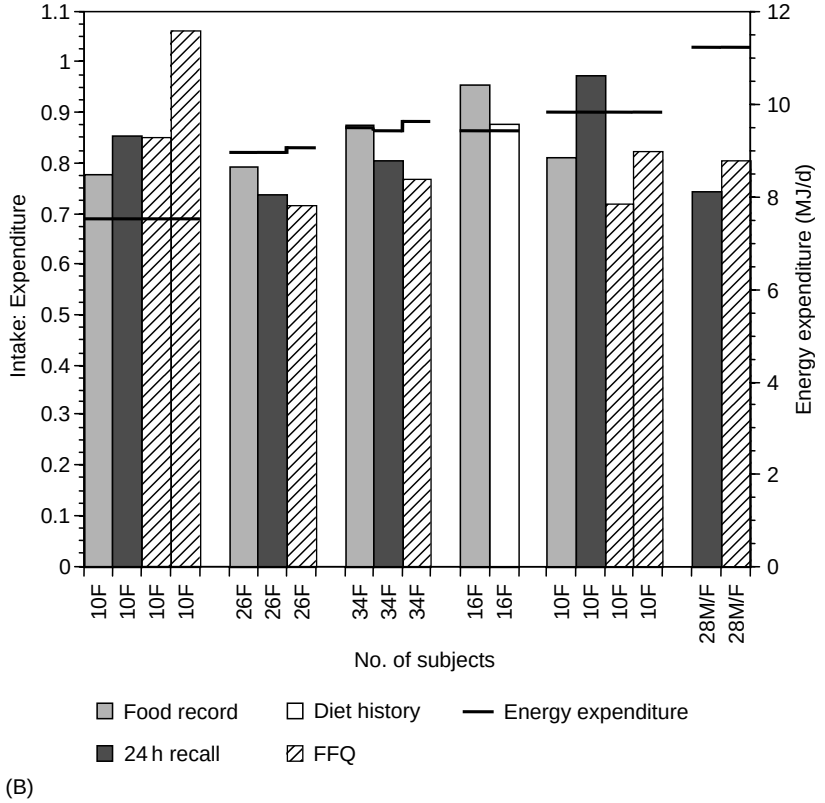


(A)



(B)

Figure 6 Accuracy of energy intake measurements assessed by DLW. (A) Dietary record data and (B) simultaneous use of more than one instrument. (Data from Trabulsi J and Schoeller DA (2001) Evaluation of dietary assessment instruments against doubly labeled water, a biomarker of habitual energy intake. *American Journal of Physiology (Endocrinology and Metabolism)* **281**: E891–E899.)

to solve it, not least because the studies are too small and indications of the nature and degree of correlation between DLW energy expenditure measurements and intake have not always been reported. The issue of detecting and correcting for bias in food and specific nutrient intake measurements remains a problem to which DLW is being applied as a biomarker of energy intake in large-scale studies.

DLW and Other Noninvasive Energy Expenditure Measurements

Although DLW can be regarded as the reference noninvasive total energy expenditure measurement, isotope cost and the need for mass spectrometric analyses will always limit it to specialist rather than widescale application. There is thus a need to validate or at least understand the limitations of preexisting methodologies and alternatives under development. A significant consideration is that although DLW measurements in an individual include basal metabolic rate as a component of the total expenditure, in alternatives the focus is most often on activities and their energy cost, and basal metabolic rate is measured separately or derived from prediction equations. This means that comparisons of total energy expenditure derived from DLW and the alternatives include a component representing approximately 70% of the total that is not dependent on the activity measurement method. In these circumstances, it is not surprising that activity-based TEE measurements often show good correlation between DLW and on average tend to be similar, but they should be treated with caution with respect to the validity of the activity measurements. Calculation of the energy cost of activity (TEE - resting metabolic rate) for comparison between methods is a much more useful comparison but is not always available.

DLW and Energy Requirements

The energy requirement of an individual is the intake from food that will balance expenditure when an individual has a body size and composition, and level of physical activity, consistent with long-term good health and that will allow for the maintenance of an economically necessary and socially desirable level of physical activity. In principle, these measurements could be obtained from the measurement of food intake or by factorial methods summing estimates of resting metabolic rate with the energy costs of activity. In practice, neither of these approaches is satisfactory; food intake is generally underestimated and no single instrument for the measurement of activity is sufficiently well validated to justify its general use. However, both in the United States (Standing Committee on the Scientific Evaluation of Dietary Reference Intakes) and internationally (FAO/WHO/UNU) the decision has been made to use DLW estimates of energy expenditure to provide the basis for the estimation of requirements. Given the relatively small number of laboratories involved in this work and its relatively short history, it is quite remarkable that sufficient data are available for this exercise. The normative US databases consist of adults ($n = 407$) and children ($n = 525$), obese adults ($n = 360$) and children ($n = 309$), and subsets for pregnant and lactating women. Regression equations derived from the data sets are used to predict requirements.

Conclusions

This article provided insight into how the DLW method works, showed how it should be used, and highlighted three areas in which it is clear that DLW has made, or at least has begun to make, a significant impact on nutrition research. The method is relatively expensive and uses scarce resources in terms of expertise, instruments, and materials. However, where the research requirement matches method capabilities, in terms of accuracy and precision, it is a uniquely effective tool.

Beneficial Effects

C Boreham and M H Murphy, University of Ulster at Jordanstown, Jordanstown, UK

This article examines the roles that physical activity, exercise, and fitness may play in the regulation of energy balance and in the etiology of major diseases such as coronary heart disease, cancer, and osteoporosis. Before proceeding, it is necessary to define the key terms of reference. 'Physical activity' can be defined as "any bodily movement produced by skeletal muscles that results in energy expenditure." 'Exercise' (often used interchangeably with 'physical activity') is defined as "physical activity which is regular, planned, and structured with the aim of improving or maintaining one or more aspects of physical fitness." 'Physical fitness' is "a set of outcomes or traits relating to the ability to perform physical activity."

Exercise and Energy Balance

Energy balance occurs when the total energy expenditure of an individual equals his or her total energy intake from the diet. If intake exceeds expenditure the result is an increase in the storage of energy primarily as body fat. If intake is below expenditure, body energy content or body fat decreases.

In humans, energy is expended in three ways: maintaining the physiological functions of the body at rest, often termed resting metabolic rate (RMR); ingesting food and digesting and assimilating nutrients, or the thermic effect of food (TEF); and skeletal muscular contractions involved in spontaneous physical activity or planned exercise. Of these components, the energy expenditure associated with physical activity and exercise is the factor that accounts for the greatest variability between individuals (**Table 1**). In addition, energy expenditure through physical activity is the only component that may be reasonably

Table 1 Estimated daily energy expenditure (approximate) for individuals of different age, weight, gender, and level of activity[a]

Status	*Estimated daily energy expenditure (kcal)*
Infant, male, age 3 months, body weight 6 kg	760 (3200 kJ)
Child, male, age 4 years, body weight 17 kg	1520 (6400 kJ)
Teenager, male, age 13 years, body weight 46 kg	2200 (9200 kJ)
Sedentary female[b]	1950 (8100 kJ)
Sedentary male[c]	2500 (10 200 kJ)
Female, moderately active[b]	2200 (9200 kJ)
Male, moderately active[c]	3000 (12 500 kJ)
Female, very active[b]	2500 (10 400 kJ)
Male, very active[c]	3200 (13 300 kJ)

[a]Values are based on estimated average requirements from a report by the Committee on Medical Aspects of Food Policy (1991). Dietary reference values are for food energy and nutrients for the *United Kingdom*.
[b]Based on female age 25 years, body weight 60 kg.
[c]Based on male age 25 years, body weight 70 kg.

controlled by an individual, and therefore it may represent an appropriate method for altering energy balance. Physical activity is estimated to make up 5–40% of daily energy expenditure depending on the activity habits of the individual, with RMR and TEF accounting for 60–75 and 10–15%, respectively.

Aside from its direct independent effect on daily energy expenditure, evidence suggests that exercise may also alter RMR, TEF, and the energy expenditure caused by spontaneous physical activity.

Energy Expenditure during Exercise

The magnitude of energy expenditure during exercise is dependent on several factors, including the mode, intensity, and duration of exercise, as well as the body mass of the individual.

When determining the metabolic cost of weight-bearing physical activity, energy expenditure needs to be expressed in relation to body size since a small person will expend less energy performing a given activity (e.g., walking up a flight of stairs) than a larger person performing the same activity. Therefore, to calculate the energy cost of a given activity it is necessary to know the energy cost in kcal (kJ) per kilogram of body weight. The term MET (metabolic equivalent) may also be used to indicate the ratio of the rate of energy expenditure during a given activity to resting metabolic rate (RMR). An example illustrates how METs are used to quantify energy expenditure during exercise. If an individual with a body mass of 70 kg expends 70 kcal (≈300 kJ) per hour at rest (RMR), and walking at a speed of 5.6 km per hour requires 280 kcal (≈1200 kJ) per hour, the energy cost of the activity is 4 METs or four times the RMR of the individual. Since body size is a determinant of both RMR and the energy expenditure during exercise, a heavier individual will have a higher RMR but will still require four times this level of expenditure (or 4 METs) to walk at the same speed. **Table 2** indicates the energy cost in METS of many popular exercise modes.

Table 2 Energy costs of popular physical activities

Activity	*Intensity*	*METs*
Walking	6.4 km h^{-1}	4
Running	10.8 km h^{-1}	11
Cycling	20.9 km h^{-1}	8
Swimming	Front crawl, moderate	8
Tennis	Singles	8
Aerobics	Moderate	6

Adapted from Ainsworth BE, Haskell WL, Leon As *et al.* (1993). Compendium of physical activities: Classification of energy costs of human physical activities. *Medicine and Science in Sports and Exercise* **25**(1): 71–80.

Energy Expenditure after Exercise

In addition to the additional energy consumed during an exercise bout, several researchers have found that energy expenditure remains elevated for a period following exercise. However, conclusions regarding the magnitude and duration of this postexercise elevation in energy expenditure have been equivocal. Studies have found an increase in energy expenditure in the postexercise period varying in magnitude from 5 kcal (21 kJ) to 130 kcal (546 kJ), with some suggesting that this additional energy expenditure lasts a few minutes and others suggesting that the elevated metabolic rate persists for up to 24 h. The divergence in the findings may be accounted for by the various modes, durations, and intensities of exercise employed in the studies as well as the methods used for measuring alterations in energy expenditure and the confounding effects of food ingestion during the recovery period. In addition, alterations in postexercise energy consumption may exhibit intraindividual variations according to the fitness level of subjects. Several mechanisms underlying this increased energy expenditure during the postexercise period have been postulated, including the energy cost of replenishing fuel stores, the cost of dissipating by-products of adenosine triphosphate (ATP) resynthesis, restoration of cellular homeostasis, and the futile cycling of energy substrates. The magnitude of this increase may be related to the intensity and duration of exercise, with longer or more strenuous activity creating a greater perturbation to homeostasis and therefore causing greater energy expenditure in restoring the body to its preexercise condition.

Effects of Exercise Training on Resting Metabolic Rate

Aside from the transient increase in energy expenditure in the period immediately following exercise, several researchers have examined the chronic effect of exercise on RMR. Although findings are far from consistent, some investigators have found that regular exercise causes a persistent augmentation in RMR. The mechanism for effect has yet to be confirmed, but it has been hypothesized that this increase may be due to the high energy turnover associated with the elevated levels of energy intake and expenditure typical of trained individuals. One beneficial effect of exercise training on resting metabolic rate is the maintenance or

increase in lean body mass. As a result of regular resistance exercise, muscle size increases (hypertrophy) or the age-related decline in muscle mass (atrophy) is reduced, contributing to an increase or maintenance of RMR.

Effects of Exercise on the Thermic Effect of Food

The TEF is largely dictated by the composition and energy content of the meal as well as an individual's body composition. However, some studies have indicated that pre- or postprandial exercise may enhance the TEF.

In addition to this acute effect of exercise, regular training may alter the TEF. In males, the thermic effect of a meal is lower in highly trained compared to untrained individuals. In one study, moderate levels of fitness were associated with a greater increase in the TEF than either high or low fitness. The authors suggest that very high or very low levels of fitness may decrease the thermic effect possibly by adaptive mechanisms, such as a lower insulin or lower noradrenaline response to feeding. Interestingly, no equivalent effect has been found in women. Studies on monozygotic twins also suggest a strong genetic factor controlling whether exercise has such an effect.

Effect of Exercise on Energy Expenditure in Spontaneous Physical Activity

In addition to the energy expenditure during planned exercise, other skeletal muscle contraction associated with spontaneous physical activity (including fidgeting) incurs an energy cost. Research indicates that the quantity of energy expended in spontaneous physical activity is highly variable between individuals. Studies show that in addition to its effect on RMR, participation in a planned exercise program increases the energy expenditure of an individual during nonexercising time.

Physiological Adaptations to Exercise Training

Aside from alterations in energy balance, regular exercise brings about many physiological adaptations. The human body is remarkably plastic in response to the increased metabolic demands of exercise training (overload), with many adaptations occurring that enable the body to function more efficiently. The nature and magnitude of these changes are dependent on the volume (duration and frequency), intensity, and type of exercise performed. For this reason, the physiological adaptation to training will be classified according to the nature of the exercise undertaken.

It is important to remember two principles when considering the physiological adaptations to exercise training. First, there is a degree of intraindividual variation in response to exercise training that may be attributed in part to hereditary factors. Second, whereas exercise training will cause adaptation, the removal of this stimulus will result in a reversal of adaptation, or 'detraining.'

Adaptations to Submaximal/Endurance Exercise Training

Submaximal exercise generally refers to an intensity of exercise that requires less than an individual's maximal oxygen uptake. Submaximal exercise challenges the body to deliver and utilise an increased amount of oxygen in the resynthesis of ATP. With training, changes occur that increase the body's ability to utilize oxygen. For simplicity, the adaptations to submaximal exercise training have been grouped according to the site at which they occur.

Central adaptations Central adaptations to regular submaximal exercise include alterations in the morphology and function of the heart and circulatory systems that allow greater delivery of oxygen to the working muscle.

The pulmonary system in healthy individuals does not provide a significant limitation to exercise, and therefore little alteration in the lung volumes, respiratory rate, or pulmonary ventilation and diffusion occurs as a result of training.

Modest cardiac hypertrophy characterized by an increase in left ventricular volume occurs in response to training. This adaptation allows an increase in stroke volume, leading to a reduction in heart rate at rest and during submaximal workloads and an increased cardiac output during maximal workloads.

Finally, an increase in total plasma volume and an increase in the total amount of hemoglobin have been observed in response to submaximal endurance training.

Peripheral Adaptations

Peripheral adaptations refer principally to changes in the structure and function of skeletal muscle that enhance its ability to use oxygen to produce energy aerobically.

As a result of endurance training, there is an increase in blood supply to the working muscle. This is achieved by an increased capillarization in trained muscles, greater vasodilation in existing muscle capillaries, and a more effective redistribution of cardiac output to the working muscle.

An increase in the activity of aerobic enzymes and an increased mitochondrial volume density (approximately 4–8%) within trained muscle have been noted. These are coupled with increased glycogen storage within the muscle and increased fat mobilization allowing a higher rate of aerobic ATP resynthesis from free fatty acids and glucose.

High-Intensity Exercise and Strength Training

High-intensity exercise requires energy utilization rates that exceed the oxidative capabilities of the muscle. Activities such as sprinting require the anaerobic resynthesis of ATP to produce and maintain high levels of muscular force and are therefore limited in duration. Strength training also relies heavily on anaerobic energy sources and requires high force production by specific muscle groups.

Adaptations to High-Intensity Exercise and Strength Training

The main alterations that occur in response to regular high-intensity exercise or strength training are improvements in the structure and function of the neuromuscular system that allow more efficient production of the forces required for these activities and an enhanced ability to produce the energy required through anaerobic processes.

Neuromuscular The initial improvements in performance that occur with high-intensity exercise training are largely a result of improved coordination of the nervous system. Increased nervous system activation, more efficient neuromuscular recruitment patterns, and a decrease in inhibitory reflexes allow the individual to produce greater levels of force.

The maximum force a muscle can exert is largely determined by its cross-sectional area. In addition to the neural adaptations, strength training stimulates an increase in muscle size. This hypertrophy occurs preferentially in fast twitch muscle fibers and is brought about by increased protein synthesis in response to resistance training. The degree to which muscle hypertrophy occurs is dependent on many factors, including gender and body type. Although some researchers have suggested that strength training may increase the number of muscle cells (hyperplasia), the results of these studies are far from conclusive.

Since both high-intensity and strength training rely largely on anaerobic processes for energy production, adaptative alterations in oxygen delivery and utilization, such as increased capillarization or mitochondrial mass of muscle cells, are relatively minor.

Metabolic In addition to the neuromuscular alterations that occur with high-intensity and strength training, several metabolic adaptations improve the ability of the muscle to resynthesize ATP from anaerobic sources. Intramuscular stores of the anaerobic energy intermediates, such as creatine phosphate (CP) and glycogen, increase after a period of supramaximal training. The activity of enzymes involved in anaerobic production of energy, such as creatine kinase and myokinase, is also increased.

Studies on the Role of Exercise/Fitness in the Etiology of Coronary Heart Disease

Coronary heart disease (CHD) has a multifactorial etiology, and major 'biological' risk factors include elevated concentrations of blood total and low-density lipoprotein (LDL) cholesterol, reduced concentration of high-density lipoprotein (HDL) cholesterol, high blood pressure, diabetes mellitus, and obesity. In addition, 'behavioral' risk factors for CHD include cigarette smoking, a poor diet, and low levels of physical activity and physical fitness associated with the modern, predominantly sedentary way of living. Among these risk factors, a sedentary lifestyle is by far the most prevalent according to data from both the United States and England (**Figure 1**).

Scientific verification of a link between an indolent lifestyle and CHD has been forthcoming during the past 40 years, with the publication of more than 100 large-scale epidemiological studies investigating the relationships between physical activity and cardiovascular health. These studies, some of which are summarized in **Figure 2**, have produced consistently compelling evidence that regular physical activity can protect against CHD.

Pooled data and meta-analyses of the 'better' studies indicate that the risk of death from CHD increases about twofold in individuals who are physically inactive compared with their more active counterparts. Relationships between aerobic fitness and CHD appear to be at least as strong. For example, in a cohort of middle-aged men followed up for an average of 6.2 years, the risk of dying was approximately double in those whose exercise capacity at baseline was <5 METS compared with those whose capacity was >8 METS. For both physical activity and fitness, adjustment for a wide range of other risk factors only slightly weakens these associations, suggesting independent relationships.

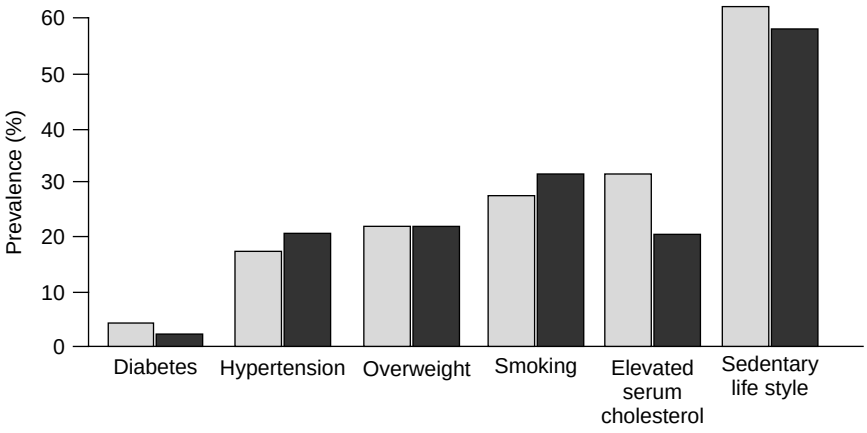

Figure 1 Estimates of the prevalence (%) of the U.S. population with selected risk factors for coronary heart disease and the population from England. In both studies, a sedentary lifestyle was taken as 'no physical activity' or irregular physical activity (i.e., fewer than three times per week and/or less than 20 minutes per session). (From Killoran AJ, Fentem P, and Caspersen C (eds.) (1994) *Moving On. International Perspectives on Promoting Physical Activity*. London: Health Education Authority, with permission.)

A common weakness of such studies is that they often rely on a single measurement of fitness or activity at baseline, with subsequent follow-up for mortality within the cohort. With such a design, it is difficult to discount the possibility that genetic or other confounding factors are influential in the observed relationship between physical activity/fitness and mortality. A further weakness in single baseline studies is that subsequent changes in activity/fitness during the follow-up are not monitored, even though they may affect the observed relationships due to the phenomenon of 'regression to the mean.'

Some prospective studies have overcome these deficiencies by examining the effects of *changes* in physical activity and fitness on mortality. One study reported on the relationship of changes in physical activity and other lifestyle characteristics to CHD mortality in 10 269 alumni of Harvard University. Changes in lifestyle over an 11- to 15-year period were evaluated on the basis of questionnaire

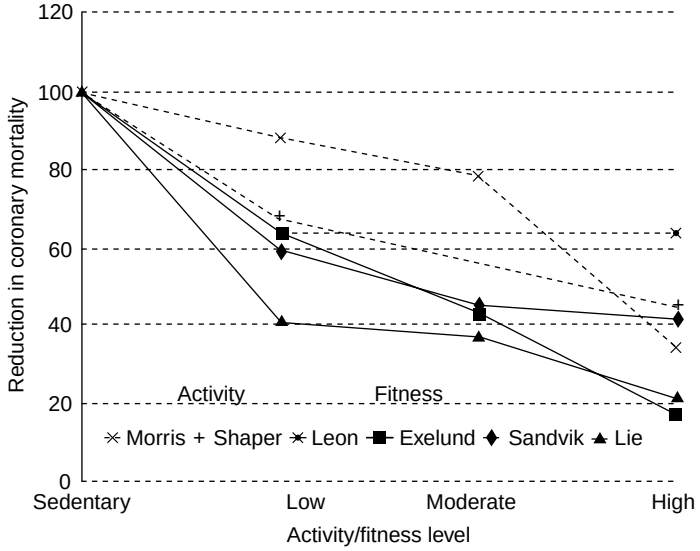

Figure 2 Summary of the results from six studies in which fitness level was determined (three studies) or activity level assessed by questionnaire (three studies) in individual populations. Follow-up was generally between 7 and 9 years except in Sandvik's study, which had a 16-year follow-up. The 'low level' group for each study represented in this figure was the activity/fitness level next to the least active/fit group. The 'high level' represents the group that was the most active/fit for the particular study. If the study participants were grouped by quintile, the 'moderate' group is the average of the third and fourth quintiles. (From Killoran AJ, Fentem P, and Caspersen C (eds.) (1994) *Moving On. International Perspectives on Promoting Physical Activity*. London: Health Education Authority, with permission.)

information, and subsequent mortality was assessed over an 8-year period. In men who were initially sedentary but started participating in moderately vigorous sports (intensity of 4.5 METS or greater), there was a 41% reduced risk of CHD compared to those who remained sedentary. This reduction was comparable to that experienced by men who stopped smoking. The second study examined changes in physical fitness and their effects on mortality. In this study of 9777 men, two clinical examinations (including treadmill tests of aerobic fitness) were administered approximately 5 years apart, with a mean follow-up of 5.1 years after the second examination to assess mortality. Results showed that men who improved their fitness (by moving out of the least fit quintile) reduced their aged-adjusted CHD mortality by 52% compared with their peers who remained unfit. Furthermore, such changes in fitness proved to be the most effective in reducing all-cause mortality when compared with changes in other health risk factors (**Figure 3**).

Mechanisms of Effect

Exercise appears to reduce the risk of CHD through both direct and indirect mechanisms. Regularly performed physical activity may reduce the vulnerability of the myocardium to fatal ventricular arrhythmia and reduce myocardial oxygen requirements. Aerobic training also increases coronary vascular transport capacity via structural adaptations and altered control of vascular resistance. Risk of thrombus formation may also be reduced with regular exercise through its effects on blood clotting and fibrinolytic mechanisms. Regular endurance exercise may also improve the serum lipid profile (particularly in favor of an enhanced HDL: total cholesterol ratio) and have beneficial effects on adipose tissue lipolysis and distribution. Regular exercise may also reduce postprandial lipemia, increase glucose transport into muscle cells, and improve the elasticity of arteries.

Exercise Prescription

For protection against CHD and other diseases associated with inactivty, exercise needs to be habitual, predominantly aerobic in nature, and current. Evidence from work carried out on British civil servants suggests that to be cardioprotective, exercise should be moderately vigorous ($\geq$7.5 kcal min^{-1} ($\geq$31.4 kJ min^{-1}) or 6 METS, equivalent to walking at approximately 3 miles per hour up a gradient of 1 in 20) and performed at least twice weekly. However, other studies have indicated that lower intensity activity is also effective as long as the total accumulated exercise energy expenditure is greater than approximately 2000 kcal week^{-1} ($\geq$8368 kJ week^{-1}).

Thus, recommendations from the U.S. Surgeon General suggest that everyone older than the age of 2 years should accumulate 30 minutes or more of at least moderate-intensity physical activity on most—preferably all—days of the week. Such activity may embrace everyday tasks such as stair climbing and walking, recreational physical activities, and more

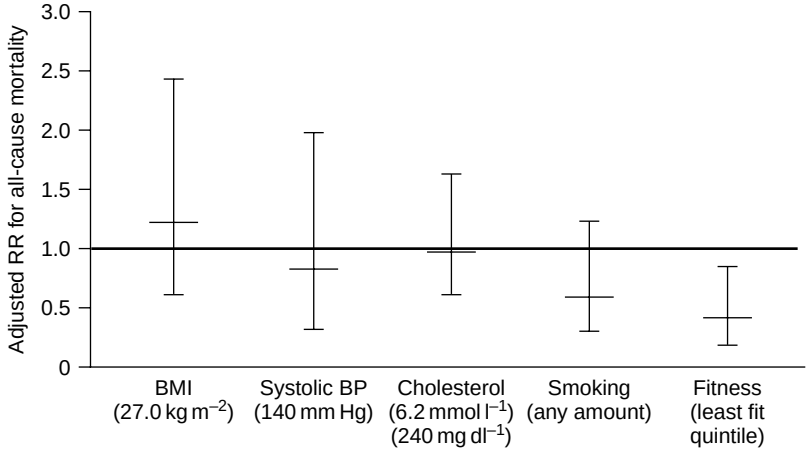

Figure 3 Relative risks (adjusted for age, family history of coronary heart disease, health status, baseline values, and changes for all variables in the figure, and interval in years between examinations) of all-cause mortality by favorable changes in risk factors between first and subsequent examinations. The analyses were for men at risk on each particular variable at the first examination. Cutoff points designating high risk are given parenthetically at the bottom of the figure. The number of men at high risk (and the number of deaths) for each characteristic were as follows: body mass index (BMI), 2691 (66); systolic blood pressure (BP), 1013 (55); cholesterol, 2212 (79); cigarette smoking, 1609 (45); and physical fitness, 1015 (56). (From Blair SN, Kohl HW, Barlow CE, Paffenbarger RS, Gibbons LW, and Macera CA, (1995) Changes in physical fitness and all-cause mortality. A prospective study of healthy and unhealthy men *JAMA*, **273**: 1093–1098, with permission.)

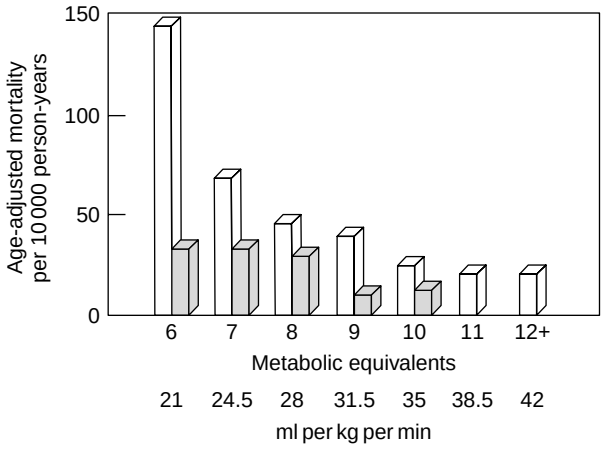

Figure 4 Age-adjusted, all-cause mortality rates per 10 000 person-years of follow-up by physical fitness categories in 3120 women and 10 224 men. Physical fitness categories are expressed as maximal metabolic equivalents (work metabolic rate/resting metabolic rate) achieved during the maximal treadmill exercise test. One metabolic equivalent equals 3.5 ml kg^{-1} min^{-1}. The estimated maximal oxygen uptake for each category is shown also. (From Blair SN *et al.* (1989) Physical fitness and all-cause mortality. A prospective study of healthy men and women. *Journal of the American Medical Association* **262**: 2395–2401, with permission.)

formal aerobic exercise programs and sports. Intermittent or shorter bouts of activity (of at least 10 minutes duration) may be accumulated throughout the day to confer similar benefits to single, continuous 30-minute bouts of exercise. A consistent finding is that previous exercise that has been abandoned confers no benefit.

Desirable aerobic fitness levels have also been described for women (maximal aerobic power of approximately 9 METs [32.5 ml kg^{-1} min^{-1}]) and men (10 METs [35 ml kg^{-1} min^{-1}]) (**Figure 4**).

Studies on the Role of Exercise/Fitness in the Etiology of Other Diseases

Obesity

Obesity is defined as an excess of adipose tissue. This condition plays a central role in the development of diabetes mellitus and confers an increased risk for CHD, high blood pressure, osteoarthritis, dyslipoproteinemia, various cancers, and all-cause mortality. The prevalence of obesity has risen dramatically in recent years, despite a decline in daily energy expenditure during the past two decades in the United Kingdom of approximately 800 kcal day^{-1} (3347 kJ day^{-1}).

Based on the principles of energy balance, such circumstantial evidence indicates that physical inactivity may play a central role in the development of obesity in humans. However, confirmatory data are scarce, particularly from well-designed prospective studies. One large-scale national study in the United States evaluated the relationship of physical activity to weight gain over a 10-year follow-up of 3515 men and 5810 women. Individuals who were sedentary at both baseline and follow-up were much more likely (relative risk, 2.3 (95% confidence interval (CI), 0.9–5.8) in men and 7.1 (95% CI, 2.2–23.3) in women) to experience considerable weight gain (>13 kg) than subjects who were active at both examinations. Evidence suggests that women who gain weight (≥6 kg) over a 1-year period expend on average 212 kcal/day less in light to moderate activities than those who maintain their normal body weight.

Difficulties are also encountered in interpreting results from intervention studies investigating the effects of exercise and/or diet on body weight, body composition, and resting metabolic rate (the latter being the single greatest component of total energy expenditure). Both energy intake and physical activity are notoriously difficult to quantify accurately, as is body fat status and distribution. Methodological differences between studies, a lack of control for possible confounding factors, and the fact that weight loss leads to an enhanced metabolic economy (due to reductions in RMR, energy cost of physical activity, and the TEF) further complicate matters. Nevertheless, exercise, particularly of the moderate-intensity type such as walking or cycling, probably helps to protect fat-free mass while promoting the loss of fat mass, but it does not appear to prevent the decline in RMR during weight loss. Similarly, long-term physical activity has minimal effects on RMR beyond its effect on lean body mass. Although studies have shown that exercise alone can reduce body weight, due to the lower total energy deficit, the rate and amount of weight loss are less than can be achieved through dieting alone.

Although the combination of exercise and dieting might be expected to improve weight loss, most data show only a modest increase (2 or 3 kg). When the total daily deficit is kept constant, diet, exercise, and diet plus exercise result in similar weight loss, but the inclusion of exercise generally results in greater fat loss and an increased lean tissue mass. There is evidence that the long-term maintenance of weight loss may require more regular activity (approximately double the current guidelines of 30 min/day) than that required to prevent weight gain in the first place. The ideal dietary and exercise prescriptions to control body weight in the long-term remain elusive.

Osteoporosis

Osteoporosis-related fractures represent a major public health concern. Once established, osteoporosis may be irreversible, emphasizing the need for primary prevention strategies based on minimizing bone loss and maximizing peak bone mass. Nearly half the variation in bone mineral density (BMD) may be attributable to nonhereditary factors. Behavioural factors of importance include diet (particularly calcium and vitamin D intakes), smoking, and the amount and type of habitual physical activity. These factors may be particularly influential during adolescence when (depending on the site) up to 90% of adult bone mineral content may be deposited, prior to the attainment of peak bone mass in the third decade of life.

Several studies on the relation of physical activity to BMD have been conducted, allowing a few general conclusions to be drawn. Clearly, bone responds positively to the mechanical stresses of exercise. Regular physical activity is likely to boost peak bone mass in young women, probably slows the decline in BMD in middle-aged and older women, and may increase BMD in patients with established osteoporosis. More research is required to clarify the type and amount of exercise that is most effective for enchancing peak bone mass. Evidence favors relatively high-impact, weight-bearing exercises (such as dancing, jumping, and volleyball), particularly during the peripubertal and adolescent years. It is unclear how physical activity and other intervention strategies, such as calcium supplementation and oestrogen replacement therapy, might interact to promote bone health.

In addition to its osteogenic effects, regular exercise may also promote better coordination, balance, and ambulatory muscle strength, thus minimising the risk of falling. The reported reduced risk of fracture (relative risk, 0.41 in men and 0.76 in women) in active individuals compared to sedentary ones is likely due to these combined direct and indirect effects of physical activity.

Cancer

In general, data relating to associations between physical activity and breast, endometrial, ovarian, prostate, and testicular cancers are inconclusive, although the suggestion that activity in adolescence and young adulthood may provide subsequent protection against breast cancer is worthy of further study. To date, the only clear evidence in this field comes from epidemiological studies relating a reduced risk of cancer of the colon to both occupational and leisure time physical activity. One such study investigated 17 148 Harvard alumni, who were assessed for physical activity at two time points, 10–15 years apart. Those who were highly active (exercise energy expenditure $\geq$2500 kcal (10 460 kJ) $\cdot$ week^{-1}) at both assessments displayed half the risk of developing colon cancer than those who were relatively inactive ($\leq$1000 kcal (4184 kJ) $\cdot$ week^{-1}). Interestingly, higher levels of physical activity at one (but not both) assessment were not associated with lower cancer risk, suggesting that consistently higher levels of activity may be necessary to provide a measure of protection. Possible biological mechanisms for this association include exercise-induced alteration of local prostaglandin synthesis (particularly prostaglandin F_2-alpha) and a decreased gastrointestinal transit time—the latter possibly decreasing the duration of contact between the colon mucosa and potential carcinogens.

Diet and Exercise

R J Maughan, Loughborough University, Loughborough, UK

Introduction

At an International Consensus Conference held at the offices of the International Olympic Committee in 1991, a small group of experts agreed a consensus statement that began by saying that "Diet significantly influences exercise performance." That is a bold and unambiguous statement, leaving little room for doubt. However, the statement went on to add various qualifications to this opening statement. These largely reflect the uncertainties in our current knowledge, but also reflect the many different issues that arise in considering the interactions between diet and exercise. Exercise may take many forms and may be undertaken for many different reasons: as the emphasis on physically demanding occupations has decreased in most parts of the world, so participation in recreational exercise and sport have increased. Even though physical activity programs have been heavily promoted in most developed countries, however, they rarely involve more than about 30% of the population, leaving a major part of the population who seldom or never engage in any form of strenuous activity.

In considering the interactions between diet and exercise, two main issues must be considered, each of which gives rise to many subordinate questions. The first question is how altered levels of physical activity influence the body's requirement for energy and nutrients: this then has implications for body composition (including the body content of fat, muscle, and bone), for the hormonal environment and the regulation of substrate metabolism, and for various disease states that are affected by body fatness, nutrient intake, and other related factors. The second question is how nutritional status influences the responses to and the performance of exercise. This has implications for those engaged in physically demanding occupations, and also for those who take part in sport on a recreational or competitive basis.

Influence of Physical Activity on Energy Balance

In the simple locomotor activities that involve walking, running, or cycling, the energy cost of activity is readily determined and can be shown to be a function of speed: where body mass is supported, as in running, or where it must be moved against gravity, as in cycling uphill, then body mass is also an important factor in determining the energy cost. For walking, running, and cycling at low speeds, there is a linear relationship between velocity and energy cost, if the energy cost is expressed relative to body mass. Across a range of speeds, the cost of locomotion is approximately $1\,kcal\,kg^{-1}km^{-1}$. Therefore, energy expenditure depends on the distance covered and the body mass and is not influenced by walking speed. In purposeful walking, where the aim is to get from one place to another, the distance is set, but where walking is part of a physical activity program, activity is more often measured by time rather than distance, so walking speed becomes an important factor in determining the energy cost. At higher speeds, the relationship between energy expenditure and speed becomes curvilinear and the energy cost increases disproportionately.

It is often recommended that 20–30 min of moderate intensity exercise three times per week is sufficient exercise to confer some protection against cardiovascular disease: if this exercise is in the form of jogging, aerobics, or similar activities, the energy expenditure will be about 4 MJ (1000 kcal) per week for the average 70-kg individual, or an average of only about $150\,kcal\,day^{-1}$ (**Table 1**). However, even a small daily contribution from exercise to total daily energy expenditure will have a cumulative effect on a long-term basis. For obese individuals, whose exercise capacity is low, the role of physical activity in raising energy expenditure is necessarily limited, but this effect is offset to some degree by the increased energy cost of weight-bearing activity.

Very high levels of daily energy expenditure are now rarely encountered in occupational tasks. The average daily metabolic rate of lumberjacks has

Table 1 Estimated average energy cost of physical activity, expressed as METS (multiples of BMR) and in kJ per kg body mass per h

Activity	*MET*	$kJ\,kg^{-1}\,h^{-1}$
Bicycling, leisure	4.0	17
Bicycling, racing $30\,km\,h^{-1}$, no drafting	16.0	67
Dancing, ballroom	3.0–5.5	13–23
Forestry, fast chopping with axe	17	71
Soccer, casual	7.0	29
Walking, slow	3.5	15
Walking, brisk uphill	5.0–7.0	21–29
Writing, desk work	1.8	7.5

been reported to be about four times the basal metabolic rate, and similar values have been reported for other very demanding occupations, suggesting that this may be close to the upper limit of physical exercise that can be sustained on a long-term basis. In the short term, sporting activities can involve much higher levels of energy output: the world record for distance run in 24 h is 286 km, which requires an energy expenditure of about 80 MJ (20 000 kcal). Such an effort, however, results in considerable depletion of the body's energy reserves, and must be followed by a period of recovery.

For athletes, very high levels of daily energy expenditure are more often a feature of training than of competition, with very high levels of energy intake reported in many sports. Measurements on runners in steady state with regard to training load and body mass show good relationships between energy intake and distance run. There are some competitive events that require high levels of activity to be sustained for many consecutive days, the most obvious examples being the multi-stage cycle tours, of which the most famous is the Tour de France. Measurements on some of the competitors have shown that they manage to maintain body weight in spite of a mean daily energy expenditure of 32 MJ (8000 kcal) sustained over a 3-week period. It was suggested that those cyclists who were unable to meet the daily energy requirement were unable to complete the race.

Measurements of oxygen uptake, heart rate, and other variables made after exercise show that the metabolic rate may remain elevated for at least 12 h and possibly up to 24 h if the exercise is prolonged and close to the maximum intensity that can be sustained. After more moderate exercise, the metabolic rate quickly returns to baseline level. Therefore, it seems likely that the athlete training at near to the maximum sustainable level, who already has a very high energy demand, will find this increased further by the elevation of postexercise metabolic rate: this will increase the difficulties that many of these athletes have in meeting their energy demand. The recreational exerciser, for whom the primary stimulus to exercise is often to control body mass or to reduce body fat content, will not benefit to any appreciable extent from this effect.

The control of food intake in relation to energy expenditure is not well understood, but it is clear that both short-term and long-term regulatory mechanisms exist. These allow the adult body weight to be maintained within fairly narrow limits in spite of wide variations in energy expenditure. It is also clear from the growing prevalence of obesity, that these control mechanisms are not perfect. The acute effects of exercise on appetite and energy intake are also unclear. A period of activity may result in a stimulation of the appetite, leading to an increase in the energy intake: the magnitude of the increased intake may exceed the total energy expenditure of the activity itself. There are, however, reports that exercise may lead to a suppression of appetite, and this is likely to be true especially of high-intensity exercise. A modest training program involving energy expenditure of 200 kcal three times per week has been reported to have no effect on energy intake. In the study of distance runners referred to above, there was a negative association between the training load (expressed as distance run per week) and body fat and a positive association between training load and energy intake: this led to a somewhat paradoxical negative association between energy intake and body fat content (**Figure 1**).

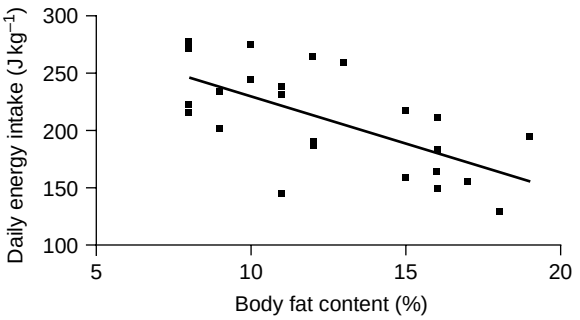

Figure 1 Association between daily energy intake and body fat content. (For further details see Maughan RJ and Piehl Aulin K (1997) Energy needs for physical activity. In: Simopoulos AP and Pavlou KN (eds.) *World Review of Nutrition*, vol. 82, pp. 18–32. Basel: Karger.)

Macronutrients and Physical Activity

Protein

The idea that protein requirements are increased by physical activity is intuitively attractive, and high-protein diets are a common feature of the diets of sportsmen and women. The available evidence does show an increased rate of oxidation of the carbon skeletons of amino acids during exercise, especially when carbohydrate availability is low. Protein contributes only about 5% of total energy demand in endurance exercise, but the absolute rate of protein breakdown is higher than at rest (where protein contributes about the same fraction as the protein content of the diet, i.e., typically about 12–16%) because of the higher energy turnover. Most recommendations suggest that individuals engaged in endurance activities on a daily basis should aim to achieve a protein intake of about

1.2–1.4 g kg^{-1} day^{-1}, whereas athletes engaged in strength and power training may need as much as 1.6–1.7 g kg^{-1} day^{-1}. In strength and power sports such as weightlifting, sprinting, and bodybuilding, the use of high-protein diets and protein supplements is especially prevalent, and daily intakes in excess of 4 g kg^{-1} are not unusual. Scientific support for such high intakes is generally lacking, but those involved in these sports are adamant that such high levels of intake are necessary, not only to increase muscle mass, but also to maintain muscle mass. This apparent inconsistency may be explained by Millward's adaptive metabolic demand model, which proposes that the body adapts to either high or low levels of intake, and that this adjustment to changes in intake occurs only very slowly.

Protein synthesis and degradation are both enhanced for some hours after exercise, and the net effect on muscle mass will depend on the relative magnitude and duration of these effects. Several recent studies have shown that ingestion of small amounts of protein (typically about 35–40 g) or essential amino acids (about 6 g) either before or immediately after exercise will result in net protein synthesis in the hours after exercise, whereas net negative protein balance is observed if no source of amino acids is consumed. These observations have led to recommendations that protein should be consumed immediately after exercise, but the control condition in most of these studies has involved a relatively prolonged (6–12 h) period of fasting, and this does not reflect normal behavior. Individuals who consume foods containing carbohydrate and proteins in the hour or two before exercise may not further increase protein synthesis if additional amino acids or proteins are ingested immediately before, during, or after exercise.

Various low-(40%) carbohydrate, high-(30%) fat, high-(30%) protein diets have been promoted for weight loss and athletic performance. Proposed mechanisms include reduced circulating insulin levels, increased fat catabolism, and altered prostaglandin metabolism. These diets can be effective in promoting short-term weight loss, primarily by restricting energy intake (to 1000–2000 kcal day^{-1}) and by restricting dietary choice. There is no evidence to support improvements in exercise performance, and what evidence there is does not support the concept.

Carbohydrate

Carbohydrate is stored in the body in the form of glycogen, primarily in the liver (about 70–100 g in the fed state) and in the skeletal muscles (about 300–500 g, depending on muscle mass and preceding diet). These stores are small relative to the rate of carbohydrate use during exercise. Fat and carbohydrate are the main fuels used for energy supply in exercise. In low-intensity exercise, most of the energy demand can be met by fat oxidation, but the contribution of carbohydrate, and especially of the muscle glycogen, increases as the energy demand increases. In high-intensity exercise, essentially all of the energy demand is met by carbohydrate metabolism, and carbohydrate oxidation rates of 3–4 g min^{-1} may be sustained for several hours by athletes in training or competition. When the glycogen content of the exercising muscles reaches very low levels, the work rate must be reduced to a level that can be accommodated by fat oxidation. Repeated short sprints will also place high demands on the muscle glycogen store, most of which can be converted to lactate within a few minutes.

Carbohydrate supplies about 45% of the energy in the typical Western diet: this amounts to about 200–300 g day^{-1} for the average sedentary individual, and is the amount that is necessary to get through normal daily activities. In an hour of hard exercise, up to 200 g of carbohydrate can be used, and sufficient carbohydrate must be supplied by the diet to replace the amount used. Replacement of the glycogen stores is an essential part of the recovery process after exercise; if the muscle glycogen content is not replaced, the quality of training must be reduced, and the risks of illness and injury are increased. Low muscle glycogen levels are associated with an increased secretion of cortisol during exercise, with consequent negative implications for immune function.

Replacement of carbohydrate should begin as soon as possible after exercise with carbohydrate foods that are convenient and appealing, and at least 50–100 g of carbohydrate should be consumed within the first 2 h of recovery. Thereafter, the diet should supply about 5–10 g of carbohydrate per kg body mass, including a mixture of different carbohydrate-rich foods. For athletes preparing for competition, a reduction in the training load and the consumption of a high carboydrate diet in the last few days are recommended: this will maximize the body's carbohydrate stores, and should ensure optimum performance, not only in endurance activities, but also in events involving short-duration high-intensity exercise and in field games involving multiple sprints.

The high-carbohydrate diet recommended for the physically active individual coincides with the recommendations of various expert committees that a healthy diet is one that is high in carbohydrate (at least 55% of energy) and low in fat (less than

30% of energy). However, where energy intake is either very high or very low, it may be inappropriate to express the carbohydrate requirement as a fraction of energy intake. With low total energy intakes, the fraction of carbohydrate in the diet must be high, but the endurance athlete with a very high energy intake may be able to tolerate a higher fat intake.

Fat

Fat is an important metabolic fuel in prolonged exercise, especially when the availability of carbohydrate is low. One of the primary adaptations to endurance training is an enhanced capacity to oxidize fat, thus sparing the body's limited carbohydrate stores. Studies where subjects have trained on high-fat diets, however, have shown that a high-carbohydrate diet during a period of training brings about greater improvements in performance, even when a high-carbohydrate diet is fed for a few days to allow normalization of the muscle glycogen stores before exercise performance is measured. It must be recognized, though, that these short-term training studies usually involve relatively untrained individuals and may not reflect the situation of the highly trained elite endurance athlete where the capacity of the muscle for oxidation of fatty acids will be much higher. For the athlete with very high levels of energy expenditure in training, the exercise intensity will inevitably be reduced to a level where fatty acid oxidation will make a significant contribution to energy supply and fat will provide an important energy source in the diet. Once the requirements for protein and carbohydrate are met, the balance of energy intake can be in the form of fat.

Micronutrients and Physical Activity

Many micronutrients play key roles in energy metabolism, and during strenuous physical activity the rate of energy turnover in skeletal muscle may be increased up to 20–100 times the resting rate. Although an adequate vitamin and mineral status is essential for normal health, marginal deficiency states may only be apparent when the metabolic rate is high. Prolonged strenuous exercise performed on a regular basis may also result in increased losses from the body or in an increased rate of turnover, resulting in the need for an increased dietary intake. An increased food intake to meet energy requirements will increase dietary micronutrient intake, but individuals who are very active may need to pay particular attention to their intake of iron and calcium.

Iron deficiency anemia affects some athletes engaged in intensive training and competition, but it seems that the prevalence is the same in athletic and sedentary populations, suggesting that exercise *per se* does not increase the risk. The implications of even mild anemia for exercise performance are, however, significant. A fall in the circulating hemoglobin concentration is associated with a reduction in oxygen-carrying capacity and a decreased exercise performance. Low serum ferritin levels are not associated with impaired performance, however, and iron supplementation in the absence of frank anemia does not influence indices of fitness.

Osteoporosis is now widely recognized as a problem for both men and, more especially, women, and an increased bone mineral content is one of the benefits of participation in an exercise program. Regular exercise results in increased mineralization of those bones subjected to stress and an increased peak bone mass may delay the onset of osteoporotic fractures; exercise may also delay the rate of bone loss. Estrogen plays an important role in the maintenance of bone mass in women, and prolonged strenuous activity may result in low estrogen levels, causing bone loss. Many very active women also have a low body fat content and may also have low energy (and calcium) intakes in spite of their high activity levels. All of these factors are a threat to bone health. The loss of bone in these women may result in an increased predisposition to stress fractures and other skeletal injury and must also raise concerns about bone health in later life. It should be emphasized, however, that this condition appears to affect only relatively few athletes, and that physical activity is generally beneficial for the skeleton.

Water and Electrolyte Balance

Few situations represent such a challenge to the body's homeostatic mechanisms as that posed by prolonged strenuous exercise in a warm environment. Only about 20–25% of the energy available from substrate catabolism is used to perform external work, with the remainder appearing as heat. At rest, the metabolic rate is low: oxygen consumption is about $250\,\mathrm{ml\,min^{-1}}$, corresponding to a rate of heat production of about 60 W. Heat production increases in proportion to metabolic demand, and reaches about 1 kW in strenuous activities such as marathon running (for a 70-kg runner at a speed that takes about $2\frac{1}{2}$ h to complete the race). To prevent a catastrophic rise in core temperature, heat loss must be increased correspondingly and this is achieved primarily by an increased rate of evaporation of sweat from the skin surface. In hard exercise in hot conditions, sweat rates can reach $3\,\mathrm{l\,h^{-1}}$, and trained athletes can sustain sweat rates

in excess of $2\,l\,h^{-1}$ for many hours. This represents a much higher fractional turnover rate of water than that of most other body components. In the sedentary individual living in a temperate climate, about 5–10% of total body water may be lost and replaced on a daily basis. When prolonged exercise is performed in a hot environment, 20–40% of total body water can be turned over in a single day. In spite of this, the body water content is tightly regulated, and regulation by the kidneys is closely related to osmotic balance.

Along with water, a variety of minerals and organic components are lost in variable amounts in sweat. Sweat is often described as an ultrafiltrate of plasma, but it is invariably hypotonic. The main electrolytes lost are sodium and chloride, at concentrations of about 20–70 $mmol\,l^{-1}$, but a range of other minerals, including potassium and magnesium, are also lost, as well as trace elements in small amounts. When sweat losses are high, there can be a substantial electrolyte loss, and intake must increase accordingly.

Failure to maintain hydration status has serious consequences for the active individual. A body water deficit of as little as 1% of total body mass can result in a significant reduction in exercise capacity. Endurance exercise is affected to a greater extent than high-intensity exercise, and muscle strength is not adversely affected until water losses reach 5% or more of body mass. Hypohydration greatly increases the risk of heat illness, and also abolishes the protection conferred by prior heat acclimation.

Many studies have shown that the ingestion of fluid during exercise can significantly improve performance. Adding an energy source in the form of carbohydrate confers an additional benefit by providing an energy source for the working muscles. Addition of small amounts (perhaps about 2–8%) of carbohydrate, in the form of glucose, sucrose, or maltodextrin, will promote water absorption in the small intestine as well as providing exogenous substrate that can spare stored carbohydrate. The addition of too much carbohydrate will slow gastric emptying and, if the solution is strongly hypertonic, may promote secretion of water into the intestinal lumen, thus delaying fluid availability. Voluntary fluid intake is seldom sufficient to match sweat losses, and a conscious effort to drink is normally required if dehydration is to be avoided. Palatability of fluids is therefore an important consideration. If exercise is prolonged and sweat losses high, the addition of sodium to drinks may be necessary to prevent the development of hyponatremia. Ingestion of large volumes of plain water is also likely to limit intake because of a fall in plasma osmolality leading to suppression of thirst.

Replacement of water and electrolyte losses incurred during exercise is an important part of the recovery process in the postexercise period. This requires ingestion of fluid in excess of the volume of sweat lost to allow for ongoing water losses from the body. If food containing electrolytes is not consumed at this time, electrolytes, especially sodium, must be added to drinks to prevent diuresis and loss of the ingested fluid.

Dietary Supplementation for Active Individuals

The use of nutritional supplements in athletes and in the health-conscious recreationally active population is widespread, as it is in the general population. A very large number of surveys have been published. A meta-analysis of 51 published surveys involving 10 274 male and female athletes of varying levels of ability showed an overall prevalence of supplement use of 46%, but the prevalence varies widely in different sports, at different levels of age, performance etc., and in different cultural backgrounds.

A wide variety of supplements are used with the aim of improving or maintaining general health and exercise performance. In particular, supplement use is often aimed at promoting tissue growth and repair, promoting fat loss, enhancing resistance to fatigue, and simulating immune function. Most of these supplements have not been well researched, and anyone seeking to improve health or performance would be better advised to ensure that they consume a sound diet that meets energy needs and contains a variety of foods.

Famines in History

Famine has afflicted humankind, shaping its demography and history from antiquity. Records of famine in ancient Egypt during the third millennium BC are depicted in bas-relief on the Causeway of the Pyramid of Unas in Saqqura. Biblical accounts of a famine resulting from drought in Egypt during the second millennium BC (Middle Kingdom) that stretched to Mesopotamia describe the devastation wrought on the land and society and the means by which Joseph predicted and managed its consequences. The fall of the Roman Empire followed repeated food shortages and famines from 500 BC to 500 AD. China experienced some 1828 famines, nearly one per year, from 108 BC to 1911 AD. The ranks of the Crusades in the eleventh and twelfth centuries swelled in response to promise of food. The storming of the Bastille and French Revolution followed decades of periodic rises in flour and bread prices that had caused widespread hunger and hardship, and hundreds of 'food riots.'

Recurrent famine motivated the settling of the New World. The Great Irish Famine in the late 1840s caused one and a half million deaths and an equal number of migrations, mostly to America. Decades of Russian famines following crop failures in the late nineteenth century resulted in waves of immigration to the US. Repeated famines led to the overthrow of Czarist Russia that ushered in the Bolshevik Revolution in the early twentieth century. Using food deprivation to wage class warfare and crush the Cossack revolution in the 1930s, Stalinist policies led to the starvation and death of 3.5 million Ukrainians. In China, multiple famines throughout the nineteenth century reportedly led to over 50 million deaths, and these continued throughout the first half of the twentieth century. Maoist communism rose to power in the 1940s understandably amidst promises of land reform and freedom from chronic hunger and periodic famine. However, collectivization of private farms and irrational rural industrialization schemes coupled with monopolistic control of food grain movement, purchase and access, abusive taxation, and repressive policies against the peasantry left China mostly food insecure throughout the 1950s and primed for what has turned out to be the worst single famine in human history (1959–60). During this period an estimated 30 million people perished, in absence of worldview and reaction, following the secretive, cultist policy failures of Mao's 'Great Leap Forward.' Famine was notorious on the Indian subcontinent throughout the mid-twentieth century, with the two final famines both occurring in Bengal in 1943, towards the end of British rule and again in Bangladesh (formerly East Bengal) in 1974–75. An India free from overt famine over the past half-century, despite continuing chronic undernutrition, has been attributed, in part, to the country's economic rise, relative peace, and democratic and popular processes that have included political accountability and a flourishing free press; lessons that still remain to be learnt by some modern states. In North Korea, for example, the effects of repeated floods in the late 1990s that ruined crops, combined with isolation, a collapsed centralized economy, and politicization and diversion of already insufficient international food aid from those most in need led to famine of devastating proportion.

In the late twentieth century famines have inflicted heavy loss of life in Africa, especially in the Greater Horn (i.e., Ethiopia, the Sudan, and Somalia). At least one modern regime's demise, that of Emperor Haile Selassie in 1974, followed famine. Famines of seemingly increased complexity

in Africa have resulted from deteriorating crop production associated with steady rainfall decline, failures in development and commerce, repressive and corrupt governance, and armed conflict leading, at times, to outright anarchy. Tragically, famines over the past 30 years have occurred at a time in human history when general understanding of causes and consequences of famine, and a global ability to monitor antecedents and intervene to avert mass starvation, disease, and death have never been greater. Yet, with conflict, especially internal civil war, rising as the decisive and yet unpredictable trigger of modern famine, stable governance with democratic processes (e.g., free press, people's participation, fair trade, etc.) is increasingly recognized to be one of the most important means for its prevention. History has increased awareness and understanding of the need for a stable, peaceful, and equitable political economy to guide the developing world away from famine in the twenty-first century.

Definition of Famine

Definitions of famine vary but all contain the necessary elements of widespread inaccessibility to food leading to mass numbers of starved individuals. Importantly, lack of access is not equivalent to nonavailability of food within a region, as most famines occur amidst food stocks sufficient to feed the afflicted population. More comprehensive definitions of famine may include elements of time dependency (e.g., steady, continuous erosion of or sudden collapse in food available for consumption), partial causation (e.g., due to natural calamity, armed conflict, or convergence of other complex causal events), class (e.g., affecting certain ethnic, geographic, economic or occupational groups more than others), and health consequence on a population scale (e.g., accompanied by epidemics of disease and high mortality) or other population responses (e.g., mass migration). While poverty-stricken communities tend to view famine as a continuum of increasing loss and oppression that typically begins long before mass casualty, formal 'external' definitions tend to invoke thresholds or shocks involving sudden inflections in trends for events that afflict large numbers of people. These may include spikes in prices of staple grains, levels of violence, destitution, mortality from starvation and infectious disease, and migratory movement. Threshold events tend to distinguish famine, which upon declaration demands a massive relief response, from endemic, chronic food deprivation, which results from extreme poverty, political corruption, developmental neglect and food insecurity and which leads to chronic, high rates of malnutrition, disease, and mortality. Yet, these factors are ones that, often when acting together, predispose underserved populations of the developing world to risk of famine. Such conditioning factors are antecedent causal elements that require more continuous, sensitive, and specific indicators to detect as well as a set of longer term economic, political, and developmental solutions to prevent. Whether continuous and evolving or more sudden, unleashed famine – where thresholds have been transgressed by masses of people – is catastrophic, distinct, and a human tragedy of unparaleled proportion.

Causes of Famine

> Starvation is a matter of some people not having enough food to eat, and not a matter of there being not enough food to eat.
>
> Amartya Sen

Large numbers of people starve during famine, which is usually followed by epidemics of lethal infectious diseases. Typically, a plethora of forces or conditions act within society to deprive people of food to survive. General food decline in a population may be an important factor, but it is neither necessary nor sufficient as a cause, as amply revealed by critical treatises of numerous famines over the past two centuries. This has led analysts to recognize that famines are complex, often with many ('component') causes that vary in their attribution, depending on the classes of society affected, and their timing, severity, duration, and degree of interaction. The constellation of causes and potential solutions of famine can be examined from ecological, economic, social, and public health perspectives, each offering different insights into the ecology of famine. While each view is valid and informative, none are complete or mutually exclusive, making it necessary to integrate these diverse perspectives to understand the complexity of famine and approaches to its prevention. In offering an epidemiologic overview, there appear to be at least three dominant causes of famine that have emerged during the nineteenth and twentieth centuries that appear particularly relevant to understanding modern famine causation (**Figure 1**): (1) market failure; (2) armed conflict; and (3) failure in central planning. Importantly, none are sole-acting causes and, therefore, for each one there are other antecedent factors, sometimes operative for years before, as well as concurrent and late-acting components that together lead to famine.

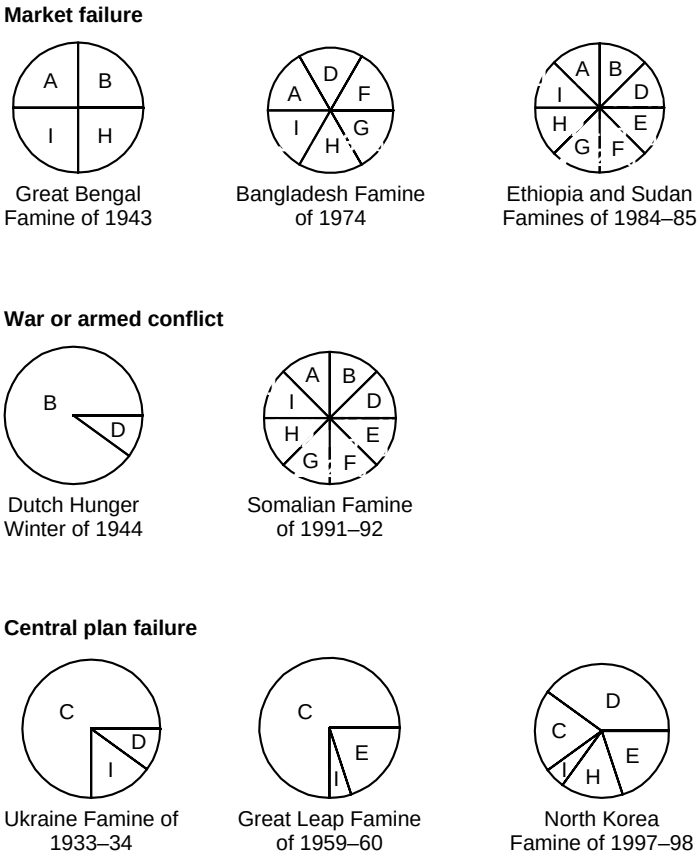

Figure 1 Complex causal networks of selected modern famines, stratified by a dominant cause. Each pie illustrates a complete cause; each wedge illustrates an assumed, essential component cause, without any one of which famine would not occur. Inclusion of causes based on literature reviews; sizes of pie slices are subjective based on descriptions in the literature (causal concepts adapted from Rothman and Greenland, 1998). A: market failure – loss of direct or trade entitlement through a combination of: (1) increased food prices due to food shortage from decreased agricultural production or importation, hoarding and speculation, or other market forces leading to unfavorable terms of exchange; plus (2) loss of means to command food through cash, labor, credit, and other assets (endowment) by vulnerable groups of society. B: war or armed conflict – declared or internal; through siege, blockade, or other expression of force, during a time course leading up to and concurrent with famine. C: central plan failure – occurring within centrally planned states lacking democratic processes, notably in twentieth century communist states; directives that disrupt infrastructure, productivity, and economic well-being, and access to food through heavy taxation, extraction of food grains, livestock and other productive assets and terror, or restrict movement of food stocks outside free-market dynamics, leading to starvation of the masses. D: natural disaster – climatological and environmental catastrophes including floods, or single, repeated or chronic droughts. E: food availability decline – food shortage resulting from poor crop production, lack of trade, poor food transport, storage and marketing sytems. F: weak infrastructure – inadequate systems of finance, credit, roads, communications, agricultural production including irrigation or flood protection systems. G: poor/unstable governance – weak and ineffective forms of governance, including anarchy. H: inadequate aid response/administrative mismanagement – inadequate national or international counter-famine measures, including employment or food procurement policies as well as withheld, slow, ineffectual, or insufficient relief. I: other causes – a catch-all 'causal complement' to those listed above, of interacting prefamine and intrafamine sociological, governmental, environmental, and market forces that render each famine unique.

Market Failure

Market failure famines occur when free, competitive market forces, driven by agriculture, transportation, communication and trade, and enabled by an abiding government fail to assure minimal entitlement to food, either directly (through subsistence) or via trade for a large sector of society. Following Amartya Sen, entitlement failure is an economic phenomenon, broadly defined, in which individuals and households are unable to obtain sufficient amounts of food through all available legal means (cash, labor, skills, credit, and other assets that comprise 'endowment') at the market's existing terms of exchange (costs of securing sufficient amounts of food). Combinations of loss of endowment and adverse shifts in the conditions of exchange (e.g., spikes in grain prices) can lead to certain classes of society being severely deprived of food. Component causes that lead to market failure-driven famine are complex, interacting over an extended time

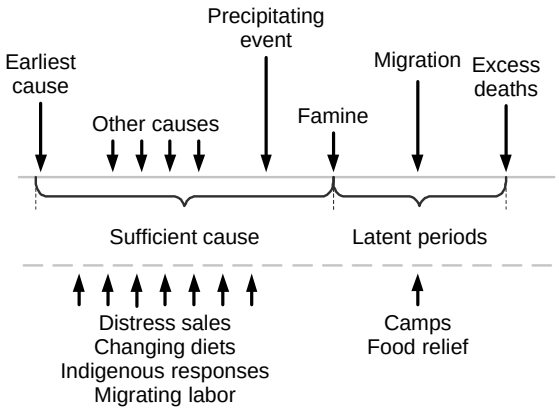

Figure 2 A model depicting actions of individual, or component, causes that can lead to a sufficient cause of famine, and societal, indigenous responses to famine predominantly caused by market failure. Famine may be latent or delayed from external view until migrations or excess deaths occur. Government relief is typically a late response to famine.

(**Figure 2**). Causes acting at various times in the pathway to market failure can be numerous, including long- and short-term adversity in climate leading to drought and excessive floods, pestilence and other causes of lost crop yield, reduced food imports or inefficient transport and marketing infrastructures. These all can lead to a national or, more often, regional declines in food availability, inflationary grain market responses to speculation and hoarding, other aspects of infrastructural neglect, ineffectual trade policies, political instability and corrupt governance, market depressions with year-round or seasonal job losses, and depletion of assets of the poor (endowment). Prior or present conflict can destabilize markets and contribute to such types of famine. Famines that can be classified as those primarily of market failure include the Great Irish Famine from 1844 to 1848, the Great Bengal Famine of 1943, the Bangladesh famine of 1974, and the Sudan famine of 1984–85. The Great Irish Famine was triggered by a potato blight that stripped the country of the only staple that Irish peasantry could afford to grow on their small parcels of land. Peasants who grew other staple grains had to sell them to pay rent to landlords. However, during these same years, there were substantial exports of wheat, barley, oats, and animal products by landowners to English markets. Food did not enter the local Irish markets because the peasants lacked effective demand.

Market or entitlement failures marked the last two great Bengal famines of the twentieth century: The Great Bengal Famine of 1943 and the Bangladesh Famine of 1974–75 (**Figure 1**). The 1943 famine, during which some 3 million people are estimated to have died, was originally judged by a Famine Inquiry Commission to be due to a shortage in rice supply. However, a seminal in-depth analysis years later by Sen showed that the famine occurred in a year during which rice production in Bengal was only 5% lower than the average of the previous 5 years. It was also a year when most economic indicators of Bengal were showing a 'boom' in growth due to World War II. Rural food stocks were being procured by the government to support military needs, subsidize rations for civil servants, and stabilize general prices of rice in Calcutta, which drove up the price of rice in rural areas. This practice, coupled with 'boat blockade' and 'rice denial' policies imposed in regions along the Bay of Bengal for reasons of defense, left certain low wage-earning rural classes (agricultural workers, day laborers, artisans, and fishermen) disentitled, and unable to acquire enough food for their own survival.

In Bangladesh, at least 100 000 people died between 1974 and 1975 in a famine that followed an unusually severe flood. During the several years leading up to the famine there were events that brought the country to a highly vulnerable state, including a devastating cyclone and tidal wave, a civil war that led to the country's independence, and a series of partial crop failures, all superimposed on preexisting high burdens of malnutrition, disease, underdevelopment, and ensuing political chaos. The flood in the middle of 1974 was expected to destroy much of the major 'aman' rice to be harvested a few months later. In anticipation of impending rice shortage, rural traders began to hoard grains in early September of that year causing rice prices to spike across the country's rural markets in a contagious pattern (**Figure 3**). Rice prices remained at about twice their normal level for months thereafter, even after it became evident that the speculated poor rice harvest was, in fact, a normal one. Thus, total and per capita aggregate grain supplies in Bangladesh remained at about average levels throughout the famine. Local area food deficits and hoarding of grains by traders led to the observed points of inflection in the price of rice throughout the country that caused the entitlements of rural wage earners to collapse, initiating a famine that resulted in extremely high mortality and massive migrations to urban centers in search of relief.

The Horn of Africa has been wracked by famine or famine-like conditions, leading to what have become classically defined as 'complex emergencies' for much of the past three decades. Aggregate food shortage has appeared to play a more variable and, at times, prominent role in recent famines in the eastern Horn. In Ethiopia, Sudan, Eritrea, and Somalia large tracts of land are drought-prone, average annual rainfall has been declining since the

Figure 3 Consecutive weekly maps of a contagious spread of spikes in the price of rice in local markets throughout rural Bangladesh from (A) late August 1974 through to (H) the end of October 1974 during a flood-associated period of a famine that reportedly killed from 100 000 to 1 million persons. (Adapted from Seaman J and Holt J (1980) Markets and famines in the third world. *Disasters* **4**(3): 283–297.)

1930s, and robust, indigenous farming and animal husbandry practices have been weakened as agricultural land has increasingly been used for growing export crops. In the Ethiopian famine of 1972–75, in which over 100 000 people died, national crop production dropped to only ~7% below normal levels, a decline that, like in Bengal in 1943 and 1974, would not have been expected to trigger a famine. However, crop production had been severely below normal in Wollo Province, where the famine began. Although the famine subsequently spread to other areas of the country, a reluctance by the government to formally recognize the famine and excessive delays in mobilizing and targeting food aid within country (whether from national or international stocks) were deemed responsible for unleashing a famine that, based on national stocks, should have been averted. Famines during 1982–85 in Ethiopia and the Sudan appeared to be more closely tied to gradual declines in national food security during the preceding decade. These trends were exacerbated by repressive governments enacting targeted, famine-promotive rather than preventive policies, resulting in civil wars and severely deteriorating economic conditions that were compounded by weak international food aid responses.

Armed Conflict

A second major class of famine comprises those precipitated or triggered by declared war or armed insurgency, leading to a siege or food blockade by a foreign power (e.g., Allied blockade of Germany in 1915–18; Nazi blockade of Holland precipitating the Dutch Winter Famine of 1944–45, and the Nazi siege of Lenningrad in 1942–44) or, as occurring more in recent years, severe civil war that disrupts normal markets as well as emergency food delivery systems (e.g., the Somalian civil war and famine of 1991–92). Armed conflict can incapacitate or destroy a country's ability to govern, develop, produce and feed itself domestically or through food aid, as scores of people become displaced, destitute, starve and die from severe malnutrition and epidemic illness. The

famine in Somalia in the early 1990s exemplifies the rapid emergence of military conflict as a precipitating cause of famine. With significant transfers of weaponry to rogue vigilante groups and increased deployments of land mines in other poor, warring countries in recent years, civil violence and lawlessness also pose a major hindrance to the effective provision of short-term relief during the acute phase of famine and to subsequent economic recovery.

Failure in Central Planning

A third class of modern famine, distinct from the other two, has resulted from failure by intent, indifference, ignorance, or incompetence of a centrally planned state to adequately provide food to all sectors of society, often as a result of totalitarian action to advance political goals outside of the rules of free trade or popular processes. Examples of this third type of famine in the twentieth century include those induced by the notorious policies of Stalin in Soviet Russia in the 1920s and 1930s. In an effort to achieve rapid industrial growth, Stalin waged class warfare among rural peasantry, abolished economic incentives, collectivized farms into massive (inefficient) production units and merged villages into socialist agro-towns, seized and exported grain for foreign exchange to fuel industrialization, restricted population movements across municipalities, and brutally suppressed all opposition. Agricultural production plummeted across regions of Russia leading to disastrous shortages (e.g., by 40% in some areas), further intensifying state seizures of food grain, especially in the grain-belt region of the Ukraine where Stalin sought to crush a nationalist revolt by forcibly extracting available food grains from the population. The actions induced the worst famine in Russian history. Between 1930 and 1937 it was estimated that nearly 15 million peasants died, of whom 7–8 million died in the Ukraine in 1933–34.

Under communist rule imposed by Mao Zedong, in 1959–60 China experienced the worst recorded famine in human history that left an estimated 30 million people dead. The Great Leap Famine was provoked through a causal chain of centrally planned policy steps during the preceding decade, modeled after Stalin and motivated by ill-conceived goals to 'Leap forward' MAO's aims were to achieve agricultural sufficiency and superiority through massive agricultural collectivization and the formation of huge peasant communes, and rapid rural industrialization through crash programs to increase steel production. The plight of tens of millions of rural peasants was tightly controlled by the state through brutal force, terror, propaganda, and state control of grain production, procurement and taxation motivated by a blind faith among civil servants in the vision and leadership of Mao. As a result of fabricated inflation of grain production figures, driven by a zeal to demonstrate success, China became a net exporter of more than a million metric tons of grain during the peak of famine mortality in the countryside in 1960, mimicking Stalinist Russia. Thus, in addition to events immediately leading to famine, some component causes contributing to the centrally planned Great Leap Famine can be traced back through the previous one to three decades and to influences beyond the borders of China.

Communist North Korea's inability to avert famine in 1997–98 amounts to the most recent example of a central planning failure, conditioned by chronic food insecurity over the previous decade and precipitated by poorly timed, torrential rains and floods in 1995–96 and drought in 1997. However, some causal elements related to how slowly and secretively the isolationist government responded, actions of governance that date back to the Korean War and Cold War politics, and politicization of food aid.

Coping Strategies

Most is known about household and community coping mechanisms in response to famines due to market failure. In cultures where food shortage or inaccessibility to large sectors of society is chronic, and threat of famine periodic, there exist indigenous responses that enable the local populace to cope, protect their entitlement, and minimize as best it can the risk of starvation as terms of exchange for food deteriorate (illustrated as a concept in **Figure 4**).

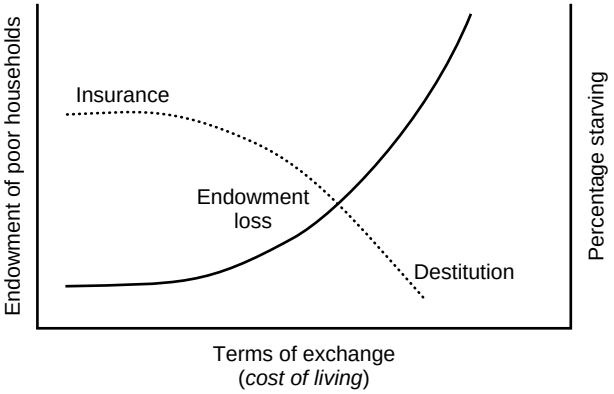

Figure 4 Illustration of collapse in entitlement. As endowment of the poor decreases toward a state of destitution with increasingly severe (costly) terms of exchange for food, the risk of starvation and famine increases.

A first line of responses may be viewed as 'insurance' against uncertainty; these are activities that can stem loss of endowment, such as restructuring the mix of crops grown or pastoral practices in ways that insulate against drought- or flood-induced shortages. Examples include planting more robust crops, dispersing crops across a wider area, staggering plantings, or increasing livestock diversity and mobility. Food preservation practices and dietary changes to include less commonly eaten foods can initially increase the size and diversity of the food base. As terms of exchange become worse, coping mechanisms aimed at survival increasingly cost households their endowment. These responses include working longer and at different jobs for lower wages, migrating far from home to find marginal work, reducing meal frequency, consuming the next planting's seeds, and expanding intake to include 'famine foods' poor in, or lacking, nutritional quality. At first these may include unusual tubers, leaves, flowers, and other plants. Household assets such as pots, utensils, watches, and small animals are increasingly sold as, eventually, are larger assets such as bullock carts, bicycles, and draft animals. Land mortgage or sales transactions become more numerous. With indebtedness and destitution, petty crime and child abandonment increase; famine foods may include tree bark, ground bone, and rodents; suicide and cannablism may occur. An indicator of severe entitlement loss in a community is the livestock-to-grain price ratio in local markets. Normally this ratio is of a figure that reflects the greater asset value of livestock compared to grain. However, it may invert as the cost of grain and feeding animals and the level of animal wasting all continue to rise, such that, at a peak of famine vulnerability, large numbers of animals may be sold at very low prices relative to the costs of grain.

Viewed over time, famine is a continuum. As household and community entitlements erode for increasing numbers due both to deteriorating conditions of exchange and endowment loss, destitution and starvation become more likely. **Figure 5** depicts a hypothetical shift in distribution of starving individuals in a poor population exposed to increasing risk of famine, where under usual conditions a small proportion of individuals routinely face the threat of starvation and wasting malnutrition (top panel). During periods of high or repeated stress, such as those of prolonged drought and internal conflict, while the population faces less food security coping mechanisms continue to protect most vulnerable groups from abject starvation, even as they near such a 'threshold' amidst inevitable losses of human and economic asset (middle panel). During severe distress of famine, entitlement has collapsed for the most vulnerable classes of society, pushing large numbers of persons into a state of starvation, leaving them destitute and migrating or dying (bottom panel). However, not all individuals starve. Some segments of society lose little or no economic ground, or benefit considerably from the plight of others by acquiring property and other assets at low prices, obtain labor at reduced wages or lend money at high interest rates. Still other segments, particularly those trading in famine relief goods and services, stand to gain large profits throughout the famine and recovery periods (depicted by the right skew). Postfamine, the economic landscape is nearly always one of greater polarization of wealth and an increase in size and vulnerability of society's poor and destitute. Peri-urban slums typically remain swollen following famine as a result of permanent migration.

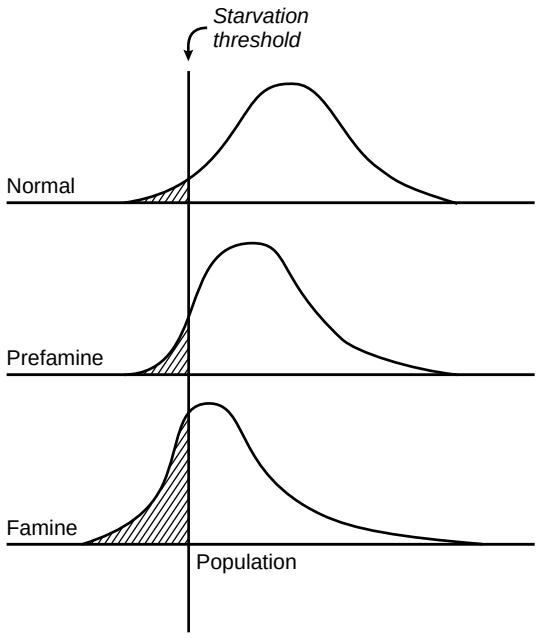

Figure 5 Shifting of a high-risk, undernourished population toward increased starvation during prefamine and famine conditions, particularly those most vulnerable. Truncated left tail area reflects hypothetical effects of coping strategies that prevent starvation. Right skew reflects polarizing of wealth, with some sectors profiting from famine.

Government and International Responses

Famine through the ages has invoked from law abiding governments preventive action, where believed indicated, and relief responses in the face of imminent catastrophe. In Genesis, Pharoah's grain taxes during years of plenty were aimed at relieving dwindling food stores in famine. During China's

Eastern Chou and Ch'in dynasties of the third century BC, as well as in India over 2000 years ago, steps formulated to prevent or relieve famine included disaster reporting procedures, cropping alterations, grain distribution, feeding kitchens, tax remissions, vulnerable group relocation, and public works construction to facilitate irrigation, food shipment or flood control. In sixteenth century England, to counter inflationary effects of speculative grain hoarding, the Tudor First Book of Orders called for enforced extraction and marketing of private grain stocks as a way to control staple prices and thwart famine. Policy response can also amount to inaction. The Great Irish Famine from 1844 to 1848 evoked a different response from the British Government: a flawed 'laissez-faire' policy intending to allow market forces to equilibrate on their own to meet local food needs, a course that never materialized as entitlement collapsed among Irish peasantry. However, learning from a century of repeated famine, Famine Codes emerged in British India in 1880 that called for massive public works coupled with food distribution and feeding centers for vulnerable groups, which served as the core famine relief policy on the subcontinent for more than a half century and have continued to guide famine relief efforts to the present day.

Today, modern preventive response by international agencies and governments can be informed and guided by surveillance systems with regional, national, and local data collection mechanisms. Examples are the Famine Early Warning System (FEWS), which functions across Sub-Saharan Africa and has been supported by the US Agency for International Development over the past two decades and the Global Information Early Warning System (GIEWS) managed by the Food and Agricultural Organization of the United Nations (FAO). The primary aim of surveillance is to detect worsening conditions in high-risk populations in sufficient time to permit effective preventive or pre-emptive action. The task is a 'tall order' given widespread, often complex, component causes that must converge in certain ways to cause famine, against a usual plethora of endemic risk factors. With early, adequate, and effective response serving as the criterion of success, modern surveillance has so far failed to prevent famine. In part, this may reveal a basic epidemiologic dilemma: Against a background of profound, widespread economic and nutritional need throughout the developing world, including numerous prefamine but intact situations arising under surveillance, famine is a rare event. Even with presumed high sensitivity and specificity, low predictive value stemming from infrequent occurrence makes action to prevent a particular famine unlikely given the enormous political and financial resources required to mount preventive responses.

Thus, the most effective preventive action relates to setting and enacting a development agenda that recognizes high risk areas and seeks to strengthen the productivity and well-being of famine-vulnerable population groups in those areas of a country. These can include boosting infrastructural, commercial, education, agricultural, and other inputs into priority areas that improve long-term economic conditions.

Preemptive government policies are directed toward relieving a prefamine condition once it becomes apparent. Setting up famine early warning systems that monitor climatic, agricultural, population mobility, economic, and nutritional indicators is considered preemptive in that such information is intended to identify high-risk trends so that corrective action could be taken long before famine becomes imminent. Normally, early warning surveillance is only possible in high-risk countries with significant international assistance. Another example is a government making large purchases of food on the international market and releasing the commodities through ration shops, food-for-work and other programs that do not disrupt the local food economy but stabilize local grain market prices instead as a means to prevent speculation throughout the period of high risk.

Lagged or relief-oriented responses comprise emergency responses to acute and enormous need that typically are enacted after famine begins and its harsh consequences are already evident in a population. These actions, usually in coordination with major international relief and donor agencies, are typically intended to relieve acute suffering and death and promote the rehabilitation of those masses who have survived to migrate, and reach encampments. By definition, lagged responses represent policy failure for governments intending to minimize the destruction, malnutrition, and mortality of famine.

FATS AND OILS

A H Lichtenstein, Tufts University, Boston MA, USA

Dietary fat is a macronutrient that has historically engendered considerable controversy and continues to do so. Contentious areas include optimal type and amount in the diet, role in body weight regulation, and importance in the etiology of chronic disease(s).

Dietary Fats and Oils: The Good, Bad, and Ugly

Dietary fats and oils are unique in modern times in that they have good, bad, and ugly connotations. The aspects of dietary fat that are classified as good include serving as a carrier of preformed fat-soluble vitamins, enhancing the bioavailability of fat-soluble micronutrients, providing essential substrate for the synthesis of metabolically active compounds, constituting critical structural components of cells membranes and lipoprotein particles, preventing carbohydrate-induced hypertriglyceridemia, and providing a concentrated form of metabolic fuel in times of scarcity. The aspects of dietary fat that can be classified as bad include serving as a reservoir for fat-soluble toxic compounds and contributing dietary saturated and *trans* fatty acids, and cholesterol. Aspects of dietary fat that can be classified as ugly include providing a concentrated form of metabolic fuel in times of excess and comprising the major component of atherosclerotic plaque, the

underlying cause of heart disease, stroke, and phlebitis.

Lipids in Food and in the Body

Fatty Acids

Fatty acids are hydrocarbon chains with a methyl and carboxyl end. The majority of dietary fatty acids have an even number of carbons. The range in chain length of common dietary fatty acids is broad. Fatty acids with 16 and 18 carbons make up the majority of fatty acids present in plants and animals. However, they are by no means the most metabolically active. Long-chain unsaturated fatty acids, such as arachidonic acid (C20:4), are common precursors of regulatory compounds.

Essential nutrients are those that the body cannot synthesize or cannot synthesize in amounts adequate to meet needs. Linoleic acid (18:2) and/or fatty acids that can be derived from linoleic acid are essential fatty acids. These specific fatty acids are essential because humans cannot introduce a double bond above the ninth carbon from the carboxyl end of the acyl chain. To maintain optimal health, they must be supplied by the diet of humans. The metabolism of linoleic acid is represented in **Figure 1**.

A wide range of fatty acids occur in nature. There are a number of features of fatty acids that distinguish one from another. In addition to chain length, they also vary with regard to degree of saturation and location of the double bond(s). Fatty acids with a single double bond are referred to as monounsaturated fatty acids, and those with two or more double bonds are referred to as polyunsaturated fatty acids (**Figure 2**). The double bonds within unsaturated fatty acids can either be in the *cis* (hydrogen atoms on the same side of the acyl chain) or *trans* (hydrogen atoms on opposite sides of the acyl chain) conformation (**Figure 3**). The *cis* conformation is most commonly found in nature. Double bonds can also vary with regard to location within the acyl chain. The presence of double bonds, per se, and their number, position, and conformation, dictates the physical properties of the fatty acids.

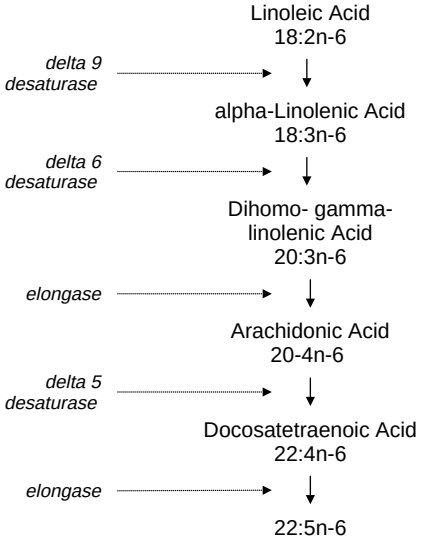

Figure 1 Metabolism of linoleic acid.

Unsaturated fatty acids of the same length with an identical number of double bonds can occur in multiple forms due to variation in the conformation of one or more of the double bonds (*cis* versus *trans*). They are referred to as geometric isomers (**Figure 3**). A common example is oleic acid (18:1c-9) and elaidic acid (18:1t-9). The presence of a *cis* relative to a *trans* double bond results in a greater bend or kink in the hydrocarbon chain. This kink impedes the fatty acids from aligning or packing together, thereby lowering the melting point of the fat. In a cell membrane this will be reflected in increased fluidity. In food this will be reflected in an oil that is liquid or fat that is soft at room temperature.

Unsaturated fatty acids of the same length with an identical number of double bonds and conformation can also occur in multiple forms due to the location of the double bonds within the acyl chain. They are referred to as positional isomers. A common example is alpha-linolenic acid (18:3n-3) and gamma-linolenic acid (18:3n-6). The difference in location of double bonds results in small alterations to the melting point yet large differences in the metabolic properties of the fatty acids. The most common distinction made among positional isomers of fatty acids is the location of the first double bond from the methyl end of the acyl chain. A fatty acid in which the first double bond occurs three carbons from the methyl end is termed an omega-3 fatty acid, frequently denoted n-3 fatty acid. This class of fatty acids is distinguished from the major class of fatty acids in which the first double bond occurs six carbons from the methyl end, termed an omega-6 or n-6 fatty acid. Enzymes that metabolize fatty acids distinguish among both positional and geometric isomers. The metabolic products of the different positional isomers of fatty acids have different and, occasionally, opposite physiological effects.

Most double bonds within fatty acids occur in a nonconjugated sequence, both in the human body and in food. That is, a carbon atom with single carbon–carbon bonds separates the carbons making up the double bonds. Some double bonds occur in

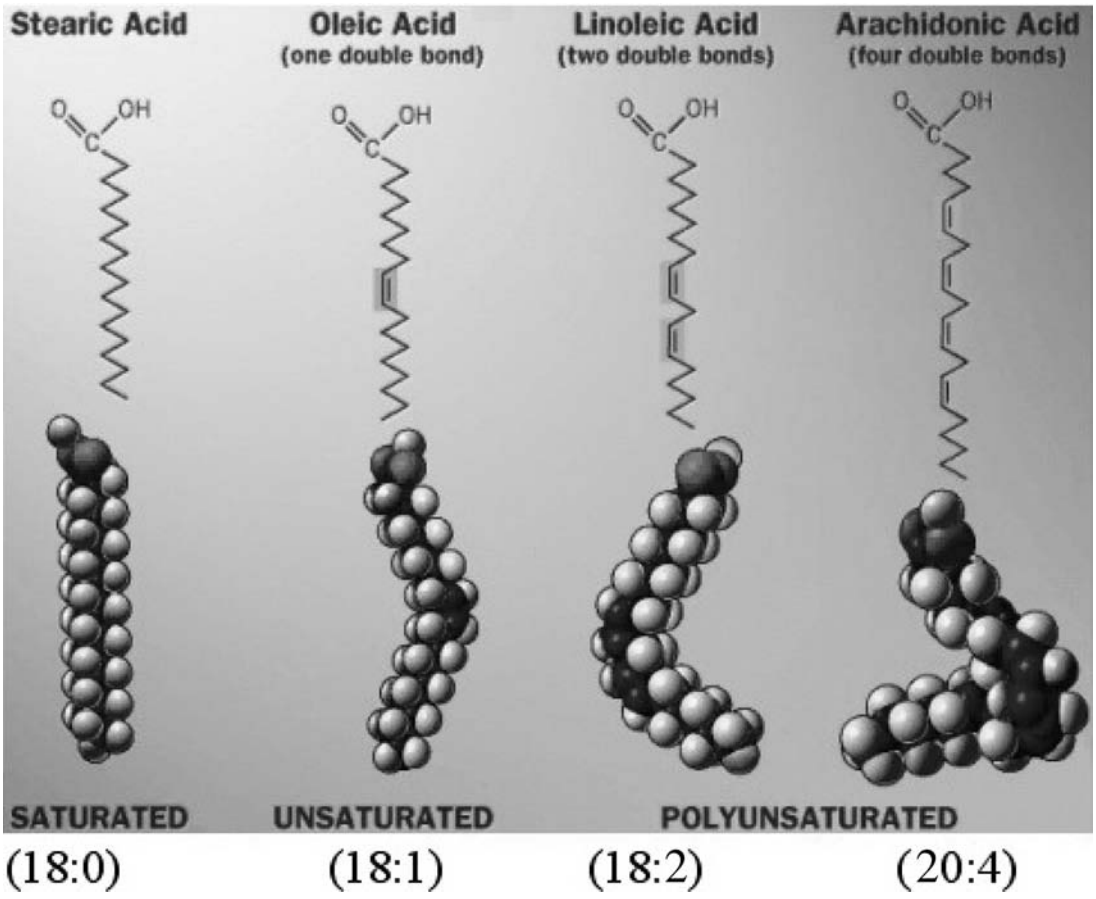

Figure 2 Saturated, monounsaturated, and polyunsaturated (n-3 and n-6) acids.

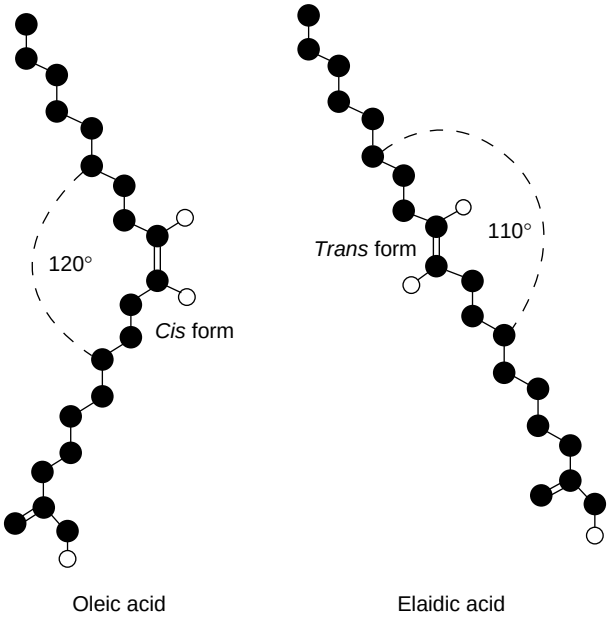

Figure 3 *Cis* and *trans* double-bond-containing fatty acids. (Copyright © The McGraw-Hill Companies, Inc.)

the conjugated form, without an intervening carbon atom separating the double bonds. Conjugated double bonds tend to be more reactive chemically (i.e., more likely to become oxidized). Although there is considerable speculation about the role of conjugated double bond-containing fatty acids and human health, the current state of knowledge is insufficient to draw any firm conclusions.

Triacylglycerol

Triacylglycerol is the major form of dietary lipid in fats and oils, whether derived from plants or animals. Triacylglycerol is composed of three fatty acids esterified to a glycerol molecule (**Figure 4**). The physical properties of the triacylglycerol are determined by the specific fatty acids esterified to the glycerol moiety and the actual position the fatty acid occupies. Each of the three carbons comprising the glycerol molecule allows for a stereochemically distinct fatty acid bond position: sn-1, sn-2, and sn-3. A triacylglycerol with three identical fatty acids is termed a simple triacylglycerol. These are exceedingly rare in nature. A triacylglycerol with two or three different fatty acids is termed a mixed

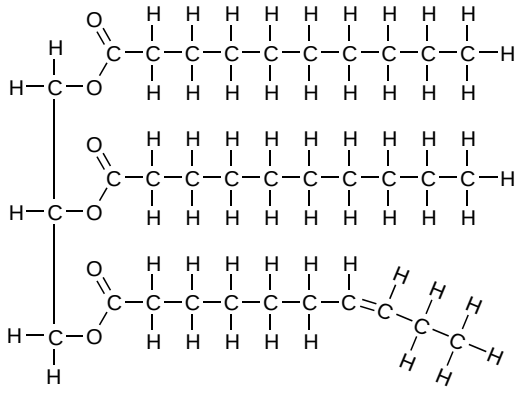

Figure 4 Triacylglycerol.

triacylglycerol, and these make up the bulk of the fat both in the human diet and in the body. The melting point of a triacylglycerol is determined by the position of the fatty acids esterified to glycerol and physical characteristics—their chain length and number, position, and conformation of the double bonds, and the stereochemical position.

Approximately 90% of the molecular weight of triacylglycerol is accounted for by the fatty acids. The fatty acid profile of the diet is reflected, in part, in the fatty acid profile of the adipose tissue triacylglycerol. Such data have been used to approximate long-term food intake patterns of humans. Manipulating the dietary fat provided to domesticated animals is being considered as one approach to modifying the fatty acid profile of meat.

Mono- and diacylglycerols have one and two fatty acids, respectively, esterified to glycerol. They rarely occur in large quantities in nature. Mono- and diacylglycerols are primarily intermediate products of triacylglycerol digestion and absorption, clearance from the bloodstream, or intracellular metabolism. They are frequently added to processed foods because of their ability to act as emulsifiers. Their presence in food products is noted on ingredient labels.

Once consumed, triacylglycerol are hydrolyzed to free fatty acids and monoglycerides in the small intestine prior to absorption. These compounds enter the intestinal cell and are used to resynthesize triacylglycerol. This lipid is then incorporated into a nascent triacylglycerol-rich lipoprotein particle, termed chylomicron, for subsequent release into peripheral circulation. Chylomicrons are secreted directly into the lymph prior to entering the bloodstream. Once in circulation, triacylglycerol are hydrolyzed before crossing the plasma membrane of peripheral cells for subsequent metabolism. The primary enzyme that hydrolyzes triacylglycerol in plasma is lipoprotein lipase. Lipoprotein lipase hydrolyzes triacylglycerol into two free fatty acids and 2-monoacylglycerol. The enzyme is attached to the luminal surface of capillary endothelial cells via a highly charged membrane-bound chain of heparin sulfate–proteoglycans. The ability of lipoprotein lipase to bind both the chylomicron particle and the cell surface ensures the cellular uptake of free fatty acids that are generated from the hydrolysis. Once inside the cell, free fatty acids can be oxidized to provide energy, metabolized to biologically active compounds, incorporated into phospholipid and cholesteryl ester, or resynthesized into triacylglycerol for storage as a potential reservoir of fatty acids for subsequent use.

Phospholipid

There are only trace amounts of phospholipid in dietary fats and oils. However, because the fatty acids in fats and oils provide substrate for the synthesis of phospholipid in the body, it is important to discuss this subtype of fat. Phospholipid is a critical structural component of all cells, both plant and animal. It is composed of two fatty acids on the sn-1 and sn-2 positions and a moiety frequently referred to as a polar head group on the sn-3 position of glycerol, the latter via a phosphate bond (**Figure 5**). Phospholipid molecules are amphipathic—that is, there are both hydrophobic and hydrophilic domains in the molecule. The two fatty acids confer hydrophobic properties and the polar head group hydrophilic properties. The specific fatty acids esterified to the glycerol backbone tend to be unsaturated fatty acids. The different polar head groups, most commonly phosphorylcholine, phosphorylserine, phosphorylinositol, or phosphorylethanolamine, result in phospholipids that vary in size and charge. Due to their amphipathic nature, phospholipids serve as the major structural component of cellular membranes by forming bilayers and in so doing also serve as a reservoir for metabolically active unsaturated fatty acids. Due to their amphipathic properties, in the

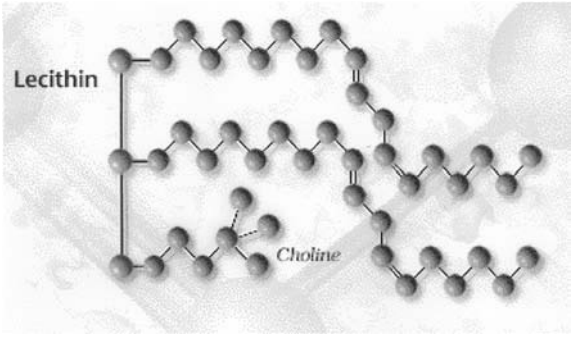

Figure 5 Phospholipid.

small intestine they play an important role in the emulsification and absorption of dietary fat and fat-soluble vitamins. On the surface of lipoprotein particles, they provide a critical component in the packaging and transport of lipid in circulation.

Cholesterol

Dietary sources of cholesterol are limited to foods of animal origin. Cholesterol is an amphipathic molecule that is composed of a steroid nucleus and a branched hydrocarbon tail (**Figure 6**). Cholesterol occurs naturally in two forms, either as free (nonesterified) cholesterol or esterified to a fatty acid (cholesteryl ester). If esterified, the fatty acid is linked to cholesterol at the number 3 carbon of the sterol ring.

Cholesterol serves a number of important functions in the body. Free cholesterol is a component of cell membranes and along with the fatty acid profile of the phospholipid bilayer determines membrane fluidity. The intercalation of free cholesterol into the phospholipid bilayer restricts motility of the fatty acyl chains and hence decreases fluidity. Free cholesterol is critical for normal nerve transmission. It makes up approximately 10% (dry weight) of total brain lipids. Cholesterol is a precursor of steroid hormones (i.e., estrogen and testosterone), vitamin D, adrenal steroids (i.e., hydrocortisone and aldosterone), and bile acids. This latter property is exploited in certain approaches to decrease plasma cholesterol levels by preventing the resorption of bile acids (recycling) and hence forcing the liver to use additional cholesterol for bile acid synthesis and in so doing creating an alternate mechanism for cholesterol excretion.

The receptor-mediated cellular uptake of cholesterol from lipoprotein particles is critical to maintaining intracellular and whole body cholesterol homeostasis. Once internalized, lipoprotein-associated cholesterol that is released from lysosomes has three major effects in the cell. The free cholesterol inhibits the activity of 3-hydroxy 3-methylglutaryl CoA reductase, the rate-limiting enzyme in endogenous cholesterol biosynthesis. This property serves to decrease cholesterol biosynthesis commensurate with the uptake of cholesterol from circulating lipoprotein particles and hence protects the cell from accumulating excess intracellular cholesterol. Free cholesterol inhibits the synthesis of receptors that mediate the uptake of lipoproteins from the bloodstream, thereby limiting the amount of additional cholesterol taken up by the cell. Free cholesterol increases the activity of acyl CoA cholesterol acyltransferase (ACAT), the intracellular enzyme that converts free cholesterol to cholesteryl ester. A high level of intracellular free cholesterol is cytotoxic, whereas cholesteryl ester is a highly nonpolar molecule and coalesces into a lipid droplet within the cell, preventing interaction with intracellular components. Increased ACAT activity is an important mechanism in preventing the accumulation of intracellular free cholesterol.

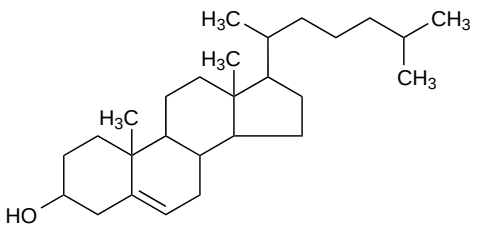

Figure 6 Cholesterol.

Cholesterol can be esterified intracellularly, as previously indicated, by ACAT. ACAT uses primarily oleoyl CoA as substrate and the resulting product is primarily cholesteryl oleate. Cholesterol can also be esterified in plasma by lecithin cholesterol acyltransferase (LCAT). LCAT uses phosphotidylcholine as substrate; the resulting products are primarily cholesteryl linoleate and lysolecithin. Cholesteryl ester is less polar than free cholesterol and this difference dictates how the two forms of cholesterol are handled—intracellularly and within lipoprotein particles.

Approximately one-third of cholesterol in plasma circulates as free cholesterol and approximately two-thirds as cholesteryl ester. Cholesterol in circulation is carried on all the lipoprotein particles (both intestinally derived chylomicrons and hepatically derived very low-density lipoprotein) or those generated during the metabolic cascade (intermediate-density lipoprotein, low-density lipoprotein (LDL), and high-density lipoprotein (HDL)). Free cholesterol is sequestered on the surface of lipoprotein particles within the phospholipid monolayer, whereas cholesteryl ester resides in the core of the lipoprotein particle. The majority of the cholesterol in circulation is carried on LDL particles. Cholesteryl ester is the major component of atherosclerotic plaque. In the arterial wall, cholesteryl ester is derived from the infiltration of lipoprotein-associated cholesteryl ester resulting from LCAT activity or is synthesized in situ as a result of ACAT activity. The fatty acid profile of the cholesteryl ester in arterial plaque can provide some indication of its source.

Other Sterols

Fats and oils derived from plants contain a wide range of phytosterols, compounds structurally similar to cholesterol. The difference between

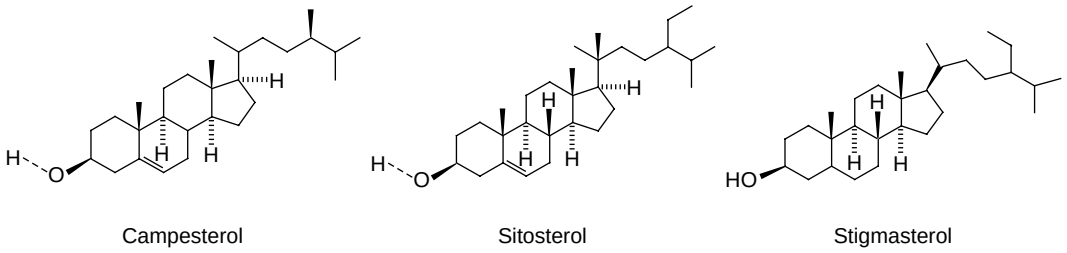

Figure 7 Plant sterols.

phytosterols and cholesterol is related to their side chain configuration and/or steroid ring bond patterns. The most common dietary phytosterols are beta-sitosterol, campesterol, and stigmasterol (**Figure 7**). In contrast to cholesterol, phytosterols are only absorbed in trace amounts. For this reason, plant sterols have been used therapeutically to reduce plasma cholesterol levels. They compete with cholesterol for absorption; hence, they effectively reduce cholesterol absorption efficiency.

The absorption efficiency of cholesterol in humans ranges from approximately 40 to 60%. Because the relative absorption of plant sterols, however low, is correlated with the percentage of cholesterol absorbed in an individual, there is considerable interest in using circulating plant sterol concentrations as a surrogate marker for cholesterol absorption efficiency. Limited data suggest efficiency of cholesterol absorption may have a significant effect on lipoprotein profiles and cardiovascular disease risk. Whether circulating phytosterols have an independent effect on cardiovascular disease risk is under investigation.

Dietary Fats and Oils and Cholesterol

Dietary fat serves critical functions in the human body. It provides a concentrated source of energy, slightly more than twice per gram than protein or carbohydrate. For this reason, the causes of energy imbalances are often attributed to this component of the diet. However, definitive data in this area are lacking.

In addition to providing a source of metabolic energy, dietary fat provides a source of essential fatty acids, linoleic acid (18:2), and/or other fatty acids that are derived from linoleic acid. Dietary fat is the major carrier of preformed fat-soluble vitamins (vitamins A, D, E, and K). The bioavailability of these fat-soluble vitamins is dependent on fat absorption. Dietary fatty acids are incorporated into compounds that serve as structural components of biological membranes and lipoproteins, and as such they serve as a reservoir for fatty acids having subsequent metabolic fates.

Fatty Acid Profile of Common Dietary Fats

Dietary fats and oils derive from both animal and plant sources, primarily in the form of triacylglycerol. The fatty acid profile of dietary fats commonly consumed by humans varies considerably (**Figure 8**). In general, fats of animal origin tend to be relatively high in saturated fatty acids, contain cholesterol, and are solid at room temperature. A strong positive association has been demonstrated in epidemiological, intervention, and animal data between cardiovascular disease risk and intakes of saturated fatty acids. The exception is stearic acid (18:0), a saturated fatty acid of which a large proportion is metabolized to oleic acid (18:1), a monounsaturated fatty acid. Fats and oils of plant origin tend to be relatively high in unsaturated fatty acids (both monounsaturated and polyunsaturated) and are liquid at room temperature. Notable exceptions include plant oils termed tropical oils (palm, palm kernel, and coconut oils) and hydrogenated fat. Tropical oils are high in saturated fatty acids but remain liquid at room temperature because they contain a high proportion of short-chain fatty acids. Hydrogenated plant oils can be relatively high in saturated and/or *trans* fatty acids due to chemical changes induced during processing, including conversion of unsaturated to saturated bonds and *cis* to *trans* double bonds.

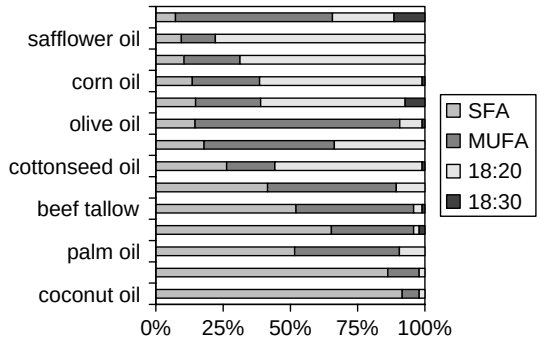

Figure 8 Relative composition of common dietary fats.

Major Contributors of Dietary Saturated, Monounsaturated, and Polyunsaturated Fatty Acids and Cholesterol

The major types of dietary fats and oils are generally broken down on the basis of animal and plant sources. The relative balance of animal and plant foods is an important determinant of the fatty acid profile of the diet. However, with the increasing prominence of processed, reformulated, and genetically modified foods, it is becoming more difficult to predict the fatty acid profile of the diet on the basis of the animal verses plant distinction.

According to the National Health and Nutrition Examination Survey (NHANES) recall data from 1999–2000, the 10 major dietary sources of saturated fatty acids in US diets are regular cheese (6.0% of the total grams of saturated fatty acids consumed), whole milk (4.6%), regular ice cream (3.0%), 2% low-fat milk (2.6%), pizza with meat (2.5%), French fries (2.5%), Mexican dishes with meat (2.3%), regular processed meat (2.2%), chocolate candy (2.1%), and mixed dishes with beef (2.1%). Hence, the majority of saturated fatty acids are contributed by regular dairy products (16%), and the top 10 sources contribute 30% of the total saturated fatty acids consumed. The increased prevalence of fat-free and low-fat dairy products provides a viable option with which to encourage a populationwide decrease in saturated fat intake. To put the value of decreasing populationwide intakes of saturated fat into perspective, it has been estimated that the isocaloric replacement of 5% of energy from saturated fatty acids with complex carbohydrate, on average, would reduce total cholesterol levels by 10 mg/dl (0.26 mmol/l) and LDL cholesterol by 7 mg/dl (0.18 mmol/l). For a person at moderately high risk of developing cardiovascular disease with a total cholesterol level of 220 mg/dl (5.69 mmol/l) and LDL cholesterol level of 140 mg/dl (3.62 mmol/l), such a dietary modification would decrease total and LDL cholesterol levels by 4.5 and 5%, respectively. Each 1% decrease in total cholesterol levels has been associated with a 2% reduction in the incidence of coronary heart disease. Using this example, that would theoretically translate into a 9% decrease in cardiovascular disease risk. However, it is important to note that decreasing the saturated fatty acid content of the diet should not necessarily be done by displacing fat with carbohydrate. As discussed in the next section, the quantity of dietary fat, relative to carbohydrate and protein, also impacts on blood lipid levels and lipoprotein profiles.

The 10 major dietary sources of monounsaturated fatty acids in US diets are French fries (3.3% of the total grams of monounsaturated fatty acids consumed), regular processed meat (2.5%), regular cookies (2.5%), regular miscellaneous snacks (2.4%), pizza with meat (2.4%), regular salad dressing (2.4%), regular cheese (2.3%), Mexican dishes with meat (2.3%), sausage (2.1%), and mixed dishes with beef (2.1%). There is little change in total or LDL cholesterol levels from the isocaloric replacement of monounsaturated fatty acids by complex carbohydrate. However, it is important to note that approximately one-half of the monounsaturated fatty acids consumed in the United States come from animal fats. Therefore, a decrease in saturated fatty acid intake would be predicted to decrease monounsaturated fatty acid intake unless vegetable oils high in monounsaturated fatty acids, such as canola or olive oil, replaced the animal fat.

The 10 major dietary sources of n-6 polyunsaturated fatty acids in US diets are regular salad dressing (8.8% of the total grams of polyunsaturated fatty acids consumed), regular white bread (4.2%), regular mayonnaise (3.0%), French fries (2.6%), regular cake (2.5%), regular cookies (2.1%), mixed dishes with chicken and turkey (2.1%), regular miscellaneous snacks (2.0%), regular potato chips (2.0%), and fried fish (2.0%). The distribution of polyunsaturated fatty acids among commonly consumed foods is wide. It has been estimated that the isocaloric replacement of complex carbohydrate with polyunsaturated fatty acids for 5% of energy, on average, will reduce total cholesterol levels by 5 mg/dl (0.13 mmol/l) and LDL cholesterol by 4 mg/dl (0.11 mmol/l). For a person at moderately high risk of cardiovascular disease with a total cholesterol level of 220 mg/dl (5.69 mmol/l) and LDL cholesterol level of 140 mg/dl (3.62 mmol/l), such a dietary modification would decrease total and LDL cholesterol levels by 2.1 and 3.6%, respectively, and potentially result in a 4% decrease in cardiovascular disease risk.

The 10 major dietary sources of cholesterol in US diets are fried eggs (16.6% of the total milligrams of cholesterol consumed), regular eggs including scrambled eggs (8.4%), mixed dishes with eggs (4.5%), mixed dishes with beef (2.9%), whole milk (2.6%), regular cheese (2.5%), fried fish (2.3%), mixed dishes with chicken and turkey (2.3%), lean cut meat (2.1%), and regular processed meat (2.1%). Eggs or foods high in eggs contribute approximately 30% of the total dietary cholesterol intake. It has estimated that reducing cholesterol intakes by 200 mg/day, on average, will reduce total cholesterol levels by 5 mg/dl (0.13 mmol/l) and LDL cholesterol by 2.6 mg/dl (0.10 mmol/l). Such a change would be predicted to have a similar risk effect as displacing 5% of energy as carbohydrate with polyunsaturated

fatty acids—that is, reducing cardiovascular disease risk by approximately 4%.

Dietary Fat and Cardiovascular Prevention

Amount in Diet

When considering the percentage of energy contributed by dietary fats and oils (amount of fat) and cardiovascular disease prevention and management, there are two major factors—the impact on plasma lipoprotein profiles and body weight. The potential relationship with body weight is important because overweight and obesity are strongly associated with elevated lipid and lipoprotein levels, blood pressure, dyslipidemia, and type 2 diabetes—all potential risk factors for cardiovascular disease. With respect to plasma lipoprotein profiles, the focus is usually on triglyceride and HDL cholesterol levels or total cholesterol:HDL cholesterol ratios.

When body weight is maintained at a constant level, decreasing the total fat content of the diet, expressed as a percentage of total energy, and replacing it with carbohydrate frequently results in an increase in triglyceride levels, decrease in HDL cholesterol levels, and a less favorable (higher) total cholesterol:HDL cholesterol ratio. Low levels of HDL cholesterol are an independent risk factor for cardiovascular disease (<50 mg/dl in females [<1.3 mmol/l] and <40 mg/dl in males, [<1.0 mmol/l]). Very low-fat diets are of particular concern in diabetic and overweight individuals who tend to have low HDL cholesterol and high triglyceride levels or those individuals classified as having metabolic syndrome (having three or more of the following: abdominal obesity, elevated triacylglycerol levels, low HDL levels, hypertension, or elevated fasting glucose levels). Because of these findings, the Adult Treatment Panel of the National Cholesterol Education Program (NCEP) revised its guidelines in 2001 from recommending a diet with less than 30% of energy as fat to a diet with 25–35% of energy as fat. Similarly, the American Heart Association and the USDA/HHS 2000 Dietary Guidelines for Americans changed their recommendations to shift the emphasis from a general recommendation to limit intakes of total and saturated fat to limit saturated and *trans* fat.

With respect to the amount of dietary fats and oils and body weight, two reviews of the long-term data have been published. Both concluded that even a relatively large downward shift in dietary fat intake, approximately 10% of energy, results in only modest weight loss of 1.0 kg during a 12-month period in normal weight subjects and 3 kg in overweight or obese subjects. However, it is important to note that in contrast to what would have been predicted, during the course of the studies included in the reviews, in no case was weight gain reported.

Fatty Acid Profile

Early evidence demonstrated that diets relatively high in saturated fatty acids increased plasma total cholesterol levels. Subsequent work demonstrated that this elevation in total cholesterol levels is contributed to by increases in both LDL and HDL cholesterol levels. It also became clear that not all saturated fatty acids had identical effects on plasma lipoprotein levels. Very short-chain fatty acids (6:0 to 10:0) and stearic acid (18:0) produce little or no change in blood cholesterol levels, whereas saturated fatty acids with short- and intermediate-chain lengths—lauric (12:0), myristic (14:0), and palmitic (16:0) acids—appear to be the most potent in increasing blood cholesterol levels. Because a large proportion of stearic acid (18:0) is rapidly converted to oleic acid (18:1), it appears to have a relatively neutral effect. The underlying mechanism by which saturated fatty acids with 10 or fewer carbon atoms have different effects from those with 12–16 carbons is yet to be determined. The current dietary recommendation as defined in the NCEP Therapeutic Lifestyle Change diet to prevent and treat cardiovascular disease is to limit intakes of saturated fat to less than 7% of total energy. The major contributors of saturated fatty acids were discussed previously.

Compared to saturated fatty acids, unsaturated fatty acids, both monounsaturated and polyunsaturated fatty acids, lower both LDL and HDL cholesterol levels. The absolute magnitude of the change is greater for LDL cholesterol than HDL cholesterol. Most data suggest that monounsaturated fatty acids have a slightly smaller effect than polyunsaturated fatty acids in lowering both LDL and HDL cholesterol levels so that the total cholesterol:HDL cholesterol ratio is similar for both categories of fat.

Quantitatively, the major n-3 polyunsaturated fatty acid in the diet is alpha-linolenic acid (18:3n-3). Major dietary sources include soybean and canola oils (**Figure** 8). Two other n-3 polyunsaturated fatty acids, eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3), referred to as very long-chain n-3 fatty acids, are found predominantly in fish, specifically dark flesh fish such as salmon, tuna, and swordfish. Dietary intakes of very long-chain n-3 fatty acids are associated with decreased risk of heart disease and stroke. Intervention studies have substantiated these findings.

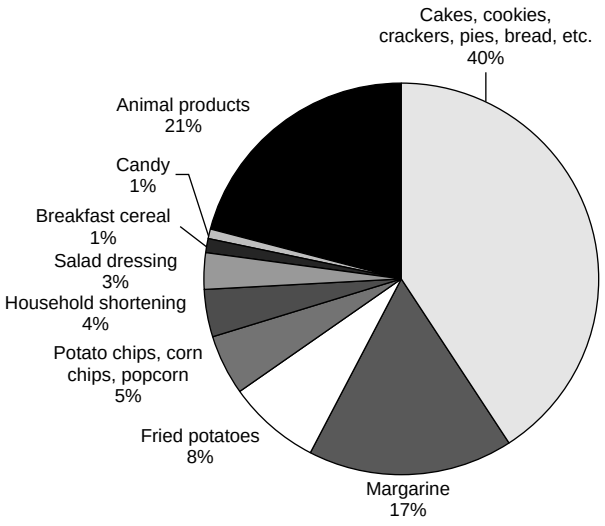

Figure 9 Major food sources of *trans* fat for US adults. (Data from www.cfsan.fda.gov/~dms/qatrans2.)

The beneficial effects of EPA and DHA are attributed to decreased ventricular fibrillation resulting in decreased sudden death, and also decreased triglyceride levels, platelet aggregation, and blood pressure. Evidence suggests that very long-chain n-3 fatty acids may decrease atherosclerotic plaque progression.

Dietary *trans* fatty acids occur naturally in meat and dairy products as a result of anaerobic bacterial fermentation in ruminant animals. *Trans* fatty acids are also introduced into the diet as a result of the consumption of hydrogenated vegetable or fish oils. Hydrogenation results in a number of changes in the fatty acyl chain: conversion of *cis* to *trans* double bonds; saturation of double bonds; and migration of double bonds along the acyl chain, resulting in multiple positional isomers. Oils are primarily hydrogenated to increase viscosity (change a liquid oil into a semiliquid or solid) and extend shelf life (decrease susceptibility to oxidation). Major contributors of *trans* fatty acids are commercially baked products (40%), animal products (21%), margarine (17%), and fried potatoes and chips (13%) (**Figure 9**). In intervention and observational studies, *trans* fatty acid intake has been associated with less favorable total cholesterol:HDL cholesterol ratios and increased risk of cardiovascular disease, respectively.

Composition of Dietary Fats

Types of fat relatively high in saturated fatty acids include butterfat (62%), beef tallow (50%), tropic oils (coconut, 87%; palm kernel, 81%; and palm oil, 49%), and lard (39%) (**Figure 8**). The content of cholesterol in these fats is 33, 14, 0, and 12 mg/tablespoon, respectively. Types of fat relatively high in monounsaturated fatty acids include canola oil (56%), olive oil (73%), and peanut oil (46%). Types of fat relatively high in polyunsaturated fatty acids include soybean oil (51%), corn oil (58%), safflower oil (74%), and sunflower oil (66%). None of the vegetable oils high in monounsaturated or polyunsaturated fatty acids contain cholesterol. The fatty acid profile of diets varies widely among individuals and depends on such factors as availability, cultural and religious dietary patterns, price, and personal preferences.

Summary

Dietary fats and oils have both positive and negative attributes with respect to health outcomes. This makes determining optimal dietary recommendations difficult. Fats and oils are primarily composed of triacylglycerol. The fatty acid composition of the triacylglycerol dictates the physical properties of the fat. During fatty acid biosynthesis, humans are unable to insert a double bond above the ninth carbon of the acyl chain. For this reason, linoleic acid and fatty acids derived from linoleic acid are essential and hence must be consumed preformed. Animal fats are the major contributors of saturated fatty acids to the diet. Vegetable oils such as canola and olive, and also animal fats, are the major contributors of monounsaturated fatty acids to the diet. Vegetable oils such as safflower, sunflower, and corn oils are the major contributors of polyunsaturated fatty acids to the diet. Dietary patterns high in saturated fatty acids have been associated with increased risk of developing cardiovascular disease, whereas dietary patterns high in unsaturated fatty acids (monounsaturated and polyunsaturated) have been associated with decreased risk. Two other subtypes of fatty acids derived from the diet potentially impact on human health: very long-chain n-3 fatty acids and *trans* fatty acids. Very long-chain n-3 fatty acids are derived primarily from fish, and intakes have been associated with decreased risk of developing cardiovascular disease. The majority of *trans* fatty acids are derived from foods made with hydrogenated fat and, to a lesser extent, from animal fats. Higher amounts in the diet have been associated with elevated LDL cholesterol levels and higher total cholesterol to HDL cholesterol ratios. Dietary fatty acid intakes are determined by the sum of individual food choices. Current general dietary recommendations from a number of sources suggest that one should consume a diet high in fruits and vegetables, whole grain products, low-fat and nonfat diary products, legumes, and lean meats. Such a dietary pattern, while accommodating

personal preferences, is consistent with a diet low in saturated and *trans* fatty acids and is predicted to reduce the risk of developing cardiovascular and other chronic diseases.

FATTY ACIDS

Contents

Metabolism

P A Watkins, Kennedy Krieger Institute and Johns Hopkins University School of Medicine, Baltimore, MD, USA

Introduction

Fatty acids and glucose are the primary metabolic fuels used by higher organisms, including man. As such, fatty acids occupy a central position in human nutrition. Fat, carbohydrate, and protein comprise the macronutrients. When nutritionists speak of fat, they are referring mainly to triacylglycerol (triglyceride), which consists of three fatty-acid molecules covalently linked to a backbone of glycerol. Several properties of fatty acids and triacylglycerol make them highly suited to the storage and provision of energy. When a gram of fatty acid is burned as fuel, about 9 kcal of energy is recovered – more than twice that yielded when a gram of

carbohydrate or protein is utilized. Unlike carbohydrates, fat can be stored in an anhydrous compact state, allowing the organism to amass large quantities of fuel reserves in times of plenty. This property can have unfortunate consequences in prosperous societies, as evidenced by the increasing incidence of obesity. Fatty acids are also fundamental building blocks for the synthesis of most biologically important lipids, including phospholipids, sphingolipids, and cholesterol esters. They are the precursors of bioactive molecules such as prostaglandins and other eicosanoids. In addition, fatty acids and their coenzyme A derivatives have many metabolic regulatory roles.

Fatty-Acid Nomenclature Conventions

In this article, fatty acids will be identified by their chain length, the number of double bonds present, and the position of the first double bond from the methyl end of the molecule. Thus 14:0 denotes a saturated fatty acid with 14 carbon atoms, 16:1*n*-9 denotes a monounsaturated fatty acid with 16 carbon atoms in which one double bond occurs nine carbon atoms from the methyl end, and 20:4*n*-6 denotes a polyunsaturated fatty acid with 20 carbon atoms in which the first of four double bonds is found six carbon atoms from the methyl end. Unless otherwise noted, all double bonds are in the *cis* configuration and double bonds in polyunsaturated fatty acids are separated by a single methylene ($-CH_2-$) group. The carboxyl carbon atom of any fatty acid is carbon-1. The adjacent carbon atom is referred to as either carbon-2 or the α-carbon; the next is carbon-3 or the β-carbon, and so on. Some examples are shown in **Figure 1**.

Physical Properties of Fatty Acids

Fatty acids are aliphatic organic acids with the fundamental structure $CH_3(CH_2)_nCOOH$, where n can range from zero to more than 26. Thus, fatty acids range from the shortest, acetic acid (2:0), to the very long-chain fatty acids containing 26 or more carbon atoms (e.g., 26:0). Although fatty acids with an odd number of carbon atoms exist in nature, most common fatty acids have an even number. The most abundant fatty acids in human lipids and in dietary lipids are the long-chain fatty acids 16:0 (palmitic acid) and 18:1*n*-9 (oleic acid) (**Figure 1**). The hydrophobic nature of the hydrocarbon chain of fatty acids containing more than eight carbon atoms renders them quite insoluble in aqueous media. It has been estimated that for every two additional carbon atoms in the fatty-acid chain its solubility decreases 10-fold.

Owing to the poor solubility of the most abundant fatty acids, free (non-esterified) fatty acids are often found associated with binding and/or transport proteins. Serum albumin has at least six binding sites for fatty acids and is the primary transporter of these molecules through the bloodstream. Several low-molecular-weight fatty-acid binding proteins have been identified and implicated in the intracellular transport of free fatty acids. While free fatty acids can associate with lipophilic cellular and organellar membranes, concentrations of these non-esterified compounds in membranes are typically very low.

Fatty-Acid Activation

Biochemically, fatty acids are rather nonreactive molecules unless they are first activated by thioesterification to coenzyme A (CoA). This reaction is catalyzed by acyl-CoA synthetases (also known as acid : CoA ligases, E.C. 6.2.1.x). The overall acyl-CoA synthetase reaction is

$$\text{RCOOH} + \text{ATP} + \text{CoA-SH} \rightarrow \text{RCO-S-CoA} + \text{AMP} + \text{PPi}$$

where PPi is inorganic pyrophosphate, ATP is adenosine triphosphate, and AMP is adenosine monophosphate. Owing to the wide diversity of fatty-acid chain lengths, many enzymes with varied substrate specificities have been identified.

It is estimated that humans have more than 25 enzymes capable of activating fatty acids and/or fatty-acid-like compounds. Acyl-CoA synthetases that activate fatty acids of similar chain lengths often have different tissue-expression patterns and/or different subcellular locations. Thus, each enzyme may direct its fatty-acid substrates into a particular metabolic pathway.

Mitochondrial Fatty-Acid β-Oxidation

To recover their stored energy, fatty acids must be oxidized. Quantitatively, the most important energy-yielding degradation pathway is mitochondrial β-oxidation (**Figure 2**). Fatty acids must first enter cells or tissues. Serum triacylglycerol, usually associated with lipoproteins, is hydrolyzed by lipoprotein lipase located on the capillary endothelium, releasing fatty acids for cellular uptake. In addition, albumin-bound circulating free fatty acids (e.g., produced by the mobilization of adipocyte fat stores) reach the cell surface. Although

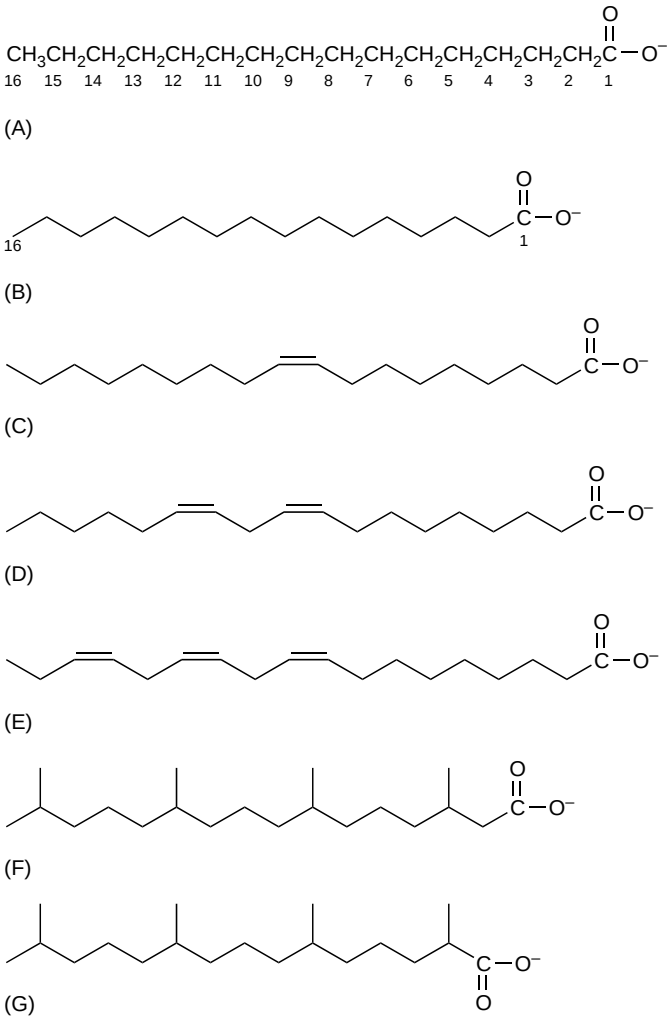

Figure 1 Fatty-acid structure and nomenclature. (A) Chemical formula and carbon atom numbering system for a 16-carbon saturated fatty acid (16:0). (B) Schematic representation of 16:0. (C) A monounsaturated fatty acid, 18:1*n*-9, showing the double bond nine carbon atoms from the methyl end (carbon 18). (D) The essential *n*-6 fatty acid 18:2*n*-6, where the first double bond is found six carbon atoms from the methyl end. The two double bonds are separated by a methylene (–CH_2–) group. (E) The essential *n*-3 fatty acid 18:3*n*-3, where the first double bond is found three carbon atoms from the methyl end. (F) Phytanic acid, a dietary β-methyl-branched-chain fatty acid (3,7,11,15-tetramethyl 16:0). The methyl group on carbon 3 prevents this fatty acid from degradation by β-oxidation. (G) Pristanic acid (2,6,10,14-tetramethyl 15:0) is the product of phytanic acid α-oxidation, in which a single carbon (carbon 1) is lost. The methyl group on carbon 2 does not preclude subsequent degradation by β-oxidation.

hydrophobic fatty acids can traverse the plasma membrane by simple diffusion, a role for membrane transport proteins in this process remains controversial. Once inside the cell, fatty acids are thought to be moved to the mitochondria (or other intracellular sites) by intracellular fatty-acid binding proteins.

Acyl-CoA synthetase activity towards long-chain fatty-acid substrates is present in the outer mitochondrial membrane. However, fatty acyl-CoAs do not readily traverse biological membranes such as the inner mitochondrial membrane. A highly sophisticated transport system has evolved to allow tight regulation of fatty-acid entry into the mitochondrion (**Figure 2**). Carnitine palmitoyl transferase 1 (CPT1), located on the inner aspect of the outer mitochondrial membrane, catalyzes a transesterification reaction:

$$\text{fatty acyl-CoA} + \text{carnitine} \rightarrow \text{fatty acyl-carnitine} + \text{CoA-SH}$$

Carnitine–acylcarnitine translocase (CACT), located in the inner mitochondrial membrane, carries the fatty acyl-carnitine inside the mitochondrion in exchange for a free carnitine molecule. CPT2, located inside the mitochondrion, then catalyzes the reversal of the CPT1 reaction. Thus, the concerted actions of CPT1, CACT, and CPT2

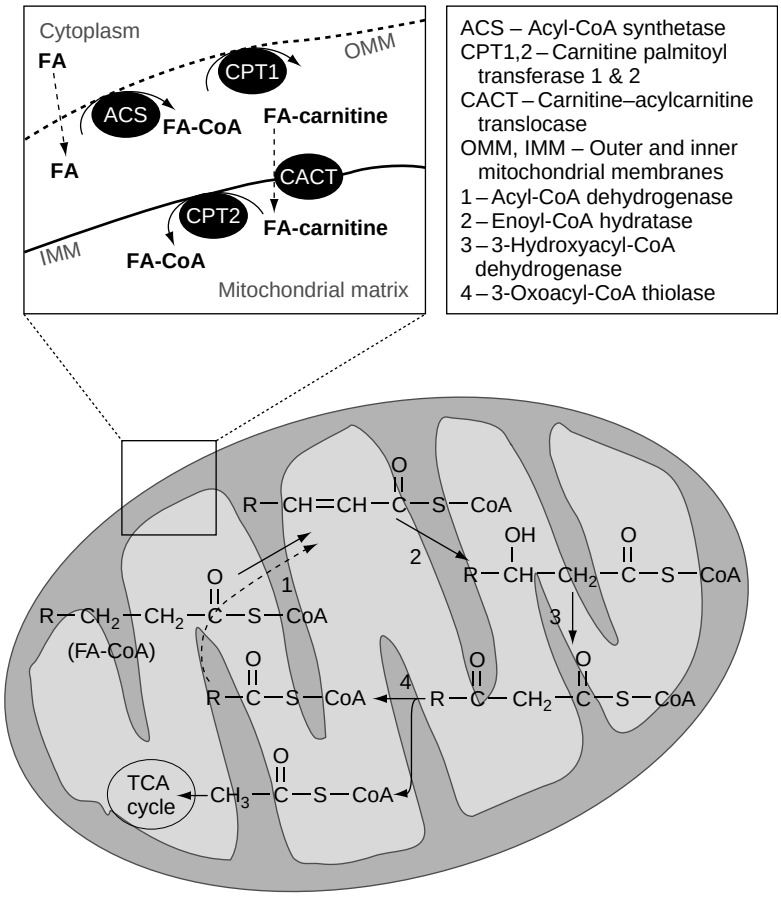

Figure 2 Mitochondrial fatty-acid (FA) β-oxidation pathway. Long-chain fatty acids are activated, converted to carnitine esters, transported across the inner mitochondrial membrane, and re-converted to their CoA thioester once in the mitochondrial matrix. Four sequential mitochondrial enzyme reactions shorten the fatty acyl-CoA (FA-CoA) by two carbon atoms, which are released as acetyl-CoA. The shortened fatty acyl-CoA can undergo additional cycles of degradation until the entire carbon chain has been converted to acetyl-CoA units. $FADH_2$ and NADH, produced in reactions 1 and 3, respectively, can enter the electron transport chain for ATP production. Acetyl-CoA enters the tricarboxylic acid (TCA) cycle, yielding additional NADH and $FADH_2$ for ATP production. Mitochondrial β-oxidation is the primary pathway for recovering the energy stored as triacylglycerol or 'fat'.

effectively translocate fatty acyl-CoA across the inner mitochondrial membrane.

Entry of fatty acids into the mitochondrion is regulated by several mechanisms. Although long-chain fatty acids can readily diffuse across the lipophilic inner mitochondrial membrane, the mitochondrial matrix lacks long-chain acyl-CoA synthetase activity. Thus, long-chain fatty acids cannot be activated intramitochondrially to enter the β-oxidation pathway. Control is also exerted extramitochondrially via malonyl-CoA, a cytoplasmic intermediate in fatty-acid biosynthesis and an indicator of high cellular energy status. Malonyl-CoA is a potent inhibitor of CPT1, prohibiting fatty acids from entering the mitochondria to be degraded.

As depicted in **Figure 2**, the four primary enzymes of mitochondrial β-oxidation act on intramitochondrial fatty acyl-CoA by sequential dehydrogenation, hydration, dehydrogenation, and thiolytic cleavage reactions. The products are (1) fatty acyl-CoA that has been shortened by two carbon atoms, (2) acetyl-CoA, (3) reduced flavin adenine dinucleotide ($FADH_2$), and (4) reduced nicotinamide adenine dinucleotide (NADH). $FADH_2$ and NADH can directly enter the electron transport chain at complex 2 and complex 1, respectively, yielding about five ATP molecules. Acetyl-CoA can be further degraded to carbon dioxide and water by the tricarboxylic acid cycle, yielding additional reducing equivalents that can enter the electron transport chain and produce ATP. Importantly, the entire β-oxidation process can be repeated using the shortened fatty acyl-CoA as a substrate. This process can be repeated until the entire carbon skeleton of the fatty acid has

been degraded to two-carbon acetyl-CoA units. Theoretically, complete oxidation of one molecule of 16:0 (β-oxidation and tricarboxylic acid cycle) will yield more than 160 ATP molecules.

Essentially all cells and tissues can use carbohydrate (glucose) for fuel, and a few (e.g., nerves and erythrocytes) are dependent on this fuel source. An important nutritional consideration is that carbon derived from fatty acids via β-oxidation cannot be converted to glucose in net quantities. In the postprandial state, however, most cell types other than nerves and erythrocytes derive the majority of their energy from fatty-acid oxidation under normal physiologic conditions. Some tissues, e.g., skeletal muscle, completely oxidize fatty acids to carbon dioxide and water. Others, e.g., liver, only partially oxidize fatty acids, using the acetyl-CoA product for biosynthethic needs. In particular, liver uses intramitochondrial acetyl-CoA for the synthesis of ketone bodies, acetoacetate and β-hydroxybutyrate (**Figure 3**). Ketone bodies can be oxidized by all tissues except the liver and provide an alternative fuel source during starvation. In particular, nervous tissue can oxidize ketone bodies. During prolonged starvation, increased ketone-body use spares the brain's requirement for glucose.

Peroxisomal Fatty-Acid β-Oxidation

Like mitochondria, peroxisomes contain pathways for the β-oxidation of fatty acids. The mechanism by which fatty acids enter peroxisomes is unclear but does not appear to involve the CPT1–CACT–CPT2 pathway. Long-chain and very-long-chain acyl-CoA synthetase activities are associated with peroxisomes, but it has not been established whether fatty acids or fatty acyl-CoAs traverse the peroxisomal membrane. The basic reactions of peroxisomal β-oxidation resemble those found in mitochondria, but the peroxisomal and mitochondrial enzymes are distinct proteins (**Figure 4**). In fact, peroxisomes contain two sets of β-oxidation enzymes, which appear to function with distinct substrates.

Unlike mitochondria, peroxisomes do not contain an electron transport chain or tricarboxylic acid cycle, and, thus, peroxisomal fatty-acid degradation is not directly coupled to energy production. Rather, peroxisomes have a more specialized fatty-acid oxidation role, degrading fatty-acid substrates that cannot be catabolized in mitochondria. Peroxisomes are indispensable for the degradation of very-long-chain fatty acids (containing more than 22 carbon atoms),

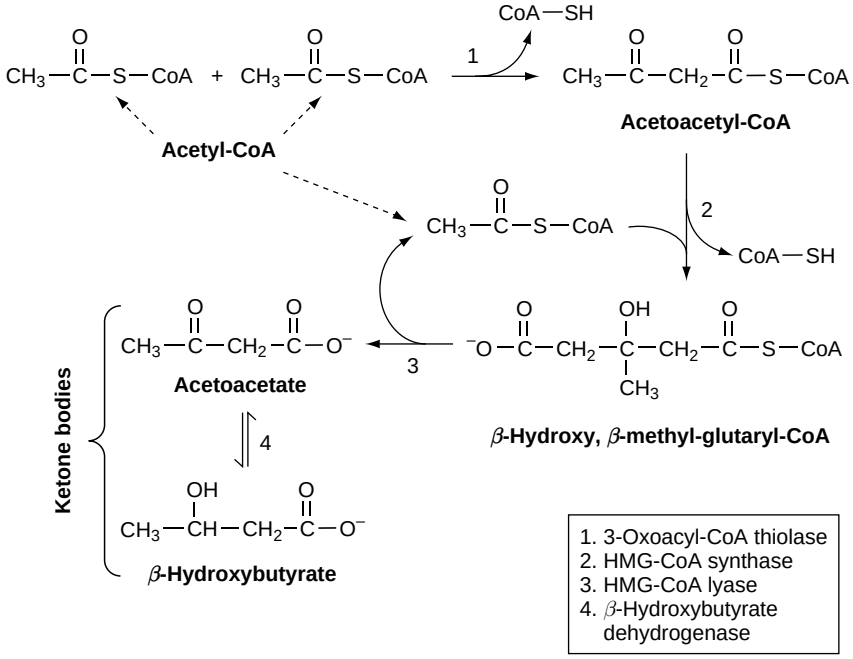

Figure 3 Synthesis of ketone bodies. In the mitochondria of hepatocytes, acetyl-CoA derived from β-oxidation is converted to ketone bodies, primarily acetoacetate and β-hydroxybutyrate, rather than entering the tricarboxylic acid cycle. Two molecules of acetyl-CoA condense in a reversal of the last β-oxidation reaction (3-oxoacyl-CoA thiolase). The product, acetoacetyl-CoA, condenses with another molecule of acetyl-CoA, yielding β-hydroxy, β-methyl-glutaryl-CoA (HMG-CoA), a reaction catalysed by HMG-CoA synthase. Cleavage of HMG-CoA by HMG-CoA lyase yields acetoacetate, regenerating one molecule of acetyl-CoA. Acetoacetate is reversibly reduced to β-hydroxybutyrate via the NAD-dependent enzyme β-hydroxybutyrate dehydrogenase. These ketone bodies can traverse the inner mitochondrial membrane, eventually reaching the bloodstream for ultimate use by the brain and other tissues.

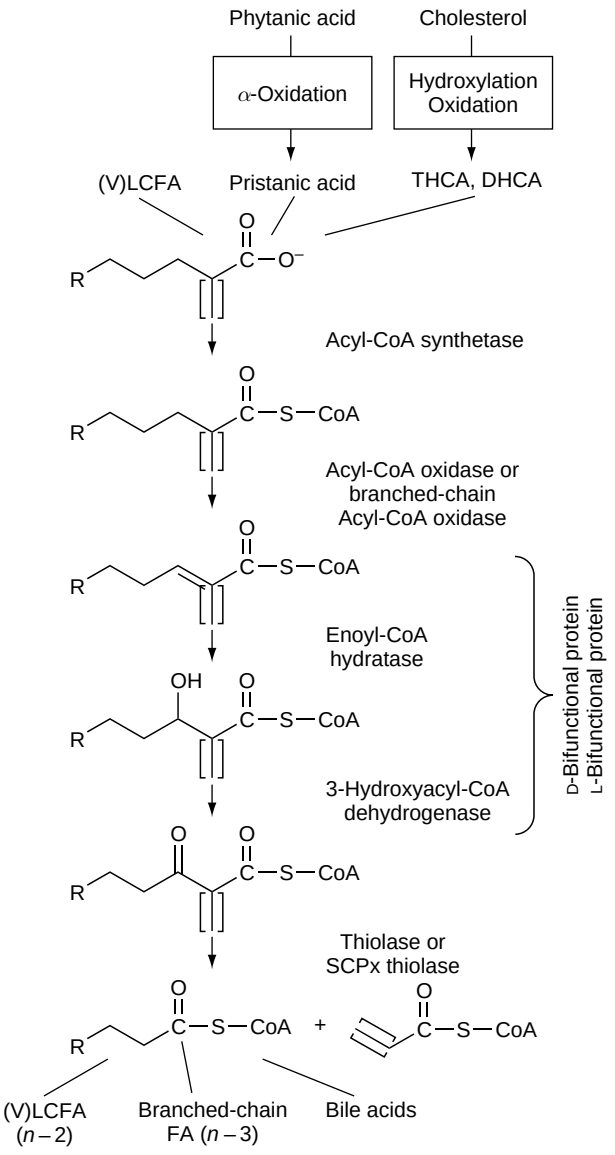

Figure 4 Peroxisomal fatty-acid (FA) β-oxidation pathways. While saturated long-chain fatty acids (LCFA) are preferentially degrade in mitochondria, saturated very-long-chain fatty acids (VLCFA) and some LCFA are shortened by peroxisomal β-oxidation. Degradation of pristanic acid, the product of phytanic acid α-oxidation, and the conversion of the cholesterol-derived 27-carbon bile-acid precursors dihydroxycholestanoic acid (DHCA) and trihydroxycholestanoic acid (THCA) to 24-carbon bile acids also require this pathway. The mechanism by which these substrates enter peroxisomes is unknown. Four enzymatic reactions serve to shorten the substrates by either two (LCFA, VLCFA) or three (pristanic acid, DHCA, THCA) carbon atoms. The 2-methyl group of the latter substrates is shown in brackets. SCPx thiolase refers to the thiolase activity of sterol carrier protein x.

which are neurotoxic if allowed to accumulate. These fatty acids undergo several cycles of peroxisomal β-oxidation until they are between eight and 10 carbon atoms long, after which they go to the mitochondria for further catabolism. Degradation of xenobiotic fatty acyl-like compounds (e.g., sulphur-substituted fatty acids and many nonsteroidal anti-inflammatory drugs) takes place in peroxisomes. Oxidation of dicarboxylic acids (from the diet or from ω-oxidation) and 2-methyl-branched-chain fatty acids (from the diet or from α-oxidation) also occurs in peroxisomes.

The peroxisomal β-oxidation pathway also fulfils an important biosynthetic role. In the hepatic synthesis of bile acids from cholesterol, the aliphatic side chain, which resembles an α-methyl-branched-chain fatty acid, must be shortened. A single cycle of peroxisomal β-oxidation will remove a three-carbon portion of the side chain, converting the 27-carbon bile acid precursors dihydroxycholestanoic and trihydroxycholestanoic acids into the 24-carbon primary bile acids chenodeoxycholate and cholate, respectively.

Fatty-Acid α-Oxidation and ω-Oxidation

Other important fatty-acid catabolic pathways include α-oxidation and ω-oxidation. α-Oxidation is required for degradation of the dietary fatty acid phytanic acid (3,7,11,15-tetramethyl-16:0). This fatty acid cannot be degraded by β-oxidation owing to the methyl group on carbon-3. In the human diet, phytanic acid is obtained from the consumption of ruminant meats, fats, and dairy products. Rumen bacteria hydrolyze chlorophyll, releasing the phytol side chain; phytol is oxidized to phytanic acid and incorporated into triacylglycerol and phospholipids by the animal. Humans typically ingest 50–100 mg of phytanic acid per day. The current view of the α-oxidation pathway, which is found in peroxisomes, is shown in **Figure 5**. After activation to its CoA derivative, phytanoyl-CoA is hydroxylated on the 2-carbon. The next reaction catalyzes the removal of a one-carbon CoA derivative as formyl-CoA. The other product of this reaction is an aldehyde, pristanal, that can be oxidized to form pristanic acid (2,6,10,14-tetramethyl-15:0). This chain-shortening reaction effectively shifts the position of the first methyl group from carbon-3 (in phytanic acid) to carbon-2 (in pristanic acid). The 2-methyl-branched chain fatty acids can then be degraded further via peroxisomal β-oxidation.

Another mechanism for degradation of fatty acids that cannot undergo β-oxidation is known as ω-oxidation. In this process, the terminal methyl group (referred to as the ω-end) of a fatty-acid chain is oxidized to a carboxylic acid via cytochrome P450 isozymes, particularly the CYP52A family, in the endoplasmic reticulum. The resulting

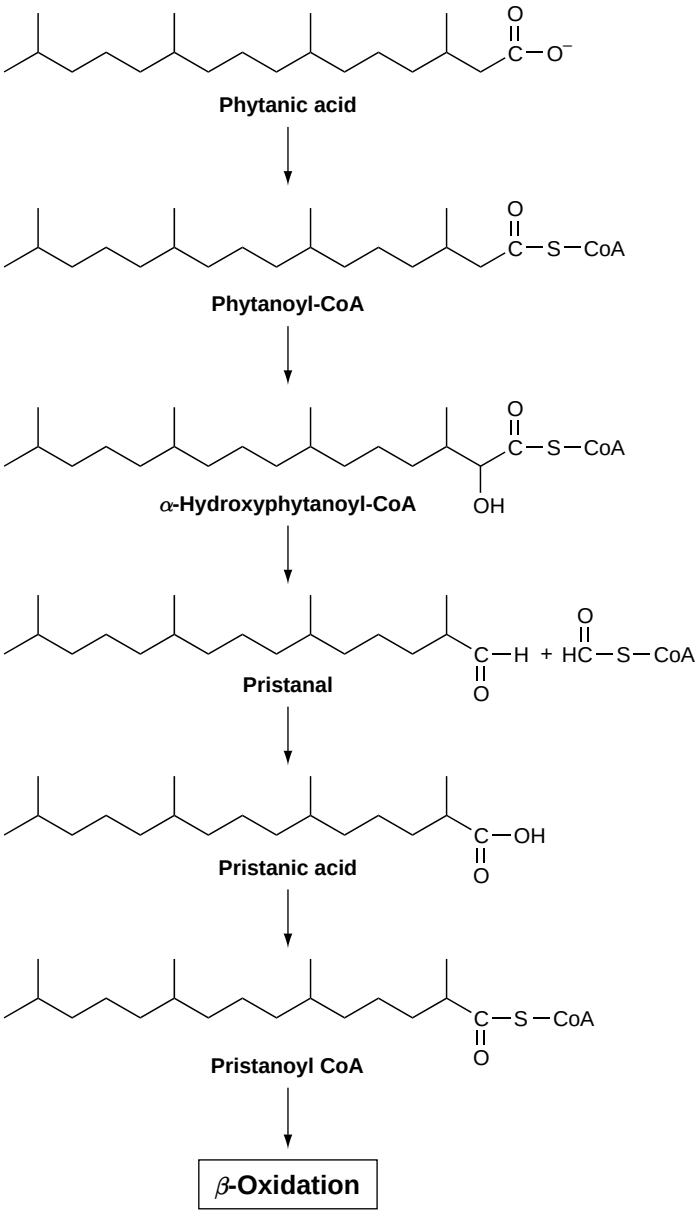

Figure 5 Peroxisomal phytanic acid α-oxidation pathway. The dietary 3-methyl-branched fatty acid phytanic acid is toxic if allowed to accumulate in the tissues. Its 3-methyl group prevents degradation by β-oxidation; therefore, this fatty acid is first shortened by one carbon atom. Like the substrates for peroxisomal β-oxidation, phytanic acid enters peroxisomes by an unknown mechanism. Activated phytanic acid is hydroxylated on carbon 2. Cleavage between carbons 1 and 2 yields a one-carbon CoA compound, formyl-CoA, and an aldehyde, pristanal. After oxidation and reactivation to the CoA derivative, pristanoyl-CoA can be degraded by β-oxidation.

dicarboxylic acids can then be at least partially degraded by β-oxidation from the ω-end, primarily in peroxisomes.

Fatty-Acid *de novo* Synthesis

Much of our need for fatty acids as constituents of phospholipids and other complex lipids is met by the diet. In addition, certain lipogenic tissues are capable of the *de novo* synthesis of fatty acids (**Figure 6**). These tissues include liver (hepatocytes), adipose tissue, and lactating mammary gland. Much of the fatty acids synthesized by all three tissues is incorporated into triacylglycerol. Hepatic synthesis is primarily for export to other tissues (in very low-density lipoproteins), while synthesis in adipocytes and mammary gland is for local storage.

The carbon used for fatty-acid synthesis typically derives from the products of glycolysis. The end product of glycolysis, pyruvate, enters the mitochondria and becomes the substrate for two separate

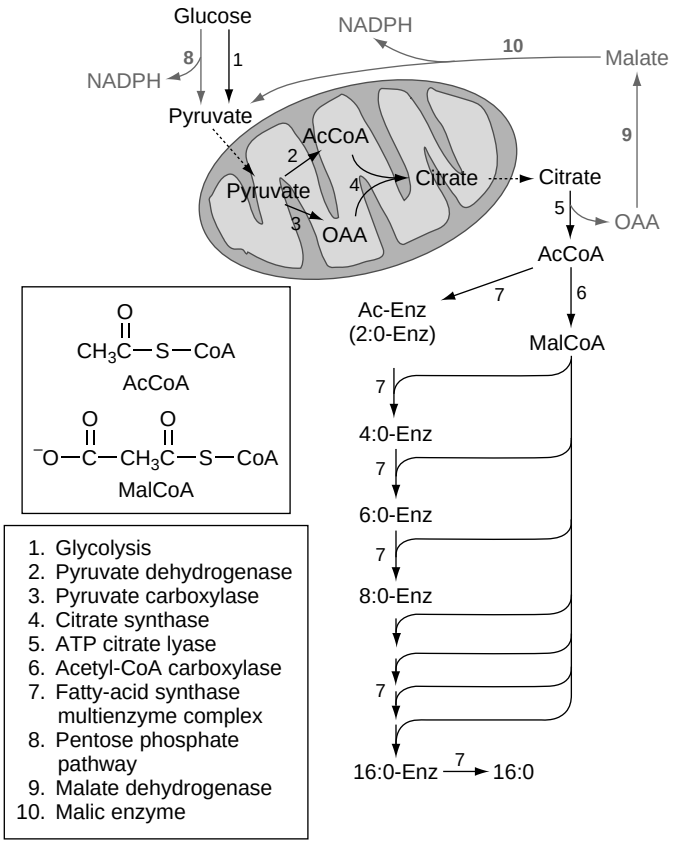

Figure 6 Fatty-acid biosynthesis. Cytoplasmic acetyl-CoA (AcCoA) is the primary substrate for *de novo* fatty-acid synthesis. This two-carbon compound most commonly derives from the glycolytic degradation of glucose, and its formation is dependent upon several reactions in the mitochondria. The mitochondrial enzyme pyruvate carboxylase is found primarily in tissues that can synthesize fatty acids. AcCoA is converted to malonyl-CoA (MalCoA) by acetyl-CoA carboxylase. Using AcCoA as a primer, the fatty-acid synthase multienzyme complex carries out a series of reactions that elongate the growing fatty acid by two carbon atoms. In this process MalCoA condenses with AcCoA, yielding an enzyme-bound four-carbon β-ketoacid that is reduced, dehydrated, and reduced again. The product is enzyme-bound 4:0. This process is repeated six more times, after which 16:0 is released from the complex. The reductive steps require NADPH, which is derived from enzyme reactions and pathways shown in grey. Enz refers to the fatty acid synthase multienzyme complex.

reactions. In one, pyruvate is decarboxylated via the pyruvate dehydrogenase complex, yielding acetyl-CoA. Lipogenic tissues also contain another mitochondrial enzyme, pyruvate carboxylase, which converts pyruvate to the four-carbon acid oxaloacetate (OAA). Acetyl-CoA and oxaloacetate condense to form the six-carbon acid citrate. As citrate accumulates within the mitochondrion, it is exported to the cytoplasm, where it is converted back to oxaloacetate and acetyl-CoA. Cytoplasmic acetyl-CoA is the fundamental building block for *de novo* synthesis of fatty acids.

The first enzyme unique to fatty-acid synthesis is acetyl-CoA carboxylase, which converts the two-carbon substrate acetyl-CoA into the three-carbon product malonyl-CoA. Citrate, in addition to being the precursor of cytoplasmic acetyl-CoA, has a regulatory role. Citrate is an allosteric activator of acetyl-CoA carboxylase and serves as a signal that there is an ample carbon supply for fatty-acid synthesis. As noted above, malonyl-CoA is a potent inhibitor of CPT1. Cytoplasmic malonyl-CoA levels will be high only when there is significant flux through glycolysis, indicative of a high cellular energy state. Under these conditions, entry of fatty acids into the mitochondria (and subsequent β-oxidation) is prevented. Interestingly, there are two isoforms of acetyl-CoA carboxylase. One is found in the above-named lipogenic tissues. The other is found in many tissues that are not capable of synthesizing fatty acids, e.g., the heart. It is thought that the primary role of the second isozyme is to regulate mitochondrial fatty-acid β-oxidation by synthesizing malonyl-CoA when cellular energy needs are being met by carbohydrate metabolism.

The subsequent reactions of fatty-acid synthesis in humans are catalyzed by a multienzyme

Table 1 Distinctions between fatty-acid β-oxidation and fatty-acid synthesis

	Fatty-acid β-oxidation	*Fatty-acid synthesis*
Tissues with active pathway	Nearly all tissues except brain, nerve, and erythrocytes	Liver, adipose, and lactating mammary gland
Subcellular location	Mitochondria	Cytoplasm
Redox cofactors	NAD, FAD	NADPH
Acyl-group carrier	CoA	Enzyme-bound acyl carrier protein
Stereochemistry of 3-hydroxy intermediate	L-	D-

complex, fatty-acid synthase. After binding of one molecule each of acetyl-CoA and malonyl-CoA to unique binding sites within the complex, a condensation reaction occurs in which carbon dioxide is released and an enzyme-bound 4-carbon 3-ketoacid is formed. Subsequent reactions include a reduction step, a dehydration step, and a second reduction step. The intermediates produced in these reactions are similar to those seen in β-oxidation (**Figure 2**), in reverse order. The product (enzyme bound) is the saturated fatty acid 4:0, which can then condense with another molecule of malonyl-CoA to start the process anew. After seven such cycles, the ultimate product is 16:0, which is released from the complex.

The reductive steps in fatty-acid synthesis require reduced nicotinamide adenine dinucleotide phosphate (NADPH). Some NADPH is produced during recycling of the oxaloacetate formed during the cytoplasmic hydrolysis of citrate, described above. Oxaloacetate is first converted to malate (via cytoplasmic malate dehydrogenase). Malate is then decarboxylated to pyruvate in an $NADP^+$-dependent reaction catalyzed by malic enzyme; NADPH is produced in this reaction. NADPH for fatty-acid biosynthesis also comes from reactions in the pentose phosphate pathway (hexose monophosphate shunt).

In several respects, the enzymatic reactions of fatty-acid synthesis are the converse of those in fatty-acid oxidation. However, there are key differences, which are summarized in **Table 1**.

Fatty-Acid Elongation

The primary product synthesized by the *de novo* pathway is 16:0. While 16:0 is an important fatty acid, there is a need to synthesize longer-chain acids. Enzymes for elongation of fatty-acids have been found in membranes of the endoplasmic reticulum and mitochondria. However, these pathways are less well-characterized than that of fatty-acid synthesis. In the endoplasmic reticulum, the reactions involved in fatty-acid elongation are very similar to those of cytoplasmic fatty-acid synthesis. The donor of the added carbon atoms is also malonyl-CoA, indicating that an active acetyl-CoA carboxylase is required for elongation. Whereas the primary reactions of fatty-acid synthesis are found within the fatty-acid synthase multienzyme complex, individual proteins catalyze the four elongation reactions (condensation, reduction, dehydration, and reduction). Like synthesis, elongation in the endoplasmic reticulum requires reducing equivalents in the form of NADPH.

Fatty-acid elongation in mitochondrial membranes is thought to be slightly different from the process in the endoplasmic reticulum. The primary difference is that the donor of elongation units is thought to be acetyl-CoA, not malonyl-CoA. The four elongation reactions are similar, but may require NADH rather than NADPH as source of reducing equivalents. Little is known about how fatty-acid elongation in either the mitochondria or the endoplasmic reticulum is regulated.

Fatty-Acid Unsaturation and the Essential Fatty Acids

Monounsaturated and polyunsaturated fatty acids are extraordinarily important in human health and nutrition. Thus, the insertion of double bonds into the carbon skeleton of a fatty acid is a vital metabolic function. However, humans are in general not capable of inserting double bonds closer than nine carbon atoms from the methyl end of a fatty acid. Thus, we are incapable of the *de novo* synthesis of two important classes of fatty acids, the *n*-3 fatty acids such as docosahexaenoic acid (22:6*n*-3) and the *n*-6 fatty acids such as arachidonic acid (20:4*n*-6). The *n*-3 fatty acids have proven to be beneficial in the prevention of coronary artery disease. The fatty acid 22:6*n*-3 has been shown to be important for the normal development of the brain and retina, leading some manufacturers to include this fatty acid in their infant formula preparations. The *n*-6 fatty acids are important constituents of membrane lipids. The fatty acid 20:4 is also the well-known precursor of prostaglandins and other bioactive eicosanoids. Since we cannot synthesize these fatty acids *de novo*, we are dependent on the presence of

at least some *n*-3 and some *n*-6 fatty acids in the diet. Linoleic acid (18:2*n*-6) and α-linolenic acid (18:3*n*-3) are the precursors of most biologically important *n*-3 and *n*-6 fatty acids; thus, they are referred to as essential fatty acids.

As noted earlier, the most abundant fatty acids in humans include a saturated fatty acid (16:0) and a monounsaturated fatty acid (18:1*n*-9). Humans can readily insert a *cis*-double bond nine carbons from the carboxyl carbon atom of a fatty acid (Δ9) in a reaction catalyzed by stearoyl-CoA desaturase (SCD1; so-named because the preferred substrate is the CoA derivative of 18:0, stearic acid). Because SCD1 is involved in the synthesis of such an abundant fatty acid, 18:1, the importance of this enzyme in metabolism was initially overlooked. However, 18:1 produced by SCD1 appears to be directed specifically towards triacylglycerol synthesis. Mice in which the SCD1 gene is disrupted have decreased adiposity. Furthermore, genetically obese leptin-deficient (ob–/ob–) mice in which the SCD1 gene is also disrupted have significantly reduced body weight compared with ob–/ob– mice, leading to the hypothesis that leptin regulates the synthesis of SCD1. Interestingly, dietary 18:1 seems to be more readily incorporated into lipids other than triacylglycerols, implying that the dietary and the SCD1-produced pools of this fatty acid are metabolically distinct. As with the *n*-3 fatty acids, dietary ingestion of monounsaturated fatty acids such as 18:1 has been associated with benefits to cardiovascular health.

Humans are also capable of inserting *cis*-double bonds either five or six carbon atoms from the carboxyl carbon atom of a fatty acid (Δ5 desaturase and Δ6 desaturase activity, respectively). These activities, when combined with the elongation pathways described above, form a powerful mechanism for synthesis of highly polyunsaturated fatty acids such as 20:4*n*-6 and 22:6*n*-3 from the dietary essential fatty acids. Previously, it was thought that humans also had the ability to insert a double bond four carbon atoms from the carboxyl carbon (Δ4 desaturase activity), as this activity was thought to be necessary for the conversion of 18:3*n*-3 to 22:6*n*-3. However, attempts to measure Δ4 desaturase activity experimentally were not successful. It is now thought that, through a series of elongation and desaturation reactions, 18:3*n*-3 is converted to the penultimate intermediate, 22:5*n*-3. Rather than using a Δ4 desaturase to complete the synthesis, 22:5*n*-3 is elongated to 24:5*n*-3, converted to 24:6*n*-3 by Δ6 desaturase, and finally chain-shortened to 22:6*n*-3 by one cycle of peroxisomal β-oxidation.

Fatty Acids as Components of Complex Lipids

Fatty acids are important building blocks for various cellular complex lipids (**Figure 7**). For simplicity, the pathways for incorporation of fatty acids into these lipids are outlined only briefly. More details can be found in any good biochemistry text. In most cases, fatty acyl-CoA and not free fatty acid participates in these biosynthetic reactions. Nearly all cells synthesize phospholipids, which are essential membrane constituents. Phospholipid synthesis takes place in the endoplasmic reticulum. It begins by fatty acylating the two free hydroxyl groups in α-glycerophosphate, a triose derived from glycolytic intermediates, yielding phosphatidic acid. Various head groups (e.g., choline, ethanolamine, inositol, or serine) can then be linked to the phosphate group. For synthesis of triacylglycerol, this phosphate moiety is removed, yielding diacylglycerol, and a third fatty acyl group is esterified to the free hydroxyl group.

Another type of lipid, the ether-linked phospholipids (e.g., plasmalogens), comprises about 20% of membrane phospholipids (**Figure 7**). Plasmalogen synthesis requires enzymes present in both peroxisomes and the endoplasmic reticulum. These lipids are thought to be part of the cellular defense mechanism against oxidative injury.

Fatty acids are also found esterified to the 3-hydroxyl group of cholesterol (cholesterol esters; ChE). ChE, which are more hydrophobic than free cholesterol, are a transport and storage form of cholesterol. ChE are found in high concentrations in low-density lipoproteins. Intracellular lipid droplets containing ChE are found in steroidogenic tissues and are thought to be a reservoir of cholesterol for steroid-hormone synthesis. The fatty acid most commonly found in ChE is 18:1. It must be activated to its CoA derivative before transfer to cholesterol in a reaction catalyzed by acyl-CoA cholesterol acyltransferase. ChE are also formed within lipoproteins by the transfer of one fatty acyl chain from phosphatidyl choline to cholesterol, a reaction catalyzed by circulating lecithin: cholesterol acyltransferase.

Synthesis of sphingolipids, which include sphingomyelin, ceramides, cerebrosides, and gangliosides, begins by the condensation of palmitoyl-CoA (16:0-CoA) with serine. The amino group of serine is then acylated by a second fatty acyl-CoA to form ceramide; the chain length of the second fatty acid can be variable. Transfer of phosphorylcholine (from the phospholipid phosphatidyl choline) to the hydroxyl group of ceramide yields

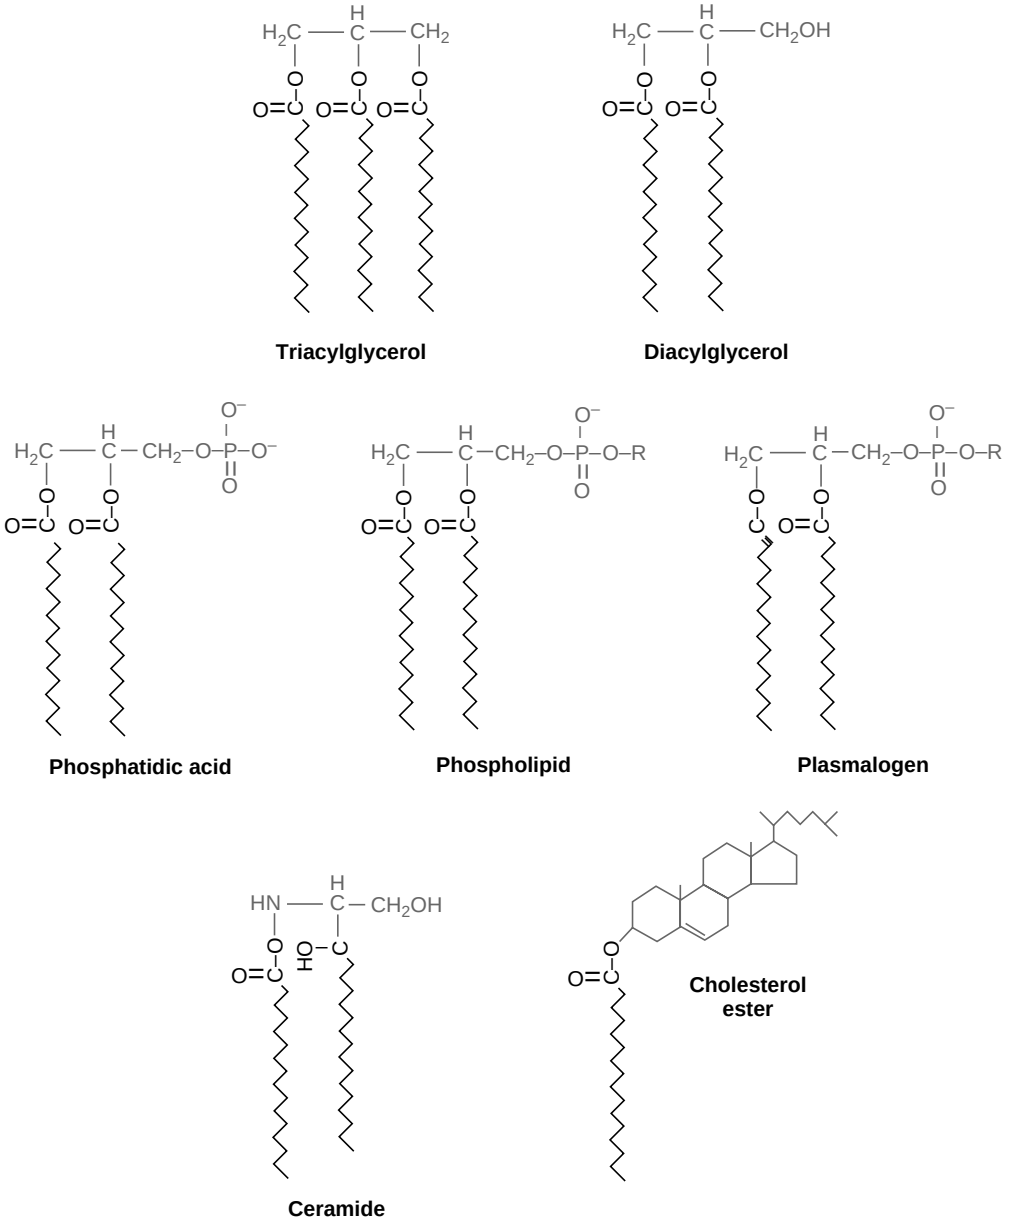

Figure 7 Fatty acids form the basis of most complex lipids. The part of the molecule derived from fatty acids is shown in black, and the part derived from other sources is shown in grey. For phospholipids and plasmalogens, R = choline, ethanolamine, inositol, serine, or a similar head group.

sphingomyelin. Alternatively, sugars (from sugar nucleotide donors) are added to produce the cerebrosides, gangliosides, and related lipids.

Eicosanoid Synthesis

The fatty acid 20:4*n*-6 (arachidonic acid) is the precursor of most eicosanoids, which include the prostaglandins, leukotrienes, and thromboxanes. Because it is an *n*-6 fatty acid, 20:4 must be derived from dietary lipids or synthesized by elongation and unsaturation of the essential fatty acid 18:2*n*-6. As with other fatty acids, cellular concentrations of unesterified 20:4 are low. Conversion of 20:4 to eicosanoids begins with an agonist-induced release of the fatty acid from the sn-2 position of membrane phospholipids via the action of phospholipase A2. Unlike most reactions of fatty acids, eicosanoid synthesis appears to use free 20:4 rather than its CoA derivative as the substrate. Cyclooxygenases (COX1 and COX2) catalyze a complex molecular oxygen-requiring reaction that converts 20:4 to

prostaglandin G2. This reaction involves carbon atoms in the middle of the acyl chain, rather than the methyl carbon (such as occurs in ω-oxidation) or the carboxyl carbon (such as occurs in nearly all other reactions of fatty acids). Prostaglandin G2 can subsequently be converted to other prostaglandins or to thromboxanes. As these compounds have potent biological effects, including mediation of inflammation, COX inhibitors are an important class of anti-inflammatory drugs. Free 20:4 is also the primary substrate for the enzyme 5-lipoxygenase, which is the first step in the synthesis of leukotrienes.

Fatty Acylation of Proteins

Covalent modification of proteins is a more recently discovered role of fatty acids. Fatty acylation of proteins frequently serves as a means of targeting or anchoring a protein to a membrane. Myristoylation, the addition of 14:0 to a protein, occurs at N-terminal glycine residues after removal of the initiator methionine. This process is generally co-translational and irreversible. N-myristoyl proteins include many signal-transduction-associated proteins, e.g., *src* and ADP-ribosylation factors. The enzyme N-myristoyltransferase catalyzes the reaction and uses 14:0-CoA as substrate.

Palmitoylation, the addition of 16:0 to a protein, is also commonly observed. This modification to the sulfydryl side chain of cysteine residues occurs post-translationally and is reversible. Both membrane-associated proteins and integral membrane proteins can be palmitoylated; examples are ion channels, neurotransmitter receptors, and sonic hedgehog. Protein palmitoyl transferases also use the CoA derivative of the fatty acid as a substrate. Several proteins are modified with both an N-terminal 14:0 and an S-linked 16:0 elsewhere in the protein chain. α-subunits of heterotrimeric G-proteins and endothelial nitric oxide synthase are examples of dually acylated proteins.

There are instances of acylation by fatty acids with chain lengths other than 14 or 16 carbon atoms. One nutritionally important example is the recently identified orexigenic peptide ghrelin. The active form of this 28-amino-acid peptide hormone has the medium-chain fatty acid 8:0 covalently esterified to the hydroxyl group of serine-3. Octanoylated ghrelin is believed to act at the level of the hypothalamus to stimulate appetite, perhaps via neuropeptide Y.

Vitamins and Fatty-Acid Metabolism

Several of the B vitamins are essential for normal fatty-acid metabolism (**Table 2**). Pantothenic acid is a constituent of CoA and is thus required for numerous reactions of fatty acids. Niacin and riboflavin are necessary for the synthesis of oxidized and reduced NAD(P) and FAD, respectively. These compounds play essential roles in fatty-acid oxidation, synthesis, and elongation. Biotin is a constituent of acetyl-CoA carboxylase and pyruvate carboxylase, both of which are involved in the synthesis of fatty acids from glucose. Thiamine is required for activity of the pyruvate dehydrogenase complex, which also participates in fatty-acid synthesis from glucose.

Regulation of Fatty-Acid Metabolism

A few specific aspects of the regulation of fatty-acid metabolism have been described above. More global regulatory mechanisms that deserve mention include those mediated by insulin and glucagon, sterol regulatory element-binding protein (SREBP) 1c, and peroxisome proliferator-activated receptor (PPAR) α. In the fed and fasted states, control of fuel metabolism is mediated to a large extent by insulin and glucagon, respectively. Effects of glucagon are mediated via cyclic adenosine monophosphate (cAMP)-dependent kinases and serve to decrease flux through glycolysis,

Table 2 Vitamins associated with fatty-acid metabolism

Vitamin	*Active form*	*Enzymes*	*Pathways*
Pantothenic acid	CoA	Many enzymes	Most reactions involving fatty acids
Niacin	NAD, NADH, NADP, NADPH	Dehydrogenases; reductases	Many pathways, particularly β-oxidation and fatty-acid synthesis and elongation
Riboflavin	FAD, $FADH_2$	Oxidases	β-Oxidation
Thiamine	Thiamine pyrophosphate	Pyruvate dehydrogenase complex; β-hydroxyphytanoyl-CoA lyase	Fatty-acid synthesis from glucose; phytanic acid β-oxidation
Biotin	Biocytin	Acetyl-CoA carboxylase; pyruvate carboxylase	Fatty-acid synthesis from glucose

thus decreasing the rate of *de novo* fatty-acid biosynthesis and increasing rates of mitochondrial β-oxidation and ketogenesis. Insulin effects are mediated through activation of its receptor tyrosine kinase and are in general opposite to those of glucagon, stimulating glycolysis and fatty-acid synthesis while inhibiting fatty-acid degradation. Insulin and glucagon have both acute and long-term effects on fatty-acid metabolism. The transcription factor SREBP1c is thought to mediate the action of insulin in upregulating genes involved in fatty-acid synthesis. Activation of PPARα on the other hand increases rates of fatty-acid oxidation and ketogenesis. Endogenous ligands for this nuclear receptor are thought to include polyunsaturated fatty acids and branched-chain fatty acids. The PPARs heterodimerize with the retinoid X receptor, and both receptors must be ligand-bound for transcriptional activation. Several mitochondrial, microsomal, and peroxisomal genes associated with fatty-acid catabolism are upregulated via PPARα stimulation.

Monounsaturated

P Kirk, University of Ulster, Coleraine, UK

Introduction

Fatty acids are described according to two characteristics: chain length and degree of saturation with hydrogen. Monounsaturated fatty acids (MUFA) have, as the name suggests, only one unsaturated bond attached to the carbon chain. This double bond is fixed in nature and is positioned on the ninth carbon atom counting from the methyl (omega) end of the fatty-acid chain. Four of these MUFA are found in significant quantities in food, the most common being oleic acid ($C_{18:1}$) (**Figure 1**). This n-9 fatty acid is capable of being synthesized by animals, including humans, but is predominantly incorporated via the diet. While butter and animal fats contain only small amounts of oleic acid, olive oil is a rich source. Olive oil, which comprises up to 70% of the fat intake in Mediterranean diets, is postulated to be effective in decreasing the risk of certain chronic diseases. These include such diseases as coronary heart disease, cancers, and inflammatory disorders, particularly rheumatoid arthritis.

Cholesterol Metabolism

Cholesterol metabolism is of fundamental biological importance. All vertebrates require cholesterol as a precursor for bile acids and hormones, including corticosteroids, sex steroids, and vitamin D. The amount of cholesterol found in tissues greatly exceeds the requirement for production of these hormones and bile acids, and the bulk of this excess is associated with the cell-membrane structure, where it is believed to modulate the physical state of phospholipid bilayers.

Cholesterol circulates in plasma as a component of lipoproteins. There are several distinct classes of plasma lipoprotein, which differ in several respects, including type of apolipoprotein and relative content of triacylglycerol and cholesterol.

Cholesterol transport

Chylomicron remnants deliver dietary cholesterol to the liver. It is then incorporated into very low-density lipoproteins (VLDL), which are secreted in

Figure 1 Structure of oleic acid, $C_{18:1}$.

plasma. The VLDL acquire cholesteryl esters and apolipoprotein E (apo E) from high-density lipoproteins (HDL) to produce intermediate-density lipoproteins (IDL), which are rapidly taken up by the liver or are further catabolized into low-density lipoproteins (LDL). These cholesterol-rich LDL particles are catabolized only slowly in human plasma and are therefore present at relatively high concentrations. Elimination of cholesterol from these extrahepatic cells is achieved by the delivery of cholesterol from cell membranes to plasma HDL in the first step of a pathway known as reverse cholesterol transport. This process allows for esterification of cholesterol and its delivery back to the liver.

LDL, HDL, and atherosclerosis

Membrane function is compromised if it contains either too much or too little cholesterol. Epidemiological studies have classified raised plasma cholesterol levels as a risk factor for atherosclerosis, and it is one of the more important predictors of coronary heart disease (CHD). Elevated plasma cholesterol concentration (hypercholesterolemia) is associated with an increased concentration of LDL, owing to either an increased rate of LDL formation or a decrease in the rate at which they are cleared from plasma, and usually a decreased concentration of HDL. Numerous dietary-intervention studies have aimed both to prevent CHD and to reduce total mortality, but almost all have been ineffective.

MUFA and CHD

Many of the trials conducted concentrated on the substitution of polyunsaturated vegetable oils for saturated fat from animal sources and on decreasing the amount of dietary cholesterol. These studies followed the reasoning that fats rich in saturated fatty acids (SFA) raised plasma cholesterol mainly by increasing plasma LDL cholesterol levels, and oils rich in polyunsaturated fatty acids (PUFA) lowered plasma cholesterol mainly by decreasing LDL cholesterol. The MUFA were first considered neutral in regard to their influence on plasma cholesterol, but more recent findings suggest a decrease in total LDL cholesterol concentration following substitution of SFA by MUFA. Moreover, clinical trials have also shown that a MUFA-rich diet does not decrease concentrations & HDL, the lipoprotein inversely correlated with CHD.

Although important links exist between cholesterol metabolism and aspects of cell function, other complicating factors must be considered. Cholesterol metabolism is sensitive to the inflammatory response that accompanies most pathological events. Tumor necrosis factor (TNF) reduces LDL and HDL cholesterol levels and inhibits lipoprotein lipase, resulting in a fall in cholesterol and an increase in triacylglycerol levels. These changes may be perpetuated beyond the acute phase if an inflammatory process is present. Cholesterol metabolism is also sensitive to genetic and environmental factors, which may have independent effects on noncardiovascular disease. As a consequence, the relationship between cholesterol levels and the presence or absence of a disease state must be interpreted with caution.

Atherogenesis and Endothelial Dysfunction

Atherosclerosis can be considered as a chronic inflammatory disease, which slowly progresses over a period of decades before clinical symptoms become manifest. The atherogenic process comprises interactions between multiple cell types, which initiate a cascade of events involving alterations in vascular production of autocoids, cytokines, and growth factors. The endothelium, because of its location between blood and the vascular wall, has been implicated in the atherogenic process from the initial stages.

Function of endothelial cells

Owing to the strategic location of the endothelium, it is able to perform many different functions. In addition to acting as a protective barrier, endothelial cells have been shown to play important roles in control of homeostasis, capillary transport, and, more importantly, regulation of the tone of underlying vascular smooth muscle. The endothelium evokes relaxation of these muscle cells, allowing vasodilation via the chemical factor endothelium-derived relaxing factor (EDRF), which has been identified as nitric oxide (NO). The EDRF or NO is vital for maintaining the vasodilatory capacity of vascular muscle and also controls levels of platelet function and monocyte adhesion. Any endothelial injury or dysfunction could therefore be an important factor in atherosclerosis.

Endothelial dysfunction

Decrease in the production, release, or action of NO may lead to enhanced expression of adhesion molecules and chemotactic factors at the endothelial surface. The exact nature of endothelial dysfunction is unknown, although possibilities include a decreased expression of NO synthase, imbalance between the production of endothelium-derived constricting and

relaxing factors, production of an endogenous NO synthase inhibitor, and overproduction of oxygen-derived free radicals including O_2^-. The release of the free radical O_2^- from smooth muscle cells is believed to be responsible for the oxidation of LDL cholesterol. Raised cholesterol levels and – more importantly – increased levels of oxidatively modified LDL cholesterol (OxLDL) are considered to be among the most powerful inhibitors of normal endothelial function and hence contribute to the process of atherogenesis.

Lipid peroxidation and atherosclerosis

Lipid peroxidation apparently plays a major role in the pathology of atherosclerosis. Atherosclerosis, which is usually a precondition for CHD, is a degenerative process leading to the accumulation of a variable mixture of substances including lipid in the endothelium of the arteries. This disease is characterized by the formation of a fatty streak and the accumulation of cells loaded with lipid: the foam cells. These cells are believed to arise from white blood cell-derived macrophages or arterial smooth muscle cells. Most of the lipid in the foam cells is in the form of LDL particles. Although research has determined that LDL receptors are responsible for the uptake of LDL by cells, the arterial uptake of LDL, which leads to development of foam cells, occurs by a different pathway. It is only when the LDL particles have undergone oxidative modification that they are available for uptake by macrophages via the scavenger receptor. During the course of oxidative modification, LDL cholesterol acquires various biological properties not present in native LDL that make it a potentially important mediator, promoting atherogenesis. The LDL, once oxidized, becomes cytotoxic and causes local cellular damage to the endothelium. This process, which enhances LDL uptake to generate foam cells, is considered one of the earliest events in atherogenesis (**Figure 2**).

MUFA and atherogenesis

Studies have looked at the oxidizability *in vitro* of LDL using nonphysiological oxidizing conditions to evaluate the susceptibility of LDL to oxidation and hence its atherogenic potential. It is well known that modification of LDL is inhibited by various antioxidants commonly present within plasma LDL particles. More recent studies, however, indicate that raising the ratio of $C_{18:1}$ to $C_{18:2}$ (linoleic acid) may also reduce the susceptibility of LDL to oxidation. The LDL is particularly vulnerable to peroxidation once PUFA form part of the lipoprotein fraction of cell membranes, as these fatty acids

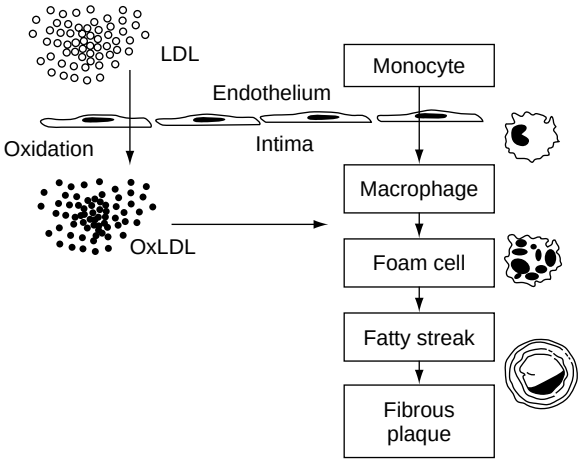

Figure 2 The role of oxidized LDL (OxLDL) in formation of foam cells. Reproduced with permission from Ashwell M (1993) *Diet and Heart Disease – A Round Table of Factors*. London: British Nutrition Foundation.

have reactive double bonds in their structures. The MUFA are much less easily oxidized as they have only one double bond. This property may confer a protective effect against CHD by generating LDL particles more resistant to oxidation. Further protection may be afforded from MUFA as they do not lower HDL. It is postulated that oxidized HDL, in contrast to oxidized LDL, is not avidly taken up by macrophages but instead inhibits the modification of LDL, thereby substantially decreasing oxidized LDL cellular uptake.

Oxidation of LDL cholesterol is, therefore, clearly linked to damage to the endothelium and hence to the process of atherogenesis. It has, however, more far-reaching effects, as it has also been linked to activation and aggregation of platelets. This process is involved in the production of occlusive thrombosis, which contributes significantly to the fibrous atherosclerotic plaque.

Thrombosis and Fibrinolysis

The importance of thrombosis in causing heart disease is receiving increasing attention. Thrombosis, in contrast to atherosclerosis, is an acute event resulting in the formation of a thrombus or blood clot, which is an aggregate of fibrin, platelets, and red cells. Blood clotting or coagulation is an important process as it is responsible for repairing tissues after injury. Under normal physiological conditions, a blood clot forms at the site of injury. Platelets are attracted to the damaged tissue and adhere to the surface. They are then activated to release substances that attract more platelets, allowing platelet aggregation and triggering coagulation mechanisms.

The coagulation cascade

The process of blood coagulation involves two pathways: the extrinsic and intrinsic pathways (**Figure 3**). The cascade is dependent on a series of separate clotting factors, each of which acts as a catalyst for the next step in the system. The process results in the formation of insoluble fibrin from the soluble protein fibrinogen. This then interacts with a number of blood components, including red blood cells, to form the thrombus. Any damage to the endothelium, therefore, causes platelet aggregation and adherence to the lining of the blood-vessel walls, thereby triggering the coagulation cascade. An imbalance of this process, by increasing the rate of thrombus formation, could increase the risk of CHD, and data have shown that levels of factor VII and fibrinogen are particularly important in balancing the coagulation cascade.

Factor VII and fibrinogen

There is accumulating evidence the factor VII is involved in arterial thrombosis and atherogenesis. The physiology of the factor VII system is intricate, not least since it can potentially exist in several forms. Activation of factor VIIc is generally achieved by tissue factor and initiates blood coagulation by subsequent activation of factors IX and X. It has been further suggested that tissue factor associated with the lipoproteins LDL and VLDL, but not HDL, may possibly generate factor VIIc activity, and a direct relationship is believed to exist between the level of factor VII complex in plasma and the dietary influence on plasma triacylglycerol concentration.

Several mechanisms have been suggested whereby an increase in plasma fibrinogen concentration may be linked to CHD. These include the involvement of fibrinogen and fibrin in the evolution of the atheromatous plaque through fibrin deposition and in

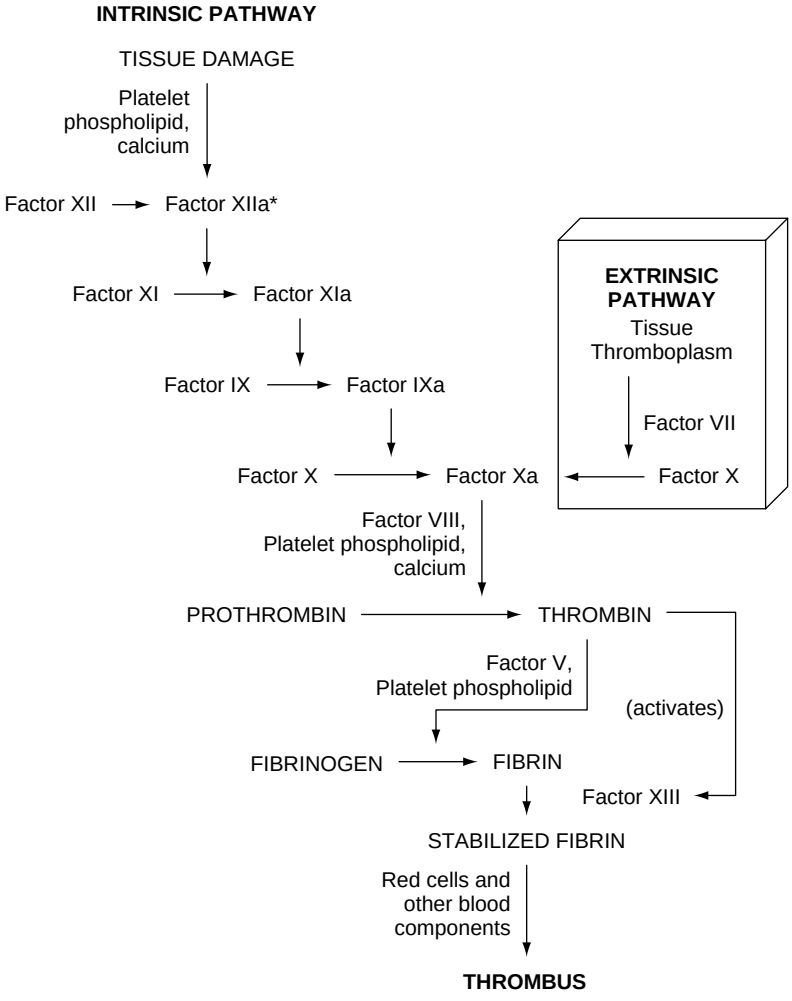

Figure 3 The coagulation cascade; a, active. Reproduced with permission from Buttriss JL and Gray J (1992) *Coronary Heart Disease II, Fact File 8*. London: National Dairy Council. Copyright National Dairy Council.

platelet aggregation through its impact on blood viscosity, which in turn is related to the risk of thrombosis. A mechanism exists to dissolve the thrombus by the breakdown or lysis of the fibrin meshwork (fibrinolysis). Plasminogen, which is generated by plasmin, is the zymosan that ultimately effects fibrinolysis. Failure of the mechanism to activate will cause obstruction of blood vessels and prevent normal blood supply.

Fibrinolysis

Investigators have shown that a decrease in the release of tissue plasminogen activator (tPA) and an elevation of plasminogen activator inhibitor 1 (PAI-1) will reduce fibrinolytic function. It has emerged that triacylglycerol-rich lipoproteins stimulate PAI-1 secretion from endothelial cells, and furthermore it has been shown that OxLDL induces secretion, whereas native LDL has no detectable effect. Lipoprotein (a) (Lp(a)) has also been linked with a decrease in fibrinolysis. Lp(a) is an LDL-like particle consisting of the protein apo(a). It is believed that apo(a) competes with plasminogen and plasmin for binding to fibrin, thus interfering with fibrinolysis; LDL and Lp(a) may represent, therefore, an important link between thrombotic and lipid mechanisms in atherogenesis.

MUFA and thrombosis

Results from animal studies have shown an elevation in platelet activation and hence greater risk of thrombosis as a result of feeding saturated fat. Platelet aggregation thresholds, however, decrease when total fat intake is decreased or when dairy and animal fats are partially replaced with vegetable oils rich in PUFA. These studies failed, however, to keep the intakes of SFA and total fat constant. More recent work has shown that, in fact, diets high in PUFA significantly increase platelet aggregation in animals, compared with MUFA-rich diets. The changes in fatty-acid composition may affect blood clotting because the increase in PUFA allows for oxidation of LDL. As previously mentioned, OxLDL is cyto-toxic, and this can cause endothelial damage leading to the activation of platelets, generation of factor VII, and hence thrombus formation. Increased dietary intakes of MUFA may also increase the rate of fibrinolysis by lowering levels of LDL cholesterol and reducing the susceptibility of LDL to oxidation, thereby affecting both PAI-1 secretion and apo(a) activity.

It must be noted that both atherosclerosis and thrombosis are triggered by inflammation, and evidence suggests that several hemostatic factors other than the glycoprotein fibrinogen not only have an important role in thrombotic events but are also recognized as potentially important CHD risk factors.

Inflammation and Oxidative Damage

Many diseases that have an inflammatory basis such as cancer, sepsis, and chronic inflammatory diseases such as rheumatoid arthritis (RA) have symptoms mediated by pro-inflammatory mediators named cytokines. These mediators, which include interleukins (IL) 1–8, tumor necrosis factors (TNF), and interferons, are essential for protection from invading bodies. They act by producing a situation in which immune cells are attracted to the inflammatory site and are activated. An inflammatory stimulus, such as tissue damage incurred by trauma or invasion of tissue by bacteria or viruses, induces production of IL-1, IL-6, and TNF from a range of immune cells, including phagocytic leucocytes and T and B lymphocytes. Once induced, IL-6, IL-1, and TNF further induce each other's production, leading to a cascade of cytokines, which are capable of producing metabolic and immune effects. Inflammatory stimuli also bring about the activation of neutrophils to release free radicals, which enhance the production of TNF and other cytokines. Overproduction of these pro-inflammatory mediators may, therefore, allow excessive release of reactive oxygen species (ROS) into extracellular fluid to damage its macromolecular components.

Oxidative damage

Free radicals are any species capable of an independent existence that contain one or more unpaired electrons. ROS is a collective term, referring not only to oxygen-centered radicals such as superoxide ($O_2^{\cdot}$) and the hydroxy radical ($^{\cdot}OH$), but also to hydrogen peroxide (H_2O_2), ozone (O_3), and singlet oxygen ($^1O_2$). These are produced as the by-products of normal metabolism and, as such, are highly reactive in chemical terms. In order to become more stable chemically, the free radical reacts with other molecules by either donating or taking an electron, in either case leaving behind another unstable molecule, and hence this becomes a chain reaction. So, although oxygen is essential for life, in certain circumstances it may also be toxic. Damage caused by ROS to cellular target sites includes oxidative damage to proteins, membranes (lipid and proteins), and DNA. PUFA are particularly vulnerable to ROS attack because they have unstable double bonds in their structure. This process is termed 'lipid

peroxidation'; because PUFA are an essential part of the phospholipid fraction of cell membranes, uncontrolled lipid peroxidation can lead to considerable cellular damage. The balance of MUFA in cell membranes is also critical to cell function, but, as already noted, MUFA are far less vulnerable to lipid peroxidation.

MUFA and inflammation

Oxidative damage by ROS to DNA and lipids contributes significantly to the etiology of cancer and atherosclerosis. A decrease in production of pro-inflammatory mediators would, therefore, be beneficial by decreasing the release of ROS. Diminishing the production of cytokines is also believed to improve the symptoms of RA. It has been suggested that olive oil may have anti-inflammatory properties as it can reduce the production of these proinflammatory mediators. Although few studies have been carried out on the benefits of olive oil on symptoms of inflammation, it is possible that olive oil produces a similar effect to fish oil. Fish oils and butter have both been shown to reverse the proinflammatory effects of one cytokine, TNF. Further research, where $C_{18:1}$ was added to a diet containing coconut oil, resulted in responses to TNF that were similar to those seen in animals fed butter. It was assumed that, as the anti-inflammatory effects of butter appeared to be due to its oleic acid content, olive oil should be more anti-inflammatory. This was put to the test, and, while both butter and olive oil reduced the extent of a number of symptoms of inflammation, olive oil showed a greater potency than butter. From this, it can be concluded that dietary factors such as olive oil may play a significant protective role in the development severity of RA.

Carcinogenesis

Cancer is second only to CHD as a cause of death in Western countries. Cancer in humans is a multistep disease process in which a single cell can develop from an otherwise normal tissue into a malignancy that can eventually destroy the organism. Carcinogenesis is believed to proceed through three distinct stages. Initiation is brought about when carcinogens mutate a single cell. This mutation provides a growth advantage, and cells rapidly proliferate during the second stage, promotion. Tumor promotion produces relatively benign growths, which can be converted into cancer in the third stage, malignant conversion. While the causes of cancer are not known with certainty, both initiation and conversion require some form of genetic alteration, and ROS and other free radicals have long been known to be mutagenic (**Figure 4**).

Oxidation and cancer

Although PUFA are the most reactive of substrates for ROS attack leading to lipid peroxidation, interest is centering on the detection of oxidized nucleic acids as an indicator of pro-oxidant conditions. It

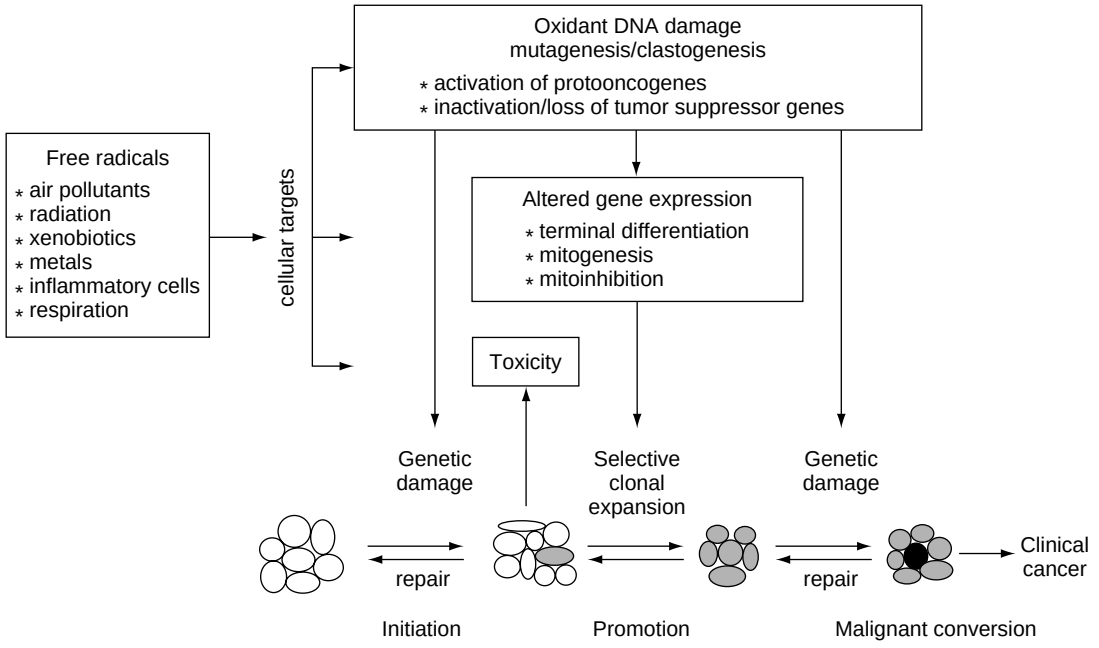

Figure 4 The role of oxidants in multistage carcinogenesis. Reproduced with permission from Guyton KZ and Kensler TW (1993) Oxidative mechanisms in carcinogenesis. *British Medical Bulletin* **49**: 523–544.

has been indicated that significant oxidative damage occurs *in vitro* and contributes to the etiology of cancer. It has become apparent that many genotoxic agents act through the common mechanism of oxidative damage to DNA. Oxidative processes may be responsible for initiating carcinogenic changes via DNA oxidative damage and may also act as tumor promoters, modulating the expression of genes that regulate cell differentiation and growth and act synergistically with the initiators. Animal studies have indicated diets containing high levels of $C_{18:2}$ as strong promoters of tumors, and this may be as a result of increased oxidative stress. The fact that MUFA are much less readily oxidized may therefore confer a protective effect against carcinogenesis.

Immune function and cancer

The diet is believed to play an important role in the onset of carcinogenesis, and there are a number of carcinogens present in food, including mycotoxins, polycyclic hydrocarbons, and pesticides. Associations have been made between dietary fat intake and morbidity and mortality from breast and colon cancer. Another possible mechanism for the proposed protective effects against cancer of olive oil compared with sunflower oil involves diet-induced alterations in host immune responses. Both the type and concentration of dietary fats have been reported to influence immune status in several animal models. The PUFA $C_{18:2}$ is necessary for T-cell-mediated immunity, but high intakes will suppress immune function and may therefore increase the risk of cancer. Furthermore, comparisons between the effects of diets rich in $C_{18:2}$ and those rich in $C_{18:1}$ on varying indicators of immune function in mice have shown that, while dietary $C_{18:2}$ predisposed animals to suppression of certain T-cell-mediated reactions, diets rich in $C_{18:1}$ did not. MUFA may therefore have a significant effect in humans against cancer, by lowering the risk of suppression of T-cell activity.

Other Physiological Effects

Because many, sometimes competing, mechanisms appear to mediate the relation between intake of MUFA and CHD incidence, no single surrogate biochemical or physiological response can predict with confidence the effect of a particular dietary pattern. For this reason examinations of the relation between specific dietary factors and CHD incidence itself are particularly valuable because such studies integrate the effects of all known and unknown mechanisms. The extremely low rate of CHD in countries with high consumption of olive oil, for instance, suggests the benefits of substituting this fat for other fats. This kind of analysis has been expanded further by noting that MUFA intake is inversely associated with total mortality as well as with CHD. Some effects may well be because of the amount of antioxidant vitamins olive oil contains. Vegetable oils are the most important source of α-tocopherol in most diets, and olive oil contains about 12 mg per 100 g. Evidence indicates that α-tocopherol functions as a free-radical scavenger to protect cellular membranes from oxidative destruction. Oxidative stress has been linked to an increased risk of many chronic diseases, including atherosclerosis, cancer, and inflammatory disorders. Other injuries such as cataract and reperfusion injury are also associated with an increase in oxidative stress and a decrease in antioxidant activity.

A large body of evidence suggests a beneficial effect of MUFA in the diet. Although much remains to be learned about the mechanisms by which $C_{18:1}$ acts, it is believed to lower risks of CHD, several common cancers, cataracts, and other inflammatory disorders. It is suggested, therefore, that consuming MUFA, for instance in the form of olive oil as used widely in the Mediterranean diet, is likely to enhance long-term health.

Omega-3 Polyunsaturated

A P Simopoulos, The Center for Genetics, Nutrition and Health, Washington, DC, USA

Introduction

Over the past 20 years many studies and clinical investigations have been carried out on the metabolism of polyunsaturated fatty acids (PUFAs) in general and on n-3 fatty acids in particular. Today we know that n-3 fatty acids are essential for normal growth and development. Research has been carried out in animal models, tissue cultures, and human beings. The original observational studies have given way to controlled clinical intervention trials. Great progress has taken place in our knowledge of the physiologic and molecular mechanisms of the n-3 fatty acids in health and disease. Specifically, their beneficial effects have been shown in the prevention and management of coronary heart disease, hypertension, type 2 diabetes, renal disease, rheumatoid arthritis, ulcerative colitis, Crohn's disease, and chronic obstructive pulmonary disease. This chapter focuses on the sources, desaturation and elongation of n-6 and n-3 fatty acids; evolutionary aspects of diet relative to n-3 fatty acids and the n-6:n-3 balance; eicosanoid metabolism and biological effects of n-6 and n-3 fatty acids; nutrigenetics – interaction between the n-6:n-3 fatty acids and the genome; effects of dietary α-linolenic acid compared with long-chain n-3 fatty acid derivatives on physiologic indexes; human studies in growth and development; coronary heart disease; inflammation – a common base for the development of coronary heart disease, diabetes, arthritis, mental health and cancer; the need to return the n-3 fatty acids into the food supply for normal homeostasis; and future considerations.

n-6 and n-3 Fatty Acids: Sources, Desaturation and Elongation

Unsaturated fatty acids consist of monounsaturates and polyunsaturates. There are two classes of PUFA: n-6 and n-3. The distinction between n-6 and n-3 fatty acids is based on the location of the first double bond, counting from the methyl end of the fatty acid molecule. In the n-6 fatty acids, the first double bond is between the 6th and 7th carbon atoms and in the n-3 fatty acids the first double bond is between the 3rd and 4th carbon atoms. Monounsaturates are represented by oleic acid an n-9 fatty acid, which can be synthesized by all mammals including humans. Its double bond is between the 9th and 10th carbon atoms (**Figure 1**).

n-6 and n-3 fatty acids are also known as essential fatty acids (EFAs) because humans, like all mammals, cannot make them and must obtain them in their diet. n-6 fatty acids are represented by linoleic acid (LA; 18:2n-6) and n-3 fatty acids by α-linolenic acid (ALA; 18:3n-3). LA is plentiful in nature and is found in the seeds of most plants except for coconut, cocoa, and palm. ALA, on the other hand, is found in the chloroplasts of green leafy vegetables and in the seeds of flax, rape, chia, perilla, and in walnuts (**Tables 1**, **2**, and **3**). Both EFAs are metabolized to longer chain fatty acids of 20 and 22 carbon atoms. LA is metabolized to arachidonic acid (AA; 20:4n-6) and LNA to eicosapentaenoic acid (EPA; 20:5n-3) and docosahexaenoic acid (DHA; 22:6n-3), increasing the chain length and degree of unsaturation by adding extra double bonds to the carboxyl end of the fatty acid molecule (**Figure 2**).

Humans and other mammals, except for carnivores such as lions, can convert LA to AA

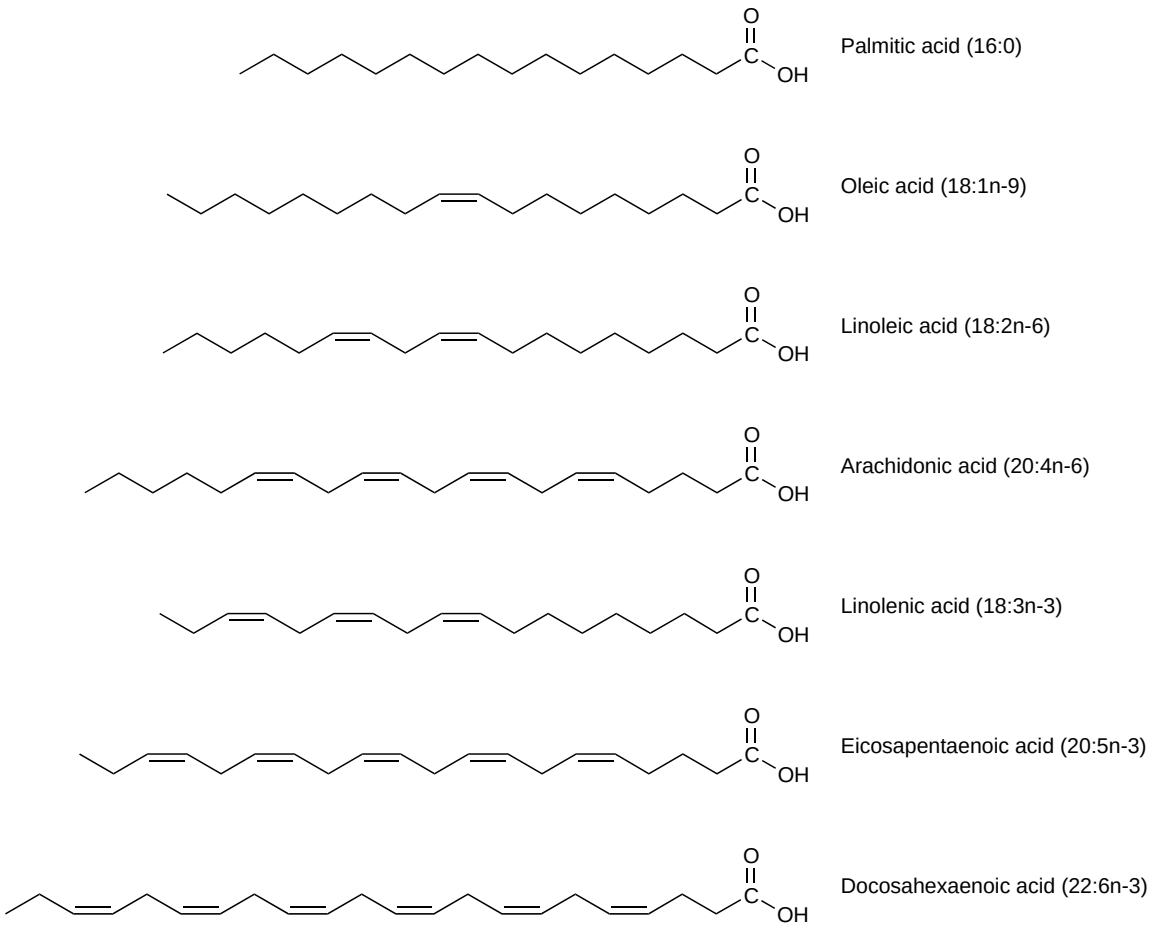

Figure 1 Structural formulas for selected fatty acids.

and ALA to EPA and DHA. This conversion was shown by using deuterated ALA. There is competition between n-6 and n-3 fatty acids for the desaturation enzymes. However, both Δ-4 and Δ-6 desaturases prefer n-3 to n-6 fatty acids. But a high LA intake interferes with the desaturation and elongation of ALA. *Trans*-fatty acids interfere with the desaturation and elongation of both LA and ALA.

Table 1 Polyunsaturated oils high in n-6 and n-3 fatty acids

n-6 oils	*n-3 oils*
Corn oil	Fish oil
Safflower oil	Chia oil
Sunflower seed oil	Perilla oil
Cottonseed oil	Flaxseed oil
Soybean oil	Canola oil
Peanut oil	Walnut oil
Sesame oil	Soybean oil[a]
Grapeseed oil	
Borage oil	
Primrose oil	

[a]note: soybean oil is higher in n-6 fatty acids than most n-3 oils, so it belongs in both categories.

Δ-6 desaturase is the limiting enzyme and there is some evidence that it decreases with age. Premature infants, hypertensive individuals, and some diabetics are limited in their ability to make EPA and DHA from ALA. These findings are important and need to be considered when making dietary recommendations. EPA and DHA are found in the oils of fish, particularly fatty fish (**Table 4**). AA is found predominantly in the phospholipids of grain-fed animals and eggs.

LA, ALA, and their long-chain derivatives are important components of animal and plant cell membranes. In mammals and birds, the n-3 fatty acids are distributed selectively among lipid classes. ALA is found in triglycerides, in cholesteryl esters, and in very small amounts in phospholipids. EPA is found in cholesteryl esters, triglycerides, and phospholipids. DHA is found mostly in phospholipids. In mammals, including humans, the cerebral cortex, retina, and testis and sperm are particularly rich in DHA. DHA is one of the most abundant components of the brain's structural lipids. DHA, like EPA, can be

derived only from direct ingestion or by synthesis from dietary EPA or ALA.

Evolutionary Aspects of Diet Relative to n-3 Fatty Acids and the n-6:n-3 Balance

On the basis of estimates from studies in Paleolithic nutrition and modern-day hunter-gatherer populations, it appears that human beings evolved consuming a diet that was much lower in saturated fatty acids than today's diet. Furthermore, the diet contained small and roughly equal amounts of n-6 and n-3 PUFAs (ratio of 1–2:1) and much lower amounts of *trans*-fatty acids than today's diet (**Figure 3**). The current Western diet is very high in n-6 fatty acids (the ratio of n-6 to n-3 fatty acids ranges between 10:1 and 30:1) because of the recommendation to substitute vegetable oils high in n-6 fatty acids for saturated fats to lower serum cholesterol concentrations. Furthermore, intake of n-3 fatty acids is much lower today because of the decrease in fish consumption and the industrial production of animal feeds rich in grains containing n-6 fatty acids, leading to production of meat rich in n-6 and poor in n-3 fatty acids. The same is true for cultured fish and eggs. Even cultivated vegetables contain fewer n-3 fatty acids than do plants in the wild. In summary, modern agriculture, with its emphasis on production, has decreased the n-3 fatty acid content in many foods: green leafy vegetables, animal meats, eggs, and even fish, while it has increased the amount of n-6 fatty acids in foods, leading to high n-6 intake for the first time in the history of human beings in many countries around the world (**Table 5**). The traditional diet of Crete (Greece) is consistent with the Paleolithic diet relative to the n-6:n-3 ratio. The Lyon Heart Study, which was based on a modified diet of Crete, had an n-6:n-3 ratio of 4:1 resulting in a 70% decrease in risk for cardiac death. As shown in **Table 6**, the higher the ratio of n-6 to n-3 fatty acids in platelet phospholipids, the higher the death rate from cardiovascular disease. As the ratio of n-6 PUFAs to n-3 PUFAs increases, the prevalence of type 2 diabetes also increases (**Figure 4**). As will be discussed below, a balance between the n-6 and n-3 fatty acids is a more physiologic state in terms of gene expression, eicosanoid metabolism, and cytokine production.

Further support for the need to balance the n-6:n-3 PUFAs comes from studies that clearly show the ability of both normal rat cardiomyocytes and human breast cancer cells in culture to form all the n-3 fatty acids from n-6 fatty acids when fed the cDNA encoding n-3 fatty acid desaturase obtained from the roundworm *Caenorhabditis elegans*. The n-3 desaturase efficiently and quickly converted the n-6 fatty acids that were fed to the cardiomyocytes in culture to the corresponding n-3 fatty acids. Thus, n-6 LA was converted to n-3 ALA and AA was converted to EPA, so that at equilibrium, the ratio of n-6 to n-3 PUFAs was close to 1:1. Further studies

demonstrated that the cancer cells expressing the n-3 desaturase underwent apoptotic death whereas the control cancer cells with a high n-6:n-3 ratio continued to proliferate.

Eicosanoid Metabolism and Biological Effects of n-6 and n-3 Fatty Acids

When humans ingest fish or fish oil, the ingested EPA and DHA partially replace the n-6 fatty acids (especially AA) in cell membranes, particularly those of platelets, erythrocytes, neutrophils, monocytes, and liver cells.

Because of the increased amounts of n-6 fatty acids in the Western diet, the eicosanoid metabolic products from AA, specifically prostaglandins, thromboxanes, leukotrienes, hydroxy fatty acids, and lipoxins, are formed in larger quantities than those formed from n-3 fatty acids, specifically EPA. As a result (**Figure 5**), ingestion of EPA and DHA from fish or fish oil leads to: (1) decreased production of prostaglandin E2 metabolites; (2) decreased concentrations of thromboxane A2, a potent platelet aggregator and vasoconstrictor; (3) decreased formation of leukotriene B4, an inducer of inflammation and a powerful inducer of leukocyte chemotaxis and adherence; (4) increased concentrations of thromboxane A3, a weak platelet aggregator and vasoconstrictor; (5) increased concentrations of prostacyclin prostaglandin I3 (PGI3), leading to an overall increase in total prostacyclin by increasing PGI3 without decreasing PGI2 (both PGI2 and PGI3 are active vasodilators and inhibitors of platelet aggregation); and (6) increased concentrations of leukotriene B5, a weak inducer of inflammation and a chemotactic agent. The eicosanoids from AA are biologically active in small quantities and if they are formed in large amounts, they contribute to the formation of thrombi and atheromas; the development of allergic and inflammatory disorders, particularly in susceptible people; and cell proliferation. Thus, a diet rich in n-6 fatty acids shifts the physiologic state to one that is prothrombotic and proaggregatory, with increases in blood viscosity, vasospasm, and vasoconstriction and decreases in bleeding time. Bleeding time is shorter in groups of patients with hypercholesterolemia, hyperlipoproteinemia, myocardial infarction, other forms of atherosclerotic disease, type 2 diabetes, obesity, and hypertriglyceridemia. Atherosclerosis is a major complication in type 2 diabetes patients. Bleeding time is longer in women than in men and in younger than in older persons. There are ethnic differences in bleeding time that appear to be related to diet. The hypolipidemic, antithrombotic, anti-inflammatory, and anti-arrhythmic effects of n-3 fatty acids have been studied extensively in animal models, tissue cultures, and cells (**Table 7**).

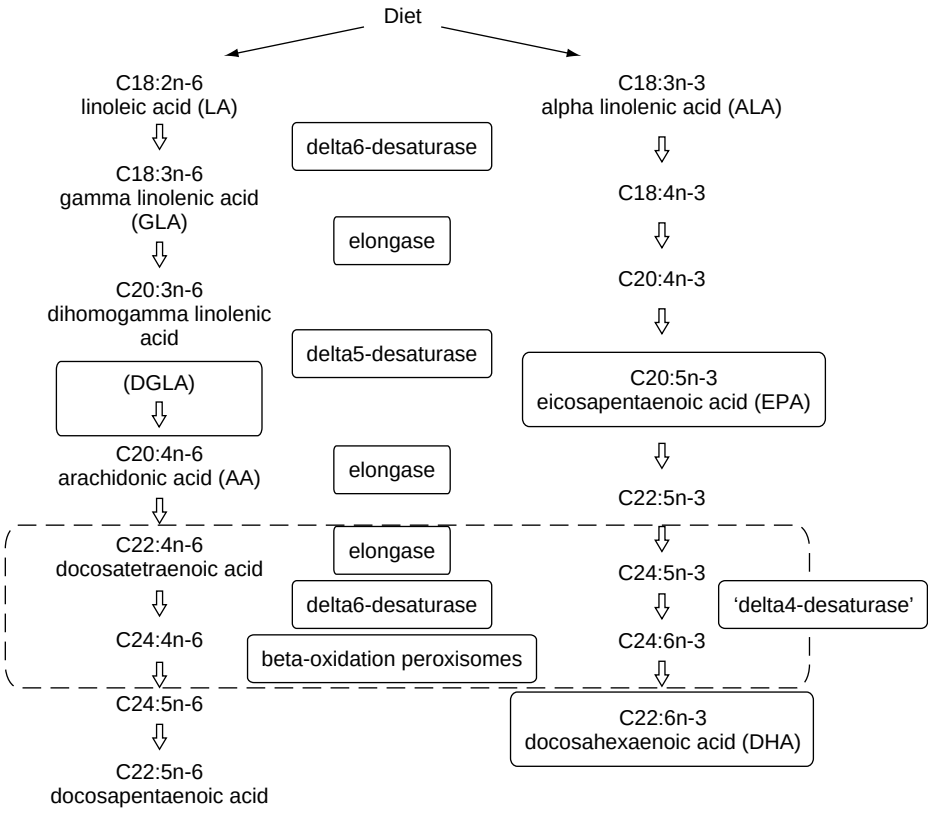

Figure 2 Essential fatty acid metabolism: desaturation and elongation of n-6 and n-3.

Nutrigenetics: Interaction between the n-6:n-3 Fatty Acids and the Genome

As expected, earlier studies focused on mechanisms that involve eicosanoid metabolites. More recently, however, the effects of fatty acids on gene expression have been investigated and this focus of interest has led to studies at the molecular level (**Tables 8**, **9**). Previous studies have shown that fatty acids, whether released from membrane phospholipids by cellular phospholipases or made available to the cell from the diet or other aspects of the extracellular environment, are important cell signaling molecules. They can act as second messengers or substitute for the classic second messengers of the inositide phospholipid and cyclic AMP signal transduction pathways. They can also act as modulator molecules mediating responses of the cell to extracellular signals. It has been shown that fatty acids rapidly and directly alter the transcription of specific genes.

5-Lipoxygenase and Atherosclerosis: An Example of Nutrigenetics/Nutrigenomics

Leukotrienes are eicosanoids derived through the action of 5-lipoxygenase (5-LO). It has been recently shown that genetic variants of the 5-LO promoter, already known to be associated with variable sensitivity to anti-asthmatic medications, also influence atherosclerosis. Variant genotypes of the 5-LO gene were found in 6% of a cohort of 470 healthy middle-aged men and women. Carotid intima-media thickness (IMT), taken as a marker of the atherosclerotic burden, was significantly increased, by 80% in the variant group compared to carriers of the common allele, suggesting increased 5-LO promoter activity associated with the mutant (variant) allele. Furthermore, dietary AA intake significantly enhanced the proatherogenic effect of 5-LO gene variants, while intake of EPA and DHA decreased (blunted) the effect of 5-LO and was associated with less IMT. EPA and DHA decrease the formation of leukotrienes of the 4-series by competing with AA (**Figure 5**) as substrates for 5-LO and generate weaker leukotrienes of the 5-series. The results of this study suggest that person with genetic variants are at higher risk for atherosclerosis at higher AA intake. It also suggests that the effects of EPA and DHA may be stronger in individuals with genetic variants associated with increased 5-LO activity. Therefore, clinical trials in the future should be controlled for genetic variation.

(1986) *Health Effects of Polyunsaturated Fatty Acids in Seafoods*. Orlando, FL: Academic Press.

Effects of Dietary ALA Compared with Long-Chain n-3 Fatty Acid Derivatives on Physiologic Indexes

Several clinical and epidemiologic studies have been conducted to determine the effects of long-chain n-3 PUFAs on various physiologic indexes. Whereas the earlier studies were conducted with large doses of fish or fish oil concentrates, more recent studies have used lower doses. ALA, the precursor of n-3 fatty acids, can be converted to long-chain n-3 PUFAs and can therefore be substituted for fish oils. The minimum intake of long-chain n-3 PUFAs needed for beneficial effects depends on the intake of other fatty acids. Dietary amounts of LA as well as the ratio of LA to ALA appear to be important for the metabolism of ALA to long-chain n-3 PUFAs. While keeping the amount of dietary LA constant (3.7 g) ALA appears to have biological effects similar to those of 0.3 g long-chain n-3 PUFAs with conversion of 11 g ALA to 1 g long-chain n-3 PUFAs. Thus, a ratio of 4 (15 g LA:3.7 g ALA) is appropriate for conversion. In human studies, the conversion of deuterated ALA to longer chain metabolites was reduced by ≅50% when dietary intake of LA was increased from 4.7% to 9.3% of energy as a result of the known competition between n-6 and n-3 fatty acids for desaturation. After ALA supplementation there is an increase in long-chain n-3 PUFAs in plasma and platelet phospholipids and a decrease in platelet aggregation. ALA supplementation does not alter triacylglycerol concentrations. Only long-chain n-3 PUFA have triacylglycerol-lowering effects. Supplementation with ALA to lower the n-6:n-3 ratio from 13:1 to 1:1 led to a 50% reduction in C-reactive protein (CRP), a risk factor for coronary heart disease.

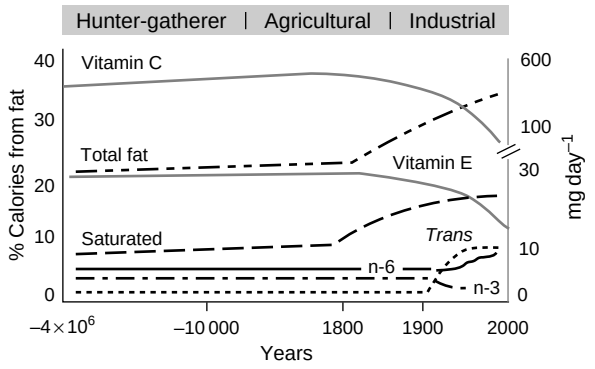

Figure 3 Hypothetical scheme of fat, fatty acid (n-6, n-3, *trans* and total) intake (as per cent of calories from fat) and intake of vitamins E and C ($mg\,day^{-1}$). Data were extrapolated from cross-sectional analyses of contemporary hunter-gatherer populations and from longitudinal observations and their putative changes during the preceding 100 years. *Trans*-fatty acids, the result of the hydrogenation process, have increased dramatically in the food supply during this century. Modified from Weber PC (1989) Are we what we eat? Fatty acids in nutrition and in cell membranes: cell functions and disorders induced by dietary conditions. In: *Fish, Fats and your Health*, Report no. 4, pp. 9–18. Norway: Svanoybukt Foundation.

In Australian studies, ventricular fibrillation in rats was reduced with canola oil as much or even more efficiently than with fish oil, an effect attributable to ALA. Further studies should be able to show whether this result is a direct effect of ALA per se or whether it occurs as a result of its desaturation and elongation to EPA and possibly DHA.

The diets of Western countries have contained increasingly larger amounts of LA, which has been promoted for its cholesterol-lowering effect. It is now recognized that dietary LA favors oxidative modification of low-density lipoprotein (LDL) cholesterol, increases platelet response to aggregation, and suppresses the immune system. In contrast, ALA intake is associated with inhibitory effects on the clotting activity of platelets, on their response to thrombin, and on the regulation of AA metabolism. In clinical studies, ALA contributed to lowering of blood pressure. In a prospective study, ALA was inversely related to the risk of coronary heart disease in men.

ALA is not equivalent in its biological effects to the long-chain n-3 fatty acids found in fish oils. EPA and DHA are more rapidly incorporated into plasma and membrane lipids and produce more rapid effects than does ALA. Relatively large reserves of LA in body fat, as are found in vegans or in the diet of omnivores in Western societies, would tend to slow down the formation of long-chain n-3 fatty acids from ALA. Therefore, the role of ALA in human nutrition becomes important in terms of long-term

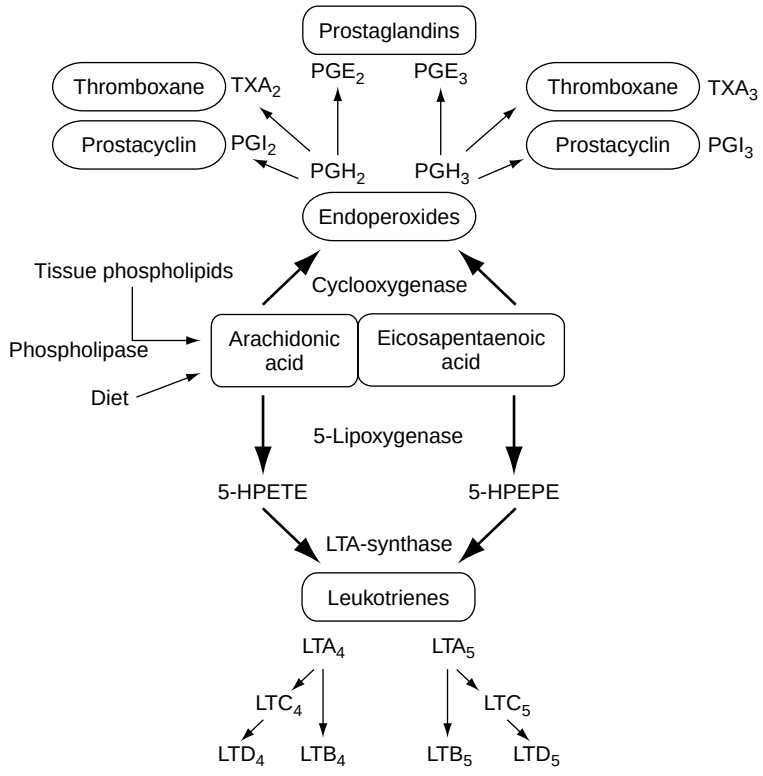

Figure 5 Oxidative metabolism of arachidonic acid and eicosapentaenoic acid by the cyclooxygenase and 5-lipoxygenase pathways. 5-HPETE denotes 5-hydroperoxyeicosatetranoic acid and 5-HPEPE denotes 5-hydroxyeicosapentaenoic acid.

dietary intake. One advantage of the consumption of ALA over n-3 fatty acids from fish is that the problem of insufficient vitamin E intake does not exist with a high intake of ALA from plant sources.

Human Studies in Growth and Development

Pregnancy and Fetal Growth

Since World War II, the role of maternal nutrition in fetal growth and development has been extensively studied in the context of protein-calorie malnutrition. The role of n-3 fatty acids has only recently come into focus, despite the evidence of its importance having been demonstrated in a series of studies between 1928 and 1930 involving rats and primates. Lipid nutrition during pregnancy and lactation is of special relevance to human development, because brain development in the human takes place during fetal life and in the first 2 years after birth. DHA is found in larger amounts in the gray matter of the brain and in the retinal membranes, where it accounts for 30% or more of the fatty acids in the ethanolamine and serine phospholipid. DHA accumulates in the neurons of the brain between weeks 26 and 40 of gestation in humans.

During the third trimester of human development, rapid synthesis of brain tissue occurs in association with increasing neuromotor activity. The increase in cell size, number, and type requires de novo synthesis of structural lipids, leading to accumulation of DHA in the brain of the human infant during the last trimester. The levels of ALA and LA are low in the brain, whereas marked accretion of long-chain desaturation products, specifically DHA and AA, occurs. More recent data indicate that the main developmental changes in the brain seem to be an increase in DHA at the end of gestation and a decrease in oleic acid (18:1n-9) and AA in phosphatidlyethanolamine (PE). Similar changes occur in the liver. Therefore, a premature infant (prior to 37 weeks' gestation) has much lower amounts of DHA in the brain and liver and is at risk of becoming deficient in DHA unless it is supplied in the diet. In the full-term newborn, about half of the DHA accumulates in the brain before birth and the other half after birth.

There is epidemiologic evidence that the birth weights of newborns in the Faroe Islands (where fish intake is high) are higher than those in Denmark, as is the length of gestation: 40.3 ± 1.7 weeks for the Faroese versus 39.7 ± 1.8 weeks for the Danish pregnant women. The average birth weight of primiparas is 194 g higher for the Faroe Islands. The higher dietary n-3 fatty acid intake quite possibly influences endogenous prostaglandin metabolism. It is

Table 7 Effects of n-3 fatty acids on factors involved in the pathophysiology of atherosclerosis and inflammation

Factor	*Function*	*Effect of n-3 fatty acid*
Arachidonic acid	Eicosanoid precursor; aggregates platelets; stimulates white blood cells	↓
Thromboxane A_2	Platelet aggregation; vasoconstriction; increase of intracellular Ca^{++}	↓
Prostacyclin ($PGI_{2/3}$)	Prevent platelet aggregation; vasodilation; increase cAMP	↑

hypothesized that the dietary n-3 fatty acids inhibit the production of the dienoic prostaglandins, especially PGF_{2a} and PGE_2, because they are involved in the mediation of uterine contractions and the ripening of the cervix that lead to labor and delivery. These important observations need to be further investigated, as the prevention of prematurity is one of the most critical issues to be overcome in perinatal medicine.

Human Milk and Infant Feeding

A number of studies from around the world indicate that human milk contains both LNA and LA and their long-chain n-6 and n-3 fatty acids, whereas cow's milk does not. The long-chain fatty acid composition of red blood cell membrane phospholipids may reflect the composition of phospholipids in the brain. Therefore, determination of red blood cell membrane phospholipids has been carried out by many investigators to determine the long-chain PUFA content in breast-fed and bottle-fed infants. As expected, the fatty acids 22:5n-3 and 22:6n-3 were higher in the erythrocytes from breast-fed infants than those from bottle-fed babies and the 20:3n-9 was lower in the erythrocytes of the breast-fed infants.

Following birth, the amount of red blood cell DHA in premature infants decreases; therefore the amount of DHA available to the premature infant assumes critical importance. Preterm infants have a limited ability to convert LNA to DHA (**Figure 2**); therefore, a number of studies have been carried out on the DHA status of the premature infant. Premature babies have decreased amounts of DHA, but human milk contains enough DHA to support normal growth of the premature baby. The amount of n-3 fatty acids in human milk varies with the mother's diet; in particular, DHA is lower in vegetarians than in omnivores. One can increase the amount of DHA in human milk by giving fish oil rich in DHA to the mother.

The need to supplement infant formula with n-3 fatty acids and, particularly, DHA for the premature is now recognized and many countries have licensed infant formula enriched with n-3 fatty acids. DHA is essential for normal visual function and visual

maturation, particularly of the premature infant. Studies are currently in progress comparing the growth and development of both the premature and full-term infant who are fed mother's milk with those who are receiving formula supplemented with n-3 fatty acids and those whose formula is not supplemented, to define precisely the effects of DHA on intelligence quotient (IQ) and overall neuromotor development. **Tables 10** and **11** show the EFA dietary recommendations for adults, pregnant women, and infants made by a scientific group at a workshop held at the National Institutes of Health in Bethesda, Maryland in 1999.

Aging

ALA deficiency has been found in patients on long-term gastric tube-feeding that included large amounts of skim milk without ALA supplementation. These patients, who were in nursing homes,

DHA to be at least[b]	0.22	0.1
EPA to be at least	0.22	0.1
TRANS-FA		
(upper limit)[c]	2.00	1.0
SAT		
(upper limit)[d]	–	<8.0
MONOs[e]	–	–

[a]Although the recommendation is for AI, the Working Group felt that there is enough scientific evidence to also state an upper limit (UL) for LA of 6.67 g day^{-1} based on a 2000 kcal diet or of 3.0% of energy.
[b]For pregnant and lactating women, ensure 300 mg day^{-1} of DHA.
[c]Except for dairy products, other foods under natural conditions do not contain *trans*-FA. Therefore, the Working Group does not recommend *trans*-FA to be in the food supply as a result of hydrogenation of unsaturated fatty acids or high-temperature cooking (reused frying oils).
[d]Saturated fats should not comprise more than 8% of energy.
[e]The Working Group recommended that the majority of fatty acids are obtained from monounsaturates. The total amount of fat in the diet is determined by the culture and dietary habits of people around the world (total fat ranges from 15% to 40% of energy) but with special attention to the importance of weight control and reduction of obesity.
If sufficient scientific evidence is not available to calculate an estimated average requirement, a reference intake called an adequate intake is used instead of a recommended dietary allowance. The AI is a value based on experimentally derived intake levels or approximations of observed mean nutrient intakes by a group (or groups) of healthy people. The AI for children and adults is expected to meet or exceed the amount needed to maintain a defined nutritional state or criterion of adequacy in essentially all members of a specific healthy population.
LA, linoleic acid; ALA, α-linolenic acid; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; *TRANS*-FA, *trans*-fatty acids; SAT, saturated fatty acids; MONOs, monounsaturated fatty acids.
Reproduced with permission from Simopoulos AP, Leaf A, and Salem N Jr (1999) Essentiality of and recommended dietary intakes for omega-6 and omega-3 fatty acids. *Annals of Nutrition and Metabolism* **43**: 127–130.

Table 11 Adequate intake (AI) for infant formula/diet

Fatty acid	*Per cent of fatty acids*
LA[a]	10.00
ALA	1.50
AA[b]	0.50
DHA	0.35
EPA[c]	
(upper limit)	<0.10

[a]The Working Group recognizes that in countries like Japan the breast milk content of LA is 6–10% of fatty acids and the DHA is higher, about 0.6%. The formula/diet composition described here is patterned on infant formula studies in Western countries.
[b]The Working Group endorsed the addition of the principal long-chain polyunsaturates, AA and DHA, to all infant formulas.
[c]EPA is a natural constituent of breast milk, but in amounts more than 0.1% in infant formula may antagonize AA and interfere with infant growth.
If sufficient scientific evidence is not available to calculate an estimated average requirement, a reference intake called an adequate intake is used instead of a recommended dietary allowance. The AI is a value based on experimentally derived intake levels or approximations of observed mean nutrient intakes by a group (or groups) of healthy people. The AI for children and adults is expected to meet or exceed the amount needed to maintain a defined nutritional state or criterion of adequacy in essentially all members of a specific healthy population.
LA, linoleic acid; ALA, α-linolenic acid; AA, arachidonic acid; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; *TRANS*-FA, *trans*-fatty acids; SAT, saturated fatty acids; MONOs, monounsaturated fatty acids.

developed skin lesions diagnosed as scaly dermatitis, which disappeared with ALA supplementation. A number of other patients were reported to have n-3 fatty acid deficiency, again patients on long-term gastric tube-feeding or prolonged total parenteral nutrition because of chronic illnesses. If a deficiency of total n-3 fatty acid intake is suspected, its concentration in plasma should be measured. A decrease in the concentration of 20:5n-3, 22:5n-3, and particularly 22:6n-3 in plasma or erythrocyte phospholipids indicates that the dietary intake of n-3 fatty acids has been low. The presence of clinical symptoms, along with the biochemical determinations, provides additional support for the diagnosis. To verify the diagnosis, it is essential that the clinical symptoms disappear upon supplementation of the deficient diet with n-3 fatty acids.

With the increase in the number of elderly persons in the population, and the proliferation of nursing homes, particular attention must be given to the nutritional requirements of the elderly, especially those who are fed enterally or parenterally.

Coronary Heart Disease

Most epidemiologic studies and clinical trials using n-3 fatty acids in the form of fish or fish oil have been carried out in patients with coronary heart disease. However, studies have also been carried out on the effects of ALA in normal subjects and in patients with myocardial infarction.

The hypolipidemic effects of n-3 fatty acids are similar to those of n-6 fatty acids, provided that they replace saturated fats in the diet. n-3 fatty acids have the added benefit of not lowering high-density

lipoprotein (HDL) and consistently lowering serum triacylglycerol concentrations, whereas the n-6 fatty acids do not and may even increase triglyceride levels.

Another important consideration is the finding that during chronic fish oil feeding postprandial triacylglycerol concentrations decrease. Furthermore, consumption of high amounts of fish oil blunted the expected rise in plasma cholesterol concentrations in humans. These findings are consistent with the low rate of coronary heart disease found in fish-eating populations. Studies in humans have shown that fish oils reduce the rate of hepatic secretion of very low-density lipoprotein (VLDL) triacylglycerol. In normolipidemic subjects, n-3 fatty acids prevent and rapidly reverse carbohydrate-induced hypertriglyceridemia. There is also evidence from kinetic studies that fish oil increases the fractional catabolic rate of VLDL (**Table 7**).

The effects of different doses of fish oil on thrombosis and bleeding time have been investigated. A dose of 1.8 g EPA day^{-1} did not result in any prolongation in bleeding time, but 4 g day^{-1} increased bleeding time and decreased platelet count with no adverse effects. In human studies, there has never been a case of clinical bleeding, even in patients undergoing angioplasty, while the patients were taking fish oil supplements. Clinical investigations indicate that n-3 fatty acids prevent sudden death. A series of intervention trials have clearly shown that the addition of n-3 fatty acids in the form of fish oil (EPA and DHA) decrease the death rate in the secondary prevention of coronary heart disease by preventing ventricular arrhythmias that lead to sudden death.

Antiarrhythmic Effects of n-3 Fatty Acids (ALA, EPA, and DHA)

Studies have shown that n-3 fatty acids, more so than n-6 PUFA, can prevent ischemia-induced fatal ventricular arrhythmias in experimental animals. n-3 fatty acids make the heart cells less excitable by modulating the conductance of the sodium and other ion channels. Clinical studies further support the role of n-3 fatty acids in the prevention of sudden death due to ventricular arrhythmias which, in the US, account for 50–60% of the mortality from acute myocardial infarction and cause 250 000 deaths a year. In the intervention trials, there was no change in lipid concentration, suggesting that the beneficial effects of n-3 fatty acids were due to their antithrombotic and antiarrhythmic effects.

The antiarrhythmic effects of n-3 fatty acids are supported by clinical intervention trials (Diet and Reinfarction Trial (DART), Lyon Heart Study, Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto miocardico (GISSI)-Prevenzione Trial, Indo-Mediterranean Diet Heart Study). Their results strongly support the role of fish or fish oil in decreasing total mortality and sudden death in patients with one episode of myocardial infarction. Therefore, the addition of 1 g/d of n-3 fatty acids is highly recommended for the primary and secondary prevention of coronary heart disease.

Inflammation: a Common Base for the Development of Coronary Heart Disease, Diabetes, Arthritis, Mental Health, Neurodegenerative Diseases and Cancer

Anti-inflammatory Aspects of n-3 Fatty Acids

Many experimental studies have provided evidence that incorporation of alternative fatty acids into tissues may modify inflammatory and immune reactions and that n-3 fatty acids in particular are potent therapeutic agents for inflammatory diseases. Supplementing the diet with n-3 fatty acids (3.2 g EPA and 2.2 g DHA) in normal subjects increased the EPA content in neutrophils and monocytes more than sevenfold without changing the quantities of AA and DHA. The anti-inflammatory effects of fish oils are partly mediated by inhibiting the 5-lipoxygenase pathway in neutrophils and monocytes and inhibiting the leukotriene B_4 (LTB_4)-mediated function of LTB_5 (**Figure 5**). Studies show that n-3 fatty acids influence interleukin metabolism by decreasing IL-1β and IL-6. Inflammation plays an important role in both the initiation of atherosclerosis and the development of atherothrombotic events. An early step in the atherosclerotic process is the adhesion of monocytes to endothelial cells. Adhesion is mediated by leukocyte and vascular cell adhesion molecules (CAMs) such as selectins, integrins, vascular cell adhesion molecule 1 (VCAM-1), and intercellular adhesion molecule 1 (ICAM-1). The expression of E-selectin, ICAM-1, and VCAM-1, which is relatively low in normal vascular cells, is upregulated in the presence of various stimuli, including cytokines and oxidants. This increased expression promotes the adhesion of monocytes to the vessel wall. The monocytes subsequently migrate across the endothelium into the vascular intima, where they accumulate to form the initial lesions of atherosclerosis. Atherosclerosis plaques have been shown to have increased CAM expression in animal models and human studies.

Diabetes is a major risk factor for coronary heart disease. EPA and DHA increase sensitivity to insulin and decrease the risk of coronary heart disease. Rheumatoid arthritis has a strong inflammatory component characterized by an increase in

interleukin (IL)-1β. n-3 fatty acids decrease IL-1β as well as the number of swollen and painful joints. Supplementation with EPA and DHA, changing the ratio of n-6:n-3 of the background diet by increasing the n-3 and decreasing the n-6 intake, is now standard treatment for patients with rheumatoid arthritis along with medication in a number of centers around the world. Similarly, changing the background diet in patients with asthma has led to decreases in the dose of nonsteroidal anti-inflammatory drugs.

These studies suggest the potential for complementarity between drug therapy and dietary choices and that increased intake of n-3 fatty acids and decreased intake of n-6 fatty acids may lead to drug sparing effects. Therefore, future studies need to address the fatty acid composition and the ratio of n-6:n-3 of the background diet, and the issue of concurrent drug use. A diet rich in n-3 fatty acids and low in n-6 fatty acids provides the appropriate background biochemical environment in which drugs function.

Psychologic stress in humans induces the production of proinflammatory cytokines such as interferon gamma (IFNγ), TNFα, IL-6, and IL-10. An imbalance of n-6 and n-3 PUFA in the peripheral blood causes an overproduction of proinflammatory cytokines. There is evidence that changes in fatty acid composition are involved in the pathophysiology of major depression. Changes in serotonin (5-HT) receptor number and function caused by changes in PUFAs provide the theoretical rationale connecting fatty acids with the current receptor and neurotransmitter theories of depression. The increased 20:4n-6/20:5n-3 ratio and the imbalance in the n-6:n-3 PUFA ratio in major depression may be related to the increased production of proinflammatory cytokines and eicosanoids in that illness. Studies have shown that EPA and DHA prolong remission, that is, reduce the risk of relapse in patients with bipolar disorder. There are a number of studies evaluating the therapeutic effect of EPA and DHA in major depression.

Earlier studies in rodents showed that ALA intake improved learning, memory and cognition. In Zellweger's syndrome (a genetic neurodegenerative disease) high amounts of DHA early in life decreased somewhat the rate of progression of the disease. A number of studies have suggested that people who eat a diet rich in fish are less likely to develop Alzheimer's disease. Learning and memory depend on dendritic spine action assembly and DHA. High DHA consumption is associated with reduced risk for Alzheimer's disease, yet mechanisms and therapeutic potential remain elusive. In an Alzheimer's disease mouse model, reduction of dietaty n-3 fatty acid resulted in 80%-90% losses of the p85 alpha subunit of phosphoinositol 3-kinase and the postsynaptic action-regulating protein drebrin as in the brain of patients with Alzheimer's disease. The loss of postsynaptic proteins was associated with increased oxidation without concomitant neuron or presynaptic protein loss. Treatment of the n-3 fatty acid restricted mice with DHA protected against these effects and behavioral deficits. Since n-3 fatty acids are essential for p85-mediated central nervous system insulin signaling and selective protection of postsynaptic proteins, these findings have implications for neurodegenerative diseases, where synaptic loss is critical, especially in Alzheimer's disease. A few case control studies suggest that higher EPA and DHA intake is associated with lower risk of Alzheimer's disease and severity of the disease. Inflammation is a risk factor for Alzheimer's disease. It remains to be determined whether low n-3 fatty acids, especially low DHA status, in patients with Alzheimer's disease is a causal factor in the pathogenesis and progression of Alzheimer's disease and other neurodegenerative diseases.

Cancer is characterized by inflammation, cell proliferation, and elevated IL-6 levels. Since EPA and DHA suppress IL-6, fish oil supplementation suppresses rectal epithelial cell proliferation and PGE_2 biosynthesis. This was achieved with a dietary n-6:n-3 ratio of 2.5:1, but not with the same absolute level of fish oil intake and an n-6:n-3 ratio of 4:1. Case control studies in women with breast cancer support the hypothesis that the balance between n-6 and n-3 in breast adipose tissue plays an important role in breast cancer and in breast cancer metastasis.

Future Work, Conclusions, and Recommendations

n-3 fatty acids should be added to foods rather than be used solely as dietary supplements, which is a quasi-pharmaceutical approach. Furthermore, the development of a variety of n-3-rich foodstuffs would allow increased n-3 dietary intakes with little change of dietary habits. n-3 fatty acids maintain their preventative and therapeutic properties when packaged in foods other than fish. Efficient use of dietary n-3 fatty acids will require the simultaneous reduction in the food content of n-6 fatty acids and their substitution with monounsaturated oils. Dietary n-3 fats give rise to higher tissue levels of EPA when the 'background' diet is low in n-6 fats. Compared to n-6 fatty acids, olive oil increases the incorporation of n-3 fatty acids into tissues.

In the past, industry focused on improvements in food production and processing to increase shelf life of the products, whereas now and in the future the focus will be on nutritional quality in product

development. This will necessitate the development of research for the nutritional evaluation of the various food products and educational programs for professionals and the public. The definition of food safety will have to expand in order to include nutrient structural changes and food composition. The dawn of the twenty-first century will enhance the scientific base for product development and expand collaboration among agricultural, nutritional, and medical scientists in government, academia, and industry. This should bring about a greater involvement of nutritionists and dieticians in industrial research and development to respond to an ever-increasing consumer interest in the health attributes of foods.

Today, more is known about the mechanisms and functions of n-3 fatty acids than other fatty acids. It is evident that Western diets are relatively deficient in n-3 fatty acids and that they contain much higher amounts of n-6 fatty acids than ever before in the evolution of human beings. Research has shown that DHA is essential for the development of the premature infant relative to visual acuity, visual function, and maturation. In the full-term infant, DHA may influence visual acuity and neural pathways associated with the developmental progression of language acquisition. These findings have led to the inclusion of DHA and AA in infant formulas in most countries around the world.

Most of the research on the role of n-3 fatty acids in chronic diseases has been carried out in patients with coronary heart disease. Intervention trials have clearly shown that n-3 fatty acids decrease sudden death and all cause mortality in the secondary prevention of coronary heart disease and in one study also in the primary prevention of coronary heart disease. The decrease in sudden death is most likely due to the anti-arrhythmic effects of n-3 fatty acids.

Most recent research suggests that the response to n-3 fatty acids may be genotype dependent, since certain individuals respond more than others. The time has come to take genetic variation into consideration when setting up clinical intervention trials. We need to move away from the long-term prospective studies and proceed with genotype-specific clinical intervention trials.

Inflammation and cell proliferation are at the base of many chronic diseases and conditions, especially atherosclerosis and cancer, but also diabetes, hypertension, arthritis, mental health, and various autoimmune diseases. Individuals carrying genetic variants for these conditions are much more prone to develop them because the high n-6:n-3 ratio leads to proinflammatory and prothrombotic states.

The time has come to return to high n-3 fatty acid levels in the diet and to decrease the n-6 intake. There is good scientific evidence from studies on the Paleolithic diet, the diet of Crete, other traditional diets (Okinawa), intervention studies, and finally studies at the molecular level using transgenic rodents that the physiologic n-6:n-3 ratio should be 1:1 or 2:1. Japan has already recommended a ratio of 2:1. Industry has moved in the direction of including n-3 fatty acids in various products starting with n-3 enriched eggs, which are based on the *Ampelistra* (Greek) egg as a model obtained under completely natural conditions and which has a ratio of n-6:n-3 of 1:1.

It is essential that Nutrition Science drives Food Science and the production of foods rather than Food Technology. This is of the utmost importance in the development of novel foods. The scientific evidence is strong for decreasing the n-6 and increasing the n-3 fatty acid intake to improve health throughout the life cycle. The scientific basis for the development of a public policy to develop dietary recommendations for EFA, including a balanced n-6:n-3 ratio, is robust. What is needed is a scientific consensus, education of professionals and the public, the establishment of an agency on nutrition and food policy at the national level, and willingness of governments to institute changes. Education of the public is essential to demand changes in the food supply.

Abbreviations

ALA	α-linolenic acid
CAM	cell adhesion molecule
CRP	C-reactive protein
DHA	docosahexaenoic acid
EFA	essential fatty acid
EPA	eicosapentaenoic acid
FAS	fatty acid synthase
GK	glucokinase
GLUT	glucose transporter
ICAM	intercellular adhesion molecule
IFN	interferon
IL	interleukin
IMT	intima-media thickness
LA	linoleic acid
LO	lipoxygenase
ME	malic enzyme
PDGF	platelet-derived growth factor
PE	phosphatidylethanolamine
PG	prostaglandin
PK	pyruvate kinase
PUFA	polyunsaturated fatty acid
TNF	tumor necrosis factor
VCAM	vascular cell adhesion molecule

Structure, Function, and Nutritional Requirements

Omega-6 (n-6) fatty acids are a class of polyunsaturated fatty acids (PUFA). They have two or more *cis* double bonds, with the position of the first double bond six carbon atoms from the methyl end of the molecule. The general formula of n-6 fatty acids is $CH_3(CH_2)_4(CH{=}CHCH_2)_x(CH_2)_yCOOH$ [where $x = 2–5$]. Linoleic acid (*cis*-9, *cis*-12-octadecadienoic acid, 18:2n-6, LA) and α-linolenic acid (*cis*-9, *cis*-12, *cis*-15-octadecatrienoic acid, 18:3n-3, ALA) are the precursor fatty acids of the n-6 and omega-3 (n-3) fatty acids, respectively. These two fatty acids cannot be made by mammals and are therefore termed essential fatty acids (EFA). In addition, mammals are unable to interconvert LA and ALA, or any of the n-6 and n-3 fatty acids, because mammalian tissues do not contain the necessary desaturase enzyme. Plant tissues and plant oils tend to be rich sources of LA. ALA is also present in plant sources such as green vegetables, flaxseed, canola, and some nuts. Once consumed in the diet, LA can be converted via chain elongation and desaturation to γ-linolenic acid (GLA, 18:3n-6), dihomo-γ-linolenic acid (DGLA, 20:3n-6), and arachidonic acid (AA, 20:4n-6) (**Figure 1**). The same enzymes involved in elongation and desaturation of the n-6 fatty acids are common to the n-3 series of fatty acids (**Figure 1**). Thus, ALA can be converted to eicosapentaenoic acid (EPA, 20:5n-3) and docosahexaenoic acid (DHA, 22:6n-3). EPA and DHA are found in relatively high proportions in marine oils.

The n-6 and n-3 fatty acids are metabolically and functionally distinct and often have important opposing physiological functions. Indeed, the balance of EFA is important for good health and normal development. Historically, human beings evolved on a diet in which the ratio of n-6 to n-3 fatty acids was about 1:1. In contrast, Western diets have a ratio of

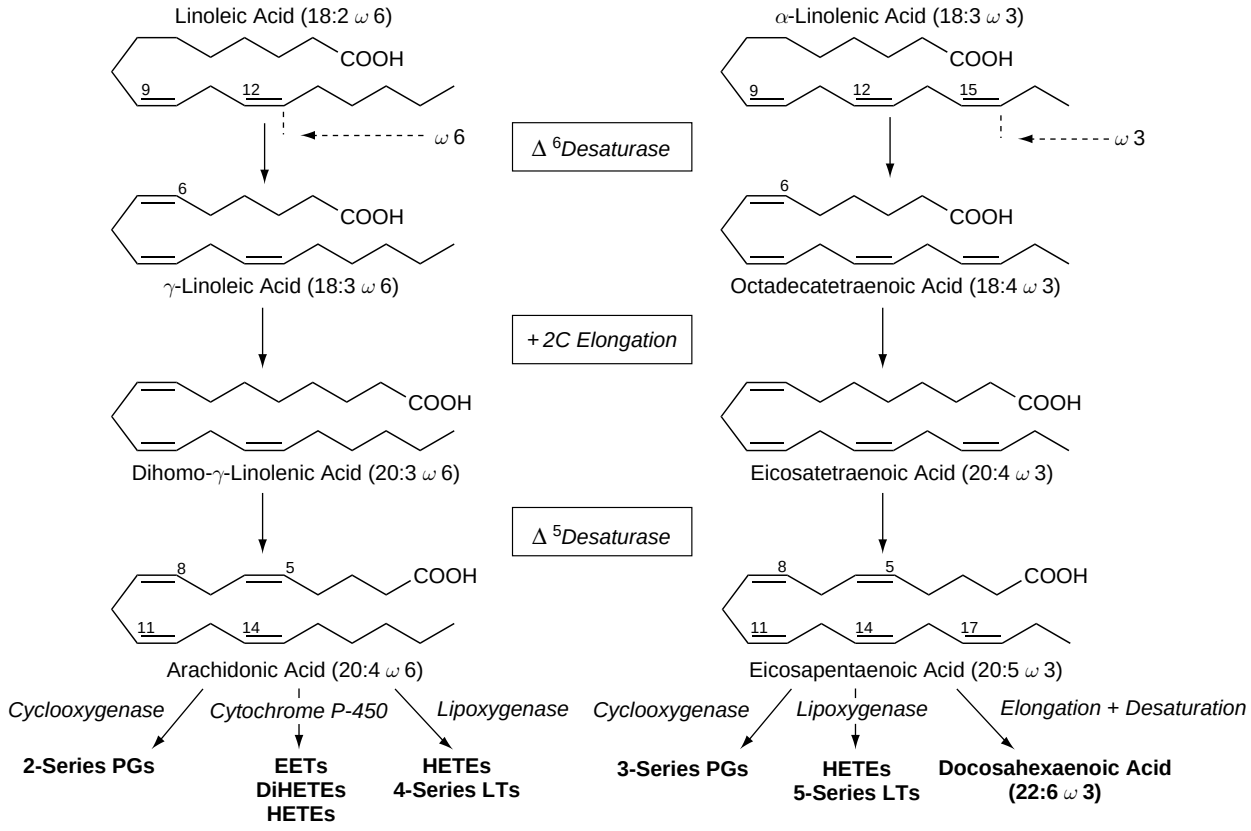

Figure 1 Essential fatty acid metabolism.

approximately 15:1. Evidence for this change in diet through history comes from studies on the evolutionary aspects of diet, modern-day hunter–gatherers, and traditional diets. Modern agriculture has led to a substantial increase in n-6 fatty acids at the expense of n-3 fatty acids, which has resulted in excessive consumption of n-6 fatty acids by humans.

The n-6 EFAs have two main functions. First, they act as structural components of membranes forming the basis of the phospholipid component of the lipid bilayer of plasma membranes in every cell in the body, thus providing a membrane impermeable to most water-soluble molecules. The length and degree of saturation of the fatty acids determine how the phospholipid molecules pack together and consequently affect membrane fluidity, signal transduction, and the expression of cellular receptors. The second role of n-6 fatty acids is as precursors to the eicosanoids (**Figure 1**). The eicosanoids are a family of 'hormone-like' compounds including prostaglandins (PGs), leukotrienes (LTs), and hydroxy- (HETEs), dihydroxy- (DiHETEs), and epoxy- (EETs) fatty acids. Eicosanoids, however, are distinct from most hormones in that they act locally, near their sites of synthesis, and they are catabolized extremely rapidly. Thus, they are considered to be locally acting hormones. The eicosanoids modulate renal and pulmonary function, vascular tone, and inflammatory responses. The enzymes involved in AA metabolism include the cyclooxygenases and lipoxygenases, which yield the 2-series PGs and 4-series LTs, respectively. Lipoxygenase also utilizes AA for the formation of the HETEs. A third pathway for the utilization of AA involves the cytochrome P-450 enzymes found in the liver, kidney, lung, intestines, heart, small blood vessels, and white blood cells. AA metabolized via cytochrome P-450 yields EETs, DiHETEs, as well as HETEs. The cytochrome P-450 metabolites play an important role as paracrine factors and second messengers in the regulation of pulmonary, cardiac, renal, and vascular function and modulate inflammatory and growth responses.

Endothelial Function, Atherosclerosis, and Cardiovascular Disease

Differences in n-6 fatty acid intake have the potential to influence several chronic diseases and disorders. This article will focus on the effects of n-6 fatty acids on cardiovascular disease and atherosclerosis.

The vascular endothelium is the most important organ controlling vascular function and consists of a single layer of epithelial cells lining blood vessels. Its primary function is to regulate vascular tone, but it plays a critical role in modulating coagulation and fibrinolysis, inflammation, smooth muscle cell proliferation, and macrophage function. Many of these functions are regulated through the release of various mediators including eicosanoids. There is multiple and close interaction of the endothelial cells with circulating cells, smooth muscle cells, and macrophages. There is also evidence that endothelial dysfunction precedes clinically apparent atherosclerosis.

Atherosclerosis is an inflammatory disease involving multiple cellular and molecular responses that lead to an alteration in vascular function and structure, and the development and progression of cardiovascular disease. Atherosclerosis is characterized by degenerative changes, deposition of cholesterol, proliferation of smooth muscle cells, involvement of a range of circulating proinflammatory cell types, and fibrosis. Resulting atheromatous plaques cause narrowing of arteries and increase the likelihood of thrombosis and occlusion. When this process occurs in the coronary arteries, the outcome is myocardial infarction and with possible death.

Eicosanoids: Relevance to Endothelial Function, Thrombosis, Inflammation, and Atherosclerosis

In general, the eicosanoids derived from AA have potent prothrombotic and proinflammatory activity. In contrast, the eicosanoids derived from EPA have reduced biological activity and are less prothrombotic and proinflammatory. Eicosanoid production is generally tightly controlled through homeostatic mechanisms. However, eicosanoid production can be significantly altered in situations in which endothelial dysfunction, atherosclerosis and plaque rupture, or various thrombotic or inflammatory conditions are present.

Prostaglandins and Leukotrienes

Prostaglandins have a central role in the regulation of platelet aggregation and vascular tone. In this regard, two of the major prostaglandins derived from AA are thromboxane A_2, produced in platelets, and prostacyclin I_2, produced in endothelial cells. Thromboxane A_2 promotes platelet aggregation and blood vessel constriction, while prostacyclin I_2 has the opposite effects. An increase in availability of EPA can decrease platelet thromboxane A_2 and increase thromboxane A_3, the latter having considerably less physiological activity. EPA supplementation also stimulates formation of prostacyclin I_3, while prostacyclin I_2 is unaffected. Prostacyclin I_3 and prostacyclin I_2 are equipotent in their biological activity. The net result following intake of n-3 fatty acids is a shift in the thromboxane/prostacyclin balance toward a reduced prothrombotic state.

Leukotriene B_4 is a potent inflammatory mediator produced by neutrophils from 20:4n-6 at the site of injury. Leukotriene B_4 is also a powerful chemotactic factor responsible for attracting neutrophils to the site of injury. Leukotriene B_5, which is produced from EPA, has significantly lower biological activity. Therefore an increased availability of EPA has the potential to reduce inflammation.

Fatty Acid Intake and Eicosanoids

The proportional concentration of the eicosanoid precursor fatty acids both circulating and in tissues depends on dietary intake. DGLA and AA can be obtained from animal meat and fat, and by desaturation and chain elongation of LA. The major dietary source of EPA is fish. EPA can also be obtained indirectly from ALA, although desaturation and chain elongation of ALA appears to be a less important pathway in humans.

Only the free form of the fatty acid precursors of eicosanoids can be utilized by the enzymes for conversion to the biologically active metabolites. However, the amount of precursor free fatty acid in the cytoplasm and circulating is usually low and so too is basal eicosanoid formation. Furthermore, basal eicosanoid formation may depend on dietary and adipose tissue fatty acid composition. The amount of eicosanoid precursor free fatty acids is controlled to a large extent by incorporation and release from cellular phospholipids. Which eicosanoids are produced during stimulated synthesis may depend on membrane fatty acid composition as well as the cell type involved. Dietary fatty acid composition, therefore, has the potential to effect basal and stimulated synthesis of eicosanoids and influence endothelial function and thrombotic and inflammatory responses.

n-6 Fatty Acids and Risk of Cardiovascular Disease

Evidence that differences in n-6 fatty acid intake can influence cardiovascular disease risk derives from several sources. Population studies may provide useful data for establishing optimal intakes of n-6 fatty acids. However, valuable information on the potential mechanisms and effects of these fatty acids is

derived from studies focusing on their impact on thrombosis, inflammation, endothelial function, and other cardiovascular risk factors.

Cardiovascular Disease: Population Studies

The incidence of cardiovascular disease within populations with either very high or very low intakes of n-6 fatty acids may provide some indication for optimal intakes of n-6 fatty acids. Within populations with low n-6 fatty acid intakes ($\leq$3%) there would appear to be a benefit of having a higher n-6 fatty acid intake on cardiovascular disease risk reduction. These observations suggest that very low n-6 fatty acid intakes increase the risk for cardiovascular disease. The presence of EFA deficiency in a significant proportion of such populations may explain the increased risk. Several populations, including the Israelis, Taiwanese, and !Kung bushmen in the African Kalahari desert, have high to very high intakes of n-6 fatty acids. The contribution of n-6 fatty acids to total energy intake is about 10% in the Israelis and Taiwanese and about 30% in the !Kung bushmen. Rates of cardiovascular disease are low in the Taiwanese, where dietary n-6 fatty acids are obtained mainly from soybean oil, and estimated to be very low in the !Kung bushmen, where dietary n-6 fatty acids were obtained mainly from the monongo fruit and nut. In the Taiwanese, the soybean oil is refined but is accompanied by a diet rich in antioxidant polyphenols, notably from tea, fruits, and vegetables. In the !Kung bushmen the oil is unrefined and is therefore likely to contain a range of phytochemicals. There is, however, a high prevalence of cardiovascular disease in the Israeli population, where n-6 PUFAs are obtained largely from refined sources. These observations suggest that a high n-6 fatty acid intake can be compatible with low risk of cardiovascular disease, but the dietary context may be very important. Given that n-6 fatty acids are susceptible to lipid peroxidation, high n-6 fatty acid intake may increase risk for cardiovascular disease when consumed against a background diet low in antioxidants. The potential impact on eicosanoid metabolism remains uncertain.

Several factors may need to be considered in the interpretation of the results of population studies. First, the effect of LA on atherosclerosis and cardiovascular disease may depend on the background intake in the population being studied. Second, any relationships observed may be confounded by intake of other foods from which LA derives. Third, LA may have differential effects on aspects of the aetiology of cardiovascular disease, including endothelial function, thrombosis, arrhythmia, and atherosclerosis.

Thrombosis

Dietary fatty acids influence thrombosis by altering the activity and function of endothelial cells, platelets, and other circulating cells—effects that can be mediated, in part, by alterations in eicosanoid metabolism. Replacement of dietary saturated fatty acids with unsaturated fatty acids, including n-6 fatty acids, generally lowers the risk of thrombosis and cardiovascular disease. Furthermore, studies have shown that an increase in n-3 fatty acid intake can increase vasodilation, attenuate platelet aggregation, and alter circulating concentrations of factors involved in coagulation and fibrinolysis. The net effect of increasing n-3 fatty acid intake is a tendency toward reduced risk for thrombosis. These findings are supported by population studies demonstrating that n-3 fatty acids may reduce the risk of thrombosis. It remains uncertain whether the major factor influencing these functions is the absolute increase in n-3 fatty acids or the relative proportions of n-6 and n-3 fatty acids in the diet and cell membranes. There is evidence, however, that increased n-3 fatty acid intake may be more beneficial in populations consuming relatively small quantities of fish, which includes many Western populations.

Much of the evidence for a potential impact of n-6 fatty acids on thrombosis derives from research on platelet function. The role of platelets in thrombosis is established and the influence of fatty acid intake on platelet function has been assessed in many studies. Platelets play a part in thrombosis by adhering to, and aggregating at, the site of injury. Platelet reactivity and increased platelet activation may increase the risk of thrombosis. *In vitro* and *in vivo* studies assessing effects of n-6 fatty acids on platelet aggregation are inconsistent. To date there is little evidence that a high n-6 fatty acid diet in humans decreases platelet aggregation and some studies are suggestive of increased aggregation with high n-6 fatty acid diets, primarily in the form of LA. The effects of AA on platelet aggregation are also not clear. One of the main difficulties in interpreting these studies is the unresolved issue as to how the *in vitro* aggregation test reflects platelet function *in vivo*.

Inflammation

Conditions of increased inflammation, such as inflammatory arthritis, dermatological conditions such as psoriasis and atopic dermatitis, chronic

inflammatory bowel disease, autoimmune diseases, and bronchial asthma, appear to be beneficially influenced by n-3 fatty acids but not by n-6 fatty acids.

Whether or not increased intake of n-6 fatty acids can exacerbate inflammation *via* increased production of proinflammatory eicosanoids remains uncertain. Results of *in vitro* studies and intervention studies in humans are generally consistent with this theoretical potential of n-6 fatty acids to enhance inflammation, at least in comparison to n-3 fatty acids and probably n-9 monounsaturated fatty acids. The importance of absolute and relative intakes of n-6 fatty acids to inflammatory processes also remains unclear. The effects of changes in n-6 fatty acid intake on inflammatory processes may depend on the background dietary fatty acid intake, as well as proportional and absolute intake of n-3 fatty acids.

Cholesterol and Lipoproteins

The major classes of circulating lipoproteins in human plasma are chylomicrons, very low-density lipoproteins (VLDL), low-density lipoproteins (LDL), and high-density lipoproteins (HDL). High fasting plasma concentrations of LDL cholesterol and triglycerides—predominantly circulating as part of VLDL—and low plasma concentrations of HDL cholesterol are associated with increased risk of cardiovascular disease. Dietary fatty acids can influence lipoprotein metabolism and therefore have the potential to influence atherosclerosis and cardiovascular disease risk. Most studies examining the effects of n-6 PUFAs on cholesterol metabolism have focused on LA, the major dietary n-6 fatty acid.

It is now established that LDL cholesterol lowering reduces the risk of cardiovascular disease. In the fasting state LDL is the major cholesterol carrying lipoprotein in human plasma. The mechanisms through which raised plasma LDL cholesterol concentrations increase cardiovascular disease risk are not entirely understood but oxidative modification of LDL is thought to be involved. An increase in LA intake results in a lowering of plasma LDL cholesterol concentrations and therefore has the potential to reduce cardiovascular disease risk. These effects may not be linear over the entire range of LA intake and most of the benefits appear to be gained by moving from lower (<2% of energy) to moderate (~4–5% of energy) intakes. In addition, it is worthy of note that the effects of dietary n-6 PUFAs are less than half that of lowering dietary saturated fatty acids. Therefore, if total fat intake is maintained, the LDL cholesterol lowering effects of increasing n-6 PUFA intake are greatly enhanced if saturated fatty acid intake is decreased.

HDL cholesterol is inversely associated with cardiovascular disease risk. The mechanism by which HDL reduces cardiovascular disease risk may involve reverse cholesterol transport and reductions in cholesterol accumulation in the arterial wall. Intakes of LA within the normal ranges of intakes in most populations do not appear to alter HDL cholesterol concentrations. However, very high intakes—above 12% of energy—can lower HDL cholesterol concentrations.

Oxidative Stress

Several lines of evidence suggest that oxidatively modified LDL plays an important role in the development of atherosclerosis. Oxidative modification of LDL involves peroxidation of PUFAs. LDL particles enriched in PUFAs have been shown to be more susceptive to oxidative modification compared to LDL particles rich in monounsaturated fatty acids. Others have also suggested that a diet high in PUFAs may overwhelm the antioxidant defenses of cells. In particular, studies have shown that LA-enriched LDL is more prone to *in vitro* oxidation than oleic acid-enriched LDL. Concern also remains with respect to the potential for increased lipid peroxidation following n-3 fatty acids. To date, however, the data *in vivo* are inconclusive, with observations of increased, unchanged, and decreased lipid peroxidation. The most plausible explanation relates to differences in the methodologies employed to assess lipid peroxidation. Much of the literature relating to PUFAs and lipid peroxidation is based on indirect and nonspecific assays, including measurement of LDL oxidative susceptibility, which relies on the isolation of LDL from plasma. In this regard, the recent discovery of F_2-isoprostanes, which are nonenzymatic prostaglandin-like products of free radical peroxidation of arachidonic acid, has allowed for the direct assessment of *in vivo* lipid peroxidation. There is now good evidence that quantitation of F_2-isoprostanes provides a reliable measure of *in vivo* oxidative stress. Using measurement of F_2-isoprostanes, recent data have demonstrated that n-3 fatty acids decrease oxidative stress. It has also been suggested that the concentration of PUFAs may be a more important factor affecting lipid peroxidation than the degree of unsaturation. Further research using better markers of lipid peroxidation is required before definitive statements can be made relating to the effect of n-6 fatty acids, and indeed PUFAs in general, on oxidative stress.

Blood Pressure

The possible effects of dietary fatty acids on blood pressure have been explored in population studies and dietary intervention trials. With the exception of studies comparing vegetarian and nonvegetarian populations, from which there is a suggestion of a blood pressure lowering effect of diets high in PUFAs, including LA, and lower in saturated fatty acids, the results of most within- and between-population studies have generally not found significant associations. The results of intervention studies suggest that n-6 fatty acids, LA in particular, may be responsible for a small blood pressure lowering effect. However, these studies are also inconsistent, with several failing to find a significant blood pressure lowering effect.

Conclusions

Diets low in n-6 fatty acids, principally LA, appear to be associated with an increased risk of cardiovascular disease. The results of studies examining the effects of LA on risk factors for atherosclerosis and cardiovascular disease are consistent with this observation. An increase in n-6 PUFA intake from a low to a moderate intake level, in conjunction with decreases in total and saturated fat intake, may beneficially influence lipoprotein metabolism, lower blood pressure, and reduce cardiovascular disease risk. Observations in populations with high n-6 PUFA intake indicate that high intakes of n-6 fatty acids (>10%) can occur together with low rates of cardiovascular disease and possibly also cancer. However, where antioxidant composition of the diet is low, there is the potential for increased risk of cardiovascular disease. An increased susceptibility of PUFAs to oxidative damage, particularly in the presence of low concentrations of protective antioxidants, may be an important factor involved. The source of n-6 PUFAs in the diet, refined versus unrefined, and the composition of the background diet may therefore be important determinants of whether high n-6 fatty acid intake increases or decreases risk of cardiovascular disease. In addition, the proportion of n-6 to n-3 fatty acids in the diet may also play an important role in determining cardiovascular risk.

The available evidence suggests that n-6 fatty acid-derived eicosanoids are generally proinflammatory and prothrombotic. In contrast, eicosanoids derived from n-3 fatty acids have attenuated biological activity on cardiovascular risk factors. The effects of altering n-6 PUFA intake, in conjunction with changes in other polyunsaturated fatty acids, as well as other classes of fatty acids, on endothelial function, thrombosis, and inflammation are not understood. The relative proportion of all the classes of fatty acids in the diet may well be more important and relevant to cardiovascular risk reduction than any single class of fatty acids. Clearly such research warrants further investigation.

Saturated

R P Mensink, Maastricht University, Maastricht, The Netherlands
E H M Temme, University of Leuven, Leuven, Belgium

Fats and oils always consist of a mixture of fatty acids, although one or two fatty acids are usually predominant. **Table 1** shows the fatty acid composition of some edible fats rich in saturated fatty acids. In the Western diet, palmitic acid ($C_{16:0}$) is the major saturated fatty acid. A smaller proportion comes from stearic acid ($C_{18:0}$), followed by myristic acid ($C_{14:0}$), lauric acid ($C_{12:0}$), and short-chain and medium-chain fatty acids (MCFA) ($C_{10:0}$ or less).

When discussing the health effects of the total saturated fat content of diets, this class of fatty acids has to be compared with some other component of the diet that provides a similar amount of energy (isoenergetic). Otherwise, two variables are being introduced: changes in total dietary energy intake and, as a consequence, changes in body weight. Normally, an isoenergetic amount from carbohydrates is used for comparisons.

Cholesterol Metabolism

Lipoproteins and their associated apoproteins are strong predictors of the risk of coronary heart disease (CHD). Concentrations of total cholesterol, low-density lipoproteins (LDL), and apoprotein B are positively correlated with CHD risk; high-density lipoprotein (HDL) and apoprotein Al concentrations are negatively correlated. Controlled dietary trials have now demonstrated that the total saturated fat content and the type of saturated fatty acid in the diet affect serum lipid and lipoprotein levels.

Total Saturated Fat Content of Diets

Using statistical techniques, results from independent experiments have been combined to develop equations that estimate the mean change in serum lipoprotein levels for a group of subjects when carbohydrates are replaced by an isoenergetic amount of a mixture of saturated fatty acids. The predicted changes for total LDL and HDL cholesterol and triacylglycerols are shown in **Figure 1**. Each bar represents the predicted change in the concentration of that particular lipid or lipoprotein when a particular fatty acid class replaces 10% of the daily energy intake from carbohydrates. For a group of adults with an energy intake of 10 MJ daily, 10% of energy is provided by about 60 g of carbohydrates or 27 g of fatty acids.

A mixture of saturated fatty acids strongly elevates serum total cholesterol levels. It was predicted that when 10% of dietary energy provided by carbohydrates was exchanged for a mixture of saturated fatty acids, serum total cholesterol concentrations would increase by $0.36\,\mathrm{mmol\,l^{-1}}$. This increase in total cholesterol will result from a rise in both LDL and HDL cholesterol concentrations. Saturated fatty acids will also lower fasting triacylglycerol concentrations compared with carbohydrates. Besides affecting LDL and HDL cholesterol concentrations, a mixture of saturated fatty acids also changes the concentrations of their associated apoproteins. In general, strong associations are observed between changes in LDL cholesterol and changes in apo-B and between changes in HDL cholesterol and apo-Al.

Figure 1 also shows that total and LDL cholesterol concentrations decrease when saturated fatty acids are replaced by unsaturated fatty acids. In addition, slight decreases of HDL cholesterol concentrations are then predicted.

Effects of Specific Saturated Fatty Acids

Cocoa butter raises total cholesterol concentrations to a lesser extent than palm oil. This difference in

American Society for Clinical Nutrition.

the serum cholesterol-raising potency of two fats high in saturated fatty acids (see **Table 1**) showed that not all saturated fatty acids have equal effects on cholesterol concentrations. **Figure 2** illustrates the effects of lauric, myristic, palmitic, and stearic acids on LDL and HDL cholesterol concentrations. Compared with other saturated fatty acids, lauric and myristic acids have the strongest potency to increase serum total and LDL cholesterol concentrations and also HDL cholesterol concentrations. Effects of lauric acid on HDL are stronger than those of myristic acid.

Scientists are not unanimous about the cholesterol-raising properties of palmitic acid, the major dietary saturated fatty acid. Many studies have indicated that, compared with carbohydrates, palmitic acid raises serum total and LDL cholesterol levels but has less effect on HDL cholesterol (**Figure 2**). However, a few studies indicated that palmitic acid might not raise total and LDL cholesterol concentrations compared with carbohydrates. It has been proposed that this negative finding is only present when the linoleic acid content of the diet is adequate (6–7% of energy). It is hypothesized that the increased hepatic apo-B100 production caused by palmitic acid, and the consequent elevation of concentrations of serum very low density lipoproteins (VLDL) and LDL particles, is counteracted by an increased uptake of LDL particles by the LDL receptor which is upregulated by linoleic acid. To explain the discrepancy with other studies, it has been suggested that in some situations, such as hypercholesterolaemia or obesity, linoleic acid is unable to increase LDL receptor activity sufficiently to neutralize the cholesterol-raising effects of palmitic acid. This theory, however, awaits confirmation, and for now it seems justified to classify palmitic acid as a cholesterol-raising saturated fatty acid.

Stearic acid, a major fatty acid in cocoa butter, does not raise total, LDL, and HDL cholesterol levels compared with carbohydrates. Also, MCFA have been reported not to raise LDL and HDL cholesterol concentrations compared with carbohydrates, but data are limited. Like carbohydrates, diets containing large amounts of MCFA increase fasting triacylglycerol concentrations compared with the other saturated fatty acids. However, such diets are the sole energy source only in parenteral or enteral nutrition or in sports drinks. Other saturated fatty acids have not been reported to raise

triacylglycerol concentrations compared with each other, but lower triacylglycerol concentrations compared with carbohydrates.

Platelet Aggregation

Increased platelet aggregation may be an important risk marker for the occurrence of cardiovascular disease, and different types of fatty acids can modify platelet aggregation *in vitro*. However, reports of research on this topic are confusing. All measurements have their limitations, and it is not known whether measurement *in vitro* of platelet aggregation reflects the reality of platelet reactivity *in vivo*.

Many methods are available to measure platelet aggregation *in vitro*. First, the blood sample is treated with an anticoagulant to avoid clotting of the blood in the test tube or in the aggregometer; many different anticoagulants are used, which all differ in their mechanism of action. Second, platelet aggregation can be measured in whole blood, in platelet-rich plasma, or (to remove the influence of the plasma constituents) in a washed platelet sample. Finally, the platelet aggregation reaction in the aggregometer can be initiated with many different compounds, such as collagen, ADP, arachidonic acid, and thrombin. Platelet aggregation can also be studied by measuring the stable metabolites of the proaggregatory thromboxane A_2 (TxA_2), thromboxane B_2 (TxB_2), the stable metabolite of the antiaggregatory prostaglandin (prostacyclin: PGI_2), or 6-keto-PGF1α.

Total Saturated Fat Content of Diets

Platelet aggregation and clotting activity of plasma were studied in British and French farmers, who were classified according to their intake of saturated fatty acids. A positive correlation was observed between thrombin-induced aggregation of platelet-rich plasma and the intake of saturated fatty acids. Aggregation induced by ADP or collagen, however, did not correlate with dietary saturated fat intake. In a follow-up study, a group of farmers consuming high-fat diets were asked to replace dairy fat in their diets with a special margarine rich in polyunsaturated fatty acids. Besides lowering the intake of saturated fatty acids, this intervention also resulted in a lower intake of total fat. A control group of farmers did not change their diets. After this intervention the thrombin-induced aggregation of platelet-rich plasma decreased when saturated fat intake decreased. Aggregation induced by ADP, however, increased in the intervention group. From these studies, it is not clear whether the fatty acid composition of the diets or the total fatty acid content is responsible for the changes in platelet aggregation. Furthermore, it is not clear if one should favor increased or decreased platelet aggregation after decreasing the saturated fat content of diets as effects did depend on the agonist used to induce platelet aggregation. Saturated fatty acids from milk fat have also been compared with unsaturated fatty acids from sunflower and rapeseed oils. Aggregation induced by ADP or collagen in platelet-rich plasma was lower with the milk fat diet than with either oil.

One of the mechanisms affecting platelet aggregation is alteration of the proportion of arachidonic acid in the platelet phospholipids. Arachidonic acid is a substrate for the production of the proaggregatory TxA_2 and the antiaggregatory PGI_2, and the balance between these two eicosanoids affects the degree of platelet activation. The proportion of arachidonic acid in membranes can be modified through changes in dietary fatty acid composition. Diets rich in saturated fatty acids increase the arachidonic acid content of the platelet phospholipids, but this is also dependent on the particular saturated fatty acid consumed (see below).

Diets rich in saturated fatty acids have also been associated with a lower ratio of cholesterol to phospholipids in platelet membranes, which may affect receptor activity and platelet aggregation. However, these mechanisms have been described from studies *in vitro* and on animals and have not adequately been confirmed in human studies.

Effects of Specific Saturated Fatty Acids

Diets rich in coconut fat have been reported to raise TxB_2 and lower 6-keto-$PGF_{1\alpha}$ concentrations in collagen-activated plasma compared with diets rich in palm or olive oils, indicating a less favourable eicosanoid profile. The main saturated fatty acids of coconut fat — lauric and myristic acids — did not, however, change collagen-induced aggregation in whole-blood samples compared with a diet rich in oleic acid. Also, diets rich in MCFA or palmitic acid did not change collagen-induced aggregation in whole-blood samples. Compared with a diet rich in a mixture of saturated fatty acids, a stearic acid diet increased collagen-induced aggregation in platelet-rich plasma. In addition, a decreased proportion of arachidonic acid in platelet phospholipids was demonstrated after a cocoa butter diet compared with a diet rich in butterfat. Changes in eicosanoid metabolite concentrations in urine, however, were not observed after either diet. These results are

conflicting and it is debatable whether measurement *in vitro* of platelet aggregation truly reflects the situation *in vivo*.

Coagulation and Fibrinolysis

Processes involved in thrombus formation include not only those required for the formation of a stable thrombus (platelet aggregation and blood clotting) but also a mechanism to dissolve the thrombus (fibrinolysis). Long-term prospective epidemiological studies have reported that in healthy men factor VII coagulant activity (factor VIIc) and fibrinogen concentrations were higher in subjects who developed cardiovascular diseases at a later stage of the study. Factor VIIc in particular was associated with an increased risk of dying from cardiovascular disease. A high concentration of plasminogen activator inhibitor type 1 (PAI-1) indicates impaired fibrinolytic capacity of the plasma and is associated with increased risk of occurrence of coronary events.

Saturated fatty acids can affect the plasma activity of some of these coagulation and fibrinolytic factors and thus the prethrombotic state of the blood. However, the effects of saturated fatty acids on coagulation and fibrinolytic factors in humans, unlike effects on cholesterol concentrations, have received little attention, and few well-controlled human studies have been reported. Also, regression equations derived from a meta-analysis, which predict the effects on coagulation and fibrinolytic factors of different fatty acid classes compared with those of carbohydrates, do not exist. Therefore, the reference fatty acid is dependent on the experiment discussed. In the epidemiological studies that have found associations between CHD risk and factors involved in thrombogenesis or atherogenesis, subjects were mostly fasted. Also, the effects of saturated fatty acids on cholesterol metabolism, platelet aggregation, and coagulation and fibrinolysis have been studied mainly in fasted subjects. It should be noted, however, that concentrations of some coagulation factors (e.g., factor VIIc) and fibrinolytic factors change after a meal.

Total Saturated Fat Content of Diets

Coagulation Results of studies on the effects of low-fat diets compared with high-fat diets provide some insight into the effects of decreasing the saturated fat content of diets. However, in these studies multiple changes are introduced which makes interpretation of results difficult.

Figure 3 demonstrates that decreased factor VIIc levels were observed in subjects on low-fat diets compared with those on high-saturated fat diets. In many of these studies, the low-fat diet provided smaller quantities of both saturated and unsaturated fatty acids and more fiber than the high-saturated fat diets. The combined results, however, suggest that, apart from a possible effect of dietary fiber, saturates increase factor VII levels compared with carbohydrates. Effects on other clotting factors are less clear. Measurements of markers of *in vivo* coagulation (e.g., prothrombin fragment $1+2$) might have provided more information on the effect of saturates on blood coagulation but were unfortunately not measured in most experiments.

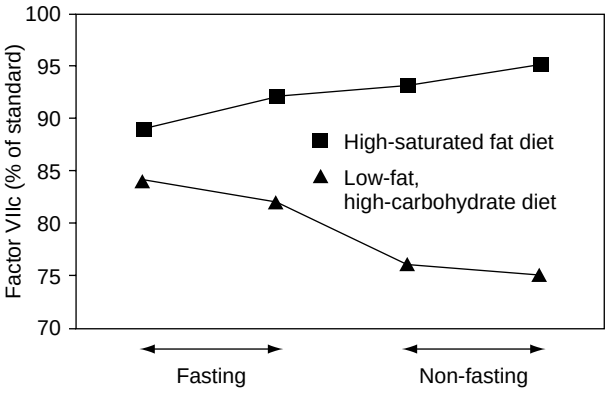

Figure 3 Effects of a high-saturated fat diet on fasting and postprandial factor VIIc activity From Miller (1998) *American Journal of Clinical Nutrition* **67**(supplement): 542S–545S. Reproduced with permission by the *American Journal of Clinical Nutrition*. © Am J Clin Nutr. American Society for Clinical Nutrition.

Fibrinolysis Effects of low-fat and high-fat diets on the fibrinolytic capacity of the blood have also been studied. A similar problem, as stated before, is that multiple changes were introduced within a single experiment. Results of longer term and shorter term studies with dietary changes of total fat (decrease of saturated and unsaturated fatty acids contents) and increased fiber content indicate beneficially increased euglobulin fibrinolytic capacity of the blood. However, when the saturated fatty acid and fiber content of two diets were almost identical and only the unsaturated fatty acid content was changed, no significant differences in fibrinolytic capacity were observed.

Little is known about the relative effects on fibrinolytic capacity of saturated fatty acids compared with unsaturated fatty acids. It has been reported, however, that diets rich in butterfat decreased PAI-1 activity compared with a diet rich in partially hydrogenated soybean oil, but whether this is because of changes in the saturated acid or the *trans* fatty acid content is not clear from this study.

As for coagulation factors, the findings on the fibrinolytic effects of saturates are still inconclusive and need to be examined by more specific assays, measuring the activities of the separate fibrinolytic factors such as tPA and PAI-1.

Effects of Specific Saturated Fatty Acids

Coagulation The interest in the effects of particular fatty acids on coagulation and fibrinolytic factors has increased since the observation that different saturated fatty acids raise serum lipids and lipoproteins in different ways (see section on cholesterol metabolism). Although results are conflicting, some studies indicate that the most potent cholesterol-raising saturated fatty acids also increase factor VII activity.

Diets rich in lauric plus myristic acids compared with a diet rich in stearic acid also increase concentrations of other vitamin K-dependent coagulation proteins. In addition, this mixture of saturated fatty acids raised $F1+2$ concentrations, indicating increased *in vivo* turnover of prothrombin to thrombin. This agreed with a study in rabbits where increased $F1+2$ concentrations were associated with increased hepatic synthesis of vitamin K-dependent clotting factors.

Diets rich in certain saturated fatty acids (lauric acid and palmitic acid) and also diets rich in butterfat have been reported to raise fibrinogen concentrations, but increases were small.

Postprandially, increased factor VIIc concentrations have been demonstrated after consumption of diets rich in fat compared with fat-free meals (**Figure 3**). The response is stronger when more fat is consumed, but this occurs regardless of whether the fat is high in saturated or unsaturated fatty acids. Only meals with unrealistically high amounts of MCFA have been reported not to change factor VIIc levels in comparison with a meal providing a similar amount of olive oil.

Fibrinolysis Increased PAI-1 activity of a palmitic acid-rich diet has been observed compared with diets enriched with oleic acid, indicating impaired fibrinolytic capacity of the plasma. However, this was not confirmed by other experiments on the effects of particular saturated fatty acids (including palmitic acid), which did not indicate changes in fibrinolytic capacity of the blood, measured as tPA, PAI-1 activity, or antigen concentrations of tPA and PAI-1.

Conclusion

Saturated fatty acids as a group affect factors involved in cholesterol metabolism. Relative to the carbohydrate content of the diet, a decrease in saturated fat content induces a favorable decrease in serum total and LDL cholesterol concentrations but unfavorably reduces HDL cholesterol concentrations. Both increasing and decreasing effects of saturates on platelet aggregation have been observed, as well as the absence of effect, so results are inconsistent and difficult to interpret. Whether the beneficial effect of a diet low in saturated fat on the prethrombotic state of blood depends on the dietary fiber content is still unclear.

Of the saturated fatty acids, lauric and myristic acids have the strongest potency to raise total and LDL cholesterol concentrations. In addition, both of these saturated fatty acids raise HDL cholesterol levels. Palmitic acid raises total and LDL cholesterol levels compared with carbohydrates but is less potent than lauric and myristic acids. Stearic acid does not raise LDL and HDL cholesterol concentrations compared with carbohydrates. Lauric, myristic, and palmitic acids increase factor VII activity in a similar way, whereas the effects of MCFA and stearic acid seem limited.

Trans Fatty Acids

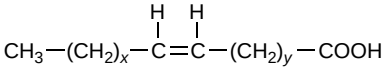
M J Sadler, MJSR Associates, Ashford, UK

Chemistry

The *trans* fatty acids are unsaturated fatty acids that contain one or more ethylenic double bonds in the *trans* geometrical configuration, i.e., on opposite sides of the carbon chain (**Figure 1**). The *trans* bond is more thermodynamically stable than the *cis* bond and is therefore less chemically reactive.

Trans bonds have minimal effect on the conformation of the carbon chain such that their physical properties more closely resemble those of saturated fatty acids than of *cis* unsaturated fatty acids. The conformation remains linear, compared with *cis* fatty acids, which are kinked (**Figure 2**). Hence, *trans* isomers can pack together more closely than their *cis* counterparts.

Trans fatty acids have higher melting points than their *cis* counterparts, while saturated fatty acids have higher melting points than both *trans* and *cis* fatty acids. For example, the melting points of C_{18}



cis configuration

fatty acids are 69.6 °C for stearic acid (18:0), 44.8 °C for elaidic acid (*trans*-18:1), and 13.2 °C for oleic acid (*cis*-18:1). The relative proportion of these different types of fatty acids influences the physical properties of cooking fats and their suitability for different uses in the food processing industry.

In addition to geometrical isomerism (*cis* and *trans*), unsaturated fatty acids also exhibit positional isomerism, where the double bonds can occur in different positions along the chain in fatty acids which have identical chemical formulae. As with *cis* fatty acids, *trans* fatty acids also occur as mixtures of positional isomers.

Occurrence

Trans fatty acids present in the diet arise from two origins. The first is from bacterial biohydrogenation in the forestomach of ruminants, which is the source of *trans* fatty acids present in mutton and beef fats. These are present at a concentration of 2–9% of bovine fat. *Trans*-11-octadecenoic acid is the main isomer produced although *trans*-9- and *trans*-10-octadecenoic acid are also produced. Thus, *trans* fatty acids occur in nature and cannot be considered to be foreign substances.

The second origin is from the industrial catalytic hydrogenation of liquid oils (mainly of vegetable origin, but also of fish oils). This produces solid fats and partially hydrogenated oils and is undertaken to increase the thermal stability of liquid oils and to alter their physical properties. The margarines, spreads, shortenings, and frying oils produced are thus more useful in the food processing industry than liquid oils. Chemically, a range of *trans* isomers is produced that, for vegetable oils containing predominantly C_{18} unsaturated fatty acids, is qualitatively similar to those produced by biohydrogenation, although the relative proportions of the

isomers may differ. Use of fish oils containing a high proportion of very long-chain (C_{20} and C_{22}) fatty acids with up to six double bonds produces more complex mixtures of *trans*, *cis*, and positional isomers. However, the use of hydrogenated fish oils in food processing is declining, owing to a general fall in edible oil prices and to consumer preference for products based on vegetable oils.

Analysis

Methods available for the estimation of total *trans* unsaturation and to determine individual *trans* fatty acids are outlined in **Table 1**. At present there is no one simple and accurate method suitable for both research applications and for use in the food industry. In dietary studies data for *trans* fatty acid intake are generally expressed as the sum of the fatty acids containing *trans* double bonds, and there is generally no differentiation between the different isomers.

A report from the British Nutrition Foundation (BNF) in 1995 highlighted concerns over the variations in estimations of *trans* fatty acid concentrations in some food products provided by different analytical techniques. A thorough review of the available analytical techniques was called for.

Sources and Intakes

The main sources of *trans* fatty acids in the UK diet are cereal-based products (providing 27% of total *trans* fatty acid intake), margarines, spreads, and frying oils (22%), meat and meat products (18%), and milk, butter, and cheese (16%). In the USA, the main sources of intake are baked goods (28%), fried foods (25%), margarine, spreads, and shortenings (25%), savory snacks (10%), and milk and butter (9%).

Typical ranges of *trans* fatty acids in foods are shown in **Table 2**. *Trans* isomers of $C_{18:1}$ (elaidic acid) are the most common *trans* fatty acids, accounting for 65% of the total *trans* fatty acids in the UK diet.

Intakes of *trans* fatty acids are difficult to assess because of:

- analytical inaccuracies;
- difficulties of obtaining reliable information about food intake.

A number of countries have attempted to assess intakes of *trans* fatty acids (**Table 3**). Reliable intake data are available for the UK, based on a 7-day weighed intake of foods eaten both inside and outside the home, for 2000 adults aged 16–64 years (**Table 3**). Data from the UK National Food Survey,

Table 1 Analytical methods for *trans* fatty acids

General method	*Determines*	*Advantages*	*Disadvantages*
Infrared (IR) absorption spectrometry	Total *trans* unsaturation	Inexpensive; reliable results provided concentrations of *trans* isomers exceed 5%; can analyze intact lipids	Unreliable results if concentrations of *trans* isomers less than 5%; interpretive difficulties—need to apply correction factors
Fourier transform IR spectroscopy	Total *trans* unsaturation	Reliable results if concentrations of *trans* isomers less than 2%	Does not distinguish between two esters each with one *trans* bond or between one ester with two *trans* bonds and one with none
Gas–liquid chromatography (GLC)	Individual *trans* fatty acids		Presence of unidentified compounds can give false estimates of *trans* fatty content
Argentation—GLC	Individual *trans* fatty acids	Saturated, monounsaturated, and diunsaturated fatty acids can be resolved	Method is time-consuming
Capillary column GLC	Individual *trans* fatty acids which can be summated to give total *trans* unsaturation	Accurate resolution of fatty acid esters including *cis* and *trans* isomers	Great skill required for preparing columns and interpretation of chromatograms
High-performance liquid chromatography	Individual *trans* fatty acids	*cis,cis*- and *trans,trans*-dienoic fatty acids can be separated	
Nuclear magnetic resonance (NMR)	Individual *trans* fatty acids	Intact lipids can be analyzed; can identify *trans*-diene isomers by use of proton (^{1}H) NMR	Equipment is costly; more use as a research tool than for general analysis

Table 2 Typical content of *trans* fatty acids in a range of foods

Food	*Content of* trans *fatty acids per 100 g product (g)*
Butter	3.6
Soft margarine, not high in PUFA	9.1
Soft margarine, high in PUFA	5.2
Hard margarine	12.4
Low-fat spread, not high in PUFA	4.5
Low-fat spread, high in PUFA	2.5
Blended vegetable oil	1.1
Vegetable oil (sunflower, safflower, soya, sesame)	0
Commercial blended oil	6.7
Potato crisps	0.2
Whole wheat crisps	0.2
Low-fat crisps	0.3
Beefburger, 100% beef frozen, fried, or grilled	0.8
Sausage, pork, fried	0.1
Sausage roll, flaky pastry	6.3
Hamburger in bun with cheese, take-away	0.5
Biscuits, cheese-flavored	0.2
Biscuits, chocolate, full coated	3.4
Chocolate cake and butter icing	7.1
Chips, old potatoes, fresh, fried in commercial blended oil	0.7
Chips, frozen, fine cut, fried in commercial blended oil	0.7

which does not include food eaten outside the home, show a steady decline in intake of *trans* fatty acids from 5.6 g per person per day in 1980 to 4.8 g in 1992. In the UK *trans* fatty acids account for approximately 6% of dietary fat, and in the USA for approximately 7–8% of dietary fat. Estimates of *trans* fatty acid intake are likely to show a downward trend because of:

- improved analytical techniques which give lower but more accurate values for the *trans* fatty acid content of foods;
- the availability of values for *trans* fatty acids in a wider range of foods which allows more accurate estimation of intakes;
- the reformulation of some products which has led to a reduction in the concentration of *trans* fatty acids in recent years.

Advances in food technology that are enabling a gradual reduction in the *trans* fatty acid content include:

1. refinements in hydrogenation processing conditions which will enable the reduction and in the future, the elimination of *trans* fatty acids;
2. the interesterification (rearrangement of fatty acids within and between triacylglycerols) of liquid oils with solid fats;
3. the future genetic modification of oils.

Table 3 Estimated intakes of *trans* fatty acids in various countries

Country	*Estimated daily intake of total* trans *fatty acids (g)*	*Year published and basis for estimation*
UK	5.6 (men) 4.0 (women)	1990: 7-day weighed intake undertaken in 1986–87 including food eaten outside the home
USA	8.1 3.8	1991: availability data 1994: food frequency questionnaire
Denmark	5.0	1995: availability data
Finland	1.9	1992: duplicate diets
Spain	2.0–3.0	1993: calculated from food consumption data
Norway	8.0	1993: food frequency questionnaire

Physiology of *trans* Fatty Acids

Extensive reviews of the health effects of *trans* fatty acids conducted in the 1980s found no evidence for any adverse effects of *trans* fatty acids on growth, longevity, reproduction, or the occurrence of disease, including cancer, from studies conducted in experimental animals.

Digestion, Absorption, and Metabolism

Trans fatty acids are present in the diet in esterified form, mainly in triacylglycerols but those from ruminant sources may also be present in phospholipids. Before absorption into the body, triacylglycerols must be digested by pancreatic lipase in the upper small intestine. There is no evidence of differences in the hydrolysis and absorption of *trans* fatty acids, in comparison with that of *cis* fatty acids. *Trans* fatty acids are transported from the intestine mainly in chylomicrons, but some are also incorporated into cholesteryl esters and phospholipids.

Trans fatty acids are incorporated into the lipids of most tissues of the body and are present in all the major classes of complex lipids. The positional distribution of *trans* fatty acids tends to show more similarity to that of saturated fatty acids than to that of the corresponding *cis* fatty acids. Some selectivity between tissues results in an uneven distribution of *trans* fatty acids throughout the body.

Trans fatty acids occur mainly in positions 1 and 3 of triacylglycerols, the predominant lipids in adipose tissue. The concentration of *trans* fatty acids in adipose tissue is approximately proportional to long-term dietary intake, and determination of the concentrations in storage fat is one method used to estimate *trans* fatty acid intake. However, this is not entirely straightforward as variation has been reported in the composition of adipose tissue obtained from different sites and depths, and factors that influence adipose tissue turnover rates such as dieting and exercise are also complicating factors. *Trans*-18:1 isomers account for approximately 70% of the *trans* fatty acids found in adipose tissue, and *trans*-18:2 isomers (*trans,trans, trans,cis*, and *cis,trans*) account for about 20%.

In heart, liver, and brain, *trans* fatty acids occur mainly in membrane phospholipids. The position of the double bond as well as the conformation of the carbon chain may determine the pattern of *trans* fatty acid esterification in phospholipids, but there is evidence that *trans*-18:1 fatty acids are preferentially incorporated into position 1 of the phosphoacylgly-cerols, as are saturated fatty acids; in contrast, oleic acid is randomly distributed.

The turnover of *trans* fatty acids parallels that of other types of fatty acids in the body, and *trans* fatty acids are readily removed from the tissues for oxidation. Studies in which human subjects were fed labelled carbon-13 isotope have demonstrated that the whole-body oxidation rate for *trans*-18:1 is similar to that for *cis*-18:1. *Trans* fatty acids are a minor component of tissue lipids, and their concentrations in tissues are much lower than their concentrations in the diet. However, research has focused on C_{18} *trans* fatty acids, and more studies are needed to investigate the effects of very long-chain *trans* fatty acids derived from the hydrogenation of fish oils.

Interactions with Metabolism of Essential Fatty Acids

From experiments mainly with laboratory animals, it has been demonstrated that relatively high intakes of *trans* fatty acids in the diet in conjunction with marginal intakes of essential fatty acids (less than 2% dietary energy from linoleic acid) can lead to the presence of Mead acid (*cis*-5,8,11–20:3) in tissue lipids and an increase in the ratio of 20:3 n-9 to 20:4 n-6. This has been interpreted to suggest early signs of essential fatty acid deficiency, with potentially increased requirements for essential fatty acids. Mead acid can accumulate in the presence of linoleic acid, if large amounts of nonessential fatty acids are also present. Two mechanisms have been suggested to explain these observations in relation to intake of *trans* fatty acids:

- that *trans* fatty acids may compete with linoleic acid in metabolic pathways;
- that *trans* fatty acids may inhibit enzymes involved in elongation and further desaturation of linoleic acid.

The consensus is that the significance of Mead acid production in humans has not been established, and further research is needed in this area. It is unlikely that a competitive effect between polyunsaturated fatty acids (PUFA) and *trans* fatty acids would arise, because of the relatively high intakes of linoleic acid in people freely selecting their own diets. Also, as there is a large body pool of linoleic acid available for conversion to long-chain PUFA, it is unlikely that the *trans* fatty acids in the body would interfere even at relatively low ratios of dietary linoleic acid to *trans* fatty acids. The appearance of Mead acid is not specifically induced by *trans* fatty acids, and experiments in animals have not demonstrated any adverse health effects of its production.

Effect of *trans* Fatty Acids on Plasma Lipoproteins

Raised plasma concentrations of low-density lipoprotein (LDL) are considered to be a risk factor for coronary heart disease (CHD); in contrast, reduced concentrations of high-density lipoprotein (HDL) are considered to increase risk. It therefore follows that to help protect against CHD, diets should ideally help to maintain plasma concentrations of HDL cholesterol and to lower those of LDL cholesterol. Dietary factors that raise LDL and lower HDL concentrations would be considered to be undesirable in this context.

Several trials have evaluated the effects of C_{18} *trans* monounsaturated fatty acids on plasma lipoproteins (**Figure 3**). The results have been relatively consistent, and the following general conclusions have been drawn from these studies:

- C_{18} monounsaturated *trans* fatty acids raise LDL cholesterol concentration; the cholesterol-raising effect is similar in magnitude to that of the cholesterol-raising saturated fatty acids, i.e., myristic (14:0) and palmitic (16:0) acids.
- C_{18} monounsaturated *trans* fatty acids decrease HDL cholesterol concentration; this is in contrast to saturated fatty acids which produce a small rise in HDL levels.
- In comparison with the effects of oleic and linoleic fatty acids, C_{18} monounsaturated *trans* fatty acids raise LDL cholesterol and lower HDL cholesterol levels.

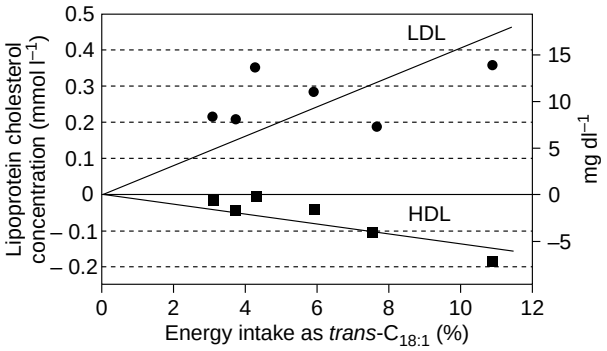

Figure 3 Effects of monounsaturated C_{18} *trans* fatty acids on lipoprotein cholesterol concentrations relative to oleic acid (*cis*-$C_{18:1}$). Data are derived from six dietary comparisons between *trans* and *cis* monounsaturated fatty acids; differences between diets in fatty acids other than *trans* and *cis* monounsaturated fatty acids were adjusted for by using regression coefficients from a meta-analysis of 27 controlled trials. The regression lines were forced through the origin because a zero change in intake will produce a zero change in lipoprotein concentrations. From Zock *et al.* (1995), reproduced with kind permission of the *American Journal of Clinical Nutrition*.

It has been calculated that 'theoretically', each 1% increase in energy from *trans* fatty acids (18:1) in place of oleic acid (*cis*-18:1) would raise plasma LDL concentration by 0.040 mmol l^{-1} (an approximately 1% increase based on average UK plasma cholesterol concentration); HDL would be decreased by 0.013 mmol l^{-1} (a 1% decrease).

The 1995 BNF Task Force calculated that, in the UK, replacing 2% energy from *trans* fatty acids with 2% energy from oleic acid would reduce mean plasma LDL cholesterol concentration by 0.08 mmol l^{-1}; plasma HDL concentration would rise by 0.026 mmol l^{-1}, and the HDL ratio would fall from 3.92 to 3.77. From estimates of the effect of changes in LDL and HDL concentrations on CHD risk, this was predicted to reduce the risk of CHD by 5–15%. In comparison, replacing *trans* fatty acids with either saturated fatty acids or carbohydrate would decrease risk by up to 8%.

The influence of *trans* fatty acids on plasma lipoproteins in relation to CHD risk would thus appear to be more unfavorable than that of saturated fatty acids, as determined by the effect on the ratio of LDL to HDL cholesterol. However, the overall magnitude of the effect would be dependent on the relative intakes of *trans* fatty acids and saturated fatty acids. In the UK *trans* fatty acids contribute about 2% of dietary energy, in contrast to saturated fatty acids which contribute about 15% dietary energy, and this needs to be considered when formulating dietary advice. The Task Force also estimated, on the same basis, that a reduction of 6% in energy from saturated fatty acids would decrease risk by 37%.

However, these conclusions of the adverse effect of *trans* fatty acid on plasma lipoprotein concentrations are not universally accepted. It has been commented that some trials used an inappropriate basis for comparison of the different diets and did not always control for other fatty acids that are known to influence blood cholesterol levels.

Several studies have suggested that *trans* fatty acids raise the plasma concentration of lipoprotein(a), particularly in individuals with already raised levels. Lipoprotein(a) has been suggested to be an independent risk marker for CHD, although this is not universally accepted.

Atherosclerosis and Hemostasis

Despite the reported effects of *trans* fatty acids on blood lipoproteins, experiments with laboratory animals have not provided evidence that dietary *trans* fatty acids are associated with the development of experimental atherosclerosis, provided that the diet contains adequate levels of linoleic acid. Similarly, there is no evidence that *trans* fatty acids raise blood pressure or affect the blood coagulation system. However, there has been no thorough evaluation of the effect of *trans* fatty acids on the coagulation system, and this is an area worthy of investigation.

The Role of *trans* Fatty Acids in Coronary Heart Disease

A number of epidemiological studies have suggested an association between *trans* fatty acids and CHD.

Case–Control Studies

A study by Ascherio in 1994 demonstrated that in subjects who had suffered acute myocardial infarction (AMI), past intake of *trans* fatty acids, assessed from a food frequency questionnaire, was associated with increased risk. *Trans* fatty acid intake per day in the top quintile was 6.5 g compared with 1.7 g in the lowest quintile. After adjusting for age, energy intake, and sex, relative risk of a first AMI for the highest compared with the lowest quintile was 2.44 (95% confidence interval, 1.42–4.10). However, there was not a clear dose–response relationship.

A case–control study of sudden cardiac death found that higher concentrations of *trans* isomers of linoleic acid in adipose tissue, compared with lower concentrations, were associated with increased risk of sudden death. After controlling

for smoking and making an allowance for social class, this relationship became insignificant.

A multicenter study in eight European countries plus Israel found that the risk of AMI was not significantly different across quartiles of the concentration of *trans*-18:1 fatty acids in adipose tissue, the multivariate odds ratio being 0.97 (95% confidence interval, 0.56–1.67) for the highest compared with the lowest quartiles. However, there were significant differences within countries. In Norway and Finland, relative risk was significantly increased in the highest compared with the lowest quartiles, but in Russia and Spain relative risk was significantly decreased in these groups. Exclusion from the multicenter analysis of the Spanish centers, which had particularly low intakes of *trans* fatty acids, resulted in a tendency to increased risk of AMI in the highest quartiles of *trans*-18:1 concentration. However, the trend was not statistically significant, and adjustment for confounding factors had no effect on the results.

A Prospective Study

The relationship between *trans* fatty acid intake and subsequent CHD events was investigated in approximately 85 000 US nurses (the Nurses Health Study). *Trans* fatty acid intake was calculated from food frequency questionnaires for women who had been diagnosed free from CHD, stroke, diabetes, and hypercholesterolemia. The subjects were followed up for 8 years and CHD events were recorded. The relative risk of CHD in the highest compared with the lowest quintile was 1.5 (95% confidence interval, 1.12–2.0), after adjustment for age, energy intake, social class, and smoking. However, there was no clear dose–response relationship between the highest and the lowest intake groups. The intake of *trans* fatty acids in the top quintile was 3.2% dietary energy compared with 1.3% in the lowest quintile.

It has been commented on that the benefit predicted by the authors, that individuals in the top quintile of intake could halve their risk of myocardial infarction by reducing their intake of *trans* fatty acids to that of the lowest quintile, seems a large effect in view of the small difference in intakes between these groups (3.3 g). The changes in plasma lipoprotein cholesterol concentrations that would be predicted to occur as a result of lowering *trans* fatty acid intake would not explain all of the observed increase in risk. Also, the study was carried out in a selected population of women and it is unclear that the findings are applicable to the whole population or to other population groups.

Cancer

Although there is much evidence concerning the effect of different intakes of different types of fats on experimental carcinogenesis, data for *trans* fatty acids are limited and are hampered by confounding due to the lack of a suitable control diet.

Studies using different tumor models in mice and rats have shown no effect of *trans* fatty acids on tumor development. Increasing the intake of *trans* fatty acids, in place of *cis* fatty acids, has not demonstrated an adverse outcome with regard to cancer risk. In humans, there is little to suggest that *trans* fatty acids are adversely related to cancer risk at any of the major cancer sites. Early studies did not generally find that *trans* fatty acids were an important risk factor for malignant or benign breast disease. One study did report an association between the incidence of cancer of the colon, breast, and prostate and the use of industrially hydrogenated vegetable fats in the USA; however, other known risk factors were not allowed for.

Cancer of the Breast

Some epidemiological evidence suggests that total fat intake may be related to increased risk of cancer of the breast, although this is by no means conclusive. There is no strong evidence that intake of *trans* fatty acids *per se* is related to increased risk of breast cancer and many studies have not reported examining this relationship. A study in which adipose tissue concentrations of *trans*-18:1 fatty acids were assessed in 380 women with breast cancer at various stages and in controls revealed no consistent pattern of association. A similar, smaller study suggested an increased risk with higher body stores of *trans* fatty acids, but it was concluded that any such association may be modified by adipose tissue concentrations of polyunsaturated fatty acids.

Cancer of the colon

Epidemiological data from the Nurses Health Study suggested a link between intake of meat and meat products and colon cancer. The data indicated that high intakes of total, animal, saturated, and monounsaturated fat were associated with increased risk. Consuming beef, pork, or lamb as a main dish was positively associated with risk; though beef and lamb contain *trans* fatty acids, there was no evidence that high intakes of *trans* fatty acids increased risk. The Health Professionals Follow-up Study (a prospective study in male health professionals of parallel design to the Nurses Health Study) found similar dietary associations for colon cancer risk,

with no suggestion of any link with intake of *trans* fatty acids.

Prostate Cancer

Dietary associations with risk of prostate cancer were also assessed from the Health Professionals Follow-up Study. High intakes of total, saturated, and monounsaturated fatty acids and of α-linolenic acid were associated with increased risk, whereas high intakes of saturated fatty acids and linoleic acid were found to be protective. Intake of *trans* fatty acids was not found to be associated with risk of prostate cancer.

Dietary Guidelines

The details of population dietary guidelines for the quality and quantity of fat intake differ between countries. However, in consideration of prevention of CHD, dietary guidelines generally reflect advice to reduce average total fat intakes to 30–35% dietary energy and to lower saturated fat intakes to approximately 10% of dietary energy. Though the effect of *trans* fatty acids on the plasma LDL/HDL ratio is less favorable than that of saturated fatty acids, dietary advice needs to reflect the relative intakes of these two types of fatty acids. Since the contribution of saturated fat intake to dietary energy is approximately 5–7 times higher than that of *trans* fatty acids, advice on *trans* fatty acids should not assume more importance than advice to lower saturated fatty acids. However, because of the unfavorable effect of *trans* fatty acids on plasma lipoprotein concentrations, the 1995 BNF Task Force report concluded that the average intake of *trans* fatty acids in the UK diet (2% of energy) should not rise, and that dietary advice should continue to focus on reducing intake of saturated fatty acids as a priority.

Extreme consumers of *trans* fatty acids may be at greater risk, and individuals with high intakes may benefit from advice to lower their intake. It has been calculated that lowering total fat and increasing carbohydrate intake (which reduces plasma HDL cholesterol) will have minimal effect on risk of CHD. Substituting *cis* unsaturated fatty acids for saturated and *trans* fatty acids would be predicted to have a greater impact. For individuals at risk of CHD, high intakes of *trans* fatty acids would appear to be undesirable. Most dietary guidelines call for a reduction in *trans* fatty acids "as much as possible" recognizing that small amounts of *trans* fats are naturally present in the food chain. The food industry in general has reduced or eliminated *trans* in many products by improving manufacturing techniques and reducing *trans* fats generated during the hydrogenation process. Additionally, several countries now have regulations requiring that *trans* fatty acid be listed on products' labels. In some cases, like in the US, *trans* must be added to the saturated fat content reported on the Nutrition Facts label, based on their similar adverse effects on health. Although listing both fats together may not be correct in chemical terms, it is a practical way to allow consumers to quickly assess the content of unhealthy fat in a product.

Conclusions

Several lines of evidence indicate that *trans* fats have an adverse effect on the lipoprotein profile and likely on risk of cardiovascular disease. Although reducing intake of *trans* fats is a desirable goal, public health policy should keep as a central recommendation the reduction of saturated fats, which constitute four to six times more percent calories in the diet than *trans* fats. Since the largest proportion of *trans* fats is generated during food processing, industry bears the main responsibility for reducing the *trans* content of its products, thus helping the general public to lower their intake of this type of fat.

FERTILITY

R E Frisch, Harvard Center for Population and Development Studies, Cambridge, MA, USA

Linking Body Fat and Reproduction

It is well documented that women who are underweight, or too lean, because of injudicious dieting, excessive athletic activity, or both, experience disruption of their reproductive ability. It is also well documented that moderate weight loss, approximately 10–15% of normal weight for height, unassociated with anorexia nervosa (where weight loss is approximately 30% below ideal weight), results in amenorrhea due to hypothalamic dysfunction. Weight loss in this moderate range is equivalent to a loss of one-third of body fat. If the excessive leanness occurs before menarche, menarche may be delayed until as late as the age of 19 or 20 years.

In addition to the disruptive effects of weight loss and athletic activity on the menstrual cycle, women who exercise moderately or who are regaining weight into the normal range may have a menstrual cycle that appears to be normal but that actually has a shortened luteal phase or is anovulatory. All of these partial or total disruptions of reproductive ability are usually reversible, after varying periods of time, following weight gain, decreased athletic training, or both.

Excessive fatness is also associated with infertility in women; fertility is restored by loss of weight. Too little or too much fat are thus both associated with infertility. It is hypothesized that these associations are causal, and that the high percentage of body fat—26–28% in women after completion of growth—is necessary for and may directly influence reproduction.

The basic question is how does the hypothalamus, the part of the brain controlling reproduction, 'know' how much fat is stored in the body? The discovery of leptin, a protein hormone made by body fat cells of women and men, provides the biochemical link between body fat and reproductive ability. Friedman and colleagues cloned a gene that encoded leptin. Leptin controls food intake, energy metabolism, and reproduction. Receptors for leptin are located in the hypothalamus, the part of the brain that controls all three of these functions in addition to temperature control and stress.

Even before the leptin discovery, the 'critical fatness' hypothesis of Frisch and McArthur led to the prediction of minimum or threshold weights for height for the onset and maintenance of regular ovulatory menstrual cycles. These weights have been found to be useful clinically as target weights for the restoration of ovulatory cycles in cases of amenorrhea due to weight loss. Both the absolute and the relative amounts of fat are important since the lean mass and the fat must be in a particular absolute range as well as a relative range (i.e., the woman must be large enough to reproduce successfully).

Why Fat? The Energy Cost of Reproduction

A human pregnancy and lactation each have a high energy cost: A pregnancy requires approximately 336 MJ (74 000 kcal) in addition to normal metabolic requirements. Lactation requires approximately 2.5 MJ (600 kcal) per day. In premodern times, lactation was an essential part of reproduction.

While the reproductive system is slowly maturing during growth, the body changes in composition as well as in size and proportions. Direct measurements of body water of girls from birth to completion of growth at ages 16–18 years show a continuous

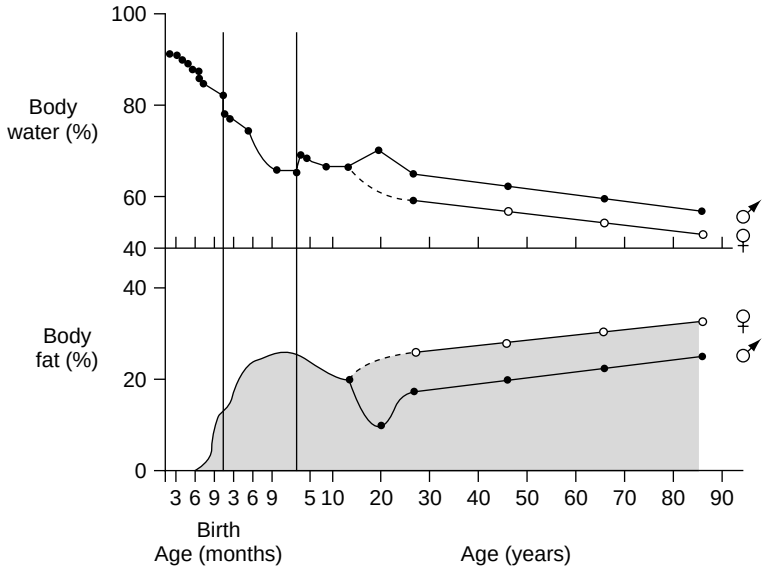

Figure 1 Changes in body water as percentage of body weight throughout the life span, and corresponding changes in the percentage of body fat. (Adapted from Friis-Hansen B (1965) Hydrometry of growth and aging. In: Brozek J (ed.) *Human Body Composition*, vol. 7, Symposia of the Society for the Study of Human Biology, pp. 191–209. Oxford: Pergamon Press.)

decline in the proportion of body water because girls have a large relative increase in body fat (**Figure 1**). This decrease is particularly rapid during the adolescent growth spurt in height and weight, which precedes menarche.

At the completion of growth, between ages 16 and 18 years, the body of a well-nourished woman contains approximately 26–28% fat and approximately 52% water, whereas the body of a man at completion of growth contains approximately 12% fat and 61% water. A young girl and boy of the same height and weight (**Table 1**) differ markedly in the percentages of body water and fat. The main function of the 16 kg of stored female fat, which is equivalent to more than 600 MJ (144 000 kcal), may be to provide energy for a pregnancy and for approximately 3 months of lactation. In prehistoric times when the food supply was scarce or fluctuated seasonally, stored fat would have been necessary for successful reproduction. Fat is the most labile component of body weight. Body fat therefore would reflect environmental changes in food supplies more rapidly than other tissues.

Table 1 Total body water as percentage of body weight: an index of fatness[a]

Variable	*Girl*	*Boy*
Height (cm)	165.0	165.0
Weight (kg)	57.0	57.0
Total body water (l)	29.5	36.0
Lean body weigt (kg)	41.0	50.0
Fat (kg)	16.0	7.0
Fat/body weight (%)	28.0	12.0
Total body water/body weight (%)	51.8	63.0

[a]Comparison of an 18-year-old girl and a 15-year-old boy of the same height and weight.
Lean body weight = total body water/0.72.
Fatness/body weight % = 100 – [(total body water/body wt %)/0.72].

Body Weight and Infant Survival

Infant survival is correlated with birth weight, and birth weight is correlated with the prepregnancy weight of the mother and, independently, her weight gain during pregnancy. From a teleologic and evolutionary view, it is economical to hypothesize that the physical ability to deliver a viable infant and the hypothalamic control of reproduction are synchronized. Adipose tissue may be the synchronizer.

Other Inputs of Adipose Tissue on Female Reproductive Ability

In addition to the message of leptin to the hypothalamus on the amount of body fat, adipose tissue makes other hormones that may directly affect ovulation and the menstrual cycle and, hence, fertility:

1. Adipose tissue is a significant extragonadal source of estrogen. Conversion of androgen to estrogen takes place in the adipose tissue of the breast and abdomen, the omentum, and the fatty marrow of the long bones. This conversion accounts for approximately one-third of the circulating estrogen of premenopausal women and is the main source of

estrogen in postmenopausal women. Men also convert androgen into estrogen in body fat.
2. Body weight, and hence fatness, influences the direction of estrogen metabolism to more potent or less potent forms. Very thin women have an increase in the 2-hydroxylated form of estrogen, which is relatively inactive and has little affinity for the estrogen receptor. Lean female athletes also have an increase in the 2-hydroxylated form of estrogen. In contrast, obese women metabolize less of the 2-hydroxylated form and have a relative increase in the 16-hydroxylated form, which has potent estrogenic activity.
3. Obese women and young girls who are relatively fatter have a diminished capacity for estrogen to bind to serum sex hormone-binding globulin (SHBG); this results in an elevated percentage of free serum estradiol. Since SHBG regulates the availability of estradiol to the brain and other target tissues, the changes in the proportion of body fat to lean mass may influence reproductive performance through the intermediate effects of SHBG.
4. The adipose tissue of obese women stores steroid hormones.

Changes in relative fatness may also affect reproductive ability indirectly through disturbance of the regulation of body temperature and energy balance by the hypothalamus. Very lean women, both anorexic and nonanorexic, display abnormalities of temperature regulation in addition to delayed response, or lack of response, to exogenous luteinizing hormone-releasing hormone.

Hypothalamic Dysfunction, Gonadotropin Secretion, and Weight Loss

It is now recognized that the amenorrhea of underweight and excessively lean women is due to hypothalamic dysfunction. Hypothalamic dysfunction has also been implicated in the amenorrhea of athletes. Consistent with the view that this type of amenorrhea is adaptive, the pituitary–ovarian axis is apparently intact and functions when exogenous gonadotropin-releasing hormone (GnRH) is given in pulsatile form or in a bolus.

Women with this type of hypothalamic amenorrhea have both quantitative and qualitative changes in the secretion of the gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), and of estrogen:

1. Levels of LH, FSH, and estradiol levels are low.
2. The secretion of LH and the response to GnRH are reduced in direct correlation with the amount of weight loss.
3. Underweight patients respond to exogenous GnRH with a pattern of secretion similar to that of prepubertal children; the FSH response is greater than the LH response. The return of LH responsiveness is correlated with weight gain.
4. The maturity of the 24-h LH secretory pattern and body weight are related. Weight loss results in an age-inappropriate secretory pattern resembling that of prepubertal or early pubertal children. Weight gain restores the postmenarcheal secretory pattern.
5. A reduced response or absence of response to clomiphene, a pituitary hormone which stimulates ovulation, is correlated with the degree of the loss of body weight and hence of fat. A normal response occurs after weight gain to the normal range.

Supportive of the view that this type of hypothalamic amenorrhea is adaptive is the finding of one study that women in whom ovulation had been induced had a higher risk of having babies who were small for their age, and this risk was greatest (54%) in those who were underweight. The authors of this study concluded that the most suitable treatment for infertility secondary to weight-related amenorrhea is dietary rather than induction of ovulation.

Physiological Basis of Reproductive Ability

Weight at Menarche

The idea that relative fatness is important for female reproductive ability followed findings that the events of the adolescent growth spurt, particularly menarche in girls, were closely related to an average critical body weight. This result was unexpected for human beings, although it was well-known for rats and monkeys that puberty (defined by vaginal opening or, more precisely, by first estrus) was more closely related to body weight than to chronological age.

In the United States, the mean weight at menarche for girls was 47.8 ± 0.5 kg at a mean height of 158.5 ± 0.5 cm and mean age of 12.9 ± 0.1 years. This mean age included girls from Denver, who had a slightly later age of menarche than that of sea-level populations due to the slowing effect of altitude on prenatal and postnatal weight growth.

Secular Trend Toward an Earlier Age of Menarche

Even before the meaning of the critical weight for an individual girl was analyzed, the idea that menarche is associated with a critical weight for a population

explained simply many observations associated with early or late menarche. Observations of earlier menarche are associated with attaining the critical weight more quickly. The most important example is the secular (long-term) trend to an earlier menarche of approximately 3 or 4 months per decade in Europe in the past 100 years (**Figure 2**). The explanation is that children become larger sooner; therefore, girls on average reach 46 or 47 kg, the mean weight at menarche of US and many European populations, more quickly. Theoretically, the secular trend should end when the weight of children of successive cohorts remains the same because of the attainment of maximum nutrition and child care; this has happened in the United States.

Conversely, a late menarche is associated with body weight growth that is slower prenatally, postnatally, or both so that the average critical weight is reached at a later age: Malnutrition delays menarche, twins have later menarche than do singletons of the same population, and high altitude delays menarche.

Components of Weight at Menarche

Individual girls have menarche at varied weights and heights. To make the notion of a critical weight meaningful for an individual girl, the components of body weight at menarche were analyzed. We investigated body composition at menarche because total body water (TW) and lean body weight (LBW; TW/0.72) are more closely correlated with metabolic rate than is body weight since they represent the metabolic mass as a first approximation. Metabolic rate was considered to be an important clue since Kennedy hypothesized a food intake–lipostat–metabolic signal to explain his elegant findings on weight and puberty in the rat.

The greatest change in estimated body composition of both early and late-maturing girls during the adolescent growth spurt was a large increase in body fat from approximately 5 to 11 kg (a 120% increase) compared to a 44% increase in lean body weight. There was thus a change in the ratio of lean body weight to fat from 5:1 at initiation of the spurt to 3:1 at menarche. The shortest, lightest girls at menarche had a smaller absolute amount of fat (8.9 ± 0.4 kg) compared to the tallest, heaviest girls (12.3 ± 0.6 kg) (the mean of all subjects was 11.5 ± 0.3 kg). However, both extreme groups had approximately 22% of their body weight as fat at menarche, as did all subjects, and the ratio of lean body weight to fat of both groups was in the range of 3:1, as it was for all subjects.

Since adipose tissue can convert androgens to estrogens, the relative degree of fatness can be

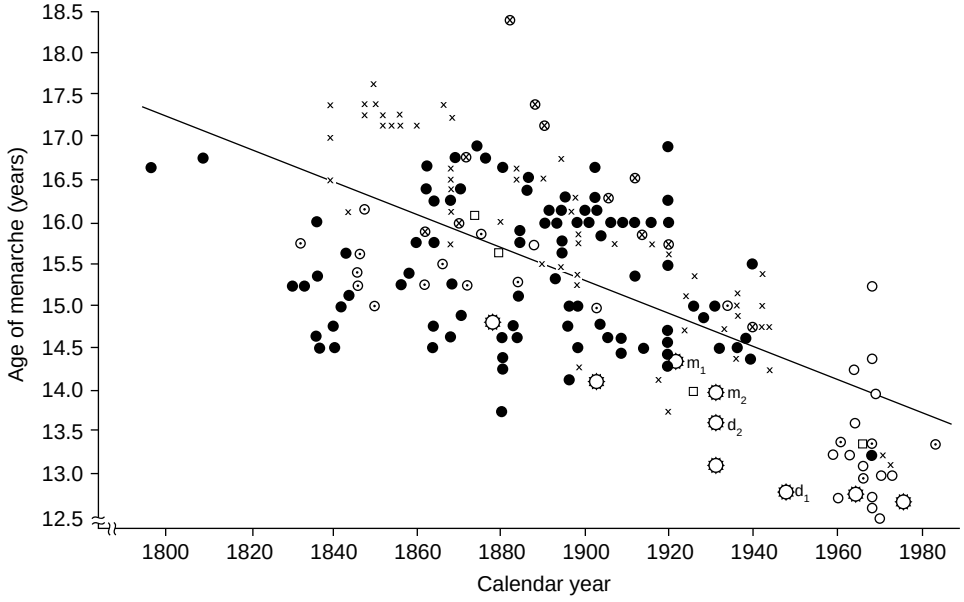

Figure 2 Mean or median age of menarche as a function of calendar year from 1790 to 1980. The symbols refer to England ⊙; France •; Germany ⊗; Holland □; Scandinavia (Denmark, Finland, Norway, and Sweden) X; Belgium, Czechoslovakia, Hungary, Italy, Poland (rural), Romania (urban and rural), Russia (15.2 years at an altitude of 2500 m and 14.4 years at 700 m), Spain, and Switzerland, all labeled ○; and the United States ☼ (data not included in the regression line). Twenty-seven points were identical and do not appear on the graph. The regression line cannot be extended indefinitely. The age of menarche has already leveled off in some European countries, as it has in the United States. (From Wyshak and Frisch (1982) Evidence for a secular trend in age of menarche. *New England Journal of Medicine* **306**: 1033–1035, with permission from the *New England Journal of Medicine*.)

directly related to the quantity of circulating estrogen. The biological effectiveness of the estrogen is also related to body weight. Rate of fat gain, therefore, is a neat mechanism for relating rate of growth, nutrition, and physical work to the energy requirements for reproduction.

Fatness as a Determinant of Minimal Weights for Menstrual Cycles

As shown in **Table 1** and **Figure 1**, total body water as a percentage of body weight is an index of fatness. In a study in the United States, this index in each of the 181 girls followed from menarche to the completion of growth at ages 16–18 years provided a method of determining a minimal weight for height necessary for menarche in primary amenorrhea and for the resumption of normal ovulatory cycles in cases of secondary amenorrhea, when the amenorrhea was due to undernutrition or intensive exercise. These weights have been found useful in the evaluation and treatment of patients with primary or secondary amenorrhea due to weight loss.

Percentiles of total body water/body weight, which are percentiles of fatness, were made at menarche and for the 181 girls at age 18 years, the age at which body composition stabilized. Patients with amenorrhea due to weight loss, other possible causes having been excluded, were studied in relation to the weights indicated by the diagonal percentile lines of total water/body weight percent (**Figure 3**). It was found that 56.1% of total water/body weight, the 10th percentile at age 18 years (equivalent to approximately 22% fat of body weight), indicated a minimal weight for height necessary for the restoration and maintenance of menstrual cycles. For example, a 20-year-old woman whose height is 165 cm (65 in.) should weigh at least 49 kg (108 lb) before menstrual cycles would be expected to resume (**Figure 3**).

The weights at which menstrual cycles ceased or resumed in postmenarcheal patients age 16 years and older were approximately 10% greater than the minimal weights for the same height observed at menarche (**Figure 4**). The explanation was that both early and late-maturing girls gain an average of 4.5 kg of fat from menarche to age 18 years. Almost all of this gain is achieved by age 16 years, when mean fat is 15.7 ± 0.3 kg, 27% of body weight. At age 18 years, mean fat is 16.0 ± 0.3 kg, 28% of the mean body weight of 57.1 ± 0.6 kg. Reflecting this increase in fatness, the total water/body weight percent decreases from $55.1 \pm 0.2\%$ at menarche (12.9 ± 0.1 years in this sample) to $52.1 \pm 0.2\%$ (standard deviation 3.0) at age 18 years.

Because girls are less fat at menarche than when they achieve stable reproductive ability, the minimal weight for onset of menstrual cycles in cases of primary amenorrhea due to undernutrition or exercise is indicated by the 10th percentile of fractional body water at menarche, 59.8%, which is equivalent to approximately 17% of body weight as fat. For example, a 15-year-old girl whose completed height is 165 cm (65 in.) should weigh at least 43.6 kg (96 lb) before menstrual cycles can be expected to begin (**Figure 4**).

The minimum weights indicated in **Figure 4** would be used also for girls who become amenorrheic as a result of weight loss soon after menarche, as often occurs in cases of anorexia nervosa in adolescent girls.

The absolute and relative increase in fatness from menarche to ages 16–18 years coincides with the period of adolescent subfecundity. During this time, there is still rapid growth of the uterus, ovaries, and oviducts.

Other factors such as emotional stress affect the maintenance or onset of menstrual cycles. Therefore, menstrual cycles may cease without weight loss and may not resume in some subjects even though the minimum weight for height has been achieved. Also, these standards apply only to Caucasian US females and European females since different races have different critical weights at menarche and it is not known whether the different critical weights represent the same critical body composition of fatness.

Since the prediction of the minimum weights for height is based on total water/body weight percent (not fat to body weight percent), successful prediction may be related to the ratio of lean mass to fat, which is normally approximately 3:1 at menarche and 2.5:1 at the completion of growth at age 18 years. No prediction can be made above the threshold weight for a particular height.

Physical Exercise, Delayed Menarche, and Amenorrhea

Does intense exercise cause delayed menarche and amenorrhea of athletes, or do late maturers choose to be athletes and dancers? We found that the mean age of menarche of 38 college swimmers and runners was 13.9 ± 0.3 years, significantly later ($p < 0.001$) than that of the general population (12.8 ± 0.05 years), in accord with other reports. However, the mean menarcheal age of the 18 athletes whose training began before menarche was 15.1 ± 0.5 years, whereas the mean menarcheal age

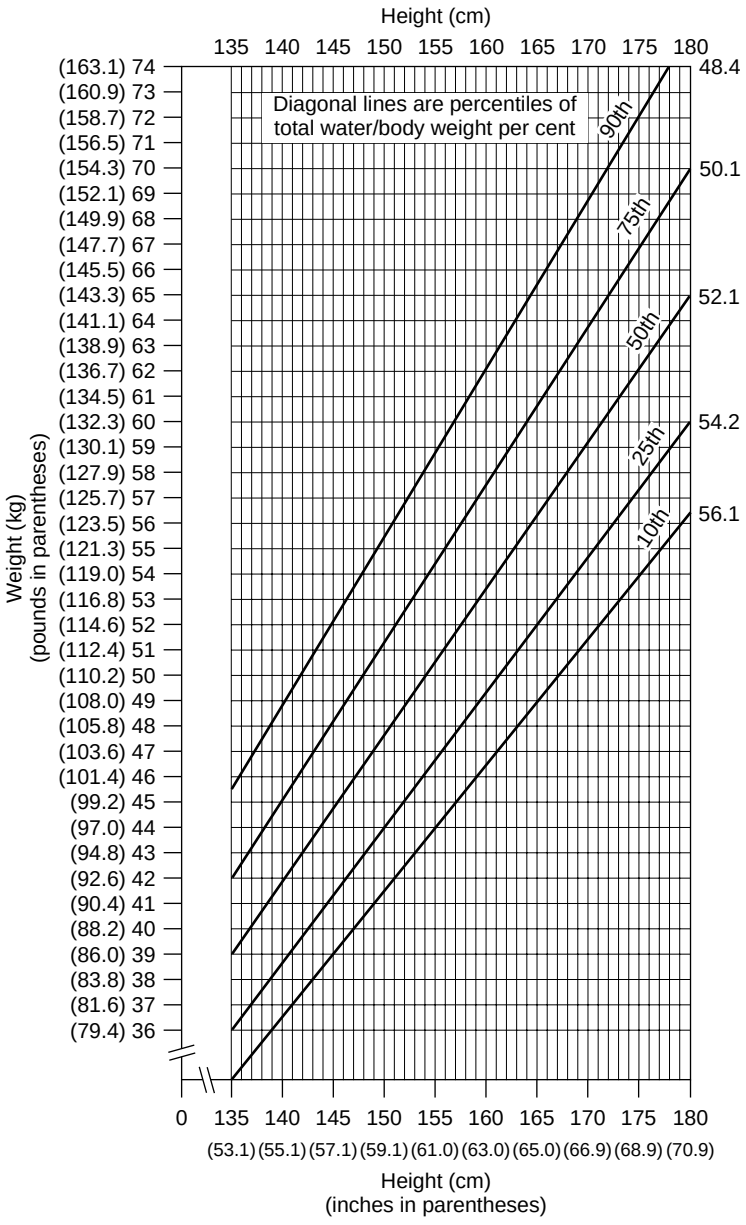

Figure 3 The minimal weight necessary for a particular height for restoration of menstrual cycles is indicated on the weight scale by the 10th percentile diagonal line of total water/body weight percent, 56.1%, as it crosses the vertical height line. For example, a 20-year-old woman whose height is 165 cm (65 in.) should weigh at least 49 kg (108 lb) before menstrual cycles would be expected to resume. (Adapted from Frisch and McArthur (1974) Menstrual cycles: Fatness as a determinant of minimum weight for height necessary for their maintenance or onset. *Science* **185**: 949–951, with permission from *Science*.)

of the 20 athletes whose training began after menarche was 12.8 ± 0.2 years ($p < 0.001$). The latter mean age was similar to that of the college controls (12.7 ± 0.4 years) and the general population. Therefore, training, not preselection, is the delaying factor. Each year of premenarcheal training delayed menarche by 5 months (0.4 years). This suggests that one constructive way to reduce the incidence of teenage pregnancy would be to have girls join teams at age 8 or 9 years and maintain regular moderate exercise. Such a program might reduce the risk of serious diseases of women in later life, as discussed later.

Training also directly affected the regularity of the menstrual cycles during the training year. Of the premenarche trained athletes, only 17% had regular cycles; 61% were irregular and 22% were amenorrheic. In contrast, 60% of the postmenarche trained athletes were regular, 40% were irregular, and none were amenorrheic. However, during intense

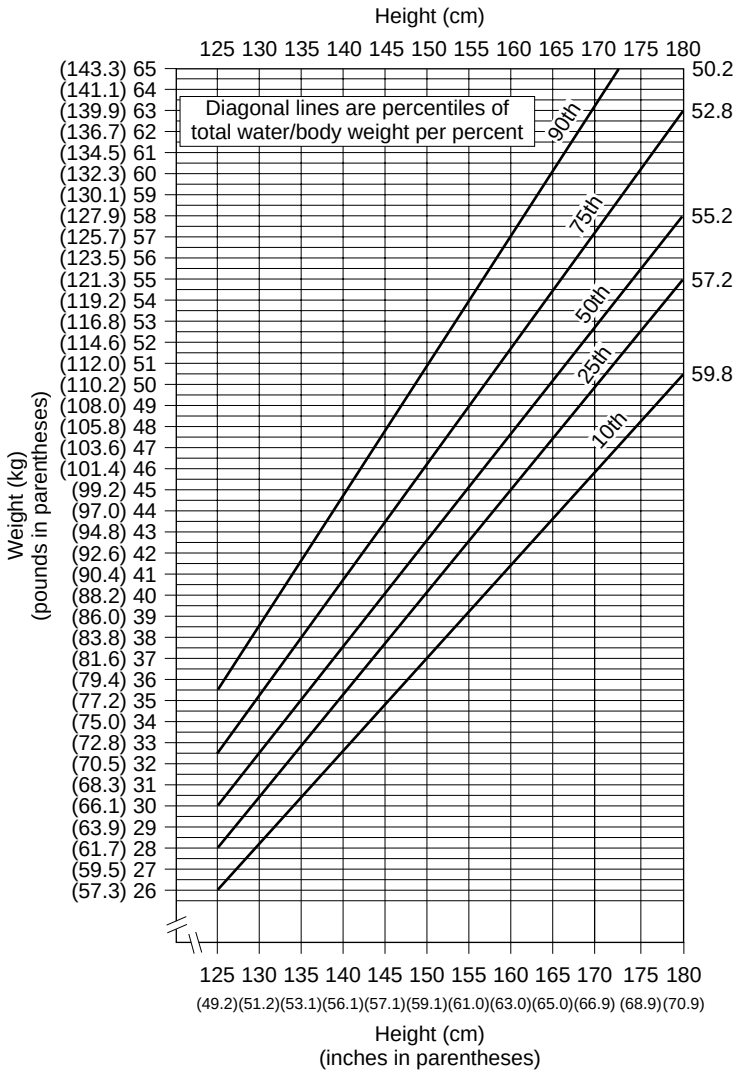

Figure 4 The minimal weight necessary for a particular height for onset of menstrual cycles is indicated on the weight scale by the 10th percentile diagonal line of total water/body weight percent, 59.8%, as it crosses the vertical height lines. The height growth of girls must be completed or approaching completion. For example, a 15-year-old girl whose completed height is 165 cm (65 in.) should weigh at least 43.6 kg (96 lb) before menstrual cycles can be expected to start. (Adapted from Frisch and McArthur (1974) Menstrual cycles: Fatness as a determinant of minimum weight for height necessary for their maintenance or onset. *Science* **185**: 949–951, with permission from *Science*.)

training, the incidence of oligomenorrhea and amenorrhea increased in both groups.

As other workers have found, plasma gonadotropins and estrogen levels were in the low-normal range in this study for the athletes with irregular cycles or amenorrhea. Progesterone was at the follicular phase level. Thyroid hormones, however, were in the normal range. These athletes had increased muscularity and decreased adiposity compared to nonathletes. The explanation for their menstrual disturbances may therefore be the same as that for dieting, nonathletic women—too little fat in relation to lean mass. Some of the swimmers and track and field athletes were above average weight for height. A raised lean mass:fat ratio may nevertheless have caused their menstrual problems because their body weight represented a greater amount of muscle and less adipose tissue than the same weight of nonathletic women.

Psychologic Stress and Changes in Weight

The psychologic stress of competition, which may increase the secretion of adrenal corticosteroids and catecholamines, thus affecting the hypothalamic control of gonadotropins, may be involved, but stress does not seem to be the main factor in many individuals.

Nutrition and Male Reproduction

Undernutrition delays the onset of sexual maturation in boys in a similar way to the delaying effect of undernutrition on menarche. Undernutrition and weight loss in men also affect their reproductive ability. The sequence of effects, however, is different from that in females. In men, loss of libido is the first effect of a decrease in energy intake and subsequent weight loss. Continued energy reduction and weight loss result in a loss of prostate fluid and then decreases in sperm motility and sperm longevity. Sperm production ceases when weight loss is approximately 25% of normal body weight. Refeeding results in a restoration of function in the reverse order of loss.

Effects of Exercise on Men

Men marathon runners have been shown to have decreased hypothalamic GnRH secretion. Also reported are changes in serum testosterone levels with weight loss in wrestlers, a reduction in serum testosterone and prolactin levels in male distance runners, and changes in reproductive function and development in relation to physical activity.

Body Mass Index

Recognition of the importance of relative fatness levels for general health and successful reproductive outcome has led to the use of the body mass index (BMI) to estimate relative fatness levels.

BMI is calculated as weight (kg)/height $(m)^2$.

A BMI of 20–25 kg/m^2 is recommended for good health and is associated with normal fertility.

A weight for height equivalent to a BMI of 18 kg/m^2 and lower is considered too low for successful reproductive ability. Research indicates that the hormonal environment for a successful pregnancy outcome will be improved with a BMI higher than 19 kg/m^2.

A BMI of 25–27 kg/m^2 is associated with a slight reduction in fertility, and that higher than 27 kg/m^2 is associated with a significantly reduced fertility.

BMI standards may not apply to athletes who train regularly because of their increased muscle mass.

Magnetic Resonance Imaging of Body Fat of Athletes and Controls

Using magnetic resonance imaging for direct quantification of body fat showed that athletes who did not differ in body weight from nonathletes had 30–40% less fat than the nonathletes. Muscles are heavy (80% water), so the body weight of an athlete does not necessarily indicate body composition. Athletes had a more sensitive insulin response to a glucose tolerance test compared to controls. The insulin area under the curve of athletes and controls was significantly related to their total fat as a percentage of total volume, determined by magnetic resonance imaging.

Athletes with menstrual disorders had significantly decreased subcutaneous and internal fat, overall and at all regional sites, compared to controls. The extent of estradiol 2-hydroxylation to 2-hydroxyoestrone, determined by radiometric analysis, was significantly ($p = 0.005$) inversely related to total fat as a percentage of total volume and to subcutaneous fat as a percentage of total volume ($p = 0.004$) overall and at each of the regional fat depots. This inverse relationship may be a determinant of the anovulatory cycles and amenorrhea of excessively lean women by a feedback to the hypothalamus since 2-hydroxyoestrone is antiestrogenic.

Long-Term Regular Exercise Lowers the Risk of Sex Hormone-Sensitive Cancers

The amenorrhea and delayed menarche of athletes raised the question: Are there differences in the long-term reproductive health of athletes with moderate training compared to nonathletes?

A study of 5398 college graduates ages 20–80 years, of whom 2622 were former athletes and 2776 were nonathletes, showed that the former athletes had a significantly lower lifetime occurrence of breast cancer and cancers of the reproductive system compared to the nonathletes. More than 82.4% of the former college athletes began their training in high school or earlier, compared to 24.9% of the nonathletes. The analysis controlled for potential confounding factors, including age, age of menarche, age of first birth, smoking, and cancer family history. The relative risk (RR) for nonathletes compared to athletes for cancers of the reproductive system was 2.53 (95% confidence limit (CL), 1.17–5.47) (**Figure 5**). The RR for breast cancer was 1.86 (95% CL, 1.00–3.47). The former college athletes were leaner in every age group compared to the nonathletes.

Although one can only speculate as to the reasons for the lower risk, the most likely explanation is that long term, the former athletes had lower levels of estrogen because they were leaner, and more estrogen was metabolized to the nonpotent catechol estrogens. Also, the former athletes may have consumed diets lower in fat and saturated fat. Such diets shift the pattern of estrogen metabolism toward the less active catechol estrogens.

Compared to the nonathletes, the former college athletes also had a lower lifetime occurrence

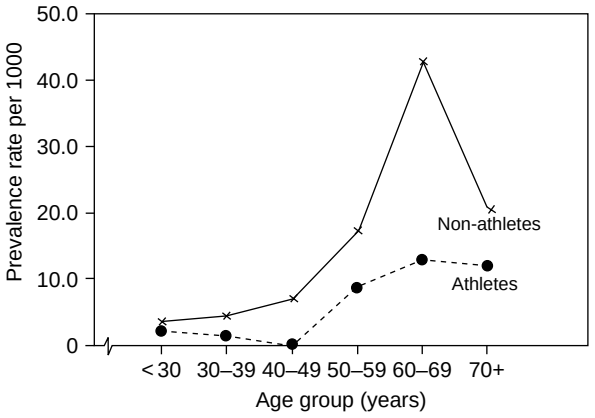

Figure 5 Prevalence rate of cancers of the reproductive system for athletes (circles) and nonathletes (crosses) by age group. (From Frisch RE, Wyshak G, Albright NL *et al.* (1985) Lower prevalence of breast cancer and cancers of the reproductive system among former college athletes compared to non-athletes. *British Journal of Cancer* **52**: 885–891, with permission from the *British Journal of Cancer*.)

(prevalence) of benign tumors of the breast and reproductive system; a lower prevalence of diabetes, particularly after age 40 years; and no greater risk of bone fractures, including risk of wrist and hip fractures, in the menopausal period.

These data indicate that long-term exercise, which was not at Olympic or marathon level but moderate and regular, reduces the risk of sex hormone-sensitive cancers and the risk of diabetes for women in later life. Data showing that moderate exercise also reduces the risk of nonreproductive system cancers suggest that other factors, such as changes in immunosurveillance, may also be involved.

Nutrition, Physical Work, and Natural Fertility

The effects of hard physical work and nutrition on reproductive ability suggest that differences in the fertility of populations, historically and today, may be explained by a direct pathway from food intake to fertility (**Figure 6**), in addition to the classic Malthusian pathway through mortality. Charles Darwin described this commonsense direct relationship between food supplies and fertility, observing the following:

1. Domestic animals that have regular, plentiful food without working to get it are more fertile than the corresponding wild animals.
2. "Hard living retards the period at which animals conceive."
3. The amount of food affects the fertility of the same individual.
4. It is difficult to fatten a cow that is lactating.

All of Darwin's dicta apply to human beings.

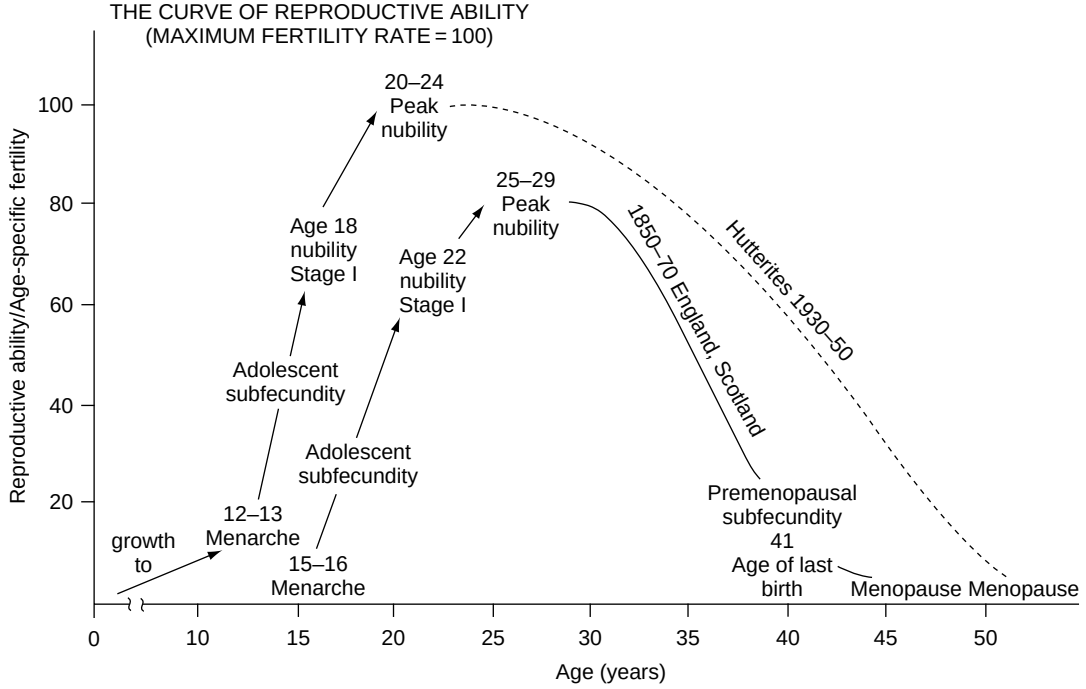

Figure 6 The mid-nineteenth century curve of female reproductive ability (variation of the rate of childbearing with age) compared with that of the well-nourished, modern Hutterites who do not use contraception. The Hutterite fertility curve (broken line) results in an average of 10–12 children; the 1850–1870 fertility curve (solid line) in approximately 6–8 children. (From Frisch (1978) Population, food intake and fertility. *Science* **199**: 22–30, with permission from *Science*.)

The Paradox of Rapid Population Growth in Undernourished Populations

In many historical populations with slow population growth, poor couples living together to the end of their reproductive lives had only 6 or 7 living births. Most poor couples in many developing countries today also have 6 or 7 living births during their reproductive life span. This total fertility rate is far below the human maximum of 11 or 12 children observed among well-nourished couples not using contraception, such as the Hutterites. However, 6 children per couple today in developing countries results in a very rapid rate of population growth because of decreased mortality rates due to the introduction of modern public health procedures. The difference between the birth rate per 1000 and the death rate per 1000, which gives the percentage growth rate, is currently as high as 2–4%. Populations growing at 2, 3, and 4% double in 35, 23, and 18 years, respectively.

British data from the mid-nineteenth century on growth rates, food intake, age-specific fertility, sterility, and ages of menarche and menopause show that females who grew relatively slowly to maturity, completing height growth at ages 20 or 21 years (instead of 16–18 years, as in well-nourished contemporary populations), also differed from well-nourished females in each event of the reproductive span: Menarche was later, for example, 15.0–16.0 years compared with 12.8 years; adolescent sterility was longer, and the age of peak nubility was later; the levels of specific fertility were lower; pregnancy wastage was higher; the duration of lactational amenorrhea was longer; the birth interval was longer; and the age of menopause was earlier, preceded by a more rapid period of perimenopausal decline (**Figure 6**). Thus, the slower, submaximal growth of women to maturity is subsequently associated with a shortened and less efficient reproductive span. The differences in the rate of physical growth of women and men result not only in a displacement of the age-specific fertility curve in time but also in a difference in the ultimate level: The faster the growth of females and males, the earlier and more efficient the reproductive ability.

Endocrinological data show that undernourished women have a longer lactational amenorrhea than do well-nourished women. The amount of suckling is not the only factor, as has been suggested in explaining reduced natural fertility. In addition, age of menarche and the other events of the reproductive span, which are known to be affected by the nutritional state, are pertinent to overall fertility.

FISH

A Ariño, J A Beltrán, A Herrera and P Roncalés, University of Zaragoza, Zaragoza, Spain

Introduction

In discussing the food uses of fishes, the term 'fish' refers to edible species of finfish, molluscs, and crustacea coming from the marine or freshwater bodies of the world, either by capture fisheries or by aquaculture. Accordingly, "fishery products" means any human food product in which fish is a characterizing ingredient, such as dried, salted, and smoked fish, marinated fish, canned seafood, minced fish flesh such as surimi, and miscellaneous products.

Fish is a source of high-quality animal protein, supplying approximately 6% of the world's protein requirements and 16.4% of the total animal protein. According to Food and Agriculture Organization figures, the contribution of fish to the total animal-protein intake is 26.2% in Asia, 17.4% in Africa, 9.2% in Europe, 9% in the former USSR, 8.8% in Oceania, 7.4% in North and Central America, 7.2% in South America, and 21.8% in the low-income food-deficit countries (including China). There are wide differences among countries in fish consumption measured as the average yearly intake per person, ranging from countries with less than 1.0 kg per person to countries with over 100 kg per person.

Edible fish muscle contains 18–20% protein and 1–2% ash; the percentage of lipids varies from less than 1% to more than 20% (in high-fat finfish), and fish has the added advantage of being low in saturated fat. In general, lean fish is not an important source of calories, which are mostly obtained from the staple carbohydrates in the diet. Fatty fish, however, is a significant energy source in many fish-consuming communities in both the developed and the developing worlds. Today it is recognized that fish is probably more important as a source of micronutrients, minerals, and particularly essential fatty acids than for its energy or protein value. The essential micronutrients and minerals in fish include vitamins A and D, calcium, phosphorus, magnesium, iron, zinc, selenium, fluorine, and iodine (in marine fishes).

The protective effect of a small amount of fish against mortality from coronary heart disease (CHD) has been established by numerous epidemiological studies. A diet including two or three servings of fish per week has been recommended on this basis, and researchers have reported a 50% reduction in CHD mortality after 20 years with intakes of as little as 400 g of fish per week.

It has been suggested that the long-chain omega-3 (*n*-3) polyunsaturated fatty acids (PUFAs) (eicosapentanoic acid (EPA; C20:5) and docosahexanoic acid (DHA; C22:6)) in fish offer this protection against CHD. Several recent studies have shown that a large intake of omega-3 fatty acids is beneficial in lowering blood pressure, reducing triacylglycerols, decreasing the risk of arrhythmia, and lowering the tendency of blood platelets to aggregate.

As fish become more popular, the reports of food-borne diseases attributed to fish have increased. Food-borne diseases linked with exposure to fish can result from the fish itself (i.e., toxic species, allergies) or from bacterial (i.e., *Clostridium botulinum*, *Listeria monocytogenes*, *Salmonella*, *Vibrio*, and *Staphylococcus*), viral (i.e., hepatitis, Norwalk gastroenteritis), or parasitic (i.e., *Anisakis* and related worms) contamination. Also, naturally occurring seafood toxins (i.e., scombrotoxin, ciguatoxins, shellfish poisoning from toxic algae) or the presence of additives and chemical residues due to environmental contamination can cause food-borne illnesses. In recent years, reports of contamination of

some fish with methylmercury have raised concerns about the healthfulness of certain fish for some populations.

General Characteristics of Finfish

A very large number of species of finfish are used for food by the world's population. The dressing percentage of finfish (60–70%) is similar to that of beef, pork, or poultry. The percentage of edible tissue in the dressed carcasses of finfish (without head, skin, and viscera) is higher than that of other food animals, because fishes contain less bone, adipose tissue, and connective tissue. There are three main categories of finfish that are widely used as foods. The bony fishes (teleosts) provide two compositional categories: white fishes (or lean fishes) and fatty fish. The third category is the cartilaginous elasmobranch fishes.

White fishes

The flesh of these fishes is very low in fat and consists primarily of muscle and thin layers of connective tissue. The concentrations of most of the B vitamins are similar to those in mammalian lean meats, although fish may contain higher amounts of vitamins B_6 and B_{12}. The mineral levels are also similar, although the very fine bones that are eaten with the fish flesh can raise the calcium content; fish is also a significant source of iodine. These fishes accumulate oils only in their livers, which are a rich source of vitamin A (retinol), vitamin D, and long-chain PUFAs in their triacylglycerols (TAGs).

Fatty Fishes

These fishes have fat in their flesh, which is usually much darker than that of white fishes, with similar blocks of muscle and connective tissue. The amount of fat is related to the breeding cycle of the fish, so that the fat content falls considerably after breeding. The flesh of fatty fishes is generally richer in the B vitamins than that of white fishes, and significant amounts of vitamins A and D are present. The mineral concentrations are not very different, but fatty fish is a better source of iron. The oil of these fishes is particularly rich in very-long-chain PUFA, especially those of the omega-3 (*n*-3) series such as EPA and DHA. These fishes accumulate oils in their muscles, belly flap, and skin (subdermal fat).

Cartilaginous Fishes

The cartilaginous fishes include the sharks and rays, whose flesh is rich in connective tissue and relatively low in fat, although they do accumulate oils in their livers. The concentrations of vitamins and minerals are very similar to those in white fish. These fishes contain urea in relatively large amounts, and so protein values based on total nitrogen are overestimated. The ammonia smell of cooked sharks and rays is not an indication that the fish is spoiled but rather is the result of enzymatic degradation of urea.

General Characteristics of Shellfish

The term 'shellfish' includes any aquatic invertebrate, such as molluscs or crustaceans, that has a shell or shell-like exoskeleton. The cephalopods have an internal shell (as in squids) or no shell (as in octopods). Owing to the presence of the tough exoskeleton, the edible portion in shellfish (around 40%) is less than that in finfish, with the exception of cephalopods, whose dressing percentage is 70–75%. The lipid content of the edible parts of most shellfish is low, as bivalves store their energy surplus as glycogen and not as depot fat, while crustaceans and cephalopods store their fat in their digestive glands (hepatopancreas). In many fish-eating communities, these foods are very highly valued gastronomically.

Molluscs

A wide range of molluscs are eaten by man, including bivalves (such as mussels, oysters, and scallops), gastropods (such as winkles and whelks), and cephalopods (such as squids and octopuses). The flesh is muscular with low levels of fat, although the fat is more saturated and richer in cholesterol than that of finfish. The mineral levels in shellfish are usually somewhat higher than those in finfish, and the vitamin concentrations are low. Bivalves and gastropods are often eaten whole after boiling or sometimes raw; usually, only the muscular mantles of cephalopods are eaten. In some cultures, only selected parts are eaten; for example, only the white adductor muscle of the scallop is eaten in North America.

Crustaceans

Crustaceans include a range of species, both freshwater (such as crayfish) and marine (such as crabs, shrimps, prawns, and lobsters). These animals have a segmented body, a chitinous exoskeleton, and paired jointed limbs. The portions eaten are the muscular parts of the abdomen and the muscles of the claws of crabs and lobsters. The flesh is characteristically low in fat and high in minerals, with vitamin levels similar to those found in finfish.

Nutritional Value of Fish and Shellfish: Introductory Remarks

Fish and shellfish are excellent sources of protein. A 100 g cooked serving of most types of fish and shellfish provides about 18–20 g of protein, or about a third of the average daily recommended protein intake. The fish protein is of high quality, containing an abundance of essential amino-acids, and is very digestible by people of all ages. Seafood is also loaded with minerals such as iron, zinc, and calcium.

The caloric value of fish is related to the fat content and varies with species, size, diet, and season. Seafood is generally lower in fat and calories than beef, poultry, or pork. Most lean or low-fat species of fish, such as cod, hake, flounder, and sole, contain less than 100 kcal (418 kJ) per 100 g portion, and even fatty fish, such as mackerel, herring, and salmon, contain approximately 250 kcal (1045 kJ) or less in a 100 g serving. Most crustaceans contain less than 1% fat in the tail muscle because depot fat is stored in the hepatopancreas, which is in the head region.

Interest in the health benefits of fish and shellfish began decades ago when researchers noted that certain groups of people – including the Inuit and the Japanese, who rely on fish as a dietary staple – have a low rate of ischemic diseases (i.e., heart attack or stroke). Fish, particularly fatty fish, is a good source of the omega-3 fatty acids EPA and DHA. These fats help to lower serum triacylglycerols and cholesterol, help prevent the blood clots that form in heart attacks, and lower the chance of having an irregular heartbeat. In fact, one study found that women who ate fish at least once a week were 30% less likely to die of heart disease than women who ate fish less than once a month. Similar benefits have been found for men. Fish consumption is also related to slower growth of atherosclerotic plaque and lower blood pressure. Especially good sources of omega-3 fats are salmon, tuna, herring, mackerel, and canned tuna and sardines.

When included in the diet of pregnant and breastfeeding women, DHA is thought to be beneficial to infant brain (learning ability) and eye (visual acuity) development. Scientists have found that women who ate fatty fish while pregnant gave birth to children with better visual development. Babies of mothers who had significant levels of DHA in their diet while breastfeeding experienced faster-than-normal eyesight development. Preliminary research also suggests that a diet rich in omega-3 fatty acids – and in DHA in particular – may help to decrease the chance of preterm birth, thus allowing the baby more time for growth and development.

Recent research found that eating just one serving a week of fish decreased the risk of developing dementia by 30%. Eating fatty fish several times a week may also lower the risk of developing prostate cancer by as much as half. A Swedish study of 3500 postmenopausal women eating two servings of fatty fish a week found that they were 40% less likely to develop endometrial cancer than those eating less than one-fourth of a serving a week.

Eating a variety of fish and seafood, rather than concentrating on one species, is highly recommended for both safety and nutrition. It is recommended that pregnant women should avoid certain species of fish and limit their consumption of other fish to an average of 400 g of cooked fish per week. The reason for this recommendation is that, whereas nearly all fish contain trace amounts of methylmercury (an environmental contaminant), large predatory fish, such as swordfish, shark, tilefish, and king mackerel, contain the most. Excess exposure to methylmercury from these species of fish can harm an unborn child's developing nervous system. It is also suggested that nursing mothers and young children should not eat these particular species of fish.

Fish Lipids

In fish, depot fat is liquid at room temperature (oil) and is seldom visible to the consumer; an exception is the belly flaps of salmon steaks. Many species of finfish and almost all shellfish contain less than 2.5% total fat, and less than 20% of the total calories come from fat. Almost all fish has less than 10% total fat, and even the fattiest fish, such as herring, mackerel, and salmon, contains no more than 20% fat (**Table 1**). In order to obtain a good general idea of the fat contents of most finfish species, flesh color might be considered. The leanest species, such as cod and flounder, have a white or lighter color, while fattier fishes, such as salmon, herring, and mackerel, have a much darker color.

The triacylglycerol depot fat in edible fish muscle is subject to seasonal variation in all marine and freshwater fishes from all over the world. Fat levels tend to be higher during times of the year when fishes are feeding heavily (usually during the warmer months) and in older and healthier individual fishes. Fat levels tend to be lower during spawning or reproduction. When comparing fat contents between farmed and wild-caught food fish, it should be remembered that farmed species have a tendency to show a higher proportion of muscle fat than their wild counterparts. Also, the fatty-acid composition of farmed fish depends on the type of dietary fat

Table 1 Fat levels in marine and freshwater fish and shellfish commonly found in the marketplace

Low (<2.5% fat) less than 20% of total calories from fat	*Medium (2.5–5% fat) between 20% and 35% of total calories from fat*	*High (>5% fat) between 35% and 50% of total calories from fat*
Saltwater fish		
Cod	Anchovy	Dogfish
Grouper	Bluefish	Herring[a]
Haddock	Sea bass	Mackerel[a]
Hake	Swordfish	Salmon[a]
Most flatfishes (flounder, sole, plaice)	Tuna (yellowfin)	Sardine
Pollock		Tuna (bluefin)
Shark		
Skate		
Snapper		
Whiting		
Most crustaceans		
Most molluscs		
Freshwater fish		
Pike	Bream	Catfish (farmed)
Perch, bass	Carp	Eel[a]
Tilapia	Trout (various)	Whitefish

[a]More than 10% fat.

used in raising the fish. Cholesterol is independent of fat content and is similar in wild and cultivated fishes.

Most protein-rich foods, including red meat and poultry as well as fish, contain cholesterol. However, almost all types of fish and shellfish contain well under 100 mg of cholesterol per 100 g, and many of the leaner types of fish typically have 40–60 mg of cholesterol in each 100 g of edible muscle. It is known that most shellfish also contain less than 100 mg of cholesterol per 100 g. Shrimp contain somewhat higher amounts of cholesterol, over 150 mg per 100 g, and squid is the only fish product with a significantly elevated cholesterol content, which averages 300 mg per 100 g portion. Fish roe, caviar, internal organs of fishes (such as livers), the tomalley of lobsters, and the hepatopancreas of crabs can contain high amounts of cholesterol.

Omega-3 PUFA in Fish and Shellfish

The PUFA of many fish lipids are dominated by two members of the omega-3 (*n*-3) family, C20:5 *n*-3 (EPA) and C22:6 *n*-3 (DHA). They are so named because the first of several double bonds occurs three carbon atoms away from the terminal end of the carbon chain.

All fish and shellfish contain some omega-3, but the amount can vary, as their relative concentrations are species specific (**Table 2**). Generally, the fattier fishes contain more omega-3 fatty acids than the leaner fishes. The amount of omega-3 fatty acids in farm-raised products can also vary greatly, depending on the diet of the fishes or shellfish. Many companies now recognize this fact and provide a source of omega-3 fatty acids in their fish diets. Omega-3 fatty acids can be destroyed by heat, air, and light, so the less processing, heat, air exposure, and storage time the better for preserving omega-3 in fish. Freezing and normal cooking cause minimal omega-3 losses, whereas deep frying and conditions leading to oxidation (rancidity) can destroy some omega-3 fatty acids.

The beneficial effects of eating fish for human health have been well documented. Research has shown that EPA and DHA are beneficial in protecting against cardiovascular and other diseases (**Table 3**). Studies examining the effects of fish consumption on serum lipids indicate a reduction in triacylglycerol and VLDL-cholesterol levels, a factor that may be protective for some individuals. Research also indicates that EPA in particular reduces platelet aggregation, which may help vessels injured by plaque formation. Fish oils also appear to help stabilize the heart rhythm, a factor that may be important in people recovering from heart attacks.

Table 2 Selected fish and shellfish grouped by their omega-3 fatty-acid content

Low-level group (<0.5 g per 100 g)	*Medium-level group (0.5–1 g per 100 g)*	*High-level group (>1 g per 100 g)*
Finfish		
Carp	Bass	Anchovy
Catfish	Bluefish	Herring
Cod, Haddock, Pollock	Halibut	Mackerel
Grouper	Pike	Sablefish
Most flatfishes	Red Snapper	Salmon (most species)
Perch	Swordfish	Tuna (bluefin)
Snapper	Trout	Whitefish
Tilapia	Whiting	
Shellfish		
Most crustaceans	Clams	
Most molluscs	Oysters

The major PUFA in the adult mammalian brain is DHA. It is among the materials required for development of the fetal brain and central nervous system and for retinal growth in late pregnancy. Brain growth uses 70% of the fetal energy, and 80–90% of cognitive function is determined before birth. However, the placenta depletes the mother of DHA, a situation that is exacerbated by multiple pregnancies. Dietary enhancement or fortification with marine products before and during pregnancy, rather than after the child is born, would be of great benefit to the child and mother. Furthermore, the food sources that are rich in DHA are also rich in zinc, iodine, and vitamin A, so it may be possible to provide several dietary supplements at one time. Deficiencies of the latter micronutrients are established causes of mental retardation and blindness.

The typical Western diet has a ratio of omega-6 to omega-3 essential fatty acids of between 15:1 and 20:1. Several sources of information suggest that a very high omega-6 to omega-3 ratio may promote many diseases, including cardiovascular disease, cancer, and inflammatory and autoimmune diseases. Fish provides an adequate intake of these omega-3 fats, thus improving the omega-6 to omega-3 fatty-acid ratio. Most experts do not advise the routine use of fish-oil supplements: they favor eating fish and shellfish regularly in the context of a healthy diet and a regular pattern of physical activity. Whereas some research shows benefits of fish-oil supplements, research has also shown that people with weakened immune systems should avoid large doses of fish oil. The final conclusion as to whether it is possible to substitute fish consumption with fish oils or omega-3 fatty-acid supplements, and gain the same reduction in mortality from CHD, awaits more studies. However, the protective role of fish consumption is unquestioned.

Fish Proteins

Both finfish and shellfish are highly valuable sources of proteins in human nutrition. The protein content of fish flesh, in contrast to the fat content, is highly constant, independent of seasonal variations caused by the feeding and reproductive cycles, and shows only small differences among species. **Table 4** summarizes the approximate protein contents of the various finfish and shellfish groups. Fatty finfish and crustaceans have slightly higher than average protein concentrations. Bivalves have the lowest values if the whole body mass is considered (most of them are usually eaten whole), whereas values are roughly average if specific muscular parts alone are consumed; this is the case with the scallop, in which only the adductor muscle is usually eaten.

The essential amino-acid compositions of fish and shellfish are given in **Table 5**. Fish proteins, with only slight differences among groups, possess a high nutritive value, similar to that of meat proteins and slightly lower than that of egg. It is worth pointing out the elevated supply, relative to meat, of essential amino-acids such as lysine, methionine, and threonine. In addition, owing in part to the low collagen content, fish proteins are easily digestible, giving rise to a digestibility coefficient of nearly 100.

The recommended dietary allowances (RDA) or dietary reference intakes (DRI) of protein for human male and female adults are in the range of 45–65 g per day. In accordance with this, an intake of 100 g of fish would contribute 15–25% of the

Table 4 Protein content of the different groups of fish and shellfish

Fish group	*g per 100 g*
White finfish	16–19
Fatty finfish	18–21
Crustaceans	18–22
Bivalves	10–12
Cephalopods	16–18

total daily protein requirement of healthy adults and 70% of that of children. A look at the dietary importance of the Mediterranean diet is convenient: one of its characteristics is the high consumption of all kinds of fish, chiefly fatty fish. In many Mediterranean countries, fish intake averages over 50 g per day (edible flesh); thus, fish protein contributes over 10% of the total daily protein requirements steadily over the whole year in those countries.

Less well known is the fact that the consumption of fish protein, independently of the effect exerted by fish fat, has been related to a decrease in the risk of atherogenic vascular diseases. In fact, it has been demonstrated that diets in which fish is the only source of protein increase the blood levels of high-density lipoprotein relative to those resulting from diets based on milk or soy proteins.

Nonprotein Nitrogen Compounds in Fish

Nonprotein nitrogen (NPN) compounds are found mostly in the fiber sarcoplasm and include free amino-acids, peptides, amines, amine oxides, guanidine compounds, quaternary ammonium molecules, nucleotides, and urea (**Table 6**). NPN compounds account for a relatively high percentage of the total nitrogen in the muscles of some aquatic animals, 10–20% in teleosts, about 20% in crustaceans and molluscs, and 30–40% (and in special cases up to 50%) in elasmobranchs. In contrast, NPN compounds in land animals usually represent no more than 10% of total nitrogen.

Most marine fishes contain trimethylamine oxide (TMAO); this colorless, odorless, and flavorless compound is degraded to trimethylamine, which gives a 'fishy' odor and causes consumer rejection. This compound is not present in land animals and freshwater species (except for Nile perch and tilapia from Lake Victoria). TMAO reductase catalyzes the reaction and is found in several fish species (in the red muscle of scombroid fishes and in the white and red muscle of gadoids) and in certain microorganisms (*Enterobacteriaceae, Shewanella putrefaciens*).

Creatine is quantitatively the main component of the NPN fraction. This molecule plays an important role in fish muscle metabolism in its phosphorylated form; it is absent in crustaceans and molluscs.

Table 6 Nonprotein nitrogen compounds in several commercially important fish species and mammalian muscle (mg per 100 g wet weight)

Compounds	*Cod*	*Herring*	*Shark species*	*Lobster*	*Mammal*
Total NPN	1200	1200	3000	5500	3500

Endogenous and microbial proteases yield some free amino-acids; taurine, alanine, glycine, and imidazole-containing amino-acids seem to be the most frequent. Glycine and taurine contribute to the sweet flavor of some crustaceans. Migratory marine species such as tuna, characterized by a high proportion of red muscle, have a high content (about 1%) of free histidine. A noticeable amount of this amino-acid has been reported in freshwater carp. The presence of free histidine is relevant in several fish species because it can be microbiologically decarboxylated to histamine. Cooking the fish may kill the bacteria and destroy the enzymes, but histamine is not affected by heat, thus becoming a hazard to consumers. The symptoms of the resulting illness (scombroid poisoning) are itching, redness, allergic symptoms, headache, diarrhea, and peppery taste. Scombroid poisoning is most common after ingesting mahi-mahi, tuna, bluefish, mackerel, and skipjack.

Nucleotides and related compounds generally play an important role as coenzymes. They participate actively in muscle metabolism and supply energy to physiological processes. They have a noticeable participation in flavor; moreover, some of them may be used as freshness indices. Adenosine triphosphate (ATP) is degraded to adenosine diphosphate (ADP), adenosine monophosphate (AMP), inosine monophosphate (IMP), inosine, and hypoxantine. This pattern of degradation takes place in finfish, whereas AMP is degraded to adenosine and thereafter to inosine in shellfish. The degradation chain to IMP and AMP in finfish and shellfish, respectively, is very fast. IMP degradation to inosine is generally slow, except in scombroids and flat fishes. Inosine degradation to hypoxantine is slower. IMP is a flavor potentiator, whereas hypoxanthine imparts a sour taste and it is toxic at high levels. ATP, ADP, and AMP decompose quickly leading to a build-up of inosine and hypoxantine. As this corresponds well to a decline in freshness, the ratio of the quantity of inosine and hypoxantine to the total quantity of ATP and related substances is called the *K*-value and used as a freshness index of fish meat.

Guanosine is an insoluble compound that gives fish eyes and skin their characteristic brightness. It is degraded to guanine, which does not have this property; therefore, brightness decreases until it completely disappears.

The NPN fraction contains other interesting compounds, such as small peptides. Most of them contribute to flavor; besides this, they have a powerful antioxidant activity. Betaines are a special group of compounds that contribute to the specific flavors of different aquatic organisms: homarine in lobster and glycine-betaine, butiro-betaine, and arsenic-betaine in crustaceans. Arsenic-betaine has the property of fixing arsenic into the structure, giving a useful method for studying water contamination.

Fish Vitamins

The vitamin content of fish and shellfish is rich and varied in composition, although somewhat variable in concentration. In fact, significant differences are neatly evident among groups, especially regarding fat-soluble vitamins. Furthermore, vitamin content shows large differences among species as a function of feeding regimes.

The approximate vitamin concentration ranges of the various finfish and shellfish groups are summarized in **Table 7**. The RDA for adults is also given, together with the percentage supplied by 100 g of fish. Of the fat-soluble vitamins, vitamin E (tocopherol) is distributed most equally, showing relatively high concentrations in all fish groups, higher than those of meat. However, only a part of the vitamin E content is available as active tocopherol on consumption of fish, since it is oxidized in protecting fatty acids from oxidation. The presence of vitamins A (retinol) and D is closely related to the fat content, and so they are almost absent in most low-fat groups. Appreciable but low concentrations of vitamin A are found in fatty finfish and bivalve molluscs, whereas vitamin D is very abundant in fatty fish. In fact, 100 g of most fatty species supply over 100% of the RDA of this vitamin.

Water-soluble vitamins are well represented in all kinds of fish, with the sole exception of vitamin C (ascorbic acid), which is almost absent in all of them. The concentrations of the rest are highly variable; however, with few exceptions, they constitute a medium-to-good source of such vitamins, comparable with, or even better than, meat. The contents of vitamins B_2 (riboflavin), B_6 (pyridoxine), niacin, biotin, and B_{12} (cobalamin) are relatively high. Indeed, 100 g of fish can contribute up to 38%, 60%, 50%, 33%, and 100%, respectively, of the total daily requirements of those vitamins. Fatty fish also provides a higher supply of many of the water-soluble vitamins (namely pyridoxine, niacin, pantothenic acid, and cobalamin) than does white fish or shellfish. Crustaceans also possess a relatively higher content of pantothenic acid, whereas bivalve molluscs have much higher concentrations of folate and cobalamin.

Table 7 Vitamin content of the different groups of fish and shellfish (mg or μg per 100 g)

A Mediterranean diet rich in fish – and especially in fatty finfish – contributes steadily over the year to an overall balanced vitamin supply. The last row of **Table 7** illustrates this; the supply of vitamins D, B_2, B_6, B_{12}, and niacin from this particular diet is more than 15% of the daily requirements; all other vitamins, except ascorbic acid, are supplied to a lesser, but significant, extent.

Fish Minerals

The approximate amounts of selected minerals contained in fish are given in **Table 8**. The first point to note is that all kinds of finfish and shellfish present a well-balanced content of most minerals, either macroelements or oligoelements, with only a few exceptions. Sodium content is low, as in other muscle and animal origin foods. However, it must be remembered that sodium is usually added to fish in most cooking practices in the form of common salt; also, surimi-based and other manufactured foods contain high amounts of added sodium. Potassium and calcium levels are also relatively low, though the latter are higher in fish than in meat; in addition, small fish bones are frequently eaten with fish flesh, thus increasing the calcium intake. Fish is a good source of magnesium and phosphorus, at least as good as meat. These elements are particularly abundant in crustaceans; fatty finfish show elevated levels of phosphorus, and bivalve molluscs have high amounts of magnesium.

Fish is a highly valuable source of most oligoelements. Fatty fish provides a notable contribution to iron supply, similar to that of meat, whereas shellfish have higher concentrations of most dietary minerals. In particular, crustaceans and bivalve molluscs supply zinc, manganese, and copper concentrations well above those of finfish. Worth mentioning is the extraordinary dietary supply of iodine in all kinds of finfish and shellfish; however, this depends on the concentration present in feed, particularly in planktonic organisms.

In summary, 100 g of fish affords low levels of sodium and medium-to-high levels of all the remaining dietary minerals. In fact, it can contribute 50–100% of the total daily requirements of magnesium, phosphorus, iron, copper, selenium, and iodine. A Mediterranean diet, rich in fatty fish and all kinds of shellfish, can lead to an overall balanced mineral supply, which may well reach over 20% of daily requirements of phosphorus, iron, selenium, and iodine.

Folate *see* **Folic Acid**

FOLIC ACID

J McPartlin, Trinity College, Dublin, Ireland

Introduction

Folic acid was initially distinguished from vitamin B_{12} as a dietary anti-anemia factor by Wills in the 1930s. The subsequent chemical isolation of folic acid and the identification of its role as a cofactor in one-carbon metabolism led to the elucidation of deficiency diseases at the molecular level. The term 'folate' encompasses the entire group of folate vitamin forms, comprising the naturally occurring folylpolyglutamates found in food and folic acid (pteroylglutamic acid), the synthetic form of the vitamin added as a dietary supplement to foodstuffs. 'Folate' is thus the general term used for any form of the vitamin irrespective of the state of reduction, type of substitution, or degree of polyglutamylation.

Folate functions metabolically as an enzyme cofactor in the synthesis of nucleic acids and amino-acids. Deficiency of the vitamin leads to impaired cell replication and other metabolic alterations, particularly related to methionine synthesis. The similar clinical manifestations of cobalamin deficiency and folate deficiency underline the metabolic interrelationship between the two vitamins. Folate deficiency, manifested clinically as megaloblastic anemia, is the most common vitamin deficiency in developed countries. Much attention has focused recently on a number of diseases for which the risks are inversely related to folate status even within the range of blood indicators previously considered 'normal.' Food-fortification programs introduced to prevent neural-tube defects (NTD) have proved effective in increasing folate intakes in populations and may be shown potentially to reduce the risk of cardiovascular disease.

Physiology and Biochemistry

Chemistry and Biochemical Functions

Folic acid (**Figure 1**) consists of a pterin moiety linked via a methylene group to a para-aminobenzoylglutamate moiety. Folic acid is the synthetic form of the vitamin; its metabolic activity requires reduction to the tetrahydrofolic acid (THF) derivative, addition of a chain of glutamate residues in γ-peptide linkage, and acquisition of one-carbon units.

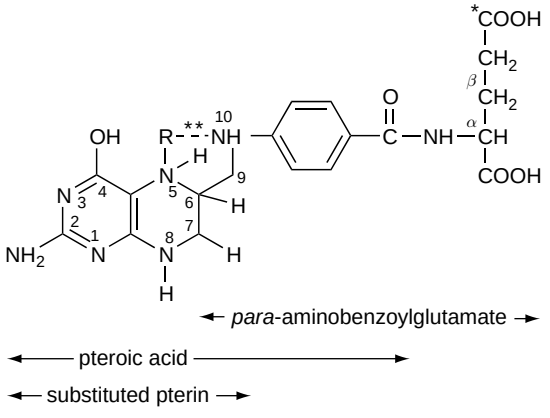

Figure 1 Structural formula of tetrahydrofolate (THF) compounds. In tetrahydrofolic acid R = H; other substituents are listed in **Table 1**. The asterisk indicates the site of attachment of extra glutamate residues; the hatched line and double asterisk indicates the N5 and/or N10 site of attachment of one-carbon units.

Table 1 Structure and nomenclature of folate compounds (see **Figure 1**)

Compound	*R*	*Oxidation state*
5-formylTHF	—CHO	Formate
10-formylTHF	—CHO	Formate
5-formiminoTHF	—CH=NH	Formate
5,10-methenylTHF	—CH=	Formate
5,10-methyleneTHF	$—CH_2—$	Formaldehyde
5-methylTHF	$—CH_3$	Methanol

One-carbon units at various levels of oxidation are generated metabolically and are reactive only as moieties attached to the N5 and/or N10 positions of the folate molecule (**Table 1**).

The range of oxidation states for folate one-carbon units extends from methanol to formate as methyl, methylene, methenyl, formyl, or formimino moieties. When one-carbon units are incorporated into folate derivatives, they may be converted from one oxidation state to another by the gain or loss of electrons.

The source of one-carbon units for folate One-carbon units at the oxidation level of formate can enter directly into the folate pool as formic acid in a reaction catalyzed by 10-formylTHF synthase (**Figure 2**). Entry at the formate level of oxidation can also take place via a catabolic product of histidine, formaminoglutamic acid. The third mode of entry at the formate level of oxidation involves the formation of 5-formylTHF from 5,10-methenylTHF by the enzyme serine hydroxymethyl transferase (SHMT). The 5-formylTHF may be rapidly converted to other forms of folate.

The enzyme SHMT is involved in the entry of one-carbon units at the formaldehyde level of oxidation by catalyzing the transfer of the β-carbon of serine to form glycine and 5,10-methyleneTHF. Other sources of one-carbon entry at this level of oxidation include the glycine cleavage system and the choline-dependent pathway; both enzyme systems generate 5,10-methylene in the mitochondria of the cell.

The removal and use of one-carbon units from folate Single-carbon units are removed from folate by a number of reactions. The enzyme 10-formylTHF dehydrogenase provides a mechanism for disposing of excess one-carbon units as carbon dioxide. (Folate administration to animals enhances the conversion of ingested methanol and formate to carbon dioxide, diminishing methanol toxicity.) Additionally, single-carbon units from 10-formylTHF are used for the biosynthesis of purines (**Figure 2**).

The one-carbon unit of 5,10-methyleneTHF is transferred in two ways. Reversal of the SHMT reaction produces serine from glycine, but since serine is also produced from glycolysis via phosphoglycerate this reaction is unlikely to be important. However, one-carbon transfer from 5,10-methyleneTHF to deoxyuridylate to form thymidylic acid, a precursor of DNA, is of crucial importance to the cell. While the source of the one-carbon unit, namely 5,10-methyleneTHF, is at the formaldehyde level of oxidation, the one-carbon unit transferred to form thymidylic acid appears at the methanol level of oxidation. Electrons for this reduction come from THF itself to generate dihydrofolate as a product. The dihydrofolate must in turn be reduced back to THF in order to accept further one-carbon units.

A solitary transfer of one-carbon units takes place at the methanol level of oxidation. It involves the transfer of the methyl group from 5-methylTHF to homocysteine to form methionine and THF. This reaction is catalyzed by the enzyme methionine synthase and requires vitamin B_{12} as a cofactor. The substance 5-methylTHF is the dominant folate in the body, and it remains metabolically inactive until it is demethylated to THF, whereupon polyglutamylation takes place to allow subsequent folate-dependent reactions to proceed efficiently.

Clinical implications of methionine synthase inhibition The inhibition of methionine synthase due to vitamin B_{12} deficiency induces megaloblastic anemia that is clinically indistinguishable from that caused by folate deficiency. The hematological effect in both cases results in levels of 5,10-methyleneTHF that are inadequate to sustain thymidylate biosynthesis. Clinically, it is essential to ascertain whether the anemia is the result of folate deficiency or vitamin B_{12} deficiency by differential diagnostic techniques. Vitamin B_{12} is essential for the synthesis of myelin in nerve tissue, a function probably related to methionine production from the methionine synthase reaction and the subsequent formation of S-adenosyl-methionine. Hence, vitamin B_{12} deficiency probably leads to nervous disorders in addition to the hematological effects. While the latter respond to treatment with folic acid, the neurological effects do not. Thus, inappropriate administration of folic acid in patients with vitamin B_{12} deficiency may treat the anemia but mask the progression of the neurological defects. Where possible, vitamin B_{12} and folate statuses should be checked before giving folate supplements to treat megaloblastic anemia. The main objection to fortifying food with folate is the potential to mask

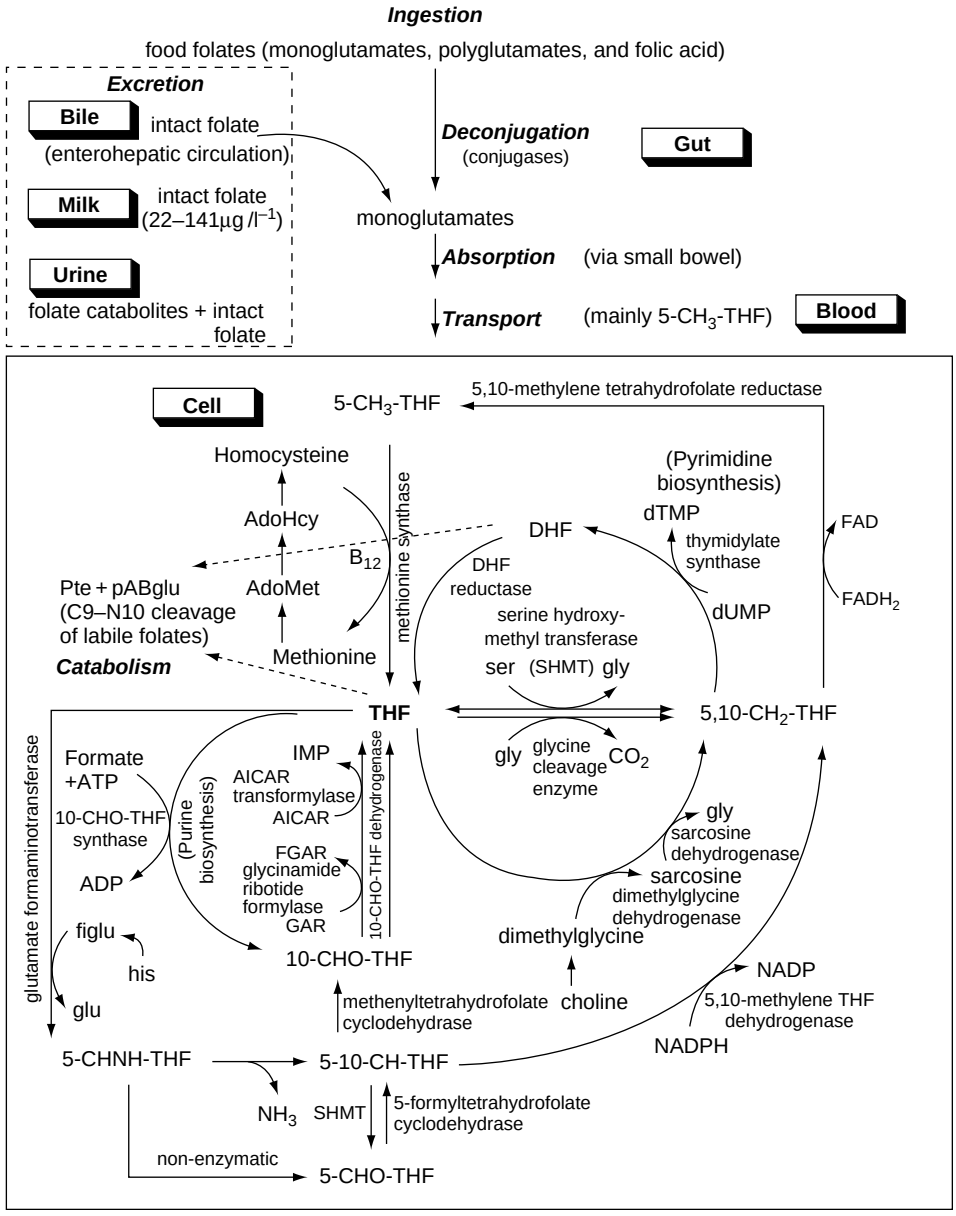

Figure 2 Physiology and metabolism of folate. GAR, glycinamide ribonucleotide; FGAR, formylglycinamide ribonucleotide; AICAR: aminoimidazolecarboxamide ribonucleotide; figlu, formiminoglutamic acid; IMP, inosine monophosphate.

vitamin B_{12} deficiency in the elderly, who are most prone to it.

In summary, the biochemical function of folate coenzymes is to transfer and use these one-carbon units in a variety of essential reactions (**Figure 2**), including *de novo* purine biosynthesis (formylation of glycinamide ribonucleotide and 5-amino-4-imidazole carboxamide ribonucleotide), pyrimidine nucleotide biosynthesis (methylation of deoxyuridylic acid to thymidylic acid), amino-acid interconversions (the interconversion of serine to glycine, catabolism of histidine to glutamic acid, and conversion of homocysteine to methionine (which also requires vitamin B_{12})), and the generation and use of formate.

Many of the enzymes involved in these reactions are multifunctional and are capable of channelling substrates and one-carbon units from reaction to reaction within a protein matrix. Another feature of intracellular folate metabolism is the compartmentation of folate coenzymes between the cytosol and the mitochondria. For instance, 5-methylTHF is associated with the cytosolic fraction of the cell, whereas most of 10-formylTHF is located in the mitochondria. Similarly, some folate-dependent

enzymes are associated with one or other compartment, though some are found in both. Metabolic products of folate-dependent reactions, such as serine and glycine, are readily transported between the two locations, but the folate coenzymes are not.

Folate Deficiency and Hyperhomocysteinemia An important consequence of folate deficiency is the inability to remethylate homocysteine (**Figure 2**). Indeed, there is an inverse correlation between the levels of folate and those of homocysteine in the blood of humans. Many clinical studies, beginning with the observations of children with homocysteinuria presenting with vascular abnormalities and thromboembolism, have demonstrated an association between hyperhomocysteinemia and an increased risk of premature atherosclerosis in the coronary, carotid, and peripheral vasculatures. Even mild hyperhomocysteinemia is recognized to be an independent risk factor for cardiovascular disease. The risk of heart disease was found to increase proportionately in most, but not all, studies, throughout the full of range of blood homocysteine concentrations. An increase in plasma homocysteine of $5\,\mu mol\,l^{-1}$ is associated with a combined odds ratio of 1.3 for cardiovascular disease. Plasma homocysteine is usually shown to be a greater risk factor for cardiovascular disease in prospective studies than in retrospective studies, probably because the populations in the former studies are older. Metabolically, homocysteine may be disposed of by the methionine synthase reaction (dependent on folate and vitamin B_{12}), the transsulfuration pathway (dependent on vitamin B_6), and the choline degradation pathway. Marginal deficiencies of these three vitamins are associated with hyperhomocysteinemia. Of the three vitamins, however, folic acid has been shown to be the most effective in lowering levels of homocysteine in the blood. Convincing evidence of the potential role of folate intake in the prevention of vascular disease has come from a significant inverse relationship between serum folate levels and fatal coronary heart disease. While most studies have focused on the homocysteine-lowering effects of folate, other benefits have also been reported. Potential mechanisms include antioxidant actions and interactions with the enzyme endothelial nitric oxide synthase.

Absorption of Folates

Food folates mainly consist of reduced polyglutamates, which are hydrolyzed to monoglutamates in the gut prior to absorption across the intestinal mucosa. The conjugase enzyme that hydrolyzes dietary folates has been found on the luminal brush border membrane in the human jejunum and has equal affinity for polyglutamates of various chain lengths. Transport is facilitated by a saturable carrier-mediated uptake system, although changes in luminal pH and the presence of conjugase inhibitors, folate binders, or other food components can adversely affect the rate of hydrolysis and intestinal absorption. Such factors account for the wide variation in the bioavailability of the vitamin from foods of plant and animal origins. Some metabolism of the resultant monoglutamate, mainly to 5-methylTHF, appears to occur during the absorption process, though this may not be necessary for transport across the basolateral membrane of the intestinal mucosa into the portal circulation. The degree of metabolic conversion of dietary folic acid depends on the dose; pharmacological amounts are transported unaltered into the circulation.

Transport in the Circulation, Cellular Uptake, and Turnover

Folate circulates in the blood predominantly as 5-methylTHF. A variable proportion circulates freely or bound either to low-affinity protein binders such as albumin, which accounts for about 50% of bound folate, or to a high-affinity folate binder in serum, which carries less than 5% of circulating folate. The physiological importance of serum binders is unclear, but they may control folate distribution and excretion during deficiency.

Though most folate is initially taken up by the liver following absorption, it is delivered to a wide variety of tissues in which many types of folate transporters have been described. Because these transporters have affinities for folate in the micromolar range, they would not be saturated by normal ambient concentrations of folate. Therefore, folate uptake into tissues should be responsive to any increases in serum folate levels arising from folate supplementation. An important determinant of folate uptake into cells is their mitotic activity, as would be expected given the dependence of DNA biosynthesis on folate coenzyme function. Folate accumulation is more rapid in actively dividing cells than in quiescent cells, a factor that is probably related to the induction and activity of folylpoly-γ-glutamate synthase. This enzyme catalyzes the addition of glutamate by γ-peptide linkage to the initial glutamate moiety of the folate molecule. Although

polyglutamate derivatization may be considered a storage strategem, this elongation is the most efficient coenzyme form for normal one-carbon metabolism. The activity of folylpoly-γ-glutamate synthase is highest in the liver, the folate stores of which account for half of the estimated 5–10 mg adult complement. Retention within the cell is facilitated by the high proportion of folate associated with proteins, and this is likely to be increased in folate deficiency.

The mobilization of liver and other stores in the body is not well understood, particularly in deficiency states, though some accounts describe poor turnover rates in folate-depleted rats. Transport across cell membranes during redistribution requires deconjugation of the large negatively charged polyglutamates. Mammalian γ-glutamylhydrolases that hydrolyze glutamate moieties residue by residue and transpeptidases that can hydrolyze folylpolyglutamates directly to mono- or di-glutamate forms of the vitamin have been described for a number of tissues. Thus, mammalian cells possess two types of enzyme that can play a key role in folate homeostasis and regulation of one-carbon metabolism: the folylpolyglutamate synthetase that catalyzes the synthesis of retentive and active folate, and a number of deconjugating enzymes that promote the release of folate from the cell. Polyglutamate forms released into the circulation either through cell death or by a possible exocytotic mechanism would be hydrolyzed rapidly by plasma γ-glutamyl-hydrolase to the monoglutamate form.

Catabolism and Excretion

Folate is concentrated in bile, and enterohepatic recirculation from the intestine accounts for considerable re-absorption and reuse of folate (about 100 $\mu g\,day^{-1}$). Fecal folates mostly arise through biosynthesis of the vitamin by the gut microflora, with only a small contribution from unabsorbed dietary folate. Urinary excretion of intact folates accounts for only a small fraction of ingested folate under normal physiological conditions. The greater amount of excretion in urine is accounted for by products that arise from cleavage of the folate molecule at the C9–N10 bond, consisting of one or more pteridines and *p*-acetamidobenzoylglutamate. The rate of scission of the folate molecule increases during rapid-mitotic conditions such as pregnancy and rapid growth. Scission of folate is perhaps the major mechanism of folate turnover in the body.

Human Folate Requirements

The folate requirement is the minimum amount necessary to prevent deficiency. Dietary recommendations for populations, however, must allow a margin of safety to cover the needs of the vast majority of the population. As is the case with most nutrients, the margin of safety for folate requirement corresponds to two standard deviations above the mean requirement for a population and should therefore meet the needs of 97.5% of the population. Thus, international dietary recommendations contain allowances for individual variability, the bioavailability of folate from different foodstuffs, and periods of low intake and increased use. Current international folate recommendations for FAO/WHO, USA/Canada, and the European Union are listed in **Table 2**.

Table 2 Recommended dietary folate allowances for various population groups ($\mu g\,day^{-1}$)

Category	*Age*	*FAO/WHO (1998)*	*USA/Canada RDA (1998)*	*EU (1993)*
Infants	Up to 6 months	80	65	100
	6 months–1 year	80	80	100
	1–3 years	160	150	100
Children	4–6 years	200	200	130
	7–10 years	300 (age 9–13 years)	300	150
Males	11–14 years	400	300	180
	15–18 years	400	400	200
	19–24 years	400	400	200
	25–50 years	400	400	200
	Over 50 years	400	400	200
Females	11–14 years	400	300	180
	15–18 years	400	400	200
	19–24 years	400	400	200
	25–50 years	400	400	200
	Over 50 years	400	400	200
Pregnant women		600	600	400
Lactating women		500	500	350

The 1998 recommendations for folate are expressed using a term called the dietary folate equivalent (DFE). The DFE was developed to help account for the difference in bioavailability between naturally occurring dietary folate and synthetic folic acid. The Food and Nutrition Board of the US National Academy of Sciences reasoned that, since folic acid in supplements or in fortified food is 85% bioavailable, but food folate is only about 50% bioavailable, folic acid taken as supplements or in fortified food is 85/50 (i.e., 1.7) times more available. Thus, the calculation of the DFE for a mixture of synthetic folic acid and food is μg of DFE = μg food folate + (1.7 × μg synthetic folate).

International recommendation tables are constantly subject to review, particularly in view of the relationship between folate status and the risk of NTD and specific chronic diseases including coronary artery disease and colorectal cancer.

Pregnancy

The crucial role of folate in the biosynthesis of precursors for DNA suggests that folate requirements may vary with age, though folate use is most obviously increased during pregnancy and lactation. Maintaining adequate folate status in women in their child-bearing years is particularly important since a large proportion of pregnancies are unplanned and many women are likely to be unaware of their pregnancy during the first crucial weeks of fetal development. Pregnancy requires an increase in folate supply that is large enough to fulfil considerable mitotic requirements related to fetal growth, uterine expansion, placental maturation, and expanded blood volume. The highest prevalence of poor folate status in pregnant women occurs among the lowest socioeconomic groups and is often exacerbated by the higher parity rate of these women. Indeed, the megaloblastic anemia commonly found amongst the malnourished poor during pregnancy probably reflects the depletion of maternal stores to the advantage of the fetal–placental unit, as indicated by the several-fold higher serum folate levels in the newborn compared with the mother. Considerable evidence indicates that maternal folate deficiency leads to fetal growth retardation and low birth weight. The higher incidence of low-birth-weight infants among teenage mothers compared with their adult counterparts is probably related to the additional burden that adolescent growth places on folate resources.

The lack of hard evidence about the extent of supplementation required in pregnancy prompted the development of a laboratory-based assessment of metabolic turnover, which involved the assay of total daily folate catabolites (along with intact folate) in the urine of pregnant women. The rationale of the procedure was that this catabolic product represents an ineluctable daily loss of folate, the replacement of which should constitute the daily requirement. Correcting for individual variation in catabolite excretion and the bioavailability of dietary folate, the recommended allowances based on this mode of assessment are in close agreement with the latest recommendations of the USA/Canada and FAO/WHO. The data produced by the catabolite-excretion method may provide a useful adjunct to current methods based on intakes, clinical examination, and blood folate measurements to provide a more accurate assessment of requirement.

Folate and Neural-Tube Defects

Much attention has focused over the past 15 years on a number of diseases for which the risks are inversely related to folate status even within the range of serum folate levels previously considered 'normal.' Foremost among these is NTD, a malformation in the developing embryo that is related to a failure of the neural tube to close properly during the fourth week of embryonic life. Incomplete closure of the spinal cord results in spina bifida, while incomplete closure of the cranium results in anencephaly. The risk of NTD was found to be 10-fold higher (6 affected pregnancies per 1000) in people with poor folate status (i.e., less than 150 μg red cell folate per litre) than in those with good folate status (400 $\mu g\,l^{-1}$). International agencies have published folic acid recommendations for the prevention of NTD. To prevent recurrence, 5 mg of folic acid daily in tablet form is recommended, while 400 μg daily is recommended for the prevention of occurrence, to be commenced prior to conception and continued until the 12th week of pregnancy. Given the high proportion of unplanned pregnancies, the latter recommendations are applicable to all fertile women. This amount, however, could not be introduced through fortification because high intakes of folic acid by people consuming fortified flour products would risk preventing the diagnosis of pernicious anemia in the general population and of vitamin B_{12} deficiency in the elderly.

The introduction of 140 μg of folic acid per 100 g of flour in the USA, calculated to increase individual consumption of folic acid by 100 $\mu g\,day^{-1}$, has reduced the incidence of abnormally low plasma folate from 21% to less than 2%, the incidence of mild hyperhomocysteinemia from 21% to 10%,

and, most importantly, the incidence of NTD by about 20% over the first years of universal fortification. Because 30% of the population takes vitamin supplements and presumably would not be expected to derive significant benefit from fortification, the actual effect may be closer to a 30% decrease due to fortification. Recent calculations suggest that, for a variety of reasons, the overall fortification amount was about twice the mandatory amount.

On balance, the introduction of food fortification with folate is regarded as beneficial not only in preventing NTD but also in reducing the incidences of hyperhomocysteinemia (mentioned earlier), colorectal cancer, and a number of neurological and neuropsychiatric diseases in which folate is postulated to play a protective role.

Lactation

Unlike during pregnancy, in which the bulk of folate expenditure arises through catabolism, during lactation the increased requirement is chiefly due to milk secretion. Several observations indicate that mammary tissue takes precedence over other maternal tissues for folate resources. For instance, maternal folate status deteriorates in both early and late lactation, but milk folate concentration is maintained or increased. Moreover, supplemental folate appears to be taken up by mammary epithelial cells preferentially over hematopoietic cells in lactating women with folate deficiency, indicating that maternal reserves are depleted to maintain milk folate content in lactating women. Recommendations are based on the maintenance requirement of nonpregnant nonlactating women and the estimated folate intake required to replace the quantity lost in milk. This increment of between 60 μg and 100 μg daily is based on a milk secretion rate of 40–60 $\mu g\,l^{-1}$ and an absorption rate from dietary sources of between 50% and 70%. The official recommendations might be underestimated, however. On the one hand, a less efficient absorption rate of 50% from a mixed diet is more likely, and, on the other hand, the most recent estimations of milk folate secretion are as high as 100 μg daily. Therefore, an additional 200 μg of folate daily or a total of 500 μg daily seems a more realistic recommended amount for lactating women.

Infants and Children

The high concentration of circulating folate in newborn infants coincides with the rapid rate of cell division in the first few months of life and is reflected in the higher folate requirement for infants on a weight basis than for adults. Though the recommendation standards (see **Table 2**) may underestimate the quantities consumed by many breastfed infants, intake is generally sufficiently above the recommendations that folate deficiency is unlikely.

Data on requirements for older children are sparse, so recommendations for up to adolescence are based on interpolations between the values for very young children and those for adults. Daily recommended levels are above 3.6 μg per kg of body weight, an amount associated with no overt folate deficiency in children and shown to maintain plasma folate concentrations at a low but acceptable level.

Adolescents and Adults

Folate recommendations for adolescents are set at a similar level to that for adults, the smaller weights of adolescents being compensated for by higher rates of growth.

The Elderly

Although folate deficiency occurs more frequently in the elderly than in young adults, recommendations are set at the same level for both groups. Reference recommendations apply to healthy subjects. However, a significant proportion of the elderly are likely to suffer from clinical conditions and to be exposed to a range of factors such as chronic smoking, alcohol, and prescription drugs that may have a detrimental effect on folate status.

Food Sources of Folate

Folate is synthesized by microorganisms and higher plants but not by mammals, for which it is an essential vitamin. The most concentrated food folate sources include liver, yeast extract, green leafy vegetables, legumes, certain fruits, and fortified breakfast cereals. Folate content is likely to depend on the maturity and variety of particular sources. Foods that contain a high concentration of folate are not necessarily those that contribute most to the overall intakes of the vitamin in a population. For example, liver is a particularly concentrated source, providing 320 μg of folate per 100 g, but it is not eaten by a sufficient proportion of the population to make any major contribution to total dietary folate intakes. The potato, on the other hand, although not particularly rich in folate, is considered a major contributor to folate in the UK diet, accounting for 14% of total folate intake because of its high consumption. Prolonged exposure to heat, air, or ultraviolet light is known to inactivate the vitamin; thus, food

Table 3 Contributions of the main food groups to the average daily intake of folate in British and US adults (%)

Food group	*USA (1994)*	*UK (1998)*
Dairy products	8.1	9.8
Meat, poultry, fish	8.5	6.5
Grain products	21.2[a]	31.8
Fruit, fruit juices	10.2	6.9
Vegetables	26.4	31.8
Legumes, nuts, soy	18.5	—
Eggs	5.1	2.4
Tea	—	4.1
Other food	2.1	5.7

[a]Prior to mandatory fortification of flour-based products.

preparation and cooking can make a difference to the amount of folate ingested; boiling in particular results in substantial food losses. The major source of folate loss from vegetables during boiling may be leaching as opposed to folate degradation. Broccoli and spinach are particularly susceptible to loss through leaching during boiling compared with potatoes because of their larger surface areas. The retention of folate during cooking depends on the food in question as well as the method of cooking. Folates of animal origin are stable during cooking by frying or grilling. In addition to highlighting good food sources, public-health measures promoting higher folate intake should include practical advice on cooking. For example, steaming in preference to boiling is likely to double the amount of folate consumed from green vegetables.

While cultural differences and local eating habits determine the contribution of different foodstuffs to folate intake (**Table 3**), as with other nutrients, globalization and the integration of the international food industry may lead to more predictable 'Westernized' diets in the developed and developing world. Internationally, much of the dietary folate in the 'Western' diet currently comes from fortified breakfast cereals, though this foodstuff is likely to be joined shortly in this regard by fortified flour products in the light of the experience of the US food fortification program. In the main, though, adherence to dietary recommendations to increase the consumption of folate-rich foods is likely to enhance the intake not only of folate but also of other nutrients essential to health.

FOOD ALLERGIES

Contents
Etiology
Diagnosis and Management

Etiology

T J David, University of Manchester, Manchester, UK

The concept that certain foods can produce adverse reactions in susceptible individuals has a long history. Hippocrates (460–370 BC) reported that cow's milk could cause gastric upset and urticaria. Later, Galen (131–210 BC) described a case of intolerance to goat's milk. It was Lucretius (96–55 BC) who said, "What is food to one man may be fierce poison to others." In the 1920s and 1930s, a fashion developed of blaming food intolerance for a large number of hitherto unexplained disorders. The uncritical and overenthusiastic nature of the claims, in addition to the anecdotal evidence on which they were based, generally discredited the whole subject. Indeed, the field of food intolerance has been described as "a model of obstruction to the advancement of learning." The whole area has provoked much controversy. The introduction of double-blind provocation tests has placed studies on a more scientific footing, but they are impractical in routine management. The lack of objective and reproducible diagnostic laboratory tests that could eliminate bias has ensured that controversy about food intolerance continues.

Definitions

The word 'allergy' is frequently misused and applied indiscriminately to any adverse reaction, regardless of the mechanism. An allergic response is a reproducible adverse reaction to a substance mediated by an immunological response. The substance provoking the reaction may have been ingested, injected, inhaled, or merely have come into contact with the skin or mucous membranes. Food allergy is a form of adverse reaction to food in which the cause is an immunological response to a food. The much broader term of 'food intolerance' does not imply any specific type of mechanism and is simply defined as a reproducible adverse reaction to a specific food or food ingredient. Outside the United Kingdom, the terminology used sometimes differs. It has been suggested that the term 'food hypersensitivity' should be used to cover all adverse reactions to food, which are then subdivided into food allergy (i.e., immunologically mediated) and food intolerance, which implies a nonimmunologically mediated event.

The term 'food aversion' comprises food avoidance, where the subject avoids a food for psychological reasons such as distaste or a desire to lose weight, and psychological intolerance. The latter is an unpleasant bodily reaction caused by emotions associated with the food rather than the food itself. Psychological intolerance will normally be observable under open conditions but will not occur when the food is given in an unrecognizable form. Psychological intolerance may be reproduced by suggesting (falsely) that the food has been administered.

The term 'anaphylaxis' or 'anaphylactic shock' is taken to mean a severe and potentially life-threatening reaction of rapid onset with circulatory collapse. The term anaphylaxis has also been used to describe any allergic reaction, however mild, that results from specific IgE antibodies, but such usage fails to distinguish between a trivial reaction (e.g., a sneeze) and a dangerous event.

An antigen is a substance that is capable of provoking an immune response. An antibody is an immunoglobulin that is capable of combining specifically with certain antigens. An allergen is a substance that provokes a harmful (allergic) immune response.

Immunological tolerance is a process that results in the immunological system becoming specifically unreactive to an antigen that is capable in other circumstances of provoking antibody production or cell-mediated immunity. The immunological system nevertheless reacts to unrelated antigens given simultaneously and via the same route.

Atopy is the ability to produce a weal-and-flare response to skin prick testing with a common antigen, such as house dust mite or grass pollen. The atopic diseases are asthma (all childhood cases but not all adult cases), atopic eczema, allergic rhinitis, allergic conjunctivitis, and some cases of urticaria.

Mechanisms of Food Allergy

Understanding of the mechanisms of food allergy is poor, and in many cases the precise mechanism is obscure.

Sensitization

The following are possible factors that contribute to immunological sensitization leading to food intolerance:

1. Genetic predisposition: food allergy is commonly familial, suggesting the importance of genetic factors.
2. Immaturity of the immune system or the gastrointestinal mucosal barrier in newborn infants may predispose to sensitisation. The numerous studies that have been performed to determine if food allergy or atopic disease can be prevented by interventions during pregnancy or lactation are based on the idea that there is a critical period during which sensitization can occur.
3. Dosage of antigen: It may be that high dosage leads to the development of tolerance, and low dosage leads to sensitization. This might help to explain the well-documented phenomenon of infants who become allergic to traces of foods that reach them through their mother's breast milk.
4. Certain food antigens are especially likely to lead to sensitization, such as egg, cow's milk, and peanut. The reason why certain foods are more likely to provoke an allergic reaction than others is poorly understood.
5. A triggering event, such as a viral infection: The evidence is anecdotal, but there is a suggestion that food allergy may develop in a previously nonallergic subject after a viral infection such as infectious mononucleosis (glandular fever).
6. Alteration in the permeability of the gastrointestinal tract, permitting abnormal antigen access: The best example of this is the suggestion that acute viral gastroenteritis may damage the small intestinal mucosa, allowing abnormal absorption of food proteins, leading to sensitization. Thus, some data suggest that in a few cases the onset of cow's milk protein allergy follows soon after an episode of gastroenteritis.

Immunological and Molecular Mechanisms

Despite the gastrointestinal barrier, small amounts of immunologically intact proteins enter the circulation and are distributed throughout the body. In normal individuals, the gut-associated lymphoid tissue (GALT), although capable of mounting a rapid and potent response against foreign substances, develop tolerance to ingested food antigens. The means by which tolerance develops is poorly understood, but it is believed that failure to develop tolerance leads to food allergy. The relatively low salivary secretory IgA concentrations, together with the large amount of ingested protein, contributes to the large amount of food antigens confronting the immature GALT. In genetically predisposed infants, these food antigens may stimulate the excessive production of IgE antibodies or other abnormal immune responses.

Heat Treatment

Heat treatment clearly affects certain (but not all) foods, most commonly rendering them less likely to provoke an allergic reaction in a subject who is allergic. Occasionally, the reverse occurs, as in the celebrated case of Professor Heinz Küstner, who was allergic to cooked and not raw fish.

In cow's milk, whey proteins are easily denatured by heat but casein is highly resistant. This observation led to the suggestion that the heat treatment of whey proteins may be a simple and logical strategy for producing a hypoallergenic infant milk formula. However, double-blind, placebo-controlled oral challenges gave rise to immediate hypersensitivity reactions to heat-treated whey protein in four of five children with cow's milk protein intolerance. The reason for these reactions is not known, but one possibility is a reaction to residual casein, which is often present in trace amounts in commercial whey preparations. The small proportion of patients with cow's milk protein intolerance likely to tolerate heat-treated cow's milk, such as evaporated milk, means that heat-treated milk is unlikely to be suitable as a substitute for a cow's milk infant formula.

Cooking reduces the allergenicity of eggs by 70%. However, one of the major allergens in eggs, ovomucoid, a heat-resistant glycoprotein that contributes to the gel-like structure of thick white, is resistant to heating. Heat appears to render a large number of fruits and vegetables less likely to provoke adverse reactions in subjects who are intolerant. Thus, for example, it is not uncommon to see children who are allergic to raw potatoes or fresh pineapple, but almost all such children can tolerate cooked potatoes or tinned pineapples. In some situations, it appears that heat can accelerate a process of denaturation that can in time occur on its own. For example, there have been studies of patients who reacted to fresh melon, pear, peach, pineapple, grape, and banana.

In each case, stewed or tinned fruit caused no reaction. Studies of fresh extracts of these fruits showed that when stored in a refrigerator, the extracts lost their ability to provoke a positive skin test after approximately 3 days.

Heating can increase the allergenicity of certain proteins through the induction of covalent modifications that lead to new antigens or increased stability. In peanuts, for example, the roasting process produces end products with greater resistance to digestion and heightened allergenicity compared with those produced by frying or boiling. This finding may partly account for the low prevalence of peanut allergy in China, where peanut is widely consumed but not roasted.

Prevalence

Unreliability of Self-Reported Food Allergy

Reports of food allergy from individuals or parents of children are notoriously unreliable. Such reports have to be treated with scepticism. It is common for parents to believe that foods are responsible for a variety of childhood symptoms. Double-blind provocation tests in children with histories of reactions to food only confirm the story in one-third of all cases. In the case of purely behavioral symptoms, the proportion that could be reproduced under blind conditions was zero. The same is true of adults' beliefs about their own symptoms. If unnecessary dietary restrictions are to be avoided, one has to be sceptical, and it may be necessary in some cases to seek objective confirmation of food intolerance. The gross overreporting of food allergy has to be borne in mind when examining data on prevalence that are based on unconfirmed subjective reports.

Population Studies

In the European Community Respiratory Health Survey administered to 17 280 adults in 15 countries covering the period 1991–1994, 12% of respondents reported a food allergy or intolerance, ranging from 4.6% in Spain to 19.1% in Australia. The foods most commonly reported to cause shortness of breath were peanut in the United States; fruit in Iceland, Belgium, Ireland, and Italy; and hazelnut in Norway, Sweden, and Germany. The reason for the variation in the reported food triggers is unknown.

A population-based study of 33 110 people in France defined food allergy on the basis of self-reported typical allergic symptoms only and found a rate of 3.5%. In adults, the main foods reported to trigger allergic reactions were seafood, fruit, and vegetables, whereas in children the main foods were egg and milk.

In a questionnaire offered to approximately 30 000 people in 11 388 households in the High Wycombe area of Britain, 3188 of the 18 582 responders (17%) thought that they had some sort of reaction to foods or food additives. A check on the nonresponders showed that they had almost no food-provoked symptoms. Particular attention was then paid to food additives, and it was found that 1372 of the 18 582 responders (7.4%) believed they had adverse reactions to food additives. Of the 1372, 649 attended for a detailed interview, and 132 gave a history of reproducible clinical symptoms after ingestion of food additives. Eighty-one of these completed a trial of double-blind, placebo-controlled challenges with 11 food additives, but a consistent adverse reaction was found in only 2 subjects. One was a 50-year-old atopic man who reported headaches after ingesting coloring agents and who reacted to challenge with annatto, which reproduced his headache at both low (1 mg) and high (10 mg) dose after 4 and 5 h, respectively. He also reacted to placebo on one occasion. The second was a 31-year-old nonatopic woman who reported abdominal pain after ingestion of foods. She had related this to ingestion of preservatives and antioxidants. Her symptoms were reproduced on challenge with annatto at low and high dose.

The parents of 866 children from Finland were asked to provide a detailed history of food allergy, and for certain foods the diagnosis was further investigated by elimination and open challenge at home. Food allergy was reported in 19% by the age of 1 year, 22% by 2 years, 27% by 3 years, and 8% by 6 years. In a prospective study of 480 children in the United States of America up to their third birthday, 16% were reported to have had reactions to fruit or fruit juice and 28% to other food. However, open challenge confirmed reactions in only 12% of the former and 8% of the latter.

Estimates of the prevalence of cow's milk protein allergy are reported to range from 0.3 to 7.5% of subjects.

Natural History

The natural history of food allergy has been little studied. It is well-known that a high proportion of children with food intolerance in the first year of life lose their intolerance in time. The proportion of children to which this happens varies with the food and probably with type of symptoms that are produced. Thus, it is common for allergy to cow's milk or egg to spontaneously disappear with time,

whereas peanut allergy is usually lifelong. In the North American study referred to previously, it was found that the offending food or fruit was back in the diet after only 9 months in half the cases, and virtually all the offending foods were back in the diet by the third birthday. A further study of nine children with very severe adverse reactions to food showed that despite the severity, three were later able to tolerate normal amounts of the offending food and four became able to tolerate small amounts.

Although it is clear that the majority of children with food intolerance spontaneously improve, it remains to be established to what extent this depends on the age of onset, the nature of the symptoms, the food itself, and other factors such as associated atopic disease.

In adults with food allergy, the problem is far more likely to be lifelong. Nevertheless, some adults do become tolerant to foods to which they were allergic. In one adult follow-up study, approximately one-third of adults were found to lose their allergy after maintaining an elimination diet for 1 year.

Cross-Reactions

This term refers to cross-reaction between different species and between different foodstuffs that may or may not belong to the same botanical family.

Animal Milk

There is a marked antigenic similarity between the proteins that cause food allergy in the milk of cows, goats, and sheep. It is often not appreciated that almost all subjects who are allergic to cow's milk protein are allergic to the milks of these other animals. This is one of the many reasons why goat's milk is not an appropriate milk substitute for an infant with cow's milk allergy.

Eggs

The eggs from turkeys, duck, goose, and seagull all contain ovalbumen, ovomucoid, and ovotransferrin, the major allergens in hens' eggs. The eggs of hens and turkeys have a similar relative potency of allergenicity. The immunochemical identity of proteins in the egg white of ducks and geese differs somewhat from that of hens, and they may have less potency as allergens. Of all the bird's eggs listed previously, the eggs of the seagull are the least allergenic and bear the least immunochemical similarity with hen's eggs.

Legumes

It is not always obvious which plants belong to the same family. The Leguminosae include beans, peas, soya, lentils, peanuts, liquorice, carob, and gum arabic. Clinical cross-reactivity is uncommon, and the degree of genetic relationship may be of little relevance. Thus, for example, patients with soya allergy are not uncommonly allergic also to peanuts, although the two legumes are not closely related.

Seafood

The taxonomic diversity (fish, molluscs, and crustaceans) suggests that complete cross-reactivity for all seafood is unlikely to be common. In one study, of 20 children with a history of allergy to cod, there was a history of allergy to sole in 11 (55%), to tuna in 7 (35%), and to mackerel, anchovy, sardine, red mullet, and salmon each in 1 (5%). Most studies of cross-reactivity are based on skin prick and IgE antibody test results, which are of little relevance to clinical sensitivity.

Food and Pollen

Cross-reactions can occur between inhaled pollen and ingested food allergens. There is a well-documented association between allergy to birch tree pollen and allergy to apple, carrot, celery, potato, orange, and tomato. This and other similar types of associations are explained by the conservation of protein across species, and a number of so-called panallergens have been described:

1. Profilins in birch pollen, hazelnut, and apple
2. Class 1 chitinases in avocado, banana, and latex
3. Lipid transfer proteins in apple and peach
4. Tropomyosin in insects and shellfish

Cross-reacting IgE antibodies reactive with related foods can often be detected in people who are allergic to a member of these food groups, but clinical reactions are uncommon.

Special Requirements for the Occurrence of Allergic Reaction to Food

In some individuals, there is a clear one-to-one relationship between the ingestion of a food and a reaction. An example is an individual with allergy to cod. Every time the subject eats cod, there is an immediate allergic reaction. In other individuals, the relationship between the food and an allergic reaction is less precise. There are a number of possible reasons for this.

Timing of Reaction and Delayed Reactions

Most allergic reactions to foods occur within minutes of ingestion of the food. However, sometimes a reaction may be delayed. This is best documented in cow's milk protein allergy, in which three types of reaction are recognized: early skin reaction, early gut reaction, and late reaction. An affected individual usually exhibits only one of these types of reaction. In the early skin reaction group, symptoms begin to develop within 45 min of cow's milk challenge. Almost all patients in this group have a positive skin prick test to cow's milk. In the early gut reaction group, symptoms begin to develop between 45 min and 20 h after cow's milk challenge. Approximately one-third of patients in this group have a positive skin prick test to cow's milk. In the late reaction group, symptoms begin to develop approximately 20 h after cow's milk protein challenge. Only approximately 20% of this late reaction group have a positive skin prick test to cow's milk, and these are mostly children with atopic eczema. Almost all children in the late reaction group present over the age of 6 months, and as a group their age at presentation is significantly higher than that of the two other groups.

Quantity of Food

The quantity of cow's milk, for example, required to produce an allergic reaction varies from patient to patient. Some patients are highly sensitive and develop anaphylaxis after ingestion of less than 1 μg of casein, β-lactoglobulin, or α-lactalbumin. In contrast, there are children and adults who do not react to 100 ml of milk but who do react to 200 ml or more. There is a relationship between the quantity of milk required and the time of onset of symptoms. In one study, the median reaction onset time in those who reacted to 100-ml milk challenges was 2 h, but the median reaction onset time in those who required larger amounts of milk to elicit reactions was 24 h.

Food-Dependent Exercise-Induced Anaphylaxis

In this unusual condition, attacks only occur when the exercise follows within a couple of hours of the ingestion of specific foods, such as celery, shellfish, squid, peaches, or wheat. The mechanisms that result in food-dependent exercise-induced anaphylaxis are obscure. This disorder, although rare, is important in the interpretation of dietary challenge studies of food intolerance because in these patients a simple double-blind food challenge without exercise will fail to validate a history of food intolerance.

Drug-Dependent Food Allergy

There are individuals who only react to specific foods while taking a drug. The best recognised examples of this are individuals who only react to foods while taking salicylate (aspirin).

Effect of Disease Activity

It is a common but poorly understood observation that children with eczema and food allergy can often tolerate some or all food triggers when the skin disease clears (usually when the child is vacationing in a sunny location).

Other Possibilities

It is not known whether food allergy can be confined to occasions when the pollen count is high or when the individual consumes certain other foods. There are no objective studies that address the complex issue of the possible additive effect of orally ingested and possibly inhaled antigens. There are subjects with allergy to foods in whom the severity of adverse reactions clearly varies from time to time, but the reasons for this variability are not known.

Diagnosis and Management

T J David, University of Manchester, Manchester, UK

Documenting Possible Food Allergies

The diagnosis of food allergy is made from the history, supported by investigations and by responses to avoidance of specific food triggers. Since the value of investigations is limited, it is especially important to obtain a clear history. There are a number of practical points to be made:

- **Speed of onset.** In general, the quicker the onset of the allergic reaction, the more reliable is the history. If a child develops a violent allergic reaction within a minute or two after ingesting a food, it is much easier to link the reaction to a specific food than if a reaction only occurs hours or days after eating a food.
- **Coincidences need to be excluded.** If a child becomes unwell (e.g., starts wheezing) an hour after eating a specific food, the wheezing could be caused by the food, or it could just be a coincidence. The more times that such a sequence has been observed, the more likely it is that there is a cause and effect relationship.
- **Observations need to be tested for internal consistency.** Someone may believe that he or she is allergic to a food if a symptom (e.g., urticaria) occurs on (say) three occasions after eating a specific food. It is important to find out:
  1. Whether the subject has had the same symptoms on other occasions when the suspect food trigger was not taken.
  2. Whether the subject has taken the suspect food on one or more other occasions without any adverse effects.

Failure to seek inconsistencies such as these is one factor that is responsible for the overdiagnosis of food allergy.

Documenting a Diagnosis of Food Allergy

If it is reported that someone is allergic to an item, it is important to probe further and find out on what basis the person has been deemed allergic. It is common to find children and adults who are believed to be allergic to a food solely on the basis of tests such as skin tests or blood tests, which are in fact almost wholly unreliable (see below). It is also common for people to believe that they are allergic to something because a health professional said so one day, which on further enquiry turns out to be on flimsy or nonexistent grounds.

Another common problem is the misinterpretation of a sequence of events. For example, a child with an ear infection is given an antibiotic, and 3 days later gets diarrhea, so the parents come to believe the child is allergic to the antibiotic. In fact the cause of the diarrhea is far more likely to be either an underlying viral infection, or a disturbance of the gut flora. Another example is the report of a child who is believed to be allergic to sesame seeds because of reactions occurring after eating buns coated with sesame seeds; many such children are in fact not allergic to sesame seeds but are reacting to the egg glaze that has been used as an adhesive for the seed coating. Another common example is the child with asthma who coughs and wheezes after drinking a diluted orange squash drink, with the result that it is believed that the child is reacting to the yellow-orange coloring agent tartrazine. If fact such reactions are more likely to be due to sulfite preservatives in the squash; sulfites trigger symptoms in 60% or more of children with asthma.

Practical Diagnostic Difficulties

Multiple Mechanisms

Reactions to foods are a heterogeneous group of disorders caused by a variety of different immunological and pharmacological mechanisms. In any individual case, the precise mechanism is often not known. No single type of laboratory test could possibly cover all the different types of possible mechanisms of reactions to foods. Even if one

focuses on food allergy, there are a number of different possible immunological mechanisms, including IgE-antibody mediated, cell mediated, and circulating immune complexes.

Inability to Predict Outcome

In many situations (e.g., atopic disease), the subject wants to know whether there will be any benefit from food avoidance (e.g., not drinking cows' milk or not eating apples). Even if there were valid tests for the diagnosis of food intolerance, the outcome of avoidance measures depends on a number of other variables. Allergen avoidance may succeed for the following reasons:

1. the patient was intolerant to the item;
2. coincidental improvement; and
3. placebo response.

The reasons why a trial of food avoidance may fail to help can be summarized as:

1. The subject is not allergic to the food.
2. The period of elimination was too short. For example, where a child has an enteropathy (damage to the small intestine) due to food allergy, it may take a week or more for improvement in symptoms to occur.
3. The food has been incompletely avoided. This may happen in a subject supposedly on a cows' milk protein-free diet who still continues to receive food that contains cows' milk proteins such as casein or whey.
4. The subject is allergic to other items, which have not been avoided. For example, a child with an allergy to cows' milk protein who fails to improve when given a soy-based milk to which they also have an allergy.
5. Coexisting or intercurrent disease, for example, gastroenteritis in a child with loose stools who is trying a cows' milk-free diet.
6. The patient's symptoms are trivial and have been exaggerated or do not exist at all and have either been imagined or made up by the parents.

It is unrealistic to expect there to be a simple test that can overcome all these problems.

Diagnostic Tests

Skin Prick Tests

The principle of skin prick tests is that the skin weal and flare reaction to an allergen demonstrates the presence of mast-cell-fixed antibody, which is mainly IgE antibody. IgE antibody is produced in plasma cells, and is distributed in the circulation to all parts of the body, so that sensitization is generalized and therefore can be demonstrated by skin testing. In the presence of specific IgE antibody, mast cells in the skin release histamine, which in turn causes a visible weal and flare reaction in the skin.

The procedure involves a drop of allergen solution being placed on the skin, which is then pricked with a hypodermic needle. Two control solutions should also be used: the diluent, in order to detect false-positive reactions; and a positive control (e.g., a histamine solution), to enable comparison with a positive result of an allergen solution. The skin prick test induces a response that reaches a peak in 8–9 min for histamine and 12–15 min for allergens. The size of the weal reaction (and not the larger red flare) is measured.

There are numerous problems with skin prick tests, including:

1. There is no agreed definition about what constitutes a positive reaction.
2. The size of the weal depends to some extent on the potency of the extract.
3. Antihistamines and tricyclic antidepressants suppress the histamine-induced weal and flare response of a skin test. The suppressive effect of antihistamines may last from a week up to several months for some of the more recently introduced nonsedating antihistamines.
4. False-positive tests: skin prick test reactivity may be present in subjects with no clinical evidence of allergy or intolerance. This is sometimes described as 'asymptomatic hypersensitivity' or 'subclinical sensitization.' Whilst many with positive skin prick tests will never develop the allergy, some subjects with positive skin prick tests do develop symptoms later. However, since the test cannot identify those who are going to develop symptoms, the skin test information is of no practical value.
5. False-positive results: skin prick test reactivity may persist after clinical evidence of intolerance has subsided. For example, in a study of children with egg allergy, it was noted that 5 out of 11 who grew out of egg allergy had persistently positive skin prick tests after the allergy had disappeared.
6. False-negative tests: skin prick tests are negative in some subjects with genuine food allergies.
7. Skin prick tests mainly detect IgE antibody. However, many adverse reactions to food are not IgE mediated, in which case skin prick tests can be expected to be negative. Taking cows'

milk protein intolerance as an example, patients with quick reactions often have positive skin prick tests to cows' milk protein, but those with delayed reactions usually have negative skin prick tests.

8. False-negative results are a problem in infants and toddlers, when the weal size is much smaller than later in life.
9. There is a poor correlation between the results of provocation tests (e.g., double-blind food challenges) and skin prick tests. For example, in one study of 31 children with a strongly positive (weal >3 mm in diameter) skin prick test to peanut, only 16 (56%) had symptoms when peanuts were administered.
10. Commercial food extracts (sometimes heat treated) and fresh or frozen raw extracts may give different results (more positives with raw foods), reflecting the fact that some patients are allergic to certain foods only when taken in a raw state. In others the reverse is the case.

Skin prick tests are mainly used in research studies. The results of skin tests cannot be taken alone, and standard textbooks on allergy acknowledge that "the proper interpretation of results requires a thorough knowledge of the history and physical findings." The problems in clinical practice are, for example, whether or not a subject with atopic disease (eczema, asthma, or hay fever) or symptoms suggestive of food intolerance will benefit from attempts to avoid certain foods or food additives. However, skin prick test results are unreliable predictors of response to such measures.

Skin test results are known to be misleading in cases of inhalant allergy (e.g., allergy to dust mites or grass pollen) but skin prick tests for food allergy are especially unreliable because of the large number of false-positive and false-negative reactions.

Intradermal Testing

Intradermal testing comprises the intradermal injection of 0.01–0.05 ml of an allergen extract. It can cause fatal generalized allergic reaction (anaphylaxis), and is only performed if a preliminary skin prick test is negative. Intradermal tests are more sensitive than skin prick testing, and hence also produce even more false-positive reactions, making the interpretation of the results of intradermal testing even more difficult than that for skin prick testing. The difficulty in interpretation of the results, the pain of intradermal injections, and the risk of anaphylaxis mean that intradermal testing has no place in the routine investigation of food allergy.

Skin Application of Food Prior to Food Challenges

There is one situation where direct application of food to the skin may be of practical value, and that is prior to a food challenge in a child in whom one fears an anaphylactic reaction. An example might be a 6-month-old infant with a history of a severe allergic reaction to egg. If the parents wish to see if the child has outgrown the allergy without directly administering egg and risking a violent reaction, a simple approach is to rub some raw egg white into the skin and observe the skin for a few minutes. If the skin application of egg in this way causes an urticarial reaction, then a gradual diminution and disappearance of this response during the succeeding months and years can probably be taken to indicate the development of tolerance, and a continuing brisk response to skin contact would constitute a deterrent to an oral challenge. However, this is only an approximate guide, and there are a number of possible reasons why such testing may give false-positive (e.g., using a raw food when the food is usually eaten cooked, such as egg or potato) or false-negative (e.g., the child is receiving antihistamine drug) results.

Tests for Circulating IgE Antibodies: the Radioallergosorbent (RAST) Test

The radioallergosorbent (RAST) test is the best known of a number of laboratory procedures for the detection and measurement of circulating IgE antibody. Unfortunately, the clinical interpretation of RAST test results is subject to most of the same pitfalls as that for skin prick testing. Additional problems with RAST tests are the cost, and the fact that a very high level of total circulating IgE (e.g., in children with severe atopic eczema) may cause a false-positive result. Depending upon the criteria used for positivity, there is a fair degree of correlation between the RAST test and skin prick test results.

Provocation Tests

A provocation test may be useful to confirm a history of allergy. An example might be a child who developed wheezing and urticaria minutes after eating a rusk that contained, as its main ingredients, wheat and cows' milk protein. To determine which component, if any, caused the reaction, oral challenges with individual components can be conducted.

However, the results of provocation tests cannot prove that improvement in a disease has been caused by food avoidance. For example, a child with atopic eczema is put on a diet avoiding many foods, and

the eczema improves. This improvement could be a coincidence, a placebo effect, or due to the diet. Just because the child is shown to react to a single food does not prove that avoidance of that food was the cause of the improvement.

Open and blind challenges Where the subject and the observer knows the identity of the administered material at the time of the challenge, the procedure is said to be an 'open' challenge. In a 'single-blind challenge' the observer but not the patient or family know the identity of the test material. To avoid bias on the part of the observer, a double-blind challenge is required. A 'double blind' challenge involves exposing the subject to a challenge substance, which is either the item under investigation or an indistinguishable inactive (placebo) substance. Neither the subject nor the observer knows the identity of the administered material at the time of the challenge or during the subsequent period of observation.

The purpose of provocation tests The aim of a food challenge is to study the consequences of food or food additive ingestion. Provocation tests are helpful:

1. to confirm a history (parents' observations of alleged food allergy are notoriously unreliable, as are adults' beliefs about their own allergies);
2. to confirm the diagnosis, for example, of cows' milk protein allergy in infancy, where the diagnostic criteria include improvement on elimination diet and relapse on reintroduction;
3. to see if a subject has grown out of a food intolerance; and
4. as a research procedure.

The food challenge should replicate normal food consumption in terms of dose, route, and state of food. It should also be performed in such a way that the history can be verified. Thus, for example, there is no point solely looking for an immediate reaction if the parents report a delayed reaction.

Open food challenges are the simplest approach, but open food challenges run the risk of bias influencing the parents' (or doctors') observations. Often this is unimportant. But in some cases belief in food intolerance may be disproportionate, and where this is suspected there is no substitute for a double-blind placebo-controlled challenge. An open challenge may be an open invitation to the overdiagnosis of food intolerance. For example, in the UK parents widely believe that there is an association between food additives and bad behavior, but in one series, double-blind challenges with tartrazine and benzoic acid were negative in all cases in a study of 24 children with a clear parental description of adverse reaction.

The double-blind placebo-controlled challenge is regarded as the state-of-the-art technique to confirm or refute histories of adverse reactions to foods. The ability to unravel food-related problems is said to be limited only by the imagination of the physician and a clever dietitian. In fact, the technique is subject to a number of potential limitations, not all of which can be overcome.

Effect of dose In some cases of food intolerance, minute quantities of food (e.g., traces of cows' milk protein) are sufficient to provoke florid and immediate symptoms. In other cases, much larger quantities of food are required to provoke a response. Hill *et al.* demonstrated that whereas 8–10 g of cows' milk powder (corresponding to 60–70 ml of milk) was adequate to provoke an adverse reaction in some patients with cows' milk protein allergy, others (with late onset symptoms and particularly atopic eczema) required up to 10 times this volume of milk daily for more than 48 h before symptoms developed.

Concealing large doses is difficult Standard capsules that contain up to 500 mg of food are suitable for validation of immediate reactions to tiny quantities of food, but concealing much larger quantities of certain foods (especially those with a strong smell, flavor, or color) can be very difficult.

Route of administration Reactions to food occurring within the mouth are likely to be missed if the challenge by-passes the oral route, e.g., administration of foods in a capsule or via a nasogastric tube. In practice, patients whose symptoms are exclusively confined to the mouth are unusual, and where there is a history of purely oral reactions an alternative challenge procedure can be employed. In subjects who are intolerant to sulfites, it is well recognized that the administration of sulfites in capsules or directly into the stomach via a nasogastric tube usually fails to provoke an adverse reaction, whereas the oral administration of solution will succeed in doing so.

Problems with capsules Capsules are unsuitable for use in children who cannot swallow large capsules, and this is a major limitation as most cases of suspected food allergy are in infants and toddlers. Furthermore, it is unsatisfactory to allow patients or parents to break open capsules and mix the contents with food or drink, as the color (e.g., tartrazine) or

smell (e.g., fish) will be difficult or impossible to conceal and the challenge will no longer be blind.

Anaphylactic shock danger There is a danger of producing anaphylactic shock, even if it had not occurred on previous exposure to the food. For example, in Goldman's classic study of cows' milk protein intolerance, anaphylactic shock had been noted prior to cows' milk challenge in 5 out of 89 children, but another 3 developed anaphylactic shock as a new symptom after cows' milk challenge. In a study of 80 children with atopic eczema treated with elimination diets, anaphylactic shock occurred in 4 out of 1862 food challenges. The risk appears to be greatest for those who have received elemental diets.

Effect of disease activity A food challenge performed during a quiescent phase of the disease (e.g., urticaria, eczema, or asthma) may fail to provoke an adverse reaction.

Additive effect of triggers Although some patients react repeatedly to challenges with single foods, it is possible (but unproven) that some patients only react adversely when multiple allergens are given together. There certainly are some subjects who only react in the presence of a nonfood trigger, such as exercise or taking aspirin.

Special types of provocation testing Other than giving a suspect food by mouth, and asking the subject to swallow it, there are some alternative approaches, which are outlined below.

Oral mucosal challenge A small portion of food is applied to the mucosa inside the mouth, and one looks for reactions such as swelling of the lips, and tingling or irritation of the mouth or tongue, possibly followed by other more generalized symptoms such as urticaria, asthma, vomiting, abdominal pain, or anaphylactic shock. Patients with food intolerance commonly make use of these oral symptoms, spitting out and avoiding further consumption of a food that provokes the symptom.

Gastric mucosal challenge In this procedure, an allergen is applied directly to the gastric mucosa via an endoscope, and the mucosa is then observed for signs of a reaction. In addition, it is possible to take biopsies of the gastric mucosa to study the histological changes and measure the tissue concentration of mediators of inflammation such as histamine.

Rectal challenges The standard test to confirm a diagnosis of celiac disease is the jejunal biopsy, in which a small portion of jejunal mucosa is obtained with the aid of a special capsule that is swallowed, and which passes into the small intestine. When in the correct location, the capsule is triggered and withdrawn; it contains a portion of intestinal mucosa, which can then be examined under the microscope. Alternatively, gluten can be instilled into the rectum, in order to look for a reaction that would signify celiac disease. This procedure requires multiple biopsies from the rectum, and it is uncertain whether the results are reliable.

Management

Dietary Elimination

The management of food allergy consists largely of elimination from the diet of the trigger food or foods. Elimination diets are used either for the diagnosis or the treatment of food intolerance, or for both. A diet may be associated with an improvement in symptoms because of intolerance to the food, a placebo effect, or the improvement may have been a coincidence. The degree of avoidance that is necessary to prevent symptoms is highly variable. Some patients are intolerant to minute traces of food, but others may be able to tolerate varying amounts. Strict avoidance and prevention of symptoms are the aims in certain instances, but in many cases it is unknown whether allowing small amounts of a food trigger could lead to either enhanced sensitivity or to the reverse, increasing tolerance. The duration required for dietary avoidance varies. For example, intolerance to food additives may last only a few years, whereas intolerance to peanuts is usually lifelong. Although food allergy is common in children, most have grown out of the problem by the age of 5 years; an important exception is those with nut allergy.

Malnutrition

Malnutrition is a major risk of unsupervised diets.

Calcium Cows' milk is an important source of calcium, and avoidance of cows' milk and its products carries the risk of an inadequate intake of calcium. Unfortunately, it is far from clear what constitutes an adequate intake for various different age groups.

Protein, energy Milk, eggs, fish, meat, wheat, and their respective manufactured food products are important sources of protein and energy. Avoidance

of these without the provision of alternative sources of protein and energy runs the risk of an inadequate intake, and growth failure, serious malnutrition, and weight loss are well documented sequelae of unsupervised and inappropriate dietary elimination.

Iodine Cows' milk and dairy products are important sources of dietary iodine. Exclusion of cows' milk products and a number of other items from the diet, coupled with the consumption of large amounts of soy milk, which has been reported to cause hypothyroidism by increasing fecal loss of thyroxine, have resulted in hypothyroidism and growth failure due to dietary iodine deficiency.

High-risk factors The risk of malnutrition from an elimination diet is particularly high in the following situations:

1. The diet is not supervised by a dietitian.
2. There is chronic disease prior to diagnosis, or concurrent chronic disease such as severe atopic eczema. The subject's nutrient requirements may be increased.
3. Malabsorption or enteropathy increases the risk of malabsorption of nutrients.
4. The subject is avoiding sunlight. The risk of vitamin D deficiency may compound the effects of a low calcium intake.
5. The subject is already on a diet that excludes multiple foods, e.g., vegan or macrobiotic diet.

The Role of the Dietitian

The dietitian has three roles in the management of elimination diets. One is to ensure that the resulting diet is nutritionally adequate, and to prevent potential deficiency states by recommending (in an infant) appropriate amounts of infant milk formula, and (in older children or adults) supplements of calcium, vitamins, and so on. Another role is to advise how to avoid specific foods, particularly those contained in manufactured foods. Third, the dietitian makes suggestions as to how to make the diet practical and palatable, and suggests recipes for use with a limited range of foods (e.g., how to make biscuits with potato flour).

Cows' Milk Protein Avoidance

Any form of cows' milk, whether fresh, skimmed, condensed, or evaporated, needs to be avoided. Also forbidden are milk products that contain casein, whey, and nonfat milk solids. Where milk substitutes are required, the choice lies between formulas based on soy protein, casein hydrolysate, or whey hydrolysate. Soya formulas are cheaper, but unsuitable for those who are also intolerant to soya.

Butter, margarine, cream, cheese, ice cream, and yogurt all need to be avoided. Fats that can be used instead include margarines made from pure vegetable fat (e.g., Tomor) and lard. Caution is required with baby foods, as a large number of manufactured products, e.g., rusks, contain milk protein. A common trap is so-called 'vegetarian' cheese, often wrongly believed to be safe for subjects with cows' milk allergy. In fact, it differs from ordinary cheese only in the use of nonanimal rennet and is unsuitable for people with cows' milk allergy. Meat, game, and poultry are all allowed, but sausages and pies should be avoided unless it is known that they are milk free. Intolerance to cows' milk protein is not a reason to avoid beef. Eggs are allowed, but not custard or scrambled egg which may contain milk. Fish is permitted, unless it is cooked in batter (which unless otherwise stated should be assumed to contain milk) or milk. Lemon curd, chocolate spread, chocolate (unless stated to be milk-free), toffee, fudge, caramels, and butterscotch are all unsuitable. All ordinary cereals (e.g., oats) are allowed, but caution is required with manufactured breakfast cereals, some of which contain milk powder.

It is essential to check the list of ingredients on the label of any manufactured foods. There is a special problem with unwrapped foods, because there is no label of ingredients. Examples include bread, sausages, or confectionery.

Egg Avoidance

Eggs (both the white and the yolk) and all products that contain egg or albumen must be avoided. As well as hen's eggs, eggs of other birds such as geese, turkeys, and quails must be avoided. Eggs are widely used to make cakes and are sometimes used in the manufacture of bread. Egg wash or glaze is commonly brushed on to the surface of rolls, buns, or baps, and also bread, cakes, and pastry used in puddings (e.g., apple pie). Sweets can be a hazard because they are usually sold without information about ingredients, and egg is included in several products.

Mayonnaise normally contains egg; custard usually does not, with the exception of egg custard and egg custard tarts. Eggs are an essential ingredient of souffles and certain sauces, such as Bearnaise or Hollandaise sauce.

Egg allergy is not a reason to avoid eating chicken.

Soy Avoidance

The major difficulty is mass-produced bread, because in the UK soy is often included as an

ingredient in flour. Soy is also found in manufactured products that contain hydrolyzed or textured vegetable protein, and minced beef, which unless described as 'pure beef' has been known to include quantities of soy protein.

Wheat-Free and Gluten-Free

These terms cause confusion; they are not interchangeable. Subjects who are allergic to wheat cannot tolerate foods that contain any type of wheat. Subjects with celiac disease can tolerate all wheat proteins other than the gluten fraction.

Peanut Avoidance

Peanut is also known as groundnut or arachis, so these three names need to be sought on labels of manufactured foods as well as some pharmaceutical products. The difficulty comes with 'vegetable oil,' which may include peanut oil; only by writing to the manufacturer of individual products can the composition of the vegetable oil be determined. It is not known to what extent subjects with peanut allergy should avoid peanut oil. Most peanut oil used in food manufacture is highly refined, and contains only very minute quantities of peanut protein. In a number of small-scale studies, subjects with peanut allergy were found not to react when given highly refined peanut oil. However, it remains possible that such oil contains traces of protein sufficient to result in enhanced reactivity, such that when the subject does ingest peanut accidentally the reaction is worse than previously. On this basis, subjects with peanut allergy should really be advised to avoid peanut oil.

Drug Treatment in the Management of Food Allergy

At present, drug treatment has little part to play in the management of food allergies. There are two exceptions. First, there are a very small number of cases in which the reaction to a food is exclusively gastrointestinal, and in whom the reaction can be blocked by taking the drug sodium cromoglycate by mouth 20 min before the trigger food is swallowed. Second, there are a small number of individuals who develop the life-threatening reaction, of anaphylactic shock when exposed to a trigger food. There are three ways in which anaphylactic shock may prove fatal. First, rapid swelling of the soft tissues in the pharynx may completely obstruct the airway; the treatment is to bypass the obstruction, either by passing an endotracheal tube, or by performing a tracheostomy. Another mechanism is severe shock, with a profound drop in blood pressure; the life-saving treatment is to restore the circulating volume with intravenous fluids and to give oxygen. The third mechanism is severe bronchoconstriction (asthma); here, the life-saving treatment is with bronchodilator drugs and artificial ventilation. If patients with life-threatening anaphylactic shock are to be saved, they must be given urgent (within minutes) medical attention. For individuals who have already experienced a life-threatening allergic reaction to a food, it is common practice to provide them with a syringe preloaded with adrenaline (epinephrine), with the aim that this should be administered while waiting for medical help. Unfortunately, self-administered adrenaline is not without its hazards (e.g., inadvertent intravenous administration causing fatal cardiac arrest), and there is no proof that it is life saving; indeed, there are many cases in which the subject died despite the use of epinephrine. Nevertheless, it is the best one can do when faced with someone who is experiencing a life-threatening allergic reaction to a food. The need for urgent medical help cannot be overemphasized.

There is little evidence that antihistamine drugs are of any value. It would be reasonable to take a nonsedating fast-acting antihistamine such as terfenadine if experiencing an allergic reaction to a food, but it is questionable whether it will have much effect.

A number of new approaches to the treatment of IgE-mediated food allergy are being examined. In a double-blind placebo-controlled study of monthly injections of a preparation of anti-IgE antibodies, treated patients with peanut allergy required significantly greater amounts of peanut protein to elicit allergic symptoms compared with control subjects. Another anti-IgE preparation has been used in the treatment of asthma but has not been evaluated in peanut allergy. Theoretically, anti-IgE antibody treatment should be protective against multiple food allergens, although it would have to be administered indefinitely. Other experimental approaches include a concoction of traditional Chinese herbs, injection of heat-killed *Escherichia coli* containing mutated recombinant peanut proteins Ara h 1 to Ara h 3, the use of immunostimulatory sequences, and the use of chimeric protein that could form complexes with allergen-specific IgE bound to mast cells and basophils.

Desensitization

In theory it ought to be possible to desensitize subjects with food allergy by giving injections of gradually increasing quantities of an appropriate extract

of the food trigger. In practice, such treatment is not available. One at present insurmountable difficulty is that desensitization (also known as hyposensitization) treatment carries a small risk of death from the treatment itself. A subject has a series of injections without any major problem, but then without warning drops dead from anaphylaxis after the next injection. There is some data to show that desensitization performed in this way can work, but such subjects would probably require maintenance injections on a permanent basis, and the very subjects most at risk of fatal anaphylaxis from accidental injection are quite probably also the ones most at risk from fatal anaphylaxis resulting from desensitization treatment.

FOOD CHOICE, INFLUENCING FACTORS

A K Draper, University of Westminster, London, UK

Food choice is about why we eat the foods we do. This would appear to be a simple and relatively straightforward matter, but human food choice is a complex phenomenon, difficult to predict, and its analysis is not a simple affair. Many factors influence our food choice, and these encompass biological, psychological, economic, social, and cultural influences. These all operate on different aspects of food choice and vary in terms of their relative

strength and influence from person to person and context to context. That said, it is a topic of public health importance for two broad reasons. First, it is important to understand the etiology of those nutritional disorders that can be attributed to dysfunctional patterns of dietary intake. This applies to both deficiency disorders, such as vitamin A deficiency, that are due to inadequate nutrient intakes and diet-related chronic diseases, such as coronary heart disease, that are partly attributable to overconsumption or an imbalanced intake of certain foods and/or nutrients. Second, it is important to reduce morbidity and mortality from these disorders via interventions, such as health education, that are designed to either increase or decrease consumption of specific foods and nutrients. The successful achievement of these objectives relies on an understanding and manipulation of the factors that influence food choice, and there is currently much emphasis on the need for health promotion to be more 'evidence-based.' Food choice, like other so-called health behaviors, is thus an important determinant of health and nutritional status and has been the focus of much research.

One of the significant features of this research is that many different theoretical frameworks drawn from both the natural and the social sciences have been used to study the phenomenon of food choice. These derive from many academic disciplines that include biology and physiology, psychology, social psychology, geography, economics, history, sociology, anthropology, political science, and even philosophy. These all approach the study of food choice in very different ways and identify different factors that influence it. This in part derives from the differing ways in which the phenomenon of food choice and the act of eating have been conceptualized. As noted previously, the question of why we eat what we do is deceptively straightforward, but eating, like sex, presents an ontological or analytical problem: Is eating a purely biological act founded on natural need and determined by physiological mechanisms and whose primary function is the meeting of nutritional requirements or is it a form of intentional social behaviour driven by social, psychological, or economic factors and that may serve nonnutritional ends, such as maintaining social relationships or expressing identity? The particular way in which the nature of food and eating are conceptualized inevitably leads to the identification of different types of factors that are seen to influence it. These methodological differences are compounded in that food choice can also be seen as the outcome of a number of different processes or phases ranging from food production and processing to shopping and finally the act of eating or consumption. Again, different academic disciplines have tended to address different steps within this chain and the way in which they impact on the choice of individuals, households, or wider social groups. Finally, the word 'choice' is somewhat problematic; it is rarely explicitly defined, but it is variously used to refer to acts of food selection that range from unconscious behavioral responses to physiological cues and conscious acts of decision making.

This lack of commensurability in research methods, definition of terms, and the actual object of study thus makes it difficult to review and summarize research findings from across different disciplines regarding the different types of factors that influence food choice. However, the main categories of influence on human food choice can be crudely divided into biological and behavioral factors, psychological factors, economic factors, and social and cultural factors. Within each of these categories, particular factors may be either positive or negative influences in that they may act to encourage or discourage choice of particular food items. These categories of influence are discussed in relation to the theoretical frameworks with which they have been studied and with a brief examination of their explanatory value is given.

Biological and Behavioral Influences

There has been an enormous amount of experimental research conducted on both humans and animals that has sought to identify biological and behavioral mechanisms that regulate food intake. This work is grouped together here with the influences on food choice identified by it because most of this work is based on the assumption that food selection or food choice can be explained by internal physiological processes, and that the principal function served by food and eating is to satisfy nutritional requirements. The notion of choice implicit in such models is therefore not one of conscious decision making but, rather, of choice as the outcome of a physiological or behavioral response to a cue or stimulus that may be either internal or external. The notion of choice thus tends to be elided with that which is eaten, and the unit of analysis is generally that of the individual organism or species.

Many different biological models of food selection have been developed and most of these are based on homeostatic models (i.e., systems that work to maintain a balance between the intake of energy and/or specific nutrients and requirements for them) and are seen to operate via stimulus–response mechanisms of various kinds. Food choice is thus seen as driven either via some kind of internal biofeedback

loop that responds to internal physiological states or stimuli, such as states of physiological need, feelings of hunger or satiety, and the energy and nutrient composition of meals, or via detection and response to external cues or influences, such as taste, smell, or the palatability of foods. Various mechanisms have been identified that act to regulate intake of energy as well as individual nutrients, although the evidence to support innate biological mechanisms governing food choice is probably strongest for overall energy intake. Some mechanisms also only appear to act in fairly extreme physiological circumstances, such as the craving for carbohydrates that follows administration of large doses of insulin. With perhaps the exception of salt and water, the evidence linking physiological needs states or cravings with the choice of specific foods is also equivocal.

The regulation of energy balance and appetite in particular has been the subject of a large amount of research. Much of this work has been carried out in relation to obesity and whether this can be linked to a faulty mechanism or genetic defect of some kind. This work is reviewed in detail elsewhere in this encyclopedia, but a number of different mechanisms have been proposed whereby energy intake and balance might be regulated. These include the adaptive thermogenesis theory (now largely discounted, this proposed that energy expenditure was flexible in some individuals and increased to expend excessive energy intakes); nutrient-based models of feeding in which the energy and/or nutrient composition of the diet is considered to lead to appetite suppression via complex gut-fill cues (e.g., the effect of carbohydrates on neurotransmitters and the central nervous system); and the glucostat, lipostat, and leptin theories, which are considered to operate via satiety effects. However, although experimental studies have shown that complex physiological changes are indeed associated with eating, that these vary with what is eaten, and that humans can respond to the covert manipulation of the energy and nutrient composition of our diets, these studies cannot explain the wide variation and flexibility in human food selection or the development of dysfunctional food habits. Humans appear to be more efficient at regulating up (i.e., eating more) when the energy content of the diet is reduced than regulating down. It has been hypothesized that this is the result of evolutionary adaptation to environments in which food supplies were scarce and/or unreliable and in which the ability to deposit energy stores would carry significant advantages. Thus, although there is evidence to support the idea that humans have some kind of appetite control knob (or even knobs) to regulate energy intake, this knob (or knobs) can be overridden, as evidenced by the increasing rates of obesity in many areas of the world.

In relation to external or behavioral cues influencing food choice, there has also been much work investigating relationships between the organoleptic or sensory properties of food, such as taste and palatability, and food preferences and choice. The palatability of food is a complex construct that combines both the sensory qualities of food (taste, smell, and texture) and our hedonic or pleasure response to that food. There has been much work on what makes certain foods more or less palatable. A high fat content, for instance, enhances the palatability of foods, and a liking for high-fat foods appears to be a universal biological disposition. A liking for sweetness and a dislike of bitter flavors also appear to be universal. Again, it has been argued that these carry evolutionary advantages because sweetness is often linked with good dietary energy sources and bitter tastes with foods containing alkaloids and other poisons. Beyond this, however, most likes and dislikes for specific tastes, flavors, textures, and food appear to be learned, often at an early age. Many food aversions, for instance, are very culturally specific.

In summary, although various stimuli, both internal and external, have been shown to influence certain aspects of human food choice, innate biological or behavioral mechanisms alone cannot explain the enormous diversity in human food choice that we see over time and place. As Rozin, a key researcher in the field of food choice, has pointed out, we need to remember that as a species humans are not specialized feeders; we can and do eat an enormous range of foods and diets that satisfy our nutritional requirements. Thus, although there is undoubtedly a physiological base to human nutrition, biology alone cannot explain the complexity of human food choice.

Psychological influences

Much research has been conducted by psychologists and social psychologists on eating behavior, and they have developed a number of different theoretical models within which food choice is conceptualised as a function of specific psychological characteristics or factors. Psychological factors that have been shown to influence food choice include our knowledge, attitudes, emotions, beliefs, intentions, social norms, feelings of self-control or efficacy, cues to act, our early and ongoing experiences, and our relationships with others, including our mothers and other caretakers. These cannot all be reviewed here, but two models that have been

particularly influential in relation to the study and attempted manipulation of food choice are discussed. Note that only psychological influences on normative food choice are discussed here and not the etiology of complex psychological disorders, such as anorexia nervosa.

The knowledge–attitudes–practice model (also known as knowledge–attitudes–behavior) is perhaps one of the most enduring models of food choice. This is a knowledge-based theory in which it is assumed that a particular practice or behavior is derived from certain attitudes, which in turn flow from our knowledge base. Although attractive in its simplicity, any causal link between nutritional knowledge alone and subsequent food choice is far from proven, and increasing an individual's level of knowledge does not necessarily lead the individual to alter his or her diet. This model has been largely discounted as providing a valid account of human behavior, but it still remains the model of food choice implicit in health education activities that seek to change our behavior via the provision of information and enhancement of knowledge about nutrition.

A number of more complex and sophisticated models of health behavior have been developed that draw on social psychology and social learning theory. These are called social cognition models because in addition to our attitudes, they incorporate the beliefs and norms that we hold about our social environment. A social cognition model that has been widely applied to the study of food choice is the theory of planned behavior developed by Fishbein and Azjen (originally called the theory of reasoned action). The theory of planned behavior has been very influential and, in brief, it posits that the principal determinant of behavior, including food choice, is our intention to perform it (i.e., our behavioral intention), which in turn is determined by our attitude toward that behavior, our social and subjective norms (these are our beliefs about what we think other people want us to do and our motivation to comply or not with their wishes), and our perceived behavioral control ('Do I think that I can do it?'—a construct similar to that of self-efficacy). Studies using this model have shown correlations between the various components of the model and consumption differences; for instance, women tend to consume less high-fat foods and also tend to have more negative attitudes toward them. They thus illustrate that in terms of psychological influences on our food choice, we tend to eat what we like to eat and intend to eat, although our likes and intentions are modified to some extent by what we think we should eat and feel we can eat.

Economic Influences

Economics has also been called the 'science of choice,' and there has been much important work by economists on the analysis of economic influences on food choice. Within economic approaches, food choice is conceptualized as an act of consumption broadly equivalent to the consumption of other goods, whether they be clothes, tractors, or dishwashers. Food choice is thus largely conflated with purchase by economists and, as with other commodities, a range of economic factors have been identified that act to both constrain and encourage our purchase of particular foods, mostly centering on the interplay between price, demand, and income.

The simplest economic model of food choice is the demand curve, which describes an individual's choice of foods as a function of his or her income and the price of the food. Thus, as the price of a particular food commodity decreases, we tend to buy more of it. As income increases, we also tend to buy more of the food as well as spend more money on food overall (although it constitutes a smaller proportion of overall expenditure, a phenomenon known as Engel's law). As consumers, however, we do not just buy for cheapness or price, and various more sophisticated economic explanations have developed, such as utility theory and indifference theory. These incorporate the notion of demand or satisfaction in addition to price or income. Utility theory states that when making choices to purchase a particular good or product from a bundle of goods, as consumers we seek to achieve maximum utility. The term 'utility' refers to the satisfaction of needs, wants, tastes, and aspirations, and choice is conceptualized in terms of maximizing these. Thus, the purchase of a food with high prestige value, such as caviar, makes 'sense' in terms of utility theory if not in terms of nutrition. Indifference theory takes the concept of satisfaction further to explain how we make choices between different combinations of goods or foods for maximum satisfaction; as we eat less of one food, such as vegetables, and more of another, such as fruit, the less willing we become to give up some vegetables to get even more fruit. Economic explanations thus move from accounts of choice on the basis of cheapness to combinations of cost-consciousness with maximizing satisfaction or utility within the budgetary constraints of income.

A number of elegant economic laws have been developed to explain and predict food consumption and patterns of expenditure, such as the wonderfully named law of starchy staples. This predicts that as income increases, traditional staple foods are replaced with more refined staples (e.g., the replacement of sorghum or millet with white rice or wheat),

and this is a pattern of change that is being seen today in countries in transition. Such 'laws' and economic analyses demonstrate how factors such as price and income influence food choice and set constraints to it.

Social and Cultural Influences

As Douglas, a famous anthropologist, stated, food is not feed, and food and eating serve many nonnutritional social functions, such as the expression of identity whether individual or national, the maintenance or rupture of social relationships, and religious and symbolic functions. These subtly influence not only what we eat but also how and where we eat and with whom we eat. Food and drink are not taken at random, but within the context of social exchanges between people and within social contexts, such as the family. Therefore, argue the social scientists, to understand the food choices of individuals we must understand the social contexts within which they occur and also the social rules that influence many aspects of our food choice. These can be seen to work at a number of different levels or in a number of ways on the food choice of individuals.

At the most basic level, it is arguably cultural rules of food use that specify the edible versus the inedible. Although the definition of 'food' might appear to be self-evident, there is huge variation cross-culturally in what is classified as edible. This is perhaps illustrated best by examining differences in what are considered edible animal species in different societies (guinea pigs—a tasty snack or domestic pet?). Beyond this basic definition of the edible versus inedible, in all cultures foods are further classified into complex subgroupings, such as hot and cold foods, foods appropriate for meals, snacks, and special events, foods to be eaten/avoided during pregnancy, and so forth. Cultural rules may also specify the food needs of different categories of people (e.g., the young or the pregnant), meal formats and their patterning over time, the way in which food is eaten and prepared, and the allocation of food within an household.

Taken as a whole, sociological studies of food can be read as a form of lay epidemiology that illustrates that not only are the attributes and values that we give to food largely culturally derived but also beliefs about food are culturally constructed and not the product of ignorance or irrational prejudices. Social science approaches to food choice thus study how choices about food are constructed and negotiated in the context of everyday life and how social rules and contexts influence this, and they can offer insights into what otherwise might appear to be irrational or dysfunctional food choices.

Table 1 A hierarchical model of food choice

Edible substances (as defined by culture and physiology)	
Excluded by	**Subsets of**
Culture and rules of allocation	Permissible foods
Availability and cost	Available and affordable foods
Palatability preferences, attitudes, experience	Preferred and chosen foods

A Hierarchy of Constraints?

There is thus a large range of factors that influence human food choice. These are a complex blend of both positive and negative influences that either encourage or constrain our choice of particular foods as well as a combination of biological, psychological, economic, and social factors. These all operate in very different ways and on different aspects of this phenomenon called food choice. How can these be sorted into any kind of scheme or hierarchy to assess their relative importance in any particular context? Various composite models of food choice have been developed, but these often become so global as to be almost meaningless. Following Wheeler, one solution is to turn the issue on its head and start with an analysis of the factors that constrain or limit choice and so identify the range of choice open to an individual in any particular context and what determines this (**Table 1**).

The relative importance of particular influences or constraints will vary from one context to another and also with how they interact, but such a hierarchical framework allows identification of what the relevant factors may be in any given situation and their relative importance for any given individual and thus what degree of choice is actually available to them.

FOOD COMPOSITION DATA

S P Murphy, University of Hawaii, Honolulu, HI, USA

Overview: Why Compile Food Composition Tables?

Food composition data are an integral component of evaluating and planning nutrient intakes. Without information on the nutrient content of foods, it is not possible to convert dietary intake data, based on foods consumed, into nutrient intake data. The science of developing accurate food composition data has advanced substantially with the advent of sophisticated laboratory equipment and methods for food analyses as well as increasingly powerful computers that are used to compile and store the results. The International Network of Food Data Systems (INFOODS) at the Food and Agriculture Organization has provided guidelines and training to help countries improve their food composition tables. However, comprehensive analyses of the many nutrients and other bioactive components of foods remain both challenging and expensive, and given the enormous variety of foods consumed throughout the world, food composition tables are often incomplete. Often, the intake calculations that are based on these tables must be regarded as estimates of true nutrient intakes. Nonetheless, for many purposes related to promoting health, nutrient intake estimates are essential and can lead to actions that improve the health of both individuals and populations.

Procedures for Compiling Food Composition Data

Nutrients to Include

As the number of recognized biologically active components of foods increases, compilers of food composition tables are faced with an ever-expanding list of possible nutrients and other components to include. Some of these are given in **Table 1**. The current version of the US Department of Agriculture's Standard Reference Database (release 16-1) contains up to 125 components for each of more than 6600 foods. Because a wide variety of analytic methods is available for determining and reporting nutrient levels in foods, it is useful to have a common convention for naming the nutrients. Many compilers are using standard nutrient names, called tag names, that have been proposed by INFOODS.

Nutrient values in a food composition table normally reflect the level in 100 g of the food item. Thus, the intake of a nutrient from a specific food can be calculated if the amount consumed is recorded in gram weights (e.g., if 100 g of whole milk has 119 mg of calcium, and a person drank a cup of milk weighing 244 g, then the intake of calcium from the cup of milk would be 291 mg). Many food composition tables also contain the weight of typical portions of each food item, and thus the nutrient profile for these portions can readily be calculated.

A related issue is whether to show nutrient profiles per 100 g of the food as consumed or 100 g of the food as purchased. Because some parts of a food may be discarded as inedible, the nutrients per 100 g as purchased will be lower for these foods. For example, a banana skin is approximately one-third of the weight of a banana. If 100 g of a banana without peel has an energy content of approximately 90 kcal, then the energy content of 100 g of banana with peel is only 60 kcal. Composition tables may simply carry a variable for the average percentage of the food that is edible, but it is obviously important to match the method used to measure the food intake (with or without inedible portions) with the way the composition of the food is given in the table.

Foods to Include

There is also a constantly expanding number of foods available in most regions of the world due to changing

Table 1 Nutrients and other food components that are often included in food composition tables

Macronutrients	*Typical units (usually per 100 g)*	*Related components that may be present in a table*
Energy	kcal and/or kJ	
Protein	g	Individual amino acids; nitrogen
Fat	g	
Carbohydrate	g	May be calculated by difference (100 minus grams of the other macronutrients)
Alcohol	g	
Water	g	
Ash	g	
Carbohydrates and fiber		
Sugars	g	Individual monosaccharides and disaccharides
Starch	g	
Dietary fiber	g	May be divided into soluble and insoluble fiber
Nonstarch polysaccharides	g	
Lignans	μg	
Glycemic load	g	Glycemic index
Fats		
Saturated fatty acids	g	Individual fatty acids
Monounsaturated fatty acids	g	Individual fatty acids
Polyunsaturated fatty acids	g	Individual fatty acids
Omega-3 fatty acids	g	
Omega-6 fatty acids	g	
Trans fatty acids	g	
Conjugated linoleic acid	mg	
Cholesterol	mg	
Minerals		
Calcium	mg	
Phosphorus	mg	
Magnesium	mg	
Iron	mg	Heme iron, non-heme iron
Zinc	mg	
Sodium	mg	
Potassium	mg	
Selenium	μg	
Copper	μg	
Chromium	μg	
Molybdenum	μg	
Manganese	mg	
Fluoride	mg	
Iodine	μg	
Vitamins		
Vitamin A	IU, μg RE, μg RAE	
Carotenoids	mg	Individual carotenoids
Retinol	μg	
Vitamin E	mg α-tocopherol	mg α-tocopherol equivalents, synthetic α-tocopherol
Tocopherols	mg	Individual tocopherols
Vitamin C	mg	
Vitamin D	μg	
Thiamin	mg	
Riboflavin	mg	
Niacin	mg	Niacin equivalents
Folate	μg, μg dietary folate equivalents	Synthetic folic acid
Vitamin B_6	mg, μg	
Vitamin B_{12}	μg	
Pantothenic acid	mg	
Biotin	μg	
Vitamin K	μg	
Other food components		
Isoflavonoids	mg	Individual isoflavonoids
Flavonoids	mg	Individual flavonoids

agricultural practices, increases in imported foods, and new commercial product formulations. Including all these foods in a single composition database has not been attempted, and instead, regions and countries have focused on compiling food composition tables that are specific for their populations. Several types of foods are usually found in such composition tables.

Basic agricultural commodities are considered essential in most tables. These include both plant and animal foods that are typically consumed by the population of interest. Frequently, composite values are given in composition tables and reflect an average of multiple samples collected from different regions of the country. For example, nutrient profiles of oranges in the United States are an average of different species of oranges grown primarily in California and Florida; the average is weighted to reflect the production of different types of oranges. Composition tables may contain both cooked and raw values for a food item, which can be helpful if a food is consumed both ways (e.g., tomatoes). Because nutrients may be lost during cooking, and also because the water and fat contents may change, it is important to have nutrient values that correspond to the form of the food that is actually consumed. In addition to cooked and uncooked forms, basic foods may also be available in processed forms, such as canned, frozen, or dried. Many of these processing procedures can alter the nutrients in foods, and thus it is sometimes desirable to have composition data for the differently processed forms of the food.

In addition to basic foods and ingredients, food composition tables usually also contain values for mixed dishes. Some of these mixtures may reflect common recipes that are used in the home, and others may represent commercially available foods, either in food stores or in restaurants. Because recipes may vary greatly, it is particularly useful if the software that accesses the composition table allows the user to alter the recipe ingredients.

Food Descriptors to Use

It is a challenging task to clearly and completely describe the foods that are in the food composition table. Food names for most tables are devised by the compilers using common names plus appropriate descriptors (e.g., cooked, raw, and canned). Ideally, the food descriptors should fully define the food item so there is no ambiguity about the scientific name, the part of the plant or animal that is consumed, and any cooking or processing that has been applied. Several schemes for describing foods have been proposed, including guidelines from INFOODS and the LanguaL system that is used by several European countries.

Sources of Composition Data

Food composition data come from a variety of sources (**Table 2**). Those that are based on laboratory analyses of foods are considered the gold standard for composition tables. Appropriate methods are often specified by the Association of Official Analytical Chemists. Accurate analytic procedures also should incorporate quality control methods, including the proper use of internal standards, and the analysis of duplicate samples to determine intersample variability.

The scheme that is used to obtain and prepare the food samples for analysis is also important. Ideally, the sample collection scheme would match the foods that are reported by the population of interest. For example, if the purpose of the analysis is to determine the nutrient content of a specific person's diet, then the analyses should be performed for a composite of the foods actually consumed or, in the case of feeding studies, for a composite of the foods to be fed. Because such analyses are usually not feasible, more general composition data are often used. Most food composition tables are intended for use across a broad population, and thus the sampling scheme should reflect the types of foods typically consumed. Often, this is an

Table 2 Sources of data for food composition tables

Source	*Comments on accuracy*
Analytic values	
By the table compilers	Generally the most accurate type of data if sampling and analyses are appropriate.
From published literature	May not be correct if the food items differ on important characteristics.
From the food industry	Values from food labels may be underestimates for nutrients added to foods.
From another composition table	May not be correct if the food items differ on important characteristics.
Imputed values	
Based on a similar food	The accuracy of this process depends on how closely the foods can be matched.
Assumed zero	Can be very accurate for some nutrients (fiber in animal products; vitamin B_{12} in plant products)
Calculated values	
From another form of the same food	Usually requires assumptions about changes such as losses due to cooking.
From a recipe	Typical recipe ingredients and proportions may be difficult to collect.
From a product formulation	Useful method for obtaining nutrient values that are not on the product label.

expensive and challenging task, particularly for national and regional tables. Once the sampling plan is devised, it is also necessary to decide on the protocol for storing and preparing the samples for analysis. Considerable nutrient losses can occur if samples are handled improperly because many nutrients are labile to heat, light, and exposure to oxygen. Methods of indicating the quality of analytic data for foods have been proposed, including attaching a confidence code to each data point so that users can decide if the composition data are appropriate for their purposes.

Analytic data are published in various forms. Many countries or regions publish tables, either printed or in electronic form. For example, large tables are compiled by the US Department of Agriculture and also by the Royal Society of Chemistry and the Department for Environment, Food and Rural Affairs in the United Kingdom. Other sources of analytic data include journal articles and books. A particularly useful journal for food composition values is the *Journal of Food Composition and Analysis*, edited by the INFOODS secretariat.

However, analytic data may not be available for all foods and nutrients of interest, and time and cost constraints may prohibit chemical analyses of these foods. In some cases, these values are left blank, and such missing values are assumed to be the same as zero values by most programs that calculate nutrient intakes. Because an appropriately estimated value for a nutrient is usually superior to a value of zero, several methods are used to derive such estimations. A frequent approach is to obtain data from the food composition table of another region or country. If the foods are of the same genus and species, then the nutrient profiles should be similar. Although variations can occur due to different cultivars within a species, as well as different conditions during growing, storage, and processing, such borrowed composition values are considered preferable to a missing value. Another approach to estimating nutrient profiles is to impute a value from a similar food that does have analytic data. If the known nutrients are similar for two foods (e.g., the macronutrient profiles), and the type of food is similar (e.g., dark green vegetables), then the missing value may be replaced with an imputed value from the similar food. Sometimes, calculations are performed to adjust for differences between the foods. Values for a cooked food can be imputed from a raw food by applying factors for nutrient losses during cooking and adjusting for differences in moisture (and sometimes also fat) content.

Another common method of obtaining composition data is to calculate the values from the ingredients in a mixture. For home-prepared foods, such calculations involve determining the proportions of each ingredient (a recipe) and any changes in moisture content during preparation (the yield). There are many challenges in determining recipes that are appropriate for a large group of individuals, but it is equally challenging to try to collect appropriate samples of these mixtures for chemical analysis. For some mixtures, multiple recipes, and thus multiple entries on the food composition table, may be needed (e.g., home-prepared beef stew, commercially canned beef stew, and beef stew from a restaurant).

Composition data may also be obtained from the nutritional labels on commercial food products, if they are available. Most countries require a list of ingredients on the label, and if the proportions of each can be estimated, then a recipe can be devised. It is more useful, however, if the label gives information on the nutrient profile, for at least some of the main nutrients. These values can be incorporated directly into the composition table and also are useful in estimating the proportions of each ingredient (e.g., the amount of wheat flour may be estimated from the carbohydrate content). Because even the most comprehensive nutrition labels seldom give values for all nutrients of interest for the users of food composition tables, recipes will be needed to estimate values for nutrients not shown on the label. Caution should be used with label values for nutrient-fortified products. Good manufacturing practice dictates that the label underestimate the levels of any nutrient, particularly vitamins, that may degrade with time. This ensures that nutrient levels are at least as high as those stated on the label, even after a substantial time on the shelf. Thus, it is always preferable to obtain average nutrient values directly from the product manufacturer if possible.

Compilations of Composition Data for Dietary Supplements

As the use of dietary supplements increases worldwide, there is an increasing need to quantify intakes of nutrients and botanical products from these sources. Compiling nutrient profiles of such products into tables can be very time-consuming because the number of products continues to grow and formulations of existing products often change over time. Furthermore, average analytic data are seldom available from the supplement manufacturers, and thus database compilers must rely on whatever information is available from the product label. In many countries, a label showing the amount of each nutrient in the product is required.

Uses of Food Composition Data

Evaluate or Plan Nutrient Intakes

Uses of food composition data are varied, and the method of compiling the data may need to be

tailored to the application of interest. Perhaps the most common use of composition data is to estimate intakes of individuals. Dietitians and other health professionals may wish to evaluate the quality of a person's current diet or to plan for changes in a diet to meet specific nutrient goals. For example, a person with elevated serum cholesterol may be counseled to reduce saturated fat and cholesterol intakes and given specific menus of diets low in these nutrients. In order to compile these menus, a nutritionist would require access to composition data for saturated fat and cholesterol in a variety of commonly consumed foods. Although the composition data are often averages across many samples of a food, this level of precision is usually acceptable for counseling applications, where long-term compliance with dietary recommendations is being examined.

Similarly, researchers often evaluate or plan diets for individuals as part of nutrition studies. However, for these applications, the required level of precision of the data may be higher. In a feeding study, it may be crucial that the composition of the menus be tightly controlled, and thus average values across many samples are not appropriate. Indeed, it may be necessary to conduct laboratory analyses of the diets that are used in feeding studies rather than rely on more general composition data.

Food composition data are also used to plan and evaluate intakes of population groups, as in dietary surveys, or in choosing menus for institutions such as schools and hospitals. When intakes are to be evaluated and averaged across a large number of people, the use of aggregated food composition data is appropriate and would lead to less error in the estimates than relying on only a small number of samples.

Some users of food composition data may wish to evaluate the nutrient content of foods as purchased at stores or markets. For example, food consumption data may be evaluated for households rather than for individuals, and these data are usually recorded as foods that are purchased for the household. In this case, the composition data must also be given per quantity of food as purchased, before any inedible portions are removed, and before cooking. Likewise, nutrition education for families may focus on making shopping lists of nutritious foods for the household, and composition data for foods as purchased will be helpful.

Food composition data may be used at an even more aggregated level in estimating food use for a region or country. For example, the US Department of Agriculture estimates the nutrient content of the US food supply annually in order to track trends. These data, often called disappearance data, assign nutrient composition values to the major commodities that are produced (minus any exports) or imported for use as food (e.g., flour, sugar, and butter). The amount of each commodity that is available for consumption is multiplied by the corresponding nutrient composition to give an estimate of nutrient consumption per capita.

Estimate Nutrient Profiles for Product Labels

The food industry also uses food composition data to justify health claims for their products (e.g., to indicate that a food product is low in fat) and, in many countries, to obtain information for printing nutrient information on the product labels. Nutrition labels are often required and are considered an important consumer guide to selecting healthy diets. Large manufacturers of processed foods usually obtain laboratory analyses of the nutrients in their products, but smaller companies may rely on calculating nutrient profiles from the product's ingredients. Restaurant chains are also increasingly likely to provide nutrient composition data for the items on their menus.

Evaluate or Plan Food Intakes

Another use of food composition data is to examine intakes from food groups—at the level of the individual, the population group, or the country. Such analyses are facilitated if each of the food items in a food composition table is assigned to a food group using a predetermined food grouping scheme. Once foods are categorized into groups, it is possible to examine intakes from each group (as grams per day) as well as nutrient intakes from each group (e.g., dietary fiber from grains). A further refinement of the food group assignments includes an indication of the number of servings that each food contains (usually per 100 g of the food). Thus, 100 g of orange juice contains approximately one-half of a serving of fruit (assuming $\frac{3}{4}$ cup, or 188 g, of juice is considered a serving). Using such a scheme, it is possible to calculate the number of servings consumed from each food group in a day and compare these intakes to dietary guidance for a country. The Food Guide Pyramid is used for such guidance in the United States, and the US Department of Agriculture has developed a Pyramid Servings Database that may be used to calculate intakes of 30 food groups (**Table 3**).

Limitations of Food Composition Data

Poor Analytic Procedures

Accurate chemical analysis of the nutrient content of foods is a challenging process and may yield

Table 3 Food groups in the USDA Pyramid Servings Database

Grain group	Total grain
	Whole grain
	Nonwhole grain
Vegetable group	Total vegetables
	Dark-green leafy vegetables
	Deep-yellow vegetables
	White potatoes
	Other starchy vegetables
	Tomatoes
	Other vegetables
Fruit group	Total fruits
	Citrus fruits, melons and berries
	Other fruits
Dairy group	Total dairy
	Milk
	Yogurt
	Cheese
Meat group	Meat, poultry, fish
	Meat (beef, pork, veal, lamb, game)
	Organ meats
	Frankfurters, sausage, luncheon meats
	Poultry (chicken, turkey, other)
	Fish (fish, shellfish, other)
	Eggs
	Soybean products (tofu, meat analogs)
	Nuts and seeds
	Cooked dry beans and peas
Pyramid tip	Discretionary fat
	Added sugars
	Alcohol

inaccurate results for a variety of reasons. For some nutrients (and other food components of interest), accurate procedures may not be available. For example, the usual procedures for analyzing the folate content of foods are known to underestimate the actual levels, and thus estimates of folate intakes are likely to be low. Both the extraction procedures and the enzyme digestion treatments may be less than optimal for food folate, and although recent procedures solve some of these problems, folate values on most food composition tables are probably underestimated. Dietary fiber in foods provides another example of possibly incorrect methods. Many older food composition tables contain a variable named fiber, but the values are for crude fiber. Crude fiber is measured using procedures that destroy some of the physiologically important fibers, and thus it is an underestimate of the true dietary fiber content. Recent methods measure either total dietary fiber (defined as all fibers that are not digested in the human gut, including lignans) or nonstarch polysaccharides (excluding lignans).

Inaccurate analyses may also occur when access to the best laboratory equipment is not available, either because the costs are too high or because the technical expertise to use the equipment is not available. For many of the antioxidant compounds, such as carotenoids and tocopherols, quantification by mass spectrometry (MS) yields the most sensitive detection limits, although analysis using high-performance liquid chromatography (HPLC) is adequate in most cases. However, because the equipment, maintenance, and reagents are often too expensive, laboratories (particularly in developing countries) may use older methods, such as spectrophotometry combined with open-column chromatography. Nutrient values derived using such methods are less accurate than those resulting from HPLC and MS methods.

Users of food composition tables should ask when and how analytic values were obtained. Likewise, compilers of these tables should clearly document the analytic procedures used to obtain all values and ensure that such information is readily available to users.

Inappropriate Sampling Procedures

The way foods are sampled and collected can also impact the quality of the composition data. Many nutrient values vary substantially across multiple samples of the same food. Nutrient composition can be affected not only by the species and cultivar of a plant but also by the growing conditions, time of harvest, and length of storage. Because it is seldom feasible to match all these factors with the diets to be analyzed, composite values, based on the average of multiple samples, are usually given in food composition tables.

Inappropriate Nutrient Forms and Expressions

An important limitation for some food composition tables is the method of expressing the activity of the nutrient. The estimation of nutrient activity is a large and expanding field of research and includes studies of both the absorption of the nutrient and its bioavailability for metabolic processes. For example, iron bioavailability has been debated extensively, and many algorithms for calculations have been proposed. Virtually all these require separating iron that is found as heme-iron in animal products from nonheme sources of iron. If these two variables are not carried on the composition table, it will not be possible to calculate iron bioavailability for specific intakes.

Vitamin A also illustrates the complexity of properly expressing the physiologically meaningful form of a nutrient. Until 1967, the vitamin A value of foods was expressed in international units (IUs), which was equivalent to 0.3 μg of retinol and 0.6 μg of β-carotene. This form of expression is still used in many

composition tables and also on nutrition labels for both foods and dietary supplements. A more relevant unit of activity, micrograms of retinol equivalents (REs), was adopted in 1967 and has been used to set recommended nutrient intake levels. A lower relative pro-vitamin A activity of carotenoids was assumed, and thus it is not possible to directly convert IUs into REs, unless both the retinol and the carotenoid levels of a food are given. Recently, the estimated pro-vitamin activity of carotenoids has been further reduced and a newer unit proposed: micrograms of retinol activity equivalents (RAEs). Again, it is not possible to convert between REs and RAEs (or between IUs and RAEs), unless the retinol and carotenoid components of a food are available. Increasingly, food composition tables are carrying separate variables for the specific forms of nutrients such as vitamin A and iron, but this is not the case for many of the older tables. Such disaggregation is an obvious advantage because it allows for recalculation of nutrient activity when there is a scientific consensus that new availability factors are needed. Tables that cannot be easily updated to reflect new information will lag behind the current knowledge and thus will have more limited usefulness.

Lack of Internal Consistency and Integrity

Compiling food composition tables involves recording nutrient profiles for many foods and many nutrients, and errors can easily occur during this process. Quality control is important in this field, just as it is in the development of any product. Developers of the most accurate composition tables always include procedures to ensure that the numbers are correct. In addition to having several people review any new data before they are added to a table, several automated types of integrity checks are possible. For example, the energy value of a food item should approximate the value calculated from the main components (4 kcal/g times the grams of protein and carbohydrate, plus 9 kcal/g times the grams of fat, plus 7 kcal/g times the grams of alcohol), and any deviations should be investigated. Likewise, the sum of all the macronutrients (water, protein, fat, carbohydrate, alcohol, and ash) should be approximately 100 g if the nutrient profiles are given per 100 g of the food. Quality control procedures such as these should be an integral part of the compilation of food composition data.

Conferences on Food Composition Issues

Most of the issues discussed in this article have been addressed at conferences specifically convened to present advances in food composition data. In the United States, the National Nutrient Databank Conference has been held annually for the past 28 years. In addition, the International Food Data Conference has been held biannually for the past 10 years. The proceedings from several recent conferences have been published in the *Journal of Food Composition and Analysis*.

FOOD FOLKLORE

J Dwyer and J Freitas, Tufts University, Boston, MA, USA

Introduction

Food folklore consists of traditional beliefs, legends, and customs about food that have been transferred from one generation to the next by word of mouth. For thousands of years, folklore espousing food's nutritional and medicinal benefits has influenced dietary practices. In this chapter, the history and evolution of food folklore is reviewed, and a guide is provided for determining the scientific validity of food folk beliefs.

History of Food Folklore

In addition to sustaining life, food has come to play a symbolic role in both religious ceremonies and cultural traditions. For example, rice has been associated with fertility in many cultures for millennia and continues to be thrown on newly married couples today. Similarly, bread has been regarded as a symbol of divinity and has played an important role in religious services and observances.

Curative properties have also been ascribed to many foods for thousands of years. In ancient Rome, cabbage was considered the perfect medicinal plant and was prescribed frequently for a wide range of ailments including warts, deafness, and drunkenness. Apples, herbs, garlic, honey, milk, peppers, and many other foods were also highly regarded in ancient cultures for their therapeutic qualities. The prescription of foods as medicines was not necessarily based on scientific fact but instead was often based on early medical theories or magic. The ancient Greeks believed that the body was composed of four humors: blood (hot and moist), phlegm (cold and moist), yellow bile (hot and dry), and black bile (cold and dry). Health was thought to result from a balance of the humors, and illness resulted from an imbalance. To counteract imbalances and restore health, physicians often prescribed specific foods, based on their perceived degree of 'heat' and 'moisture'. For example, fever, a 'hot' 'dry' condition, was attributed to an excess of yellow bile, and 'cool' 'moist' foods, such as cucumbers, were prescribed to treat it. In contrast, oedema, a 'cool' 'moist' condition, was treated with foods that were viewed as 'warm' and 'dry'. The hot, cold, moist, and dry properties of food were also regarded as important in other ancient societies, including China, where achieving a balance between the opposing forces of yin (cold/moist) and yang (hot/dry) has guided traditional medical practice for centuries and continues to be popular today.

The Doctrine of Signatures, based on the notion that 'like cures like', was also popular in the nineteenth century. Therapies were chosen on the basis of similarities of color, aroma, shape, and other characteristics. For example, beet juice, which is deep red, was thought to be an effective cure for blood diseases, while yellow plants were believed to alleviate jaundice and other liver ailments. The pungent odours of onions and garlic were thought to ward off disease, stimulate strength and bravery, arouse libido, and banish evil spirits. Walnuts resemble the brain and so were eaten to improve intellect. The ginseng root, with its resemblance to the human torso, was used by the Chinese as a panacea (**Figure 1**).

The common names of many foods reflect folklore about their curative properties, as shown in **Table 1**. For example, the word ginseng is derived from the root words *gin*, meaning man, and *sing*, meaning essence.

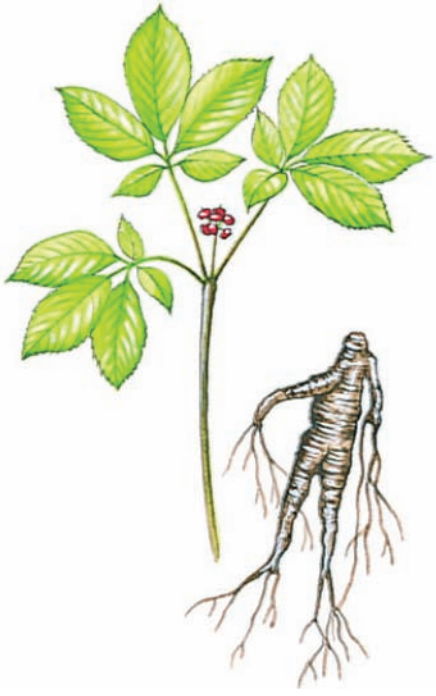

Figure 1 The universal healing properties of ginseng were attributed to the resemblance of its root to the human body. Reproduced with permission from The American Heritage Dictionary of the English Language, Boston, 4th edn, 2000.

Table 1 Food names related to food folklore

Herb (botanical name)	*Folklore*
Blackeye root (*Tamus communis*)	Heals bruises, removes discoloration
Bloodroot (*Sanguinaria candensis*)	Cures blood disorders and heart disease
Birthwort (*Aristolochia longa*)	Alleviates complications associated with childbirth
Eyebright (*Euphrasia officinalis*)	Cures disorders of the eyes
Ginseng (*Panax quinquefolium*)	General human panacea
Heartsease (*Viola tricolor*)	Relieves heart ailments
Liverwort (*Anemone hepatica*)	Relieves liver disorders
Lungwort (*Sticta pulmonaria*)	Cures pulmonary diseases
Maidenhair fern (*Asplenium trichomanes*)	Prevents balding, promotes hair growth
Snakeroot (*Aristolochia serpentaria*)	Antidote for snake bites
Spleenwort (*Asplenium*)	Remedy for disorders of the spleen

Food Folklore Today

While some food folk beliefs continue to be passed down from generation to generation, others have been discarded over the years, and new ones have been introduced. Today, food folklore is spread not only by word of mouth from person to person, but also to large numbers of people simultaneously via the mass media and the Internet. The growing popularity of alternative therapies, organic products, and functional foods has led to the development of new food folklore and increased the popularity of some traditional notions. Several examples of commonly held food folk beliefs of both the past and present are provided in **Table 2**.

Food and nutrition-science concepts that have developed over the past two centuries are newcomers to human thinking about the relationships between food and health. Although some food beliefs, such as the association of carrots with eyesight, have some scientific basis, many others remain unsupported by, or in opposition to, recent scientific findings. Pseudoscience, rather than sound evidence, provides the basis for much of today's food folklore. It is important for food and nutrition professionals to be knowledgeable about current food folk beliefs, because these ideas influence popular views about diet–health relationships. In order to identify beliefs that are of major health significance, it is useful to consider the strength of the belief in folklore and the strength of the scientific evidence surrounding it, as shown in **Table 3**. When folkloric belief and scientific evidence are both strong and in agreement with each other, the folklore is unlikely to pose a major health threat. Similarly, when food folklore and the scientific evidence surrounding it are both weak, few practical problems exist. However, when scientific findings refute, or fail to support, popular food folk beliefs, public health may be threatened. For example, despite folklore that ephedra promotes rapid weight loss, a recent evidence-based review suggests that it does not and that it may even be harmful. Often, though, it is not that the scientific evidence regarding food folklore is weak but that it is unproven or undetermined, indicating that more research needs to be done.

Folklore and Evidence: Fact or Fiction?

Totality of the Evidence

Food folklore cannot be taken as fact without evidence. Single studies are usually inadequate for demonstrating cause–effect relationships, and no single study alone is enough to prove that something is fact or folklore. It is important to consider the totality of evidence and the type and quality of the available research. When many different types of evidence are all supportive of a relationship, the weaknesses of individual studies are mitigated and causal inference is strengthened.

Ideally, the best way to conduct a scientific evaluation of a question is to perform an evidence-based expert review of many randomized double-blind placebo-controlled clinical trials, meta-analyses, and other studies. An evidence-based review often entails the use of statistical techniques to reanalyze the results of many small studies, as well as expert judgment. If all systematic evidence-based reviews produce comparable conclusions, the scientific evidence is good that the folklore belief is justified.

Comprehensive reviews are especially important for far-reaching questions that have implications for large populations. They are also necessary for questions regarding important issues, including life and death, and those that involve very large costs or imply large reimbursements. However, because such reviews are significantly time consuming and require much expertise and money, they can be done only for a few very important questions. For example, the National Institutes of Health (NIH) has sponsored such reviews of obesity treatment, the American Institutes of Cancer Research has done reviews to substantiate their population-based recommendations, and the health

Table 2 Food folkore: current and historic beliefs

Food	*Folklore*
Fruits	
Apple	'An apple a day keeps the doctor away'; prevents cavities and tooth decay
Blueberries	Cure for kidney and urinary-tract ailments; improves vision and memory
Cherries	Cherry gum dissolved in wine relieves a cough; ensure continued fertility
Citrus fruits	Prevent scurvy; Cause low blood pressure; cure the common cold
Cranberries	Prevent scurvy; prevent cure or urinary-tract infections
Currant	Relieves sore throat
Fig	Relieves toothache; mild laxative
Grapefruit	Should be avoided completely when taking medication; burns calories, dissolves fat, aids in weight loss; is 'good for you'
Raspberry	Raspberry leaf tea promotes contractions and aids in labor
Vegetables	
Beets	An effective cure for anemia; help build iron-rich blood
Carrots	Important for good eyesight
Celery	Promotes weight loss
Garlic	Stimulates digestion; inhibits germs; cleanses the blood and intestines; lowers cholesterol and blood pressure
Lettuce	Induces sterility
Onions	Cooked onions cure the common cold; good for the heart
Peppers	Cure for a cold
Potatoes	A historic cure for impotence; prevent scurvy; soothe and soften the skin; are fattening
Spinach	Builds strong muscles
Grains	
Bread	Is the body of the supernatural; cures disease and protects against evil; is a fattening; food brown bread has more fiber than white bread
Flaxseed	Effective cure for constipation; prevents cancer; lowers cholesterol
Oats	Oatmeal and oat bran can prevent heart disease
Dairy	
Milk	Prevents scurvy; helps to heal ulcers; causes constipation; unpasteurized milk has more nutrients than pasteurized; a glass of milk before bed causes drowsiness; mothers who drink a lot of milk have colicky babies; milk and other dairy products are fattening and should be avoided on a low-fat diet; the calcium in milk and other foods causes kidney stones
Yoghurt	Prevents vaginal yeast infections; cures vaginitis, constipation, and diarrhea; yoghurt applied topically heals a sunburn
Meat	
Beef	Eating beef and other red foods causes high blood pressure; extra protein from beef makes muscles stronger
Chicken soup	Cure for the common cold
Eggs	Drinking raw eggs helps build muscle; brown eggs are healthier than white eggs; people with high cholesterol should not eat eggs
Legumes	Beans are a natural laxative
Seafood	Fish is a brain food; fish is good for the heart and prevents heart attacks; pregnant women should avoid eating fish; oysters increase sexual potency
Fat, sweets, and alcohol	
Olive oil	Protects against breast cancer
Cod liver oil	Relieves rheumatism, aching muscles, and stiff joints; prevents rickets
Sugar	Causes tooth decay; causes hyperactivity; eating too much causes diabetes and heart disease
Honey	Is natural and will not raise blood-sugar levels; a mix of honey and water is a good cure for colic
Chocolate	Causes acne; eating chocolate helps to prevent heart disease
Salt	A no-salt diet protects against high blood pressure; sea salt is healthier than table salt; salt tablets prevent muscle cramps
Alcohol	Helps to warm the body in cold weather; acts as a sleep aid if consumed before bedtime; red wine is good for the heart; a nip of brandy cures a cold; drinking alcohol with raw oysters ensures they are safe

effects of ephedrine were recently summarized in an evidence-based review by the Office of Dietary Supplements. Unfortunately, for much food folklore, such studies have never been done.

Type of Evidence

In determining the validity of food folklore, not only the totality of evidence but also the type and quality of available evidence are important. As shown in

Table 3 Folklore: separating fact from fiction

Folklore	Scientific evidence: Strong	Scientific evidence: Weak
Strong	Fact[a]	Fiction/ undetermined[b]
Weak	Emerging science[a]	Fiction[a]

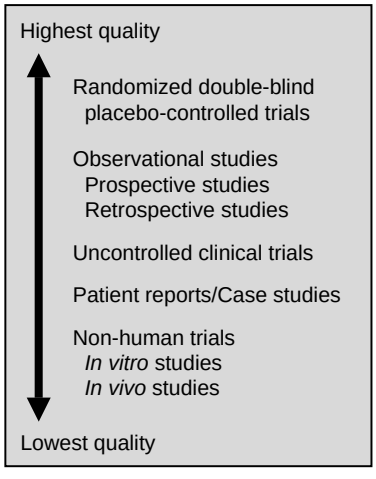
[a]Unlikely to be a major threat
[b]Potential threat to public health

Table 4, the strength of the association between eating a food (cause) and a health outcome (effect) can be ranked according to the type of evidence presented. The best evidence comes from studies that have the most control over the claim or treatment being evaluated and eliminate other factors that may suggest an effect was present, when really it was not. Although randomized double-blind placebo-controlled clinical trials are considered the 'gold standard' for determining diet–health relationships, such studies are rarely available. Lesser levels of evidence must usually be used.

Randomized double-blind placebo-controlled trials When randomized double-blind placebo-controlled trials show a relationship between a specific food and a health effect, the evidence is considered to be very good. These studies exert rigorous control over the claim or treatment being evaluated and over the people who are subjected to it (by randomization) and the assumptions of both the experimenters and the participants (by placebos and blinding). Multiple studies of this type, with an expert review of all other types of data, are considered to be the 'gold standard' for establishing cause–effect relationships. Other types of evidence and studies are lower in the hierarchy, because they are not as definitive in identifying true cause and effect.

Although single randomized trials and non-randomized clinical studies are somewhat less definitive, they are still valuable, because they also permit control over the treatment being evaluated. Often, however, these studies are not large enough, or the study sample is not representative, so the results cannot be generalized to the problem at hand. Other factors that may weaken these studies are not counting of dropouts, lacking or unconvincing placebos, and inappropriate points or biomarkers serving as surrogate end points.

Table 4 Ranking the quality of the evidence



Observational studies Human studies that involve observation rather than direct intervention provide evidence that is satisfactory but less conclusive. These studies are designed to test a relationship between an exposure of interest (folk belief) and a health outcome. Observational studies include both cohort studies (prospective) and case–control studies (retrospective). In a prospective study, a group exposed to the treatment of interest and an unexposed group are followed forward in time. The health outcomes in both groups are observed and evaluated after controlling for confounding factors with the use of statistics. In contrast, retrospective studies compare individuals who have already developed an outcome of interest (case) against those who have not (control). Factors contributing to the development of the outcome are then determined by looking backward in time. Because observational studies cannot be precisely controlled, it is more difficult to establish cause and effect. However, when confounding factors can be adequately controlled for, these studies provide suitable evidence to support diet–health relationships.

Uncontrolled clinical trials Clinical studies in which everyone is treated, in which only those who ask for the treatment are treated, or in which some are treated based on unsubstantiated clinical convictions are suspect. In such studies, no randomization occurs and neither the researcher nor the participant is blinded to the treatment. Therefore, it cannot be determined whether the treatment is actually the cause of the observed results or whether biased

convictions of both experimenters and study participants are falsely contributing to the results. Better evidence is needed before it can be stated with assurance that the folklore based on such observations is true.

Patient reports, case studies, and folklore Even weaker human evidence of cause and effect comes from single medical case reports and anecdotal evidence. These types of evidence are also biased since those who experience success from the treatment are much more likely to report their stories than those who do not.

Animal studies and laboratory experiments Non-human studies involving living animals (*in vivo* studies) or tissue cultures (*in vitro* studies) are useful in providing information on the possible biological plausibility, dose response, and action of a treatment. However, their ability to predict outcomes in humans is poor. Therefore, these studies are unconvincing and should be used only to support other types of evidence.

Guide for Separating Food Folklore Facts from Fiction in Clinical Situations, and A Practical Example

For summarizing and evaluating food folklore involving diet–health relationships, health professionals need to not only evaluate the evidence but also use their clinical judgment and communications skills to relate this to clients or patients. How can food folklore be evaluated in discussions with laypeople and in counselling situations? The strategies are similar to those employed in research and in more formal evidence-based reviews, but contextual realities require tailoring of the approach. One method of evaluation is provided, as shown in **Table 5**, and an actual clinical example follows.

The problem One example of currently popular food folklore is the notion that people on medication should not drink grapefruit juice. Although there is scientific evidence that grapefruit juice interacts with certain medications, making them incompatible, the facts do not suggest either that grapefruit must be eliminated from the diet of those taking medications or that all drugs exhibit these interactions. The process of reviewing this food folklore with the patient to arrive at this conclusion is outlined in detail below.

Table 5 Steps to evaluating food folklore in clinical situations

1. Report
2. Review
3. Recall
4. Relate
5. Recommend
6. Revise

In the late 1980s, in a study examining the interaction between alcohol and felodopine (a calcium antagonist used to lower blood pressure), it was accidentally discovered that grapefruit juice, which was being used as a placebo, dramatically altered the drug's metabolism. The drug was a common one, the juice dose – about 6 ounces (180 ml) – was within the range many people drink, and the effects were large (similar to a doubling of the drug dose). Therefore, it was of potential clinical importance. Since then, more than 200 scientific papers have been published in peer-reviewed journals on the issue of drug interactions with grapefruit, confirming the original observations. By the mid-1990s, the finding had received a great deal of media coverage and the notion that grapefruit juice was dangerous for those on prescription drugs had become a subject of food folklore. This particular bit of folklore is an example of a strongly held belief for which there is some scientific evidence. Under the circumstances, how should clinicians advise patients?

Report In counselling, it is important for the clinician to relate to the patient and establish two-way communication to learn about the folk belief. It may be useful to determine the strength of the individual's conviction about this folklore as well as the source of the belief and whether there is a potential conflict of interest. When the health professional actively listens, it is more likely that the patient will listen, understand, accept, and follow recommendations.

Review In clinical situations, it is also important for health professionals to review all the evidence surrounding the patient's professed food folk belief. A vital piece of information to consider is safety. Although many prescription drugs have side-effects, they are taken under the supervision of a physician, who can monitor adverse effects and take steps to control them. Because folk remedies are often self-administered, such safeguards are lacking. If there is evidence that the implementation of food folklore is likely to be hazardous to health, it must be discouraged. Folk remedies that are effective for one purpose but have negative side-effects must also be cautioned against.

For example, when the patient's prescription drug is one that is metabolized by cytochrome 3A (CYP 3A), a dramatic effect can occur if grapefruit juice or other forms of the fruit are consumed. Grapefruit juice enhances the effects of these drugs over time by decreasing their oral clearance. However, the effects of the interaction depend on the nature of the drug (for some drugs there is little or no effect) and the size of the interaction. Interaction occurs only if the drug is metabolized by CYP 3A, if it normally undergoes pre-systemic extraction with CYP 3A, and if it is given orally. The interactions vary. For example, with the statins – drugs commonly used to lower serum cholesterol – they are strong for simvastatin and lovastatin, moderate for atorvastatin and cervastatin, and low for fuvastatin and pravastatin. Similarly, sedatives, hypnotics, and other drugs vary as to whether they induce interactions or not.

Recall The CYP P450 superfamily consists of many enzymes. They are labelled as follows: CYP (family 1, 2, 3, etc.) (subfamily A, B, C, etc.) (isoform 1, 2, 3, 4, etc.). There is individual variability in the expression of these enzymes, which is probably in part genetic.

CYP 3A is an enzyme that is involved in the metabolism of many drugs. It is present in the liver and gut mucosa and is induced or inhibited by drugs and other chemicals. Under certain conditions, components of foods can also affect it. The CYP 3A enzyme in the gut mucosa (enteric CYP 3A) is affected by grapefruit juice, but CYP 3A in the liver is not. The phytochemicals that are thought to have these effects are furanocoumarin derivatives in the juice, which reversibly and irreversibly inhibit the CYP 3A in the gut mucosa. When grapefruit juice and certain drugs are taken together orally, this leads to effects on their pre-systemic extraction (first-pass metabolism). In consequence, pre-systemic extraction of the drug is reduced, and, because of this, more of the drug reaches the circulation over time. With this increased systemic exposure to the drug, there is an increased drug effect. The duration of the juice's effect depends on the dose and on the time it takes for the enzyme to regenerate. The liver CYP 3A is not affected by grapefruit juice (although it may be affected by some drugs that also affect gut CYP 3A). Thus, the grapefruit–drug interaction does not happen with drugs administered intravenously, since they bypass the gut.

About one-fifth of American households consume grapefruit juice, and it is considered a 'good food' since it has the American Heart Association heart check and the American Cancer Society endorsement. Many older people take their medications and juice together at breakfast. Many people who are elderly take medications, and some of these drugs may pose problems. Therefore, this folklore is highly relevant from the clinical standpoint.

For the grapefruit interaction to take place, the patient must be taking a drug that affects the gut CYP 3A and he or she must express a significant amount of CYP 3A. People differ in these respects, and there may be racial as well as other genetic differences.

Relate The clinician or nutrition scientist must build on his or her own knowledge and that available from expert reviews or sources and place it in the clinical context. Common sense is needed to fit the information to the patient's realities. The facts, which are that most drugs do not interact with grapefruit, must be related to the folklore and the patient's actual condition. Many grapefruit–drug interactions are modest and not clinically important. Fortunately, for every therapeutic class of drugs there is an option that is not affected by the grapefruit interaction.

Recommend In responding and making recommendations, considerations include their importance, feasibility, and effectiveness for the patient. The information is then particularized to fit the patient or questioner's problem and needs.

This is the time to particularize for the patient and lead him or her to the next level of understanding. With many drugs there is no interaction, and the patient can be told to drink the juice if he or she wishes but to alert the physician if adverse reactions occur. It may be possible to change the medication if a major interaction exists, or, for modest interactions, it may be enough to avoid taking drugs and grapefruit juice at the same time and to avoid consuming large quantities (four or more glasses) of juice.

The patient should be praised for asking about possible food–drug interactions and told that these reactions sometimes occur, but do not usually exist. Is the information relevant – that is, if the patient is on a statin, is it the type that is involved in interactions? Does the patient *want* to drink grapefruit juice? If not, the issue is moot. What are patient reactions, and is reassurance needed?

Revise Fortunately, in counselling, although a relatively rapid response is usually required, there is an ongoing relationship with the individual that permits follow-up. The clinician can follow up and revisit the issue later if necessary when more information becomes available or when additional questions arise.

For example, a patient might ask whether, since the drug effect is enhanced with the consumption of grapefruit juice, he or she could save money by taking more grapefruit juice and continuing with lovastatin. The response to this legitimate question is no, not because it is theoretically impossible but because it is difficult to titre the drug, individual differences exist, and reactions are unpredictable, so such a strategy is not recommended.

Conclusions

Food folklore is alive and well and is likely to continue. For summarizing and evaluating food folklore involving diet–health relationships, health professionals need to not only evaluate the evidence but also use their clinical judgment and communications skills to relate this to patients. The six Rs (report, review, recall, relate, respond, recommend, and revise if necessary) provide a guide for evaluating food folklore in clinical situations.

FOOD FORTIFICATION

Contents

Developed Countries

R Nalubola, Center for Food Safety and Applied Nutrition, US Food and Drug Administration, MD, USA

Published by Elsevier Ltd.

Introduction

Food fortification is increasingly recognized as an effective public health intervention to alleviate nutritional deficiencies. Nutrients may be added to foods to either restore nutrients lost during processing (restoration or enrichment), introduce nutrients not naturally found in the food, or increase the levels of nutrients to above those naturally present in the food (fortification). The terms 'enrichment' and 'fortification' are often used interchangeably to simply refer to the addition of nutrients to food; however in some countries these terms have specific regulatory definitions. In this article, food fortification refers to all such nutrient additions.

History and Current Market Place

Food fortification has been practiced for several decades in developed countries. Historically, certain staple foods have been fortified to alleviate deficiency diseases in the general population, such as the iodization of salt to alleviate goiter, addition of vitamin D to milk to prevent rickets, and enrichment of cereal products with thiamin and niacin to alleviate beriberi and pellagra. For example, in the US, fortification began with the iodization of salt in the State of Michigan in 1924. The practice of salt iodization had spread rapidly throughout the rest of the country by 1928. With the revolution of nutritional science and the elucidation of chemical structures of several nutrients in the 1930s, the production of synthetic preparations of nutrients became possible. By 1934, vitamin D was routinely being added to milk. Although an effort to enrich cereal flours and products with B vitamins and iron started in the 1930s, the enrichment program began in earnest only in 1941 with about 40% of the flour in the country being fortified by 1942. Furthermore, in 1951, the Committee of Food and Nutrition of the National Research Council recommended the addition of vitamin A to table fats (margarine). Several other developed countries experienced similar initiation and implementation of food fortification as a strategy to alleviate nutrient deficiencies in the general population. More recently, cereals fortified with folic acid have been introduced in several countries to increase the folic acid intake of women of childbearing age and reduce the rates of neural tube defects, and the results are already measurable. Foods commonly fortified in developed countries are listed in **Table 1**.

Although the original intent of food fortification was to correct or prevent widespread nutrient deficiencies, the focus now has shifted in developed countries to optimal intakes of nutrients for the prevention of chronic diseases and for overall health and well-being. Classic nutrient deficiency diseases such as goiter and pellagra are no longer common in developed countries at least, in part, due to food fortification programs. However, suboptimal intakes of nutrients such as calcium and vitamin D may occur. In addition, there is heightened consumer awareness and demand for more healthful foods. Consequently, food industries perceived a market for foods with improved nutritional profiles, resulting in a proliferation of fortified foods in the current market place. Ready-to-eat breakfast cereals are a prime example of industry-initiated food fortification. Published reports indicate that in 1969, only about 16% of the breakfast cereals in the US market place were fortified; that number rose to about 92% in 1979 following certain legislative actions providing more flexibility to industry for the addition of nutrients to foods. A market survey in Germany highlights the heterogeneity of current fortification practices: a total of 288 fortified foods in six different food categories (beverages, sweets, cereals, milk products, powdered instant beverages, and ready-to-eat meals) were found to be fortified with a wide range of nutrients.

Table 1 Foods commonly fortified in developed countries

Foods	*Nutrients*
Cereal grain flours and products	Thiamin, riboflavin, niacin iron, and folic acid
Milk and milk products	Vitamins A and D
Fats and spreads	Vitamins A and D
Salt	Iodine
Ready-to-eat breakfast cereals	Many vitamins and minerals
Juices and other beverages	Vitamin D and calcium
Infant foods	Many vitamins and minerals

Characteristics of a Fortification Program

Food fortification can be mandatory (required by government regulations) or voluntary (permitted by government regulations and policies). Some characteristics of both types of fortification programs are presented in **Table 2**. As with any intervention, each of these has certain advantages and limitations that have to be considered to determine the regulatory course that is most appropriate for the country and for the public health concern at hand. For example, it is reported that voluntary fortification of foods with folic acid in Australia and New Zealand, while demonstrating benefits, has not reached the target population to the extent intended. Therefore, policymakers are considering mandatory fortification as an option to ensure sufficient folate intake among all women in Australia and New Zealand.

At the international level, the Codex Alimentarius Commission has adopted a set of criteria which allow for the rational addition of nutrients to improve the nutritional quality of the overall food supply and prevent indiscriminate fortification of foods, while acknowledging that the need for, and appropriateness of, addition of nutrients to foods will depend on the nutritional problems of a country, the characteristics of the target populations, and

Table 2 Characteristics of mandatory and voluntary food fortification

Mandatory fortification	*Voluntary fortification*
• Initiated by government[a]	• May be initiated by government or by industry
• Regulations require addition of nutrients	• Regulations provide for optional addition of nutrients
• Food vehicle(s) are staple foods consumed in significant and relatively stable amounts	• Both staple and nonstaple foods are used as food vehicles
• Driven primarily by a documented need for a public health intervention	• Driven primarily by consumer demand and market forces
• Resource-intensive, coordinated multi-sector effort	• Relatively fewer resources are needed, particularly from the public sector
• Targeted to reach populations at risk of deficiency	• Can be introduced quickly
• Excessive intakes of fortified nutrients are minimized	• In the case of breakfast cereals, proven to make substantial contributions to nutrient intakes
• Adverse effects on other nutrient intakes or health conditions due to fortification are curtailed	• Random fortification and overfortification of the food supply is a potential concern although this can be minimized by appropriate regulatory restrictions
• Fortification levels and food vehicles are tightly controlled	
• A cost-effective nutrition intervention for governments	
• Proven to be an effective strategy to eliminate micronutrient deficiencies in the general population	

[a]While government-initiated fortification is usually mandatory, it can be 'voluntary' in that food companies have the option of selling unfortified versions of the food provided they are appropriately labeled. For example, in Canada, 'flour' or 'enriched flour' is required to contain specified amounts of thiamin, riboflavin, niacin, folic acid, and iron (B.13.001, Food and Drug Regulations) and 'milk' is required to be fortified with vitamin D (B.08.003, Food and Drug Regulations). In the US, however, 'enriched flour' is required to contain these nutrients, but 'flour' is not (Title 21 of the Code of Federal Regulations, sections 137.105 and 137.165) and 'milk, vitamins A and D added' is required to contain specified amounts of these vitamins, but 'milk' is not (21 CFR 131.110).

their food consumption patterns. The Codex general principles for the addition of essential nutrients to foods (CAC/GL 09-1987) state the following:

- The nutrient should be present at a level that will not result in an excessive or an insignificant intake of the added nutrient considering the amounts from other sources in the diet.
- The nutrient should not result in an adverse effect on the metabolism of any other nutrient.
- The nutrient should be sufficiently stable in the food during packaging, storage, distribution, and use.
- The nutrient should be biologically available from the food.
- The nutrient should not impart undesirable characteristics to the food, or unduly shorten shelf-life.
- The additional cost should be reasonable for the intended consumers, and the addition of nutrients should not be used to mislead the consumer concerning the nutritional quality of the food.
- Adequate technology and processing facilities should be available, as well as methods of measuring and/or enforcing the levels of added nutrients.

The Codex principles mirror the criteria proposed in the US (in 1974) as conditions to be met to support food fortification, including the following:

- There should be a demonstrated need for increasing the intake of an essential nutrient in one or more population groups.
- The food selected as a vehicle should be consumed by the population at risk and intake of this food should be stable and uniform.
- The amount of nutrient added should be sufficient to correct or prevent the deficiency when the food is consumed in normal amounts by the population at risk.
- The addition of the nutrient should not result in excessive intakes.

Many developed countries have adopted various regulations to either require or permit manufacturers to fortify their food products in a safe and appropriate manner, and to market such products in a manner that is truthful and not misleading to consumers. In some countries, such as Norway, Finland, and Denmark, voluntary fortification has been considered unnecessary and potentially harmful and, therefore, is generally restricted. However, in many other countries, such as the US, UK, Canada, Switzerland, and Belgium, regulations are less restrictive allowing foods to be fortified voluntarily as long as fortification is safe and harmful levels of nutrients are avoided.

Contribution of Food Fortification to Nutrient Intakes

Individual nutrient intakes in developed countries are strongly influenced by food fortification. The amounts of thiamin, riboflavin, niacin, and iron in

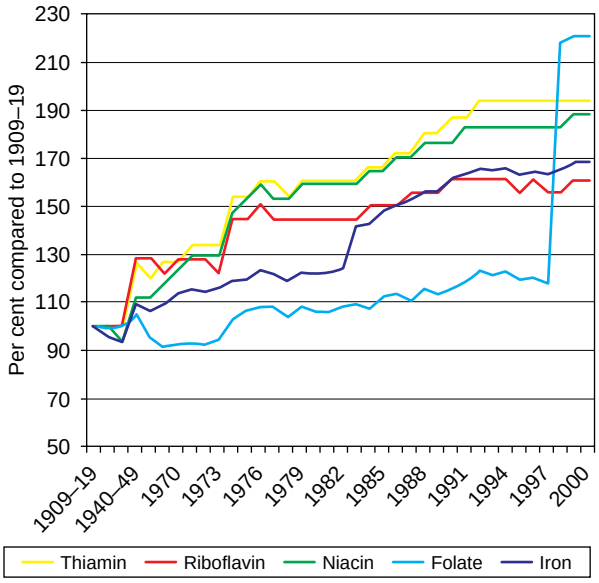

Figure 1 Trends in the amounts of thiamin, riboflavin, niacin, folic acid, and iron in the US food supply between 1909 and 2000. Fortification of cereal grain products with thiamin, riboflavin, niacin, and iron was initiated in 1941 and fortification levels were adjusted in 1973. The levels of iron were reversed in 1978 and then increased in 1981. Folate fortification began in 1998. Source of data: Gerrior S, Bente L, and Hiza H (2004) *Nutrient Content of the United States Food Supply, 1909–2000*. Home Economics Research Report No. 56. United States Department of Agriculture, Center for Nutrition Policy and Promotion, Alexandria, VA, USA.

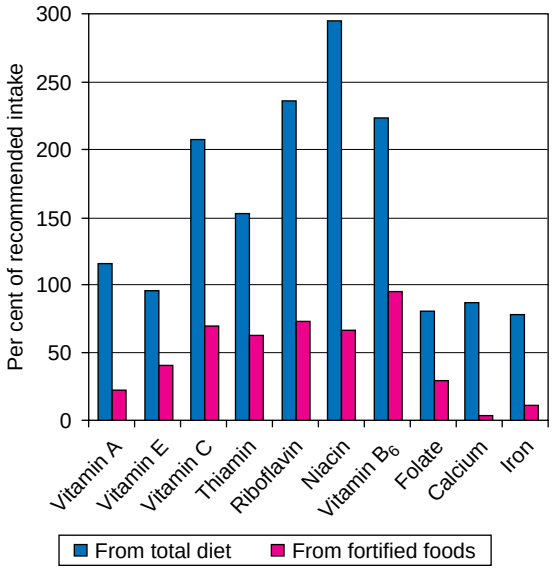

Figure 2 Nutrient intakes from the total diet and fortified foods among 2–13-year-old German children in 1996. Source of data: Sichert-Hellert W, Kersting M, Alexy U, and Manz F (2000) Ten-year trends in vitamin and mineral intake from fortified food in German children and adolescents. *European Journal of Clinical Nutrition* **54**(1): 81–86.

the US food supply markedly improved following fortification of cereal grain products in the 1940s (**Figure 1**). Cereal grain products provided about 31% of the thiamin in the food supply in 1909–19 compared to about 59% in 2000; 14% of riboflavin in 1909–19 to 39% in 2000; 30% of niacin in 1909–19 to 45% in 2000; and 33% of iron in 1909–19 to 52% in 2000. Similarly, fortification sharply increased the amounts of folate in the food supply since its inception in 1998. Cereal grain products accounted for 23% of folate in the food supply in 1909–19, which rose to 35% in 1997 and, following fortification, jumped to 70% in 1998 and remained there in the most recent data of 2000.

An analysis of food consumption patterns between 1985 and 2000 among German children and adolescents showed that food fortification increased the intakes of several vitamins and minerals by 20–50%. In the case of vitamins A, C, thiamin, riboflavin, niacin, and B_6, fortification raised already adequate intakes from nonfortified foods. In the case of vitamin E and folate, inadequate intakes from nonfortified foods were increased to 100% and 80%, respectively, of reference intake levels (**Figure 2**). Fortified foods accounted for less than 5% of total calcium intake, 10–20% of iron, vitamin A, and folate intakes, 40–50% of vitamin C, E, thiamin, riboflavin, and niacin intakes, and up to 80% of vitamin B_6 intake among this population group.

Calcium fortification of flour is estimated to have supplied up to 30% of the total calcium intake in Danish adults and 13% of total calcium intake in adolescents in Britain. A Swedish multicenter study, 1980–81, on food habits and nutrient intake in children aged 1–15 years revealed that enriched low-fat milk and margarine are important food sources of vitamin A in this population group. Vitamin D-fortified margarine is estimated to provide up to 48% of the total vitamin D intake among Australian men and women.

While government-initiated fortification of foods can greatly change the nutritional profile of the food supply, the contribution of foods voluntarily fortified by industry should also be considered. In the US, such fortified foods are reported to increase intakes of several nutrients, some of which are already adequately provided by nonfortified foods and standardized enriched foods (**Table 3**). Among voluntarily fortified foods, ready-to-eat breakfast cereals are the most significant food category, accounting for the top food source of many vitamins and minerals in several countries, including the US, UK, France, and Spain. Fortified juices and beverages appear to be another substantial contributor, primarily for intakes of vitamins C and D. Fortified breakfast cereals are associated with higher intakes

Table 3 Contribution of voluntary food fortification to nutrient intakes in the US population ≥ 1 year of age[a]

Nutrient	*Median intake (% RDA)*		*Contribution of voluntarily fortified food[b] sources to median intake (% RDA)*
	Excluding voluntarily fortified food[b] sources	*Including voluntarily fortified food[b] sources*	
Vitamin A	70	85	15
Vitamin C	98	122	24
Thiamin	101	113	14
Riboflavin	107	119	12
Niacin	104	117	13
Folate	99	122	23
Calcium	76	76	0
Iron	84	96	12
Zinc	66	70	4

[a]Source of data: Berner LA, Clydesdale FM, and Douglass JS (2001) Fortification contributed greatly to vitamin and mineral intakes in the United States, 1989–91. *Journal of Nutrition* **131**: 2177–2183.
[b]In this analysis, researchers determined the contribution of voluntarily fortified foods, namely the food categories ready-to-eat cereals and fortified cooked cereals, vitamin-and mineral-fortified drinks, meal replacements and supplements, and calcium-fortified milk beverages and juices. Standardized, enriched foods (i.e., foods governed by federal food standards of identity), including enriched flour, enriched bread, enriched rice, enriched pasta, and vitamin-fortified milk, were excluded in this analysis.

of vitamin A among children in Spain and Northern Ireland. In the UK, which has a long tradition of fortification, fortified foods contribute positively to nutrient intakes. For example, in the UK, in 1950, red meat and vegetables were the primary sources of iron and vitamin C, respectively, among 4-year-olds. However, by 1992, most dietary iron came from fortified breakfast cereals and most vitamin C was provided by fortified beverages. Similarly, fortified breakfast cereals were found to be the principal source of folic acid and the second most important food source of vitamins B_6 and D among children in Spain.

Effectiveness of Food Fortification as a Public Health Intervention

The benefits, at a national level, of historical fortification efforts are generally not well documented; however, epidemiological evaluations of pilot-scale programs are considered to have played an important role in the widespread implementation of these programs. Iodization of salt was found to decrease the incidence of goiter by 74–90% in different counties in the State of Michigan in the US in the first 10 years of the program (1924–35). Salt iodization is credited with the elimination of endemic cretinism and endemic goiter in Switzerland. Since its inception in 1922, periodic evaluations of the program triggered increases in fortification of levels of iodine, most recently in 1998. In 2001, an evaluation of a national sample of Swiss school children and pregnant women showed adequate iodine status, underscoring the importance of iodized salt in that nation's food supply and the value for periodic monitoring in the success of a fortification program.

A successful intervention with vitamin A-fortified margarine initiated in Newfoundland in 1944–45 led to a marked improvement in vitamin A status, as indicated by serum retinol levels in a sample of the population. Similarly, observations on the curative effects of milk fat, but not of margarine, eventually led to the enrichment of margarine with vitamin A in Denmark.

An evaluation of the possible health impact of niacin fortification of cereal grains in the US showed that fortification played a significant role in the decline of pellagra-attributed mortality in the 1930s and 1940s and, finally, in the elimination of pellagra in the country. Fortification was particularly significant during a period when food availability and variety were considerably less than are evident today.

Effectiveness of iron fortification is less clear owing primarily to the complex etiology of anemia. Several cereal grain products and other foods, especially breakfast foods, are commonly fortified with iron in developed countries and iron fortification is generally assumed to be responsible, at least in part, for the marked reduction in the prevalence of iron deficiency anemia in these countries. However, many other factors, such as improved socioeconomic conditions, increased meat intake, and iron supplementation may have played important roles. Furthermore, the most common iron source used in cereal fortification in Western countries is reduced iron, which has been found to be poorly bioavailable. Nevertheless, the effectiveness of iron

fortification is apparent in some cases. For example, in Sweden, fortification of flour with iron was withdrawn in January, 1995, because the benefits of such fortification were considered uncertain. However, recent investigations suggest that, after accounting for possible confounding factors, iron intake decreased by 39% and iron deficiency anemia increased by 28% among adolescent girls in the 6 years following withdrawal of iron fortification. The effectiveness of iron fortification is also clear in the case of targeted fortification of infant foods. The use of iron-fortified infant formulas and cereals is credited with the virtual elimination of iron deficiency among American infants.

The effectiveness of food fortification as a public health strategy is evident in the case of recent folate fortification efforts. Since its inception in November, 1998, folic acid fortification (150 μg per 100 g of food) in Canada has produced measurable benefits. In Newfoundland, the average rates of neural tube defects, which remained unchanged between 1991 and 1997, fell by 78% with concurrent increases in blood folate levels of women after the implementation of folic acid fortification. This survey did not find evidence of improved folate status masking hematological manifestations of vitamin B_{12} deficiency, which was a concern carefully considered in setting the fortification levels of folic acid. Studies in other Canadian provinces also report significant reductions in neural tube defects: up to 32% in Quebec, 48% in Ontario, and 54% in Nova Scotia. Folate fortification is also reported to be associated with a 60% reduction in neuroblastoma, an embryonic tumor, among Canadian children.

In the US, enriched cereal grain products have been required to be fortified with 140 μg of folic acid per 100 g of food since January, 1998. Since then, folate levels of baked products, cereal grains, and pasta have doubled or tripled and breakfast cereals are one of the most highly fortified food sources of folate. Consequently, typical folic acid consumption in the country is estimated to have increased by more than 200 $\mu g\,day^{-1}$ due to fortification, along with a substantial improvement in folate status of different population groups. According to the Centers for Disease Control and Prevention, the rates of neural tube defects fell by about 26% from 1995–96 to 1999–2000 in the US although there is debate that this figure may be an underestimate. Careful monitoring and surveillance of the long-term effects of these fortification programs is needed to ensure desired benefits without unintended consequences.

Several factors are considered essential for the success of fortification as a public health intervention. Key among them are:

- a documented need for food fortification, i.e., assessing the gap between current and desired intakes;
- choosing an appropriate food vehicle(s) that is consumed by most of the population in relatively constant amounts;
- setting a fortification level that is not only efficacious in the target population but also safe for the general population;
- resolving any concerns of adverse nutrient interactions;
- establishing clear fortification regulations and policies;
- a public education campaign to increase consumer awareness; and
- periodic assessments of the impact of the intervention to determine any necessary adjustments to the fortification policy to ensure that the desired benefits are achieved and that excessive intakes are minimized.

Relevant government bodies, food industry, professional health organizations, consumer associations, and trade organizations play important roles in formulating a coordinated and concerted effort in the successful implementation of the fortification program.

Emerging Issues

As noted above, both mandatory and voluntary fortifications have played important roles in the overall nutritional adequacy of food supply in developed countries. While classic nutrient deficiency diseases have been alleviated, there is increasing awareness that suboptimal intakes of nutrients may occur in some population subgroups. For example, calcium and vitamin D intakes may be inadequate, particularly among women and the elderly. In the US, median calcium intakes among adolescent girls and adult women are below the recommended Adequate Intake levels. Similarly, the lowest dietary intakes of vitamin D in the US are reported by female teenagers and female adults, with only about 30% of adolescent girls and 20–25% of women cosuming sufficient dietary vitamin D to meet the Adequate Intake levels. Dietary patterns are changing among teenagers with a preference for soft drinks over milk and other dairy beverages. Up to 90% of older adults in the US are reported to consume inadequate amounts of vitamin D. In Australia and New Zealand, women and the elderly are also considered high-risk groups for marginal vitamin D status. In Europe, a substantial percentage of the elderly are reported to have low vitamin D status, ranging from about 10% in the Nordic countries to about 40% in France. Current

scenarios of food fortification do not appear to be reaching the population groups most at risk of these deficiencies.

In contrast, overfortification and random fortification of the food supply is also a growing concern. Where the regulatory system in the country permits, a wide variety of foods are being fortified with a broad spectrum of nutrients. The need for such a vast number of fortified foods for generally nutritionally adequate populations, particularly given the wide consumption of vitamin and mineral supplements, is questioned. Recently, advances in scientific knowledge have enabled estimations of upper (safe) levels of intake and various government agencies have established tolerable upper intake levels for different micronutrients. These upper levels of nutrient intake are being carefully considered as countries continue to monitor their existing fortification programs and policies to appropriately balance risks of deficiency and toxicity in well-nourished populations.

Another emerging issue relates to the so-called 'functional foods' as consumers look for foods associated with health benefits beyond basic nutrition. Nutrition research in the recent past has shifted from evaluating the benefits of the whole food itself to the benefits of bioactive components isolated from such foods. Substances such as lycopene, lutein, and probiotics are being added to foods with claimed health benefits, although the efficacy of such fortification is largely unknown.

Conclusion

Fortification of foods commonly consumed by populations at risk of micronutrient deficiencies has been demonstrated to be an effective public health intervention. Iodization of salt, fortification of milk with vitamin D, and the addition of thiamin, riboflavin, niacin, and iron to cereal grain products have a long history in several developed countries, some starting as early as the 1920s. More recently, several countries have either required or permitted the fortification of cereal grain products with folic acid. In addition, where the regulatory environment permits, the food industry has voluntarily fortified a variety of foods with a wide array of nutrients. The importance of food fortification in the diets of developed countries is clear. Surveys indicate that fortified foods make significant contributions to the intakes of nutrients among different population groups, resulting in improved nutrient status and/or related health conditions. The success of food fortification in developed countries can be attributed to several factors, notably cooperation among different sectors to raise consumer awareness and demand for more healthful foods. However, as the popularity of fortified foods grows and trends toward random fortification and overfortification of the food supply continue, careful monitoring of existing fortification programs and policies become more critical to ensure not only the adequacy but, perhaps more importantly, the safety of food fortification in generally well-nourished populations.

Developing Countries

O Dary and J O Mora, The MOST Project, Arlington, VA, USA

Introduction

Micronutrient deficiencies are a consequence of diets with low variety, which are common in developing countries where the diet is based on starchy foods. Fortification of commonly consumed edible products is a potential solution to increase the intake of micronutrients. However, feasibility and effectiveness of fortification depends on production in the industrial setting, reliable food control mechanisms, and frequent and sufficient consumption of the fortified products. These criteria are not common in developing countries, and this limits the potential of this intervention to improve the health of their inhabitants. Nevertheless, some examples already exist that show that food fortification is feasible and useful in developing countries. Increasing, urbanization in these countries makes fortification an essential food technology for their immediate future.

The Need to Improve Micronutrient Intakes in Developing Countries

Micronutrient deficiency is a consequence of a lack of variety in the diet. This condition is aggravated in developing countries, where the diets consist primarily of low-cost starchy foods. **Table 1** shows the micronutrient density of wheat, wheat flour, maize-meal, corn-masa flour, and rice. In all cases, the cereal-based derivatives are good sources of energy, but are very poor in most micronutrients, in particular zinc, iron, calcium, and vitamins associated with foods of animal origin, such as vitamins A, B_2, and B_{12}. These products are also poor in folate and vitamin C. Extraction of flour from cereal grains increases the energy density by two times in the case of corn, and by three times in the case of wheat (**Table 1**), but reduces the original micronutrient content of the grain by 30–85%. **Table 1** illustrates that white wheat flour (extraction rate lower than 80%) is not a good source of any micronutrient, whereas rice and, especially, corn derivatives maintain satisfactory quantities of vitamin B_6 and niacin. Corn sub products also retain some zinc, and adequate amounts of vitamin B_1. Iron content is also higher, but the presence of strong iron-absorption inhibitors, especially in corn-masa flour, makes corn derivatives poor sources of this nutrient. Processing of the corn grains with lime (calcium oxide) to produce masa-flour increases the content of zinc, calcium, and niacin. Nevertheless, considering that 50% or more of energy is satisfied through the consumption of these foods in poor populations of developing countries, it is easy to explain why they are at very high risk of suffering the consequences of vitamin and mineral deficiencies.

Table 2 illustrates that, in general, diets in developing countries are not only poor in energy (less than 77% adequacy) but also in zinc, iron, calcium, vitamin B_{12}, folate, vitamin A, and vitamin B_2. Adequacies of these micronutrients are from 35% to 70% of the estimated average requirement (EAR). Vitamin B_1, niacin, and vitamin C have better adequacies, although these are still unsatisfactory, being in the order of 70–100% of the EAR. Iodine deficiency, as in most human societies in the world, is

Table 1 Micronutrient density of main energy sources in developing countries (per 100 g of product)

Nutrient	*EAR*[a]	*Wheat*	*White wheat flour*	*Maize-meal*	*Corn-masa flour*	*Rice*
Energy (kcal)		112	364	361 (% EAR)	365	360

B_2	1.1 mg	16	5	11	5	5
B_6	1.1 mg	9	4	34	31	14
Niacin	12 mg	50	8	14	20	13
Vitamin C	37 mg	0	0	0	0	0

[a]EAR, estimated average requirement is the average (median) daily nutrient intake level estimated to meet the needs of half the healthy individuals in a particular age and gender group.
[b]EAR for white wheat flour (low extraction flour) = 10.8 mg; and for corn-masa flour = 43.2 mg.

Table 2 Nutrient adequacy in some developing countries (approximate % EAR in diet)[a]

Nutrient	*EAR*	*S. Africa (1999)*	*Bangladesh (1995–96)*	*Nicaragua (1993)*	*Mexico (2000)*	*Philippines (1998)*[b]
Energy (kcal)		77	75	75	67	70
Zinc	11.7 mg	56	–	77	51	–
Iron	21.6 mg	65	53	48	38	61
Calcium	833 mg	61	41	82	77	58
B_{12}	2.0 μg	280	–	90	–	–
Folate	320 μg	89	–	35	66	–
Vitamin A[c]	429 μg	106	66	50	60	49
B_1	1.0 mg	140	118	70	–	76
B_2	1.1 mg	157	45	82	–	73
B_6	1.1 mg	118	–	128	–	–
Niacin	12 mg	127	155	71	–	89
Vitamin C	37 mg	193	87	140	83	119

[a]Almost all individuals in the population should have an intake equal or greater than the corresponding EAR. In this table, adequacy rates smaller than 100% means that half or more of the population is not fulfilling the nutritional requirement.
[b]Data for children 4–8 years old.
[c]Conversion factor for vitamin A from plant sources was changed from 1:6 to 1:12 (retinol:β-carotene).

also widespread due to the absence of foods containing this nutrient. It seems that only vitamin B_6 may be the exception for micronutrient deficiencies in developing countries. Improvement in micronutrient adequacy cannot be expected with a simple increase of the consumption of food (in order to satisfy the daily energy requirements) without changes in the quality of the diet, because inadequacies originate from the low-micronutrient content of the usual foods consumed.

In South Africa, nutrient adequacy for vitamin B_{12}, vitamin A, and vitamin B_2 was better than in the other countries included in **Table 2**; this may be a consequence of the greater consumption of eggs and milk in this country. Similarly, Nicaragua and Mexico presented lower deficiency for calcium, which is obviously associated with the consumption of corn-masa flour.

It is generally recognized that developing countries require not only an increase in intake of iodine, vitamin A, and iron, but also most vitamins and minerals.

Conditions Limiting the Implementation of Effective Food Fortification Programs in Developing Countries

Many of the micronutrient deficiencies in developing countries might be solved by raising the consumption of foods of animal origin (eggs, milk, fish, poultry, and meat). However, this strategy is difficult to implement in the short term because of its high cost, as well as cultural and religious beliefs. Thus, food fortification seems an attractive alternative. However, fortification is not a simple task in developing countries, as explained below.

Small Proportion of Centrally Produced Foods

Food fortification is a technology, and hence it necessitates the existence of processing centers (industrial plants or fortification facilities), which must have a minimum technological development that is compatible with the advantages of large market economies and quality control procedures. If this requirement is not satisfied, it would be wasteful, worthless, and risky to try to implement a food fortification program, because of prohibitive cost and unsafe practices. The salt iodization program is occasionally mentioned as an example against this statement, but this cannot be used as a model of other food fortification programs, as explained later. Factories for processed foods (breakfast cereals, pastas, vegetable fats, beverages, and the like) exist in most developing countries but, unlike the situation in developed countries, their products are generally out of the reach of the populations at risk. Food staples such as corn, rice and, in some situations wheat, are produced and processed locally in very small facilities, and hence they are very difficult or impossible to fortify. Fortification of rice still faces cost and technological constraints, especially in regions where rice is the main staple.

The difficulty of finding suitable vehicles to be fortified in the developing world has led to investigation of the fortification of oil, sugar, salt, fish and soy sauces, curry powder, and, in the past, other condiments such as monosodium glutamate. The main limitation of these food vehicles is that they allow the addition of only one or very few micronutrients.

Low Consumption of Potential Food Vehicles

The effectiveness of food fortification in developing countries is hampered by the fact that those edible products that are amenable to fortification, are not consumed frequently enough or in sufficient amounts by the most at risk individuals. In the past, it was assumed that increasing the level of micronutrients in the food vehicle may overcome this constraint. It is now realized that the content of micronutrients in widely consumed products depends on keeping their consumption safe for everyone (especially for individuals with very large consumption), on maintaining the technological compatibility with the properties and uses of the food vehicle, and on maintaining the price of the product within an acceptable range. As a consequence, the fortification formulations are more or less fixed by maximum possible values, which in turn determine that a minimum daily consumption of the fortified vehicles is necessary in order to provide useful amounts of micronutrients. This condition reduces the potential benefits of food fortification for very poor families, as well as for small children, because they usually consume low amounts of industrially manufactured products.

Table 3 illustrates the minimum consumption amounts of industrially produced foods to supply from 20% to 70% of the EAR of iodine, iron, and vitamin A through fortification. This range was selected under the assumption that a source of a nutrient is one that provides at least 20% of the EAR of that nutrient, and if a food supplies 70% EAR it means that that food might be sufficient to supply all of the amount needed to complement the diet with that nutrient. Daily consumption amounts should be in the following ranges: oil, 5–20 ml for vitamin A; sugar, 10–35 g for vitamin A; low-extraction wheat flour, 40–140 g for iron, and 50–150 g for vitamin A; salt, 4–15 g for iron, and slightly less for vitamin A and iodine; and fish/soy sauce, 6–20 ml for iron. Ideally, consumption patterns should be equal to or higher than the uppermost figure of the range, but never below the lowest value to have public health significance. If consumption is within the range, then probably more than one product should be fortified and consumed.

Weak Enforcement and Monitoring Capabilities

Many developing countries have regulations and laws making food fortification mandatory. However, those legal instruments often remain without compliance because of the impossibility of enforcing them. There are also many examples of false, misleading, and exaggerated claims regarding the presence of micronutrients in the foods. These claims are used as simple advertizing tools but without checking that the products really contain the vitamins and minerals in the amounts that are declared on the labels. The lack of reliable food control mechanisms is a barrier to the effectiveness of fortification in developing countries.

Low Bioavailability of Iron and Other Minerals

Iron is a relatively abundant mineral in plant sources, but its bioavailability is very low. Iron in cereal-based diets – without fermentation or elimination of the bran – might be $\leq 5\%$ absorbed.

Table 3 Consumption range of fortified foods to supply 20–70% EAR[a] (range of consumption/(minimum fortification level in ppm[b]))

Nutrient	*Oil*	*Sugar*	*Wheat flour*	*Salt*	*Fish/soy sauce*
Iodine	–	–	–	1.5–5.0 g[c] / (25 ppm)	–
Iron[d]	–	–	45–165 / (45 ppm)	4.0–15.0 g / (500 ppm)	6–20 ml / (350 ppm)
Vitamin A	5–20 ml / (20 ppm)	10–35 g / (10 ppm)	50–175 g / (2.0 ppm)	3.0–10.0 g / (35 ppm)	–

[a]Approximately equivalent to 15–50% Recommended Nutrient Intake (RNI). It is assumed that a food should supply at least 20% EAR of a nutrient to be considered as a source of that nutrient; and that a supply of 70% would mean that that food would be sufficient to complement the whole recommendations of that nutrient.

[b]Higher levels cannot be used because risk of excessive intakes for individuals who consume large amounts of these foods; high cost; or technological incompatibility. Supply of EAR was estimated considering losses during storage, transportation and distribution, and after food preparation.

[c]In the case of iodine, because iodized salt is almost its only source, the nutritional goal should be to supply 100%EAR, which means that the usual salt consumption should be 7 grams/day.

[d]In all cases, assuming a diet with iron bioavailability of 10%.

Many developing countries assume that their diets have 10% bioavailability for iron, but in fact this is not the case. This fact has caused iron deficiency to be underestimated, and the estimation of the potential impact of iron fortification overestimated. Perhaps a similar situation may be happening with zinc and calcium.

In a diet with abundant iron-absorption inhibitors (rice, high extraction wheat and corn flours, and cornmasa flour), even the most absorbable iron compounds, such as NaFeEDTA and ferrous bisglycinate, have absorption rates not higher than 10%. Water-soluble or acid-soluble iron salts, such as ferrous sulfate and ferrous fumarate, respectively, are absorbed at rates of from 5% to 10%, depending on the content of iron absorption inhibitors in the diet. Electrolytic iron and other difficult to dissolve iron compounds are absorbed in even lower proportions. This condition combined with the fact that the most absorbable iron compounds change the sensory characteristics of foods (color, flavor, and odor) makes the improvement of iron status in cereal-based diets through food fortification a very difficult challenge.

Use of electrolytic iron deserves a special mention because, once in the fortified food, it cannot be distinguished from other types of elemental iron, such as reduced iron and atomized iron, whose bioavailability rates are even lower. The impossibility of enforcement makes the use of electrolytic iron an unattractive option under the conditions in developing countries.

Price of Fortified versus Nonfortified Product

When fortification is being considered as a public health strategy, feasibility analyses regarding cost implications and trade practices are usually neglected in favor of biological efficacy trials. This approach has produced reports and publications showing biological impact but it has not supported the creation of true and effective programs. This was the case when monosodium glutamate was fortified with vitamin A in the Philippines and Indonesia in the 1980s. The nutrient was bioavailable and metabolically efficacious, but the fortified product had a very short life span in the market. This was principally due to the 17% reduction in weight of the sachets in order to keep the price similar to the unfortified product. The consumers noticed the difference and preferred to choose the unfortified alternative. The fortified product also had problems with color and micronutrient segregation, but the uncompetitive price was the main reason for the failure of the program.

Table 4 shows the annual cost per person of providing 70% of the EAR through food fortification. In the case of iodine, the annual cost is only US$0.003 per person. Iodine is the only micronutrient to combine several properties that permit us to recommend a 'universal' measure to provide iodine in most countries of the world. These characteristics are: its mineral nature (resistant to environmental factors, mainly in the form of potassium iodate even when combined with raw salt); very low cost; very small interactions with the food matrix; very low nutritional requirements (microgram range); and absence of foods that are good sources of this nutrient. These properties make it possible to use only one carrier, i.e., salt, without the need to consider other ways to complement the amounts of iodine supplied by this means. No other nutrient has all these attributes. Therefore, iodization of salt is the exception and not the model for food fortification.

Table 4 also shows that independently of the food vehicles that can be used to increase the dietary iron, the annual investment would depend on the price of the type of iron that must be used to be compatible with the food matrix. Thus, to supply 70% EAR throughout the year using ferrous fumarate would cost US$0.045 per person' using encapsulated ferrous sulfate US$0.257, and using NaFeEDTA US$0.405. These iron compounds are compatible with white wheat flour, salt and fish/soy sauce, respectively.

Table 4 Annual cost per person of providing 70% EAR through food fortification[a] (US$)

Nutrient	*Oil*	*Sugar*	*Wheat flour*	*Salt*	*Fish/soy sauce*
Iodine	–	–	–	0.003	–
Iron	–	–	0.045[b]	0.257[c]	0.405[d]
Vitamin A[e]	0.023	0.150	0.130	0.175	–
Total	0.023	0.150	0.175	0.435	0.405

[a]At the levels of fortification and consumption indicated in **Table 3**.
[b]Ferrous fumarate.
[c]Encapsulated ferrous sulfate.
[d]NaFeEDTA.
[e]All cases, except oil, use microencapsulated vitamin A. Oil uses fat-soluble vitamin A.

The nature of the two latter vehicles does not allow use of other iron alternatives at this time.

Similarly, the cost of fortification with vitamin A would change if the nutrient is added to an oily matrix (US$0.023/year per person), or to a dry or water-soluble matrix (US$0.130 to US$0.150/year per person) such as wheat flour, sugar, or salt.

In principle, the less costly alternatives should be used preferentially, but if these food matrixes are not consumed regularly nor in sufficient amounts, then the more expensive options are necessary. **Table 4** illustrates that the total annual costs, even in the most costly cases of food fortification, are inexpensive enough compared with the large public health benefits that are expected from the prevention of the consequences of these micronutrient deficiencies.

However, the viability of the fortification program depends not only on the total annual cost, but also on the relative price increase of the food vehicle, because the difference in price compared to the unfortified choice will determine the feasibility of production, trade, and enforcement. Thus, using the case of salt as an example (**Table 5**), adding iodine increases the price by 0.6%, iron by 16.7%, and vitamin A by 11.7%. Then, it is logical to conclude that considering salt as a vehicle of iron and vitamin A, although it might be technologically compatible and biologically efficacious, would face a lot of opposition from the producers with high risk of noncompliance in the absence of strong enforcement capabilities. In theory, this type of fortification is possible and has potential biological impact, but in practice the substantial challenges might impede their implementation.

Table 5 also includes the production cost and the price increase for other fortification examples. It is easy to see that double or triple fortification of salt, or iron fortification of fish/soy sauce, would need very strict and reliable enforcement systems and permanent financial mechanisms, in order to be sustainable and efficient interventions.

Table 5 and **Table 6** show that flours are suitable for the addition of several micronutrients simultaneously, and that the price increase is relatively low. Therefore, flours should be used to their maximum potential wherever and whenever it is possible.

Examples of Food Fortification Programs in Developing Countries

Despite the multiple limitations that affect food fortification in the developing world, there are several examples that confirm its feasibility and benefits.

Vegetable Fats and Oil Fortified with Vitamin A and D

Addition of vitamin A to margarine and other vegetable fats started in 1918 in Denmark, when cases of xerophthalmia were associated with the replacement of butter by margarine. Then, the practice of nutritional equivalence, that is emulating the nutritional composition of butter, was adopted by the industry. Thus, vitamin A and D started to be added to margarine and other vegetable fats. Despite the fact that the bioavailability and utilization of vitamin A has been confirmed experimentally in the Philippines and other countries, the compliance and effectiveness of this practice at the national level has not been documented. Similarly, the addition of vitamin A in oil has been proven to be efficacious in

Table 5 Production cost of food fortification[a]

Food (price)	*Oil (US$0.50/kg)*	*Sugar (US$0.40/kg)*	*Wheat flour (US$0.40/kg)*	*Salt (US$0.30/kg)*	*Fish/soy sauce (US$0.50/kg)*
Nutrient	(US$ per Metric Ton/(% price)				
Iodine	–	–	–	1.75 (0.6%)	–
Iron	–	–	0.90[b] (0.2%)	50.00[c] (16.7%)	55.00[d] (11.0%)
Vitamin A[e]	3.50 (0.7%)	12.00 (2.7%)	2.02 (0.5%)	35.00 (11.7%)	–

[a]At the levels of fortification indicated in **Table 3**.
[b]Ferrous fumarate.
[c]Encapsulated ferrous sulfate.
[d]NaFeEDTA.
[e]All cases, except oil, microencapsulated vitamin A.

Table 6 Characteristics of a suggested fortification formulation for white wheat flour[a]

Nutrient	*Level (mg kg^{-1})*	*Cost (US$ per Metric Ton)*	*% Price*[b]	*% EAR in 100 g consumption*[c]
Zinc	30.0	0.16	0.04	52
Iron	45.0	0.90	0.22	48
B_{12}	0.01	0.59	0.15	45
Folic acid	2.0	0.32	0.08	97[d]
Vitamin A	2.0	2.02	0.51	39
B_1	6.0	0.30	0.08	45
B_2	4.0	0.24	0.06	39
B_6	5.0	0.25	0.06	47
Niacin	45.0	0.54	0.14	38
Total	–	5.32	1.34%	–

[a]Formulation adequate for daily consumption of 50–200 g day^{-1}. If consumption is greater, micronutrient levels should be reduced. Countries might reduce the levels of some micronutrients based on their particular nutritional profile and presence of other fortification programs with large public health coverage.
[b]Assuming US$0.40/kg.
[c]Considering losses during food preparation.
[d]Dietary folate = 1.7 × folic acid.

Brazil, but national effectiveness studies are still pending. Oil is currently fortified with vitamin A in Coted'Ivoire, Mali, Morocco, Nigeria, Oman, Philippines, Uganda, and Yemen. These programs have been designed to provide at least 100 μg vitamin A (23% EAR), which may have some biological consequence in a portion of the population. The main restriction of this practice is the destruction of vitamin A when oil is exposed to light inside transparent bottles.

Sugar Fortified with Vitamin A

In the 1970s, the Central American countries suffered from vitamin A deficiency. The only food that was identified as a good vehicle for fortification (centrally produced, affordable fortification cost, and widely consumed) was sugar. The technology of the addition of vitamin A was developed and, together with the introduction of the intervention, its biological effectiveness was evaluated. Vitamin A level increased in serum and breast milk of individuals in poor communities. Sugar is now the most important source of this nutrient in El Salvador, Guatemala, Honduras, and Nicaragua. It supplies 200–1000 μg of vitamin A (50–200% EAR), depending on the daily consumption pattern (30–150 g day^{-1}). Nowadays, vitamin A deficiency is practically nonexistent in those countries. Zambia started this program in 1998 but, differentiate from, Central America, the impact has been modest due to the lower sugar consumption (20 g day^{-1}) and sugar use (50% of population compared with nearly 100% in Central America). Nevertheless, sugar is the main source of vitamin A for those who consume it in Zambia. Nigeria has already started to implement this program for all sugar refined in the country. The vitamin A added to sugar is microencapsulated, and hence the type of packaging has little influence on its stability.

Wheat Fortified with Multiple Micronutrients

The practice of adding micronutrients to restore the nutritional quality of wheat grain with iron, vitamins B_1 and B_2, niacin, and sometimes calcium has been followed by many wheat flour mills in developing countries since the 1950s, especially in those industries with links to companies in the US and Canada. Nevertheless, attention to fortification of wheat flour was raised in the 1990s as a measure advocated by international organizations to reduce iron deficiency. Generally, the iron source is elemental iron, either electrolytic or reduced iron; exceptions are Central America where ferrous fumarate is used, and Peru, Cuba, and Chile, which use ferrous sulfate. A study in Sri Lanka, where an additional 12 mg day^{-1} of reduced (28% EAR) or electrolytic (56% EAR) iron was provided, did not find any improvement in hemoglobin levels after 2 years of treatment. Similarly, a study in Bangladesh, which supplied 3.3 mg day^{-1} of reduced iron (35% EAR) to 6–15-year-old children failed to modify any parameter associated with iron status. Only Chile has indirect evidence that iron from fortified wheat flour contributes to maintain good nutritional status of this nutrient. Wheat flour consumption in that country (250 g day^{-1}) provides 7.5 mg day^{-1} iron from ferrous sulfate (69% EAR). Other studies are on-going with the purpose of assessing if it is legitimate to use electrolytic iron for the fortification of wheat flour.

Most recently, attention has been given to folic acid, after evidence that neural tube defects in the US and Canada were reduced by the intake of an

additional 200 μg day^{-1} of folic acid (106% EAR), by means of the consumption of cereals fortified with this nutrient. These results have been confirmed in Chile, where bioavailability and biological utilization of folic acid was also clearly demonstrated.

Experimental efficacy trials of wheat flour fortified with vitamin A in the Philippines and Bangladesh have established that biological impact can be found with intake levels of 100–200 μg day^{-1} (25–50% EAR). Despite this finding, vitamin A has not been widely considered as a micronutrient to be added to wheat flour, although South Africa, Nigeria, and the Philippines have regulations including this micronutrient as part of the formulation. In comparison with sugar, addition of vitamin A to wheat flour has a lower cost and slightly better stability.

In addition to iron and folic acid, many countries also include vitamins B_1, B_2, and niacin in the fortification formulations. This is the practice followed by most Latin American countries. Now, Latin America is also considering the incorporation of vitamin B_{12} and zinc. Biological effects of the presence of other nutrients apart from iron and vitamin A have not been systematically evaluated in developing countries. However, when wheat flour fortification started in the US, it was documented that cases of beriberi, ariboflavinosis, and pellagra, associated with vitamins B_1, B_2, and niacin deficiencies, respectively, decreased drastically.

Wheat flour fortification has now extended to Bahrain, Jordan, Morocco, Saudi Arabia, Pakistan, Iran, Indonesia, and some regions of China, Central Asian countries and a few African countries.

Corn Products Fortified with Multiple Micronutrients

In Venezuela, precooked and degermed corn flour is fortified with iron (reduced iron and ferrous fumarate, in a mixture 2:3), vitamins B_1, B_2, niacin, and vitamin A. The usual consumption of this food provides 2.4 mg of iron from ferrous fumarate (22% EAR), and 1.6 mg from reduced iron (3.7% EAR). It also supplies 200 μg of vitamin A (47% EAR). A formal evaluation of this program has not been carried out, although it has been associated with maintenance of the iron status of the population despite the economical deterioration of the country. This argument is controversial because the additional supply of iron is not high, and the prevalence of anemia was low only in the year when fortification was introduced, whereas anemia rates after fortification were similar to those existent before fortification. Without a study under controlled conditions it is difficult to assign the mentioned effect to this program. Fortified precooked corn flour is theoretically more important as a source of vitamin A than iron, but no experimental evidence has been obtained in this regard. Nevertheless, it is interesting to note that a national nutritional survey, carried out in 2002, did not find vitamin A deficiency in Venezuelan preschoolers.

In Africa, maize-meal is currently being used as a vehicle for iron, zinc, vitamin A, and B complex vitamins, including in some cases vitamin B_{12}. Biological impact has not been evaluated.

Masa-corn flour is fortified with iron (reduced, or ferrous fumarate, or ferrous bisglycinate), and vitamins B_1, B_2, and niacin, in some Central American countries, and in Mexico also with zinc. Efficacy trials have shown the better bioavailability of NaFeEDTA over reduced iron in this matrix, although NaFeEDTA has not been used as yet in an industrial setting.

Salt Fortified with Iodine and Fluoride

Most developing countries have joined the initiative for universal salt iodization; evidence obtained worldwide confirms that this provides sufficient iodine to human populations. However, some countries have started to reduce the content of iodine, because of concerns of unnecessary or excessive supply. A few countries, such as Colombia, Costa Rica, Jamaica, Mexico and Uruguay, have also utilized salt as a vehicle for delivering fluoride with the purpose of reducing tooth decay. In Costa Rica, tooth decay was reduced 65% after 12 years of initiating the program. As in the case of iodine, fluoride content has recently been lowered after epidemiological monitoring determined that excessive fluoride was being supplied.

Soy/Fish Sauces and Curry Powder Fortified with Iron

Efficacy trials carried out with soy sauce in China and fish sauce in Vietnam that were fortified with NaFeEDTA have shown an impact on reduction of anemia and improvement in the iron status indicators. The amount of iron supplied was 10 mg day^{-1}, which is about 93% of the EAR assuming a diet with 10% iron bioavailability. The plan is now to make these experiences national programs. A similar study with curry powder in South Africa provided similar conclusions. In these cases, effectiveness and technical feasibility have been proven, and the existence of the program depends now on assuring industrial acceptance, permanent financing, and continuous enforcement.

Implications and Conclusion

The examples described in the previous section demonstrate that food fortification is possible and that it can be effective in developing countries. However, it is important to point out that the biological impact depends on the chemical properties and amounts of the micronutrients that are supplied and not on the fortified food itself. It is not a surprise that biological impact has been found in efficacy trials using many edible products as the fortification vehicles, such as biscuits, milk, sugar-based beverages, and "sprinkles." If these products contain the proper form and amount of micronutrients, it is highly probable that they will produce the expected biological outcomes.

Although food fortification has limitations in developing countries, mainly due to low accessibility and affordability of industrially produced foods by poor sectors of the population, the increasing trend of urbanization makes this strategy very important. Quality of the diets will be improved, and hence the health and well being of millions of persons. The aim is to supply sufficient micronutrients to populations having poor-quality diets, and fortification is one of the most efficient mechanisms to achieve this goal.

FOOD INTOLERANCE

T J David, University of Manchester, Manchester, UK

Definition of Food Intolerance

Food intolerance can be defined as a reproducible adverse reaction to a specific food or food ingredient, and it is not psychologically based. Although this appears straightforward, there are a number of difficulties with this definition, and these are discussed below.

Lack of Definition of 'Adverse Reaction'

One problem with our definition of food intolerance is the lack of definition of what constitutes an adverse reaction. All eating causes reactions, which include satiety, feeling warm, the urge to defecate (due to the gastrocolic reflex), and weight gain.

Variation in Tolerance

People vary in their tolerance of events. For some, flatus is an unacceptable and embarrassing problem, whereas for others it is the normal effect of eating baked beans.

Any Food taken in Excess may be Harmful

The definition above does not take into account dosage. Large quantities of certain foods may result in disease in certain individuals, although such disorders are not usually included in the category of food intolerance. Any food, however harmless, can be harmful if taken in excess. Notable examples of this are:

1. Apples, pears, and honey are rich sources of fructose, a sugar which in early childhood is not well absorbed if taken in large quantities. Thus, if a child takes a quantity of fructose in excess of that which can be absorbed in the gastrointestinal tract, the result will be loose stools (diarrhea) due to the osmotic effect of unabsorbed fructose. It should be noted that whereas this applies to normal children, there is in addition a small number of children who are especially poor at handling ingested fructose, and in these children even small quantities of fructose-containing foods will cause florid diarrhea.
2. Chicken liver is a rich source of vitamin A. There are reported cases of infants who were fed large quantities of chicken liver, and who developed raised intracranial pressure as a consequence of vitamin A toxicity.
3. In those who are genetically predisposed, ingestion of an excess of purine-rich foods contributes to hyperuricemia, leading to gout, a disorder which is not usually regarded as a form of food intolerance.

Principal Mechanisms and Pathophysiology of Food Intolerance

The principal mechanisms resulting in food intolerance and the pathophysiology (where this is understood) are discussed below.

Food Allergy

The term 'allergy' implies a definite immunological mechanism. This could be antibody mediated, cell mediated, or due to circulating immune complexes. The clinical features of an allergic reaction include urticaria (nettle rash), angioedema, rhinitis (sneezing, nasal discharge, blocked nose), worsening of pre-existing atopic eczema, asthma (wheezing, coughing, tightness of the chest, shortness of breath), vomiting, abdominal pain, diarrhea, and anaphylactic shock.

Enzyme Defects

Inborn errors of metabolism may affect the digestion and absorption of carbohydrate, fat, or protein. In some subjects the enzyme defect is primarily gastrointestinal, causing defects in digestion or absorption. An example is lactase deficiency (see below). In other subjects, the enzyme defect is systemic. An example is the rare disorders of hereditary fructose intolerance, described below.

Lactase deficiency An example of an enzyme defect causing food intolerance is lactase deficiency. In this condition, which is primarily a disorder that affects infants and young children, there is a reduced or absent concentration of the enzyme lactase in the small intestinal mucosa. Affected individuals are unable to break down ingested lactose, the main sugar found in milk, and which if unabsorbed passes into the large intestine, where there are two consequences. One is an osmotic diarrhea. The other is that some of the unabsorbed lactose is broken down by intestinal bacteria, accompanied by the production of gas (hydrogen) leading to abdominal distension and flatus and the production of organic acids that cause perianal soreness or excoriation. The production of hydrogen, its absorption into the bloodstream, and its excretion in the breath lead to a very simple and elegant test for sugar intolerance: the breath hydrogen test. In this test, the subject swallows a portion of the sugar which one suspects the subject cannot absorb. Breath is collected every half an hour and the hydrogen content is measured. In the normal individual, the sugar is absorbed and hydrogen is not produced. In the intolerant individual, the sugar is not absorbed, hydrogen is produced, and a steep rise in hydrogen concentration is found in the exhaled air.

The management of lactose intolerance is to avoid foods that contain lactose (mainly cows' milk and its products). For infants it is worth noting that the soya-based infant formulas are lactose free. In theory, an alternative is to add microbial β-galactosidase to cows' milk, which can produce a lactose-free milk, with the inconvenience that it has a sweeter flavor and requires a 24-h incubation period at 4 °C.

In infants and young children, lactase deficiency is usually a transient problem occurring after an episode of gastroenteritis, but it is commonly a feature of any disease that causes damage to the intestinal mucosa (e.g., celiac disease). Levels of lactase tend to fall during mid to later childhood, and in a

number of populations (e.g., African, Mexican, Greenland Eskimo) a high proportion of adults have very little lactase activity. This adult deficiency is believed to have a genetic basis. Man is the only animal apart from the domestic cat that drinks milk after weaning, and deficiency of lactase in adults could in certain populations be considered the normal state.

Hereditary fructose intolerance In this condition, which has autosomal recessive inheritance, there is deficiency of the liver enzyme fructose 1,6-bisphosphate aldolase. As a result, fructose-1-phosphate accumulates in liver cells, and acts as a competitive inhibitor for phosphorylase. The resulting transient inhibition of the conversion of glycogen to glucose leads to severe hypoglycemia (low blood glucose concentration). Affected infants are symptom free as long as their diet is limited to human milk. If they receive milk formulas or any food that contains fructose they develop attacks of hypoglycemia, shock, coma and convulsions. There may be jaundice, an enlarged liver, and sometimes progressive liver disease. The treatment requires the complete elimination of fructose from the diet, which may be difficult as fructose is a widely used food additive and sweetener. A trivial but interesting feature of the condition in survivors is a notable reduction in dental caries, a beneficial result from the need to avoid many types of confectionery.

Pharmacological Mechanisms

Caffeine A good example of a pharmacological agent found in food with the ability to cause adverse reactions is caffeine. The stimulant effect, which may be welcome at times but unwelcome at others, of 60 mg caffeine in a cup of tea or 100 mg caffeine in a cup of coffee are well recognized. What is less well recognized is that heavy coffee or tea drinkers can suffer a number of other side effects of caffeine, which stimulates gastric secretion and can cause heartburn, nausea, vomiting, diarrhea, and intestinal colic. Also common are irregular heartbeats, episodes of rapid pulse, sweating, tremor, anxiety, and sleeplessness. Caffeine also has a diuretic effect.

Sodium nitrite Another pharmacological effect occurs when unusually large quantities of sodium nitrite are ingested. Sodium nitrite is an antioxidant used as an antibacterial agent, and in quantities of 20 mg or more it can cause dilatation of blood vessels causing flushing and headache, and urticaria.

Tyramine, histamine, and other vasoactive amines A further example of a pharmacological mechanism is the adverse effect of various vasoactive amines such as tyramine, serotonin, tryptamine, phenylethylamine, and histamine, which are found in a range of foods such as tuna, pickled herring, sardines, anchovy fillets, bananas, cheese, yeast extracts (such as Marmite), chocolate, wine, spinach, tomato, and sausages. There appear to be three main mechanisms in operation:

1. An abnormally high intake of vasoactive amines, such as histamine or tyramine, either because of a high content in food or because of synthesis of these chemicals in the gut by bacteria.
2. An abnormal effect whereby drugs or chemicals in food interfere with the enzymes that break down vasoactive amines.
3. An abnormal release from mast cells of histamine and other mediators of inflammation, triggered by eating certain foods such as strawberries, shellfish, and alcohol.

Vasoactive amines are the normal constituents of many foods. They arise mainly from the decarboxylation of amino acids, but they may also develop during normal food cooking and during the storage of food. **Table 1** shows the histamine level of various sausages. The term 'semi-dry' when applied to sausages (**Table 1**) means sausages that are fermented for varying periods. During this sausage ripening process, the histamine concentration increases, depending upon the length of the ripening process. It is estimated that 70–1000 mg of histamine ingested in a single meal is necessary for the

Table 1 Histamine levels in sausages

Type of sausage	*Histamine level (mg/100g)*	
	Mean	*Range*
Cooked sausages[a]		
Bologna	0.55	0.19–0.84
Cooked salami	0.83	0.47–5.86
Kosher salami	0.50	0.33–0.97
Semidry sausages[a]		
Thuringer cervelat	2.35	1.03–3.63
Thuringer	1.19	0.31–2.56
Dry sausages[a]		
Italian dry salami	2.14–24.5[b]	0.42–36.4[b]
Pepperoni	1.03–38.1[b]	0.72–55.0[b]
Chorizo	2.29	0.60–8.08

[a]The sausages were obtained from retail markets in the San Francisco Bay area.
[b]Depending upon the brand tested.
Source: Taylor SL, Leatherwood M, Lieber ER (1978) A survey of histamine levels in sausages. *Journal of Food Protection* **41**: 634–637.

onset of toxicity, depending on individual sensitivity. Thus, 130 g of the pepperoni sample that contained 55.0 mg histamine per 100 g (see **Table 1**) would be necessary to cause symptoms in the most sensitive individuals.

The largest amounts of histamine and tyramine are found in fermented foods such as cheese, alcoholic drinks, sausage, sauerkraut, and tinned fish. Badly stored food (see below) such as mackerel and tuna can also contain large amounts of histamine.

The effects of large doses of tyramine, histamine, and other vasoactive amines are extremely variable. Histamine causes flushing (by dilatation of blood vessels), constriction of smooth muscle in the intestine and the bronchi, increased heart rate, headache, fall in blood pressure, and asthma. Tyramine causes constriction of blood vessels, and it stimulates the release of noradrenaline from nerve endings. It can also cause the release of histamine and prostaglandins from mast cells. Dietary tyramine is known to induce hypertension and headache in patients who are taking monoamine oxidase inhibitor drugs. This effect has been shown to be due to inhibition, by these drugs, of intestinal and hepatic metabolism of tyramine, so that the amine accumulates.

The variable effect of histamine taken by mouth is in part due to the varying degree of inactivation in the gastrointestinal tract. Histamine is inactivated by mucoproteins that are produced in the gastrointestinal tract mucosa, but this inactivation can be blocked by other amines such as cadaverine and putresceine, which also bind strongly to mucoproteins. Thus, when food is taken that contains cadaverine and putresceine, more histamine can be absorbed. In fact, most of the histamine that is absorbed is degraded as it is transported across the mucosa by the intestinal enzyme diamine oxidase. Cadaverine and putresceine also have a high affinity for diamine oxidase, and can also interfere with the inactivation of histamine by this enzyme. Another barrier to the absorption of histamine is provided by the liver enzyme methyl transferase.

Thus, the effect of histamine and other vasoactive amines on an individual will depend on a number of factors, which include:

1. The amount of vasoactive amine that is present in food.
2. The amount of histamine released (as a result of an allergic process).
3. The permeability of the gastrointestinal tract, including inactivation by mucus and by mechanisms in the gut mucosa.
4. Interference with the synthesis or release of enzymes involved in amine breakdown (e.g., liver damage causing reduced activity of methyl transferase).

Tyramine and migraine There has been interest in a possible relationship between dietary tyramine and migraine. One hypothesis is that some patients with migraine have defective metabolism of ingested tyramine in the intestinal wall, which leads to increased absorption, apparently explaining why foods that contain tyramine can provoke attacks in susceptible individuals. However, there is no evidence that the activity of monoamine oxidase, the main tyramine metabolizing enzyme, is lower in patients with food-induced migraine than in other individuals prone to migraine, although levels of monoamine oxidase in platelets are generally lower in patients with migraine.

Set against these theoretical arguments, in fact most attempts to induce migraine by tyramine challenge in children and adults have been unsuccessful. Furthermore, a controlled study of exclusion of dietary vasoactive amines in children with migraine failed to demonstrate benefit. In the latter study, patients were randomly allocated to either a high-fiber diet low in dietary amines or a high-fiber diet alone. Although there was no significant difference in the results for the two groups, both groups showed a highly significant decrease in the number of headaches, emphasizing the need for a control diet in studies designed to show that dietary manipulation improves disease.

Of the foods reported to be common triggers of attacks of migraine, only cheese is rich in tyramine. Chocolate is low in this and other vasoactive amines, and red wine usually contains no more tyramine than white wine. Alcoholic drinks, particularly red wine, are commonly reported to provoke attacks of migraine. Whether these attacks are due to the alcohol itself or some other compound is a matter of debate. The major chemical difference between red and white wine is the former's high concentration of phenolic flavonoids such as anthocyanins and catechins, which as well as having direct effects on blood vessels may also inhibit the enzyme phenolsulfotransferase. Patients with food-induced migraine were shown to have significantly lower levels of platelet phenolsulfotransferase activity, and it has been hypothesized (but not proven) that low activity of this enzyme could lead to an accumulation of phenolic or monoamine substrates, which in turn might directly or indirectly provoke attacks of migraine.

Regardless of the possible mechanism, there are a number of subjects with migraine who are made worse by specific dietary triggers such as cheese or wine, for whatever reason, and avoidance of specific food triggers in susceptible subjects may prove helpful in reducing the frequency of attacks.

11β-hydroxysteroid dehydrogenase and liquorice Liquorice contains an enzyme that inhibits 11 β-hydroxysteroid dehydrogenase, resulting in sodium and water retention, hypertension, hypokalemia, and suppression of the renin–aldosterone system.

Irritant Mechanisms

Certain foods have a direct irritant effect on the mucous membranes of the mouth or gut, such as the irritant effect of coffee or curry. In certain individuals, food intolerance only occurs in the presence of a coexisting medical disorder. For example, the ingestion of spicy food, coffee, or orange juice provoke esophageal pain in some patients with reflux esophagitis. This effect is unconnected to the temperature or acidity of the food, or to any effect on the lower esophageal sphincter. The treatment in susceptible individuals is to avoid the trigger food item.

Specific Drug–Food Combinations

One example of drug-induced food intolerance is potentiation of the pressor effects of tyramine-containing foods (e.g., cheese, yeast extracts, and fermented soya bean products) by monoamine oxidase inhibitor drugs. Another is the effect of taking alcohol in patients with alcohol dependence during treatment with disulfiram (Antabuse). The reaction, which can occur within 10 min of alcohol and may last for several hours, consists of flushing and nausea.

Toxic Mechanisms

Nature has endowed plants with the capacity to synthesize substances that are toxic, and thus serve to protect them from predators whether they be fungi, insects, animals, or humans. Thus, many plant foods contain naturally occurring toxins. On a worldwide scale, reactions to naturally occurring toxins may outnumber allergic reactions, although it is currently fashionable to pay more attention to the latter.

Protease inhibitors Soya beans were originally introduced into the US as a source of oil, the extracted meal being used as a by-product that could provide animals with a source of protein. However, it was recognized that it was necessary to subject soya beans to heat treatment if they were to support the growth of animals. It was later found that the substance responsible for growth inhibition in raw soya beans was a protease (trypsin) inhibitor and it is now known that protease inhibitors are widely distributed throughout the plant kingdom, particularly in legumes, and to a lesser extent in cereal grains and tubers. In addition to inhibition of growth, one of the most characteristic responses of most animals to trypsin inhibitor is enlargement of the pancreas. The depression of growth is believed to result from endogenous loss of protein (i.e., loss into the gastrointestinal tract) due to hypersecretion by the pancreas. Soya beans products that have been adequately heat treated to inactivate trypsin inhibitor are safe for consumption.

Lectins There is a protein present in most legumes and cereals that has the property of being able to agglutinate the red blood cells of various species of animals: the so-called phytohemagglutinins or lectins. Some of these lectins, such as ricin from the castor bean, are extremely toxic. Others, such as those in the soya bean, are nontoxic. Lectins appear to be responsible for the fact that many other legumes, unless properly cooked, not only fail to support the growth of animals but can lead to death. Lectins are found in many food items commonly consumed in the human diet including tomatoes, bean sprouts, raw vegetables, fruits, spices, dry cereals, and nuts, and it is not known whether these are harmful in any way. However, it is well recognized that inadequate cooking of red kidney beans can cause severe gastrointestinal upset, with vomiting and diarrhea. It is for this reason that it is recommended that raw red kidney beans should be cooked by initially boiling hard for 10 min.

Lathyrogens Lathyrism is a paralytic disease that is associated with the consumption of chickling pea or vetch, *Lathyrus sativus*. The causative factor is believed to be an amino acid derivative, β-*N*-oxalyl-, -diaminopropionic acid; this is a metabolic antagonist of glutamic acid, a substance that is involved in the transmission of nerve impulses in the brain.

Mimosine Mimosine is an amino acid that comprises 1–4% of the dry weight of the legume *Leucaena leucocephala*, and consumption of its leaves, pods, and seeds leads to hair loss in animals. Mimosine is also a goitrogen (see below).

Djenkolic acid In parts of Sumatra the djenkol bean is a popular food item. The bean is a seed of the leguminous tree, *Pithecolobium lobatum*, and resembles the horse chestnut in size and color. Consumption of this seed leads to kidney failure that is accompanied by blood and needle-like clusters in the urine, which have been identified as containing the amino acid djenkolic acid.

Goitrogens Substances capable of producing goiter are present in plants belonging to the cabbage family, including cabbage, turnip, broccoli, cauliflower, brussel sprouts, kale, rape seed, and mustard seed. Cows' milk is a vector for the transmission of goitrogens from animals fed kale and turnips, and may have been responsible for endemic goiter in countries such as Australia and Finland.

Cyanogens A number of plants are potentially toxic because they contain glycosides from which hydrogen cyanide may be released by enzymatic hydrolysis. The most common plants eaten by humans, in order of their potential cyanide content, are: lima beans (*Phaseolus lunatus*), sorghum, cassava, linseed meal, black-eyed pea (*Vigna sinensis*), garden pea (*Pisum sativum*), kidney bean (*Phaseolus vulgaris*), Bengal gram (*Cicer arietinum*), and red gram (*Cajanus cajans*).

Vicine and convicine These are β-glucosides that are present in broad beans (*Vicia faba*). When consumed by individuals with deficiency of the enzyme glucose-6-phosphate dehydrogenase, these substances precipitate the condition of favism, which is characterized by anemia caused by hemolysis of red blood cells. The enzyme deficiency is a genetic disorder that is confined largely to inhabitants of countries surrounding the Mediterranean basin (Italy, Sicily, Lebanon, Israel, and north Africa) although individuals of the same ethnic background residing in other countries may also suffer from favism.

Cycasin Cycad seeds or nuts are obtained from *Cycad circinalis*, a palm-like tree that grows throughout the tropics and subtropics. The seeds, unless thoroughly washed, are extremely toxic, causing poisoning in humans and tumors in experimental animals. The toxic ingredient methyl-azoxymethanol, the aglycone of cycasin, is released on hydrolysis of cycasin by intestinal bacteria.

Pyrrolizidine derivatives Pyrrolizidine alkaloids are found in a wide variety of plant species. The toxic ingredient belongs to a class of compounds that are derivatives of pyrrolizidine. Large numbers of people have been poisoned through consumption of cereal and grain crops contaminated with pyrrolizidine-containing plants. It is also possible that milk from cows grazing on pastures that contain such plants could act as a vector for the transmission of pyrrolizidine to humans. In one part of western USA one such plant, the tansy ragwort (*Senecio jacobea*) is readily consumed by cows and goats, and the milk from such animals has been shown to contain significant amounts of a pyrrolizidine derivative, jacoline.

Lupin alkaloid Milk from animals that have eaten plants from the lupin family, notably *Lupinus latifolius*, may contain quinolizidine alkaloids such as anagyrine. There is strong evidence that these alkaloids are teratogenic in animals, causing severe bony deformities, and there is some evidence that similar defects may occur in the offspring of human mothers who drink alkaloid-containing milk in pregnancy.

Other examples There are numerous other examples of toxic substances present in foodstuffs. These include solanidine in potatoes, cyanide in tapioca, mycotoxins in mushrooms and cereal grains, and phototoxic furocoumarins in angelica, parsley, dill and celeriac, which in sufficient quantities can give rise to a wide variety of toxic reactions (**Table 2** and **Table 3**).

Table 2 Examples of toxic constituents of plant foodstuffs and their role in plant physiology

Toxic constituent	*Type of food containing toxic constituent*	*Physiological role of toxic constituent*	*Role in plant defense: mechanism of toxic constituent*
Protease inhibitors	Legumes, cereals, potatoes, pineapple	?Prevents degradation of storage protein during seed maturation	Part of defense against invading microbes following mechanical damage to leaves
Hemagglutinins	Legumes, cereals, potatoes	(a) Attach glycoprotein enzymes (b) Role in embryonic development/ differentiation (c) Role in sugar transport or store (d) ?Involved in root nodule nitrogen-fixing bacteria symbiosis	(a) Counteract soil bacteria (b) Antifungal (c) Protect against seed predators
Glucosinolates	Radish, horseradish, turnip, cabbage, rape seed	?Disease & insect resistance role	
Cyanogens	Almonds, cassava, corn, peas, butter beans, bamboo shoots		
Saponins	Alfalfa, French beans, soya beans		

Adapted from: Leiner IE (ed.) (1980) *Toxic Constituents of Plant Foodstuffs*, 2nd edn. New York: Academic Press.

Table 3 Examples of foodborne toxins or toxin-producing organisms, excluding plant foodstuffs

Pathogen or toxin	*Principal symptoms*	*Common food source*
Bacillus cereus	(a) diarrhea	Proteinaceous food, vegetables, sauces, puddings
	(b) Vomiting	Fried rice
Bacillus subtilis	Vomiting, diarrhea	Meat and pastry
	Flushing, sweating	Meat/seafood with rice
Bacillus licheniformis	Diarrhea	Cooked meat and vegetables
Clostridium botulinum	Neuroparalytic disease (botulism)	Meat, fish, vegetables, hazelnut conserve
Clostridium perfringens	Diarrhea, abdominal pain	Meat, poultry
Salmonella enteridis	Diarrhea, abdominal pain, fever, vomiting	Poultry, eggs
Staphylococcus aureus	Vomiting, abdominal pain, diarrhea	Numerous but specially cooked high-protein foods
Verotoxin-producing *Escherichia coli*	Hemorrhagic colitis	Ground beef
Listeria monocytogenes	Listeriosis	Unpasteurized cheese, undercooked meat
Dioxins and dibenzofurans	Adverse effects uncertain when consumed in quantities found in food	Fish
Cantharidin	Sensitivity to urethra and genitalia; priapism	Frogs that have Meloidae (blister beetles)
Methyl mercury	Brain damage	Fish, bread
Toxic alkaloid (saxitoxin) in dinoflagellates and plankton	Diverse neurological disorders (paralytic shellfish poisoning)	Clams, oysters, scallops, and mussels
Brevetoxins	Paraesthesia, abdominal pain, diarrhea, transient blindness, paralysis, death (neurotoxic shellfish poisoning)	Clams, oysters, scallops, and mussels
Ciguatera toxin	Diverse gastrointestinal and neurological disorders	Fish (especially reef predators)
Tetrodotoxin	Diverse gastrointestinal and neurological disorders	Puffer fish, certain newts
Domoic acid	Vomiting, diarrhea, hyperexcitation, seizures, memory loss (amnesic shellfish poisoning)	Mussels
Okadaic acid, dinophysis toxins, yessotoxin, pectenotoxins	Diarrhea, vomiting, abdominal pain (diarrhetic shellfish poisoning)	Mussels, scallops
Scombrotoxin (usually histamine)	Headache, palpitations, gastrointestinal disturbance	Mackerel, tuna, and related species
Tetramine (red whelk poisoning)	Diplopia, dizziness, leg pains	Whelks
Grayanotoxins (in honey from areas of Turkey where Rhododendrons are grown)	Hypotension, bradycardia, vomiting, sweating	Honey
Unknown (? in algae) (turtle flesh poisoning)	Cardiorespiratory failure, death	Turtles

Food Storage

Chemical changes in food during storage can produce substances that cause food intolerance. An example is intolerance to ripe or stored tomatoes in subjects who can safely eat green tomatoes, where ripening of the fruit produces a new active glycoprotein. Some adverse reactions resulting from food storage come into the category of toxic reactions, such as the rise in levels of histamine and tyramine in certain foods during storage as a result of bacterial decarboxylation. An example of this is the production of histamine in badly stored mackerel and other fish: scombroid fish poisoning. Contamination of food by antigens such as storage mites or microbial spores may give rise to adverse effects, particularly asthma and eczema. Contamination of food by microorganisms may result in adverse effects. For example, celery, parsnip, and parsley may become infected with the fungus *Sclerotinia scleriotiorum* ('pink rot'), resulting in the production of the photosensitizing chemicals psoralen, 5-methoxypsoralen, and 8-methoxypsoralen.

Practical Applications

Food arouses not only the appetite but also the emotions. The passion for food that is natural (i.e., free from extraneous ingredients) is not new; in 1857, a survey of adulterants in food showed that childrens' sweets were commonly colored by red lead (lead oxide), lead chromate, mercuric sulfide, and copper arsenite. By the late 1850s, 'pure and unadulterated' had become the stock advertising slogan of those anxious to cash in on the then

newly awakened fears of the public. The current scale of the use of additives in food comes as a surprise to most people, and it is understandable that many should find these substances vaguely menacing. Nonetheless, the current phobia of food additives and food processing, and the obsession for so-called natural or health food arises largely out of misinformation and ignorance. Obsession with so-called natural or health food ignores the wide range of naturally occurring toxins in foods. The concept of health food is wholly misleading. For example, a survey of 'crunchy' peanut butter showed that 11 out of 59 samples from health food producers contained over 100 $\mu g\,kg^{-1}$ of aflatoxins, over 10 times the proposed maximum permitted level for total aflatoxins. Only one of the 26 samples from other producers contained aflatoxins in excess of 10 $\mu g\,kg^{-1}$, and none contained more than 50 $\mu g\,kg^{-1}$.

Mycotoxins

J D Groopman and T W Kensler, Johns Hopkins University, Baltimore, MD, USA

Mycotoxins are toxic fungal metabolites of enormous chemical diversity that naturally contaminate the human food supply. These compounds induce an array of toxicologic effects when consumed in sufficient quantities. The three major genera of mycotoxin-producing fungi are *Aspergillus*, *Fusarium*, and *Penicillium*. This field has been comprehensively reviewed by the Council for Agricultural Science and Technology (CAST) and concisely by Etzel. The potential production of mycotoxins is insidious since fungal growth can occur both prior to and after grain harvest. Ecological conditions such as drought or damage to seeds by insects or mechanical harvesting can enhance mycotoxin production during both growth and storage. Mycotoxin production also occurs over a wide range of moisture content, relative humidity, and temperature. The major crops affected throughout the world are corn, peanuts, cotton, wheat, rice, and the processed food derived from these commodities.

Following the discovery of the carcinogenic aflatoxins 40 years ago, the search for mycotoxins has led to the identification of more than 100 toxigenic fungi and more than 300 mycotoxins worldwide. Most of these mycotoxins have not been linked to any toxic syndromes in animals or people, but some, such as aflatoxins, certain trichothecenes, fumonisins, and ochratoxins, have been implicated in highly lethal episodic outbreaks of mold poisoning in exposed animals and/or human populations. Mycotoxins with carcinogenic potency in experimental animal models include aflatoxins, sterigmatocystin, ochratoxin, fumonisin, patulin, and penicillic acid. Of these agents, aflatoxin B_1 has been classified as a category I human carcinogen by the International Agency for Research on Cancer (IARC). This article briefly describes the occurrence, biological effects, mechanistic studies, and where available, epidemiological associations of dietary exposure to major mycotoxins with human disease outcomes.

Aflatoxins

Chemistry and Occurrence

The aflatoxins (AFs) were discovered as the causative agent of turkey X disease, which resulted in the death of thousands of turkey poults, ducklings, and chicks fed a contaminated peanut meal. Chemically, the AFs are a highly substituted coumarin moiety containing a fused dihydrofurofuran moiety. Four major AFs designated B_1, B_2, G_1, and G_2 are produced by *A. flavus* and *A. parasiticus*. AFB_1 and AFB_2 were named because of their strong blue fluorescence under ultraviolet light, whereas AFG_1 and AFG_2 fluoresced greenish-yellow.

Commodities most often shown to contain AFs are peanuts, various other nuts, cotton seed, corn, and rice. Human exposure can occur from consumption of AFs from these sources and the products derived from them, as well as from tissues, eggs, and milk (AFM_1) from animals that have consumed contaminated feeds. When contamination occurs, AFB_1 generally predominates. Although contamination by the molds may be universal within a given geographical area, the levels or final concentrations of AFs in the grain product can vary from less than 1 ppb to greater than 12,000 ppb. It is important to note that obvious contamination of a commodity with *A. flavus* or *A. parasiticus* does not necessarily indicate the presence of AFs, and the appearance of a sound, uninfected sample of commodity does not preclude the existence of significant quantities of AFs.

Widespread concern regarding the toxic effects of AFs in humans and animals and possible transfer of residues from animal tissues and milk to humans has led to regulatory actions governing the interstate as

well as global transport and consumption of AF-contaminated food and feed commodities. The US Food and Drug Administration has set the action levels of AF in commodities. For feeding mature nonlactating animals, the action level is 100 ppb; for commodities destined for human consumption and interstate commerce, it is 20 ppb; and for milk it is 0.5 ppb.

Toxic Effects

AFs are potent liver toxins, and their effects in animals vary with dose, length of exposure, species, breed, and diet or nutritional status. These toxins may be lethal when consumed in large doses; sublethal doses produce a chronic toxicity, and low levels of chronic exposure can result in cancer, primarily liver cancer, in many animal species. AFB_1, the most potent and most commonly occurring AF, is acutely toxic to all species of animals, birds, and fishes tested. Sheep and mice are the most resistant, whereas cats, dogs, and rabbits are the most sensitive species. Chronic aflatoxicosis is characterized by bile duct proliferation, periportal fibrosis, icterus, and cirrhosis of liver. Prolonged exposure to low levels of AFB_1 leads to hepatoma, cholangiocarcinoma, or hepatocellular carcinoma and other tumors. The molecular basis for the toxicology of aflatoxin has been reviewed by Wild and Turner.

Some cases of acute aflatoxicosis in humans have been reported in the literature, especially in the subpopulations of developing countries. Clinical manifestations were characterized by vomiting, abdominal pain, pulmonary edema, and fatty infiltration and necrosis of the liver. There was a putative aflatoxin poisoning in western India when there was consumption of heavily molded corn. There were at least 97 fatalities, and these deaths occurred only in households where the contaminated corn was consumed. Histopathology of liver specimens revealed extensive bile duct proliferation, a lesion often noted in experimental animals after acute AF exposure. An incident of acute aflatoxicosis in Kenya was also associated with consumption of maize highly contaminated with AF. There were 20 hospital admissions with a 20% mortality. Also, the consumption of AF-contaminated noodles resulted in acute hepatic encephalopathy in children in Malaysia. Up to 3 mg of AF was suspected to be present in a single serving of contaminated noodles.

Carcinogenicity in Animals

AFB_1 is a potent liver carcinogen in many species of animals, including rodents, nonhuman primates, and fish. In appropriate circumstances, dependent on such variables as animal species and strain, dose, route of administration, and dietary factors, significant incidences of tumors have been induced at sites other than the liver, such as kidney and colon. AFB_1 has been demonstrated to induce liver tumors in two species of lower primates: the tree shrew (*Tupaia glis*) and the marmoset (*Saguinus oedipomidas*). All liver tumors of the tree shrew were classified as hepatocellular carcinoma (HCC) and developed in a manner similar to those of the rat. Unlike the case with rats, in the marmoset histologic observation revealed the association of cirrhotic changes with liver tumor development. Rhesus monkeys have also proven to be susceptible to AFB_1 carcinogenicity. Data from 47 monkeys, representing three species (rhesus, cynomolgus, and African green), that had received AFB_1 have been published. Primary liver tumor incidence was 19% (5/26) in animals surviving for longer than 6 months, and total tumor incidence in these animals was 50% (13/26).

Metabolism

Metabolism plays a critical role in the biological activity and disposition of AF. To produce a DNA damage product, AFB_1 undergoes an initial two-electron oxidation by the cytochrome P450 family members CYP1A2 and CYP3A4, yielding aflatoxin B1-8,9-oxide. This epoxide reacts with the *N*7 atom of guanine to form a pro-mutagenic DNA adduct (aflatoxin–*N*7–guanine). The aflatoxin–DNA adduct is unstable and undergoes depurination, leading to its urinary excretion. Aflatoxin B1-8,9-oxide is also a substrate for several isoforms of human glutathione *S*-transferases (GSTs), which yield a stable, nontoxic, polar product that is excreted in the bile. The aflatoxin–glutathione product also undergoes sequential metabolism in the liver and kidneys to be excreted as a mercapturic acid (aflatoxin–*N*-acetylcysteine) in the urine. Aflatoxin B1 also undergoes extensive oxidation, which is catalyzed by cytochrome P450s. In addition to formation of the 8,9-oxide, oxidation by CYP1A2 yields a stable urinary metabolite, aflatoxin M1, that is excreted in milk. Aflatoxin M1 is less carcinogenic or mutagenic than aflatoxin B1, but it is equally toxic. The oxidation products of aflatoxin can be excreted without further biotransformation or can be conjugated by UDP-glucuronosyl transferases. Collectively, these end products of aflatoxin biotransformation are biomarkers of exposure to aflatoxin and risk of hepatocellular carcinoma.

Aflatoxin and Human Cancer

HCC is the fifth leading cause of cancer mortality throughout the world, and in areas of Asia and Africa it accounts for nearly 70% of all cancer deaths. Furthermore, due to the lack of symptoms in the early stages and rapid growth rates of tumors, most HCCs are discovered in very advanced stages. The 5-year mortality rate for individuals diagnosed with HCC is greater than 95%. In the People's Republic of China, HCC is the third leading cause of cancer mortality and accounts for at least 250,000 deaths per year, with an incidence in some counties approaching 100 cases per 100,000 per year. Moreover, in high-risk regions of the world the median age of onset of HCC is decades earlier than in the United States.

In the early 1990s, nested case–control studies conducted in Shanghai utilized these biomarkers to establish a significant association between aflatoxin exposure and HCC. They showed that the risk of HCC increased dramatically (60-fold) in individuals who had been exposed to aflatoxin and had chronic hepatitis infection compared to those with neither the chemical nor viral exposures. Additional studies in Qidong and Taiwan have confirmed this striking chemical–viral interaction. The underlying mechanism for this interaction remains poorly understood.

The relationship between aflatoxin exposure and development of human HCC is further highlighted by molecular biological studies on the *p53* tumor suppressor gene, the most common mutated gene detected in many human cancers. The initial results came from three independent studies of *p53* mutations in HCCs occurring in populations exposed to high levels of dietary AF and found high frequencies of G → T transversions, with clustering at codon 249. On the other hand, studies of *p53* mutations in HCCs from Japan and other areas where there is little exposure to AF revealed no mutations at codon 249.

A positive correlation has been observed between population estimates of aflatoxin exposure and the proportion of HCC cases with a *p53* 249^{ser} mutation detected in plasma. Kirk and colleagues analyzed restriction length fragment polymorphisms to detect this mutation in the plasma of liver cancer patients in The Gambia, West Africa. Jackson *et al.* subsequently used mass spectrometry to detect the same mutation in matched plasma and tumor samples from cancer patients in Qidong. Continuing validation of this biomarker in a prospective cohort has shown that it can be detected 1 or more years in advance of HCC diagnosis. Collectively, these genetic serum markers reveal a new paradigm for early identification of at-risk individuals and HCC diagnosis.

Fumonisins

Occurrence

The fumonisins are a class of mycotoxins produced by *Fusarium moniliforme*, a fungus that is a ubiquitous contaminant of corn, and are also found at high levels in milk and cereal products. Six fumonisins have been isolated and characterized from *F. moniliforme*. They are designated as fumonisin B_1 (FB_1), B_2, B_3, B_4, A_1, and A_2. Only FB_1 and FB_2 appear to be toxicologically significant and have been studied to any extent. FB_1 and FB_2 were first isolated in 1988 and invariably occur together, with FB_2 at levels of 15–35% of FB_1. Levels of FB_1 have annual variation but are consistently in the 0.5 to 2 ppm range in US cornmeal and have been reported as high as 150 ppm in corn destined for human consumption in South Africa. Regulatory limits for fumonisins in commodities are currently being promolugated worldwide.

Toxicity

Fusarium moniliforme contaminated corn has been associated with several human and animal diseases, including luekoencephalomalacia (LEM) in horses, pulmonary edema in swine, and hepatoxicity in horses, swine, and rats. Both culture material from *F. moniliforme*-inoculated corn and pure FB_1 are capable of producing similar effects in animals. Neurotoxic signs and symptoms, including loss of feed consumption, lameness, ataxia, oral and facial paralysis, and recumbency, begin within days after initial consumption of moldy corn or by direct administration of FB_1 and may be rapidly followed by seizures and morbidity. Focal malacia and liquefaction of cerebral white matter with peripheral hemorrhage is the pathognomonic finding.

Studies have provided possible insights into the mechanisms of toxicity. The fumonisins bear considerable structural similarity to the long-chain (sphingoid) base backbones of sphingolipids. It was demonstrated that incubation of rat hepatocytes with fumonisins inhibited sphingosine biosynthesis. FB_1 increased the amount of the biosynthetic intermediate sphinganine, which suggests that fumonisins inhibit the conversion of sphinganine to *N*-acyl-sphinganines. It was subsequently shown, using mouse cerebellar neurons in culture, that FB_1 inhibited ceramide synthase in mouse brain microsomes with a competitive-like kinetic behavior with respect to both sphinganine and stearoyl-CoA. Thus, disruption of the *de novo* pathway of sphingolipid biosynthesis may be a critical event in

the diseases that have been associated with consumption of fumonisins.

Carcinogenicity in Animals

Rats fed a diet supplemented with maize contaminated with the *F. moniliforme* that had caused an outbreak of LEM in horses all developed hepatic nodules, cholantiofibrosis, or cholangiocarcinomas within 6 months. Lifetime studies in rats fed diets containing maize inoculated with *F. moniliforme* yielded a high incidence of liver tumors. The carcinogenicity of FB_1 has been directly assessed in a study in which a semipurified diet containing 50 mg/kg of pure (>90%) FB_1 was fed to rats. Ten out of 15 FB_1-treated rats (66%) developed primary HCC.

Human Health Effects

In an initial study in high-risk and low-risk regions of Transkei (South Africa) for esophageal cancer, cancer rates were correlated with the proportion of maize samples infected by *F. moniliforme*. In a follow-up study, the mean proportions of maize kernel infected with *F. moniliforme* in both healthy and moldy maize samples from households in the high-incidence esophageal cancer area were significantly higher than those in the low incidence area. FB_1 and FB_2 levels in healthy maize samples from the low-risk area were approximately 20 times lower than those in healthy samples from high-risk areas. One study estimated that naturally poisoned horses consumed levels of fuminisins equivalent to those shown to be toxic experimentally, and that humans in high esophageal cancer risk areas can potentially consume levels higher than those shown to be carcinogenic in rats.

A number of surveys have been conducted in Henan Province in northern China. Fungal strains from samples of wheat, corn, dried sweet potato, rice, and soya beans were cultured and isolated in five counties with a high incidence of esophageal cancer and three with a low incidence. The frequency of contamination by *F. moniliforme* was significantly higher in food samples from high-risk areas, although the frequency of contamination by all other fungi analyzed was also significantly higher in samples from the high-risk counties. Although these studies, as well as those conducted in South Africa, demonstrate correlations between high esophageal cancer rates and contamination of foods, primarily corn, with *F. moniliforme*, the specific role of the fumonisins or other related toxins in the etiology of this cancer remains to be firmly established.

Ochratoxins

Occurrence

Ochratoxins are a group of structurally related metabolites that are produced by *A. ochraceus* and related species, as well as *P. viridicatum* and certain other *Penecillium* species. The major mycotoxin in this group is ochratoxin A (OA), which appears to be the only one of major toxicological significance. Chemically, OA contains an isocoumarin moiety linked by a peptide bond to phenylalanine. OA has been detected in many food commodities throughout the world but is found primarily in grains grown in northern temperate areas resulting in contamination of breads and cereal products. In addition to cereals, animal products such as sausage can be significant human dietary sources of OA. Although OA has been found in many foodstuffs in many countries, the highest frequency of OA contamination in foods (~10%) was encountered in Croatia, where Balkan endemic nephropathy (BEN) is highly prevalent. Moreover, average concentrations are higher in foods from nephropathic regions. Many countries have set regulatory limits for OA ranging from 1 to 50 ppb for food and from 100 to 1000 ppb for animal feeds.

Toxicity

The toxicity of OA varies considerably with dose and between species. Dogs and pigs are the most sensitive species (0.2 and 1 mg/kg body weight, respectively). Synergistic effects of OA with other mycotoxins, such as citrinin and penicillic acid, on the LD_{50} were seen in mice following intraperitoneal injection. OA is nephrotoxic to a number of animal species, and the presence of OA in feed is believed to be the most important cause of spontaneous mycotoxic porcine and poultry nephropathy. OA also produces hepatic toxicity at high doses. OA is teratogenic in mice, rats, and hamster, and the major target in the fetus is the developing central nervous system. OA is also immunosuppressive at low doses, affecting immune function at both the level of antibody synthesis and natural killer cell activity. The toxic mechanism of OA has been shown to be inhibition of protein synthesis by competition with phenylalanine in the phenylalanyl-tRNA synthetase-catalyzed reaction. OA also inhibits other enzymes that use phenylalanine as a substrate, such as phenylalanine hydroxylase. The effect of OA on protein synthesis is followed by an inhibition of RNA synthesis, which may affect proteins with a high turnover. OA has also been found to enhance lipid peroxidation *in vivo*.

Carcinogenicity

OA has been tested for carcinogenicity by oral administration in mice and rats. The kidney, and in particular the tubular epithelial cells, was the major target organ for OA-induced lesions. In male ddY and DDD mice, atypical hyperplasia, cystadenomas, and carcinomas of the renal tubular cells were induced, as were neoplastic nodules and hepatocyte tumors of the liver. In B6C3F1 mice, tubular-cell adenomas and carcinomas of the kidneys were induced in male mice, and the incidences of hepatocellular adenomas and carcinomas were increased in male and female mice. In male and female F344 rats, OA induced neoplastic effects in the kidneys.

Human Health Effects

It has been suggested for several decades that excessive exposure to OA plays a substantive role in the development of BEN. BEN is a bilateral, noninflammatory, chronic nephropathy in which the kidneys are extremely reduced in size and weight and show diffuse cortical fibrosis. Functional impairments are characterized by progressive hypercreatininemia, hyperuremia, and hypochromic anemia. In an endemic area of Croatia, an extremely high incidence of urinary tract tumors in the endemic areas for BEN, particularly urothelial tumors of the pelvis and ureter, has been reported. In Bulgaria, 16 cases of urinary tract tumors were reported among 33 autopsied patients with BEN. A causal relationship between exposure to OA and these human diseases is suggested by (i) similarities in the morphological and functional renal impairments induced by OA in animals and those observed in BEN and (ii) the finding that foods from the endemic areas are more heavily contaminated with OA than foods from disease-free areas. Analyses of serum samples in European countries from nearly a dozen studies revealed that blood from healthy humans was contaminated with OA at concentrations of 0.1–40 ng/ml. The frequency of contamination of human sera, which ranged from 4 to 57%, seems to indicate continuous, widespread exposure of humans to OA.

An association between BEN and/or urinary tract tumors and OA content in blood samples has been reported. Among 61 patients with BEN and/or urinary tract tumors, 14.8% had levels of 1 or 2 ng/ml and 11.5% had more than 2 ng/ml OA in their blood. This proportion was significantly higher than that in a control group of 63 individuals from unaffected families in the endemic villages (7.9 and 3.2%, respectively). A case–control study provided molecular evidence for the possible role of ochratoxin in the development of urinary tract tumors in Bulgaria.

Trichothecenes

The trichothecenes are a family of more than 150 structurally related compounds produced by several fungal genera (*Fusarium*, *Cephalosporium*, *Myrothecium*, *Stachybotrys*, and *Trichoderma*). Chemically, they are sesquiterpenes characterized by a double bond at position C-9, an epoxide ring at C-12, and various patterns of hydroxy and acetoxy substitutions at positions C-3, C-4, C-15, C-7, and C-8. There are four naturally occurring trichothecene mycotoxins (deoxynivalenol, nivalenol, T-2 toxin, and diacetoxyscirpenol) produced in food and feed by *Fusarium* species.

Deoxynivalenol

Deoxynivalenol (DON) is probably the most widely distributed *Fusarium* mycotoxin. Its occurrence in foods in North America, Japan, and Europe is common, but the concentration is relatively low; however, its contamination in cereals in some developing countries, particularly in southern China and areas of South America and Africa, is usually high during some years. In 1980 and 1981 in Canada and 1982 in the United States, DON was found in wheat as the result of severe infestations with the wheat scab fungus, *F. graminearum*. In both countries, the soft winter wheats were the most severely affected. In Canada, dried corn was found to contain higher levels of DON. Several countries have set guidelines or official tolerance levels for DON in food and feed. The range varies from 0.005 to 4 mg/kg. Acute mycotoxicoses affecting fairly large numbers of people and caused by ingestion of DON-contaminated food have been reported in China, India, and other countries.

T-2 Toxin

T-2 toxin is produced primarily by *F. sporotrichioides* and has been reported in many areas of the world. It is formed in large quantities in the unusual circumstance of prolonged wet weather at harvest. Natural contamination of foods and feeds by T-2 toxin in the United States has been reported in only one incident involving heavily molded corn. An official tolerance level of 0.1 mg/kg was established for T-2 toxin in grains in Russia.

T-2 toxin, as the representative trichothecene, has been well studied for its toxic effects on various animal models and has been reviewed in detail.

General signs of toxicity in animals include weight loss, decreased feed conversion, feed refusal, vomiting, bloody diarrhea, severe dermatitis, hemorrhage, decreased egg production, abortion, and death. Histologic lesions consist of necrosis and hemorrhage in proliferating tissues of the intestinal mucosa, bone marrow, spleen, testis, and ovary. T-2 toxin can alter hemostasis and affect cellular immune response in animals, and it is a strong inhibitor of protein and DNA synthesis. T-2 toxin is also teratogenic in mice and rats. As the major trichothecene mycotoxin, T-2 toxin has been implicated in a variety of animal and human toxicosis, such as alimentary toxic aleukia, Msleni joint disease, scabby grain toxicosis, and Kashin–Beck disease.

Other Mycotoxins

Zearalenone

Zearalenone (ZEN) is produced primarily by *F. graminearum* and is among the most widely distributed *Fusarium* mycotoxins. It is associated mainly with maize but occurs in modest concentrations in wheat, barley, sorghum, and other commodities. An official tolerance level of 1 mg/kg ZEN in grains, fats, and oils was established in Russia. Proposed levels in other countries are 0.2 mg/kg ZEN in maize in Brazil and 0.03 mg/kg in all food in Romania. ZEN has estrogenic effects in domestic pigs and experimental animals. F-2 toxicosis and hyperestrogenism are two diseases in pigs caused by ZEN. ZEN is teratogenic to mice and rats and induces chromosomal anomalies in cultured rodent cells. Its carcinogenicity was tested by administration in the diet of mice in one experiment and in that of rats in two experiments. An increased incidence of hepatocellular adenomas was observed in female mice, and an increased incidence of pituitary adenomas was observed in mice of both sexes. No increase in the incidence of tumors was observed in rats.

Sterigmatocystin

Sterigmatocystin is produced by several species of *Aspergillus*, *Penicillium luteum*, and a *Bipolaris* species. Chemically, sterigmatocystin resembles the AFT and is a precursor in the biosynthesis of AFT. It has been detected at low concentrations in green coffee, moldy wheat, and in the rind of hard Dutch cheese. Sterigmatocystin is a hepatotoxin and is less potent than the AFT. It was mutagenic in the Ames test, the *Rec* assay, and the *Bacillus subtilis* assay. It can covalently bind to DNA and form DNA adducts. It has been proven that sterigmatocystin is carcinogenic to rats and mice, mainly inducing liver tumors.

Patulin

Patulin is produced primarily by *P. expansum*. Other *Penicillium* and *Aspergillus* species can also be patulin producers. Commodities found contaminated with patulin are mainly fruits and fruit juices in Europe and North America. Patulin is appreciably stable in apple and grape juices, and it may constitute a potential threat to humans. Currently, 11 countries have set regulatory limits for patulin in fruit juice ranging from 30 to 50 ppb. The toxicity of patulin has been studied in many experimental models, including chicken, quail, cat, cattle, rabbit, mice, and rats. The toxic effects on these animals were found to be edema and hemorrhage in brain and lungs; capillary damage in the liver, spleen, and kidney; paralysis of motor nerves; and convulsions. Patulin is also an immunosuppressive agent that inhibits multiple aspects of macrophage function.

Pesticides

M Saltmarsh, Alton, UK

What are Pesticides?

Pesticide is a generic term that covers a wide range of natural and synthetic chemicals (over 700 in total) that are used to protect crops from attack from pests, both before and after harvest. There are many different sorts of pests. The term includes insects, slugs and snails, nematode worms, mites, rodents, weeds, molds, bacteria and viruses. The chemicals can be applied before and during growth of the plant or on to the stored crop as, for example, fumigants, which are used to kill pests that have infested stored cocoa or grain. Chemicals used to treat pests on animals are not included; they are considered as veterinary medicines.

The pesticide formulation used by the farmer will include the pesticide chemical itself and a number of other chemicals that enable it to be applied and to work as effectively as possible. These will include solvents, adhesives, and surface-active agents such as emulsifiers. In some cases other chemicals, known as 'safeners,' are applied to minimize the damage done to the crop while maintaining the effectiveness of the spray on the target.

It is estimated that worldwide usage of pesticides is around 2.5 million tons with a cost in 1997 of US$21 billion.

Why Do We Need Pesticides?

Food crops are subject to attack by a multitude of pests and diseases and pesticides are applied to minimize the damage to the crop. It has been estimated that without protection world cereal crop yields would fall by between 46 and 83%. History is littered with records of crop failures and famine caused primarily by rodent, insect or fungus. Some of these events have had a wide-ranging and long-lasting effect, like the 1845–1846 Irish potato famine and the 1917–1918 German 'turnip winter,' the latter so called because the potatoes rotted and turnips were the only stored root crop that was available to feed the population through the winter. Both these events, in which 1.5 million and 700 000 people died, respectively, were caused by potato blight, infection by the fungus *Phytophthora infestans*. Famine caused by massive swarms of locust is still all too common in Northern Africa and Arabia. Less spectacular but as disastrous is the loss of an estimated 30% of harvested crops in India to rodents.

In addition to the loss of the crop, pesticides are used to control agents which make the crop toxic rather than healthy. Two examples are the toxins caused by fungi. When an insect bores into a peanut it allows spores of the fungus *Aspergillus flavus* to enter and grow, producing the aflatoxins, a series of carcinogens. When rye (*Secale cereale*) grows in damp conditions a fungus, *Claviceps purpurea*, can grow on the seed. If this seed is subsequently ground into flour and made into bread it can cause consumers to suffer hallucinations, gangrene, and death. Outbreaks amounting to epidemics were common in the Middle Ages in Europe and one occurred as recently as 1951 in France.

A second reason relates not so much to quantity as to quality. Supermarkets in the developed nations offer a wide range of fresh produce at competitive prices. Consumers do not like holes made by slugs and snails in their fresh lettuce. They do not expect scab marks on their apples, or holes made by small maggots in their carrots. Flour millers do not expect to have to clean the grain from weed seeds before milling. Even small defects can dramatically reduce the value of the crop, or indeed make it unsaleable, and the need for a competitive price requires minimal labor input so that application of pesticide is essential.

Types of Pesticides

There are currently around 600 pesticides, both natural and synthetic. Natural pesticides include both chemicals derived from plant sources and biological agents such as parasitic wasps, mites, bacteria, and chemicals contained within or exuded by plants or bacteria. While there is no inherent reason why natural products should be any safer than synthetic ones (after all, insect

venoms and toxins and poisonous plants are natural), it appears that the risks do lie in their potential impact on the environment rather than on their effect in food. There are also increasing numbers of cases where plants have been given a gene which expresses a natural pesticide (see *Bacillus thuringiensis*, below).

At the time of writing, naturally derived pesticides make up less than 5% of the world pesticide market, but a great deal of work is being devoted to the screening of natural sources and this proportion will certainly increase. The most successful natural product development so far has been that of the pyrethrin insecticides, of which 33 are currently available.

The largest classes of pesticides are pyrethrins, organochlorines, organophosphates, and carbamates, although there are many smaller classes with only one or two members. The chemical structures of the key members of the major groups are given in **Table 1**.

Important Pesticide Groups

This list covers the important pesticide groups and some individual pesticides but does not attempt to be comprehensive.

Pyrethrins

Pyrethrins are chemically related to pyrethrin, which is a secondary metabolite found in the flowers of the pyrethrum plant (*Chrysanthemum cinerariaefolium*). Dried pyrethrum flowers were used as an insecticide in ancient China and in the middle ages in Persia. The dried flowers are still used. Current production is around 20 000 tons per annum centered in Kenya and Tanzania. The pyrethrins are effective insecticides, having very low dose rates and rapid knockdown of insects but being harmless to mammals under all normal conditions. Natural pyrethrins break down rapidly under the influence of oxygen and UV light. This limits their use in agriculture, but recently synthetic analogs have been developed to overcome these problems. Starting from the structure of the natural product a large number of synthetic compounds have been made. It is worth noting how they differ in effectiveness: deltamethrin is a broad range insecticide; allethrin is particularly toxic to house flies (*Musca domestica*) but much less effective with other insects; flumethrin is active against cattle ticks; while others are acaricides or miticides with little or no insecticidal activity.

Bacillus thuringiensis

Bacillus thuringiensis is a widely distributed bacterium that during sporulation produces a crystal inclusion which is insecticidal when ingested by the larvae of a number of insect orders. Susceptible orders include Lepidoptera, Diptera, and Colcoptera. The action of *B. thuringiensis* was first observed in 1901 as the cause of a disease of silkworms. Several strains of the bacterium have been identified with activity against a range of insects including cabbage looper, tobacco budworm, mosquito, black fly, and more recently nematodes, ants and fruit flies. While the bacterium appears an ideal insecticide (having a toxicity 300 times greater than synthetic pyrethroids), it requires careful use. It is most effective against neonates and early larval instars so that spraying must be timed for egg hatch. It also has no contact activity and must be ingested so the plant must be well covered to ensure the insect receives a lethal dose. Furthermore it has a half-life in the field as short as 4 h, so careful timing is essential for it to be effective. Despite these limitations, it has been shown to be an important component of crop management programes.

One way of overcoming the problems of application of *B. thuringiensis* is to incorporate the gene responsible for expression of the protein into the crop plant. This has been achieved with maize (*Zea mays*) to protect against the European corn borer, with cotton (*Gossypium hirsutum*) to protect against a range of budworms and bollworms, and with potato (*Solanum tuberosum*) against Colorado beetle. (Cotton may seem irrelevant in a text on food but cottonseed oil is used extensively in cooking oils, margarines, and industrial fats.) This genetic modification has great benefits but care has to be taken that the food product has not changed in some unpredicted way. All genetically modified foods have to be extensively tested and cleared by regulatory agencies before release.

Neem oil

This is an oil obtained from the neem tree, *Azadirachta indica* A. Juss. It has been used as an insecticide in India and Africa but is increasingly being developed as a significant commercial product. It contains a number of compounds, one of the most active being azardirachtin, which is an insect antifeedant but also shows growth inhibitory and endocrine disrupting effects. This product and its individual components is at the beginning of its commercial development, which is likely to result in a series of products as significant as those from pyrethrum.

Table 1 Chemical structure and acceptable daily intake (ADI) of some pesticides

Compound	*Class*	*Structure*	*ADI (mg per kg body weight)*
Deltamethrin	Pyrethrin		0.01
DDT	Organochlorine		0.02
Lindane (HCH)	Organochlorine		0.008
Chlorfenvinphos	Organophosphate (mixture of two isomers)		0.002
Malathion	Organophosphate		0.02
Propoxur	Carbamate		0.02
Simazine	Triazine		0.005
Glufosinate			0.02
Glyphosate			0.3

Microbial phytotoxins

These are herbicides and include the highly commercially successful glufosinate, a synthetic form of phosphinothricin, first isolated from *Streptomyces hygroscopicus*, a soil-borne microbe. This compound is a potent, irreversible inhibitor of glutamine synthetase which is used in plants for photorespiration. Many attempts have been made to make synthetic variants of phosphinothricin

without success. Other members of this group include anisomycin and herboxidiene, derived from other *Streptomyces* strains. The veterinary insecticide, avermectin is derived from *Streptomyces avermitilis*.

Organochlorines

The organochlorines were the first group of synthetic insecticides and without them the dramatic decrease in malaria observed in the 1950s would have been impossible. The best known of this class is DDT (dichlorodiphenyltrichloroethane) but others include 2,4 DD, hexachlorbenzene, and lindane. Of these only lindane (γ-hexachlorocyclohexane, see **Table 1**) is still in use in the developed world.

These compounds are very slow to break down in the environment and one result of this persistance was the decline in bird numbers graphically described by Rachel Carson in the book *Silent Spring*. The problem was that DDT was concentrated through the food chain and predator birds in particular were failing to raise chicks. Since the organochlorine pesticides and other sources of organochlorines in the environment have been largely phased out, numbers of many species of birds are rising again. It is recognized that pesticides are still having an adverse influence on numbers of some birds that inhabit farmland. However, this is not a straightforward effect. In the case of the grey partridge, for example, it is because herbicides have reduced the number of weeds, which in turn has reduced the number of insects that feed on the weeds, resulting in fewer insects for the chicks to eat.

The mechanism of action of the organochlorines is not known in detail although they appear to act on the central nervous system. In humans the organochlorine compounds tend to accumulate in the body fat and in mothers' milk. While there is no direct evidence that they cause mutations or cancers, there is concern that lindane may be a carcinogen and its role in breast cancer is still under review. However, in contrast, DDT and γ-HCH have both been shown to inhibit tumors in mice initiated by aflatoxin B_1.

Although organochlorine pesticides have largely been phased out in Europe, analysis for them continues and low levels of lindane are still being detected in milk in the UK (typically at $0.005\,mg\,kg^{-1}$ compared with the maximum residue limit (see below) of $0.008\,mg\,kg^{-1}$ and an acceptable daily intake (see below) of 0.05 mg per kg body weight).

Organophosphorus compounds

Organophosphorus compounds generally contain both sulfur and phosphorus linked to carbon atoms. Their discovery was a by-product of the development of nerve gases. The group includes parathion, malathion, dimethoate, diazinon, and chlorfenvinphos. They are used as herbicides, insecticides, and fungicides. They break down quickly in the environment and do not concentrate in body fats, although they may be stored for some time. However, their mode of action – inhibition of acetylcholine esterase – means that they affect both insects and mammals and their use depends on the effective dose in the target species being below the sensitivity of other species.

Acute effects of sublethal doses of organophosphates in man include sweating, salivation, abdominal cramps, vomiting, muscular weakness, and breathing difficulties. Concern has also been expressed about long-term effects following acute exposure. Research suggests that some victims may show reductions in some neurobehavioral tests when tested some months after exposure. There are also concerns that people who do not appear to have suffered acute poisoning have subsequently developed debilitating illnesses. Symptoms include extreme exhaustion, mood changes, memory loss, depression, and severe muscle weakness.

Carbamates

Carbamates are derived from carbamic acid and are used against both insects and weeds. They are also acetylcholine esterase inhibitors. They are very reactive and are used up rapidly after application.

Methyl bromide

Methyl bromide was for many years the fumigant of choice for destroying insects in stored crops, but it is now being withdrawn as part of the general restriction on volatile organohalogen compounds because of their damaging effect on the ozone layer. It is being replaced by a number of less environmentally damaging compounds, including phosphine, although none currently available is as effective or as cheap as methyl bromide.

Phosphine

Phosphine has been used as a fumigant for many years. It is highly reactive and leaves no residues but great care has to be taken in its application because it is very toxic to humans.

Control of Pesticides

Control over pesticides is exercised in two ways: stringent testing on new pesticides before they are permitted and measurement of the residue in the crop.

Testing pesticides

There are a number of national and international bodies that approve new pesticides within their areas of responsibility. These include Codex Alimentarius, the European Union, and the US Food and Drug Administration (USFDA). Currently, within the European Union, registration of pesticides is being harmonized under Directive 91/414 EEC. Annexe 1 of this directive will identify all active ingredients permitted in pesticides. As yet this annexe is incomplete and member states are still acting under their national laws.

Within the UK pesticide registration is carried out under the Control of Pesticide Regulations 1986 and is the responsibility of the Ministry of Agriculture, Fisheries, and Food who are advised by the Advisory Committee on Pesticides.

In the USA a new Food Quality Protection Act of 1996 replaced both the Food, Drug, and Cosmetic Act and the Insecticide, Fungicide, and Rodenticide Act to provide a comprehensive regulatory scheme for pesticides.

In order to gain approval for use, pesticides are subjected to an extensive testing program including toxicity tests on mammals, plants, insects, fungi, birds, bees, fish, earthworms, and other soil organisms. The toxicity studies include effects of pesticides on fetuses and infant animals. There are also environmental tests which include laboratory tests on the breakdown and movement of the chemical in plants, soil, water, air, mammals, birds, and fish. These latter tests determine the rate of decay in the various species. Laboratory tests are followed by prolonged field trials to determine the fate of the chemical and its breakdown products in the environment and to estimate how the pesticide is concentrated up the food chain. On average it takes about 10 years to develop a new pesticide at a cost of about £50 million. The complete dossier of results has to be submitted to the approval body who determine whether the tests have been sufficiently rigorous to allow an acceptable daily intake (ADI) of the pesticide to be set. The ADI is defined as the amount of a pesticide that can be taken in each day throughout a person's life with the practical certainty, on the basis of all known facts, that no harm will result. This is determined on the basis of the highest level at which the pesticide has no observable effect in animal tests. This is then reduced by a factor of 10 in case humans are more sensitive than the animals used in the tests, and by a further factor of 10 to allow for cases where some humans may be more sensitive than others. In some cases, where the data show unusual effects, the safety factor can be increased from 100 to 500 or 1000. In practice the amount of pesticides to which the population is exposed is far below this level.

Table 1 includes the ADI for a number of the more common pesticides. There is no evidence that there are any cases where the combined effects of two pesticides are greater than the sum of their individual effects, in other words there is no evidence of synergy in toxicology between the different pesticides. Once maximum residue limits (MRL see below) for foodstuffs have been set on the basis of good agricultural practice, a total dietary intake is determined by considering all commodities in which the pesticide is likely to be used, and assuming the upper range of consumption, all foodstuffs at the MRL and no losses during transport, storage or food preparation. This figure is then compared with the ADI. For all permitted pesticides in the UK the figure is below the ADI.

Maximum residue limits

Maximum residue limits (MRLs) are statutory limits set on individual active ingredient and foodstuff combinations. They are based on residue levels which result when the pesticide is used according to the instructions on the label and in accordance with good agricultural practice (GAP). MRLs may be used to ensure that the pesticides are only being used in accordance with GAP. Many countries have codes of good operating practice with training for farmers and operators to ensure that pesticides are used at optimal levels. Some countries rely on the Codex Alimentarius Committee on Pesticide Residues to establish MRLs, while others set their own. (Codex Alimentarius is an international body which has over 120 countries as members and their standards are increasingly being accepted as the basis of world trade in foodstuffs.)

In the USA the FDA used to set tolerances for pesticide/foodstuff combinations but under the 1996 Act it sets a level for each pesticide in all foods based on the principle of a reasonable certainty of no harm. This is defined as a lifetime cancer risk of less than 1 in a million. There is also a requirement that residue tolerances must be specifically determined as being safe for children.

Within the EU, individual member states have historically set their own MRLs which differ from

state to state. Directive 76/895 established a common MRL setting regime and a series of subsequent directives has fixed the levels for a series of pesticides in fruit, vegetables, cereal products, and products of animal origin. There is an ongoing program to harmonize the levels throughout the Union.

Most industrialized countries have pesticide surveillance programs which cover both home-produced and imported commodities and these report annually. The EU has an annual specific coordinated program to check compliance in nominated combinations of pesticide and foodstuff. MRLs require sophisticated equipment for their determination because the levels are so low and the minimum detectable limit depends on the foodstuff. For example the tolerance for aldrin and dieldrin (two organochlorines) in the USA is between 0.05 and 0.1 mg kg^{-1} (parts per million), depending on the foodstuff. There are over 600 different active ingredients available commercially. Because there are so many, laboratories around the world have developed sophisticated rapid analytical techniques to allow them to screen pesticides by class so that retailers, food manufacturers, and governments can carry out analyses as a matter of routine.

The MAFF 7th Report of the UK Working Party on Pesticide Residues in 1996 showed 68% of samples had no detectable residue, 31% had residues below the MRL, and <1% were over the MRL. Similar results were obtained by the FDA who report results with relation to the tolerance to the pesticide/commodity combination. In 1995, of over 9000 samples analyzed, 64% had no detectable residues, 34% had residues below the tolerance, <1% had residues over the tolerance and <1% had residues for which there is no tolerance in that particular pesticide/commodity combination.

In all cases where MRLs or tolerances are exceeded follow-up action is taken. For home-produced materials, this involves investigation of the grower and prosecution if necessary. For imports, exceeding the level causes the consignment to be refused entry.

Maximum levels of pesticides are also set for drinking water. Pesticides get into water from spraying, runoff, percolation or from treatment of fish in aquaculture. Good practice is increasingly being developed to minimize the levels in raw water and treatment works are developing systems to reduce incoming levels to levels acceptable for drinking water.

Endocrine Disruption

The possibility that a number of chemicals discharged into the environment as a result of human activity may disrupt the endocrine system of a wide range of mammals has recently been given considerable prominence. Among the chemicals cited are the organochlorine pesticides, most of which have now been withdrawn for other reasons. While there is no doubt that there are a significant number of cases of endocrine disruption, the evidence to point to any particular chemical as a cause is lacking. It is also worth noting that deliberate endocrine disruption is a mechanism of a number of natural insecticides which act so as to inhibit development of juvenile larvae to adults. Fortunately these pesticides are reactive and usually have a short life in the field.

It is also true that there are very many naturally occurring endocrine disruptors, including the phytoestrogens present in vegetables, notably soya beans, peas, beans, cabbage, and hops. However, since this issue is very serious a considerable amount of work has now been initiated and its results will have implications for future testing of pesticides.

Future Prospects

In many parts of the world it is recognized that there has been too great a reliance on pesticide use and not enough on improving agricultural practices. There is increasing pressure to move towards minimizing pesticide usage in order to both improve the environment and to reduce cost. This is being done by using newer, more specific pesticides and by adopting improved agricultural practices and integrated pest management (a combination of biological and chemical control).

Biological control is not new. In the 1930s *Macrocentrus homonae* was introduced into Sri Lanka from Indonesia to control the tea small leaf roller (*Adoxophyes*) with such success that no chemical control measures are needed for this pest even today. More recently there have been some impressive results from using predator insects, for example in the control of cassava green mite (*Mononchellus tanajoa*) in West Africa and white fly in European greenhouses.

In terms of agricultural practice, improved crop hygiene, crop rotation, better understanding of optimal timing of application, and varying sowing dates, together with the development of more powerful and more discriminating pesticides has brought about a decrease in pesticide inputs. This is seen dramatically in the case of oil seed rape (canola). Less than 1% of the weight of herbicide applied to this crop in 1983 was applied in 1993.

Unfortunately pests develop resistance to individual pesticides over time and research is continually

needed to develop both new pesticides and resistant varieties of crops to keep the pests in check. There has been some success with new pesticides having new modes of action such as the antifeedants and antimolting agents, but this will be a continuing battle for the foreseeable future.

Bacterial Contamination

N Noah, London School of Hygiene and Tropical Medicine, London, UK

The burden of gastroenteritis (GE) in the world, in terms of both morbidity and mortality, is enormous. In the developing world (e.g., Southeast Asia), diarrhea vies with acute respiratory tract infection as the leading cause of death in childhood. Even in the more developed world, infectious GE is a significant cause of illness and time lost from work, and death does occur. Infectious intestinal disease in England is estimated to cost the country £743 million p.a. (in 1994–95 prices). GE caused by bacteria was far more costly than that caused by viruses. The more sophisticated surveillance systems become, the more GE they uncover.

Not all GE is caused by food. Probably most GE is caused by poor hygiene leading to direct or indirect transmission of infection without the assistance of food. Nevertheless, a major cause of infectious GE throughout the world is contaminated food. The definition of food poisoning (FP) is not straightforward. In essence, FP is an acute gastroenteritis caused by food. Hepatitis A, typhoid, and brucellosis, however, are not usually considered as FP, whereas botulism is, even though it causes paralysis and not GE, as is listeria, which causes septicemia and meningitis.

Bacteria are the most common known cause of FP and, with the possible exception of the Norwalk-like viruses, of GE also. As one would expect, bacterial FP is more common in summer than winter.

Bacteria produce their effects on the intestinal tract either by direct invasion of the mucosa or by the production of toxin. Some of the toxins are produced outside the intestinal tract—in the food; others are formed in the intestine. Some invasive bacteria also produce a toxin in the intestine. This article provides an overview of the bacterial causes of FP.

Bacterial Toxins

There are three main forms of bacterial enteric toxin:

Enterotoxin producing excess fluid secretion into the gut (cholera and some types of *Escherichia coli*)
Cytotoxin causing inflammation and mucosal damage (shigella and enterohemorrhagic *E. coli*)
Neurotoxin affecting the nervous system (botulism and staphylococcal toxin)

Some *E. coli* strains produce toxin; these are dealt with under Invasive Bacteria. Red kidney bean, scombrotoxin and other fish toxins, and heavy metal poisoning are dealt with elsewhere in this book.

Staphylococcal Food Poisoning

Background Staphylococcal food poisoning (SFP) is one of the few causes of bacterial FP that can commonly be attributed to a food handler. Humans frequently carry staphylococci either in an infected site or asymptomatically. Infected sites include wounds and abscesses, which may be the source of large numbers of staphylococci. Asymptomatic sites include throat, nostrils, fingernails, or hair. In general, only coagulase-positive staphylococci (*Staphylococcus aureus*), and only certain types, produce enterotoxin. Rarely, some coagulase-negative strains may occasionally produce toxin. Because the organism is also carried by many animals, outbreaks attributable to inadequate processing of a precontaminated food can occur also.

Growth and survival Staphylococci are killed by normal cooking temperatures. Any staphylococci that survive because of inadequate heat penetration or, more frequently, by postcooking contamination from a food handler will, if it is an enterotoxigenic strain and given the right conditions of warmth, moisture, pH, and time, produce toxin. Growth of staphylococci and production of toxin are optimum at approximately 20–37 °C, but growth can occur between 8 and 48 °C. This toxin is fairly heat stable; boiling for approximately 30 min is required to destroy it. Canning is usually, but not always, sufficient. The toxin is also resistant to radiation.

Many foods can cause SFP. Because the organism can grow in foods with high salt or sugar content (possibly because there is less competition from other organisms), ham is a common cause of SFP,

as are desserts, especially those containing cream. Other foods implicated include meats and other high-protein foods, salads with mayonnaise, canned mushrooms, cream, cheese, salami, and eggs (and probably any moist food). Cows with mastitis may occasionally infect milk.

Characteristic sequence of events A whole leg of ham is prepared for consumption and cooked. It is then sliced warm by a chef who has no skin lesions. The slices are overlapped on a tray. The tray is covered and left to cool for several hours before being refrigerated. Staphylococci from the nose of the chef are conveyed to the warm ham slices. Because of the large surface area, and the large bulk of covered overlapping slices of meat taking time to cool, staphylococci grow and toxin is formed. Refrigerating or reheating the meat will not destroy toxin. Similarly, ice cream may be contaminated during the preparation process by a food handler. If it is then left at room temperature, it will allow the staphylococci to grow and form toxin. Freezing the dish afterwards does not destroy toxin, and consumers are likely to contract SFP regardless of how long the ice cream is kept frozen.

Clinical features The toxin is an enterotoxin and a receptor in the gut appears to be necessary. There may also be a neurotoxic effect that acts on the vomiting center in the brain. With SFP, onset of symptoms is often dramatic. Vomiting is the most prominent symptom. It occurs between 2 and 4 h but may range from 30 min to 8 h after eating. Nausea, abdominal colic, and diarrhea are also common. Generally, as with most toxins, the higher the concentration (or the greater the amount ingested), the shorter the incubation period and the more severe the symptoms. Individual susceptibility is also a determining factor in severity. The illness is usually over in a day or two, but deaths have occurred, sometimes as a result of acute hypotension (another well-known but rare effect of the toxin).

Diagnosis Because many people carry staphylococci, it is important to ensure that the type causing an outbreak of FP is the same in the carrier and those affected; merely showing that a food handler carries staphylococci is insufficient. The organism can be grown from, or enterotoxin can be detected in, implicated foods, which usually contain $>10^6$ organisms/g. The organism can also be isolated from vomit or stool of patients and from the hands, nose, abscess, or infected wound of the food handler. Phage typing of strains, with detection and typing of enterotoxin, can also be performed. Enterotoxins A–I are recognized, although type A used to be the most common. With the advent of polymerase chain reaction, other types are being seen more frequently. As with all FP, the absence of laboratory-supporting evidence does not necessarily mean that the diagnosis is wrong or the implicated food innocent.

Bacillus cereus

Background *Bacillus cereus* is widely distributed in the environment and is not a contaminant of food. It is found in rice and other natural foods, such as herbs and spices, cream, and dry foods.

Growth and survival Unlike the staphylococci, *B. cereus* is a spore-forming organism that survives prolonged boiling. It causes two fairly distinct types of food poisoning, emetic and diarrheic. The diarrheal toxin is heat labile and, like *Clostridium perfringens*, formed in the gut. The foods commonly associated with it are 'proteinaceous' and, like *C. perfringens*, associated with meats, stews, desserts, and sauces. The emetic type is 'farinaceous,' associated mainly with cooked rice, and produces an illness similar to SFP. Different serotypes of *B. cereus* cause these two different forms of FP, and the toxins are different also. Other members of *Bacillus* sp. are discussed later. Some strains will grow at refrigeration temperatures in milk and other foods.

Clinical features and characteristic sequence of events The emetic type of *B. cereus* FP is caused by preformed toxin (cereulide) in food, usually rice that has cooled slowly. This usually happens when a large bulk of rice, as in Chinese restaurants, is allowed to cool at room temperature for many hours, often overnight. The center of the mass will stay warm for a long enough period for the spores of the bacillus to germinate and form toxin. The toxin is heat stable and will survive the quick frying given to it in a Chinese restaurant. The incubation period is usually short (1–6 h), and the symptoms, predominantly vomiting, tend to be milder than those for SFP, which it otherwise resembles.

The diarrheal form of *B. cereus* FP is similar to that caused by *C. perfringens*. The toxin, unlike the emetic type, is an enterotoxin formed in the intestine and is heat labile. The predominant symptoms are diarrhea and abdominal colic. The incubation period, as expected for an organism that multiplies in the intestine and then produces its toxin, is also longer (8–16 h). This type of *B. cereus* FP can be caused by a wide variety of foods, including meat, vegetables, and dairy products.

Diagnosis The mere presence of *B. cereus* in a food is insufficient because it is a normal contaminant of many natural foods. The diagnosis is confirmed by the finding of the organism in high concentrations [10^6–10^8/g, minimum 10^5] in cooked rice, or other food for the diarrheic type, and obtaining it from the stool or vomit of cases. Alternatively, the same serotype should be present in food and patient specimen. Detection of the toxin in the food may also be sufficient.

Clostridium botulinum

Background *Clostridium botulinum* is an anaerobic spore-forming bacterium widely distributed in soil and mud. The toxin is the most lethal substance known to man, with a LD_{50} of 0.00003 μg/kg body weight. In one incident, an adult was paralysed for more than 6 months after eating less than two teaspoonfuls of a rice salad. Tetanus toxin from *Clostridium tetani* and ricin from the castor bean (the next most toxic substances) have LD_{50} values of 0.0001 and 0.02 μg/kg, respectively. The seven toxin types, A–G, affect the nervous systems of vertebrates, animals, and birds more commonly than man. Birds in aquatic environments seem especially susceptible to mass die-offs caused by botulism. Invertebrates are not susceptible but can harbor the bacteria and toxins in their bodies. Types A, B, and E are the only toxins that affect man. Type E is acquired from fish. Type C is the main bird toxin, although types D and E are also important.

Growth and survival Because the organism grows anaerobically, special conditions have to be present for it to cause FP. Fortunately, although the organism is ubiquitous, FP caused by it is rare. First, the spores have to be present, which is not uncommon because they are widely, although patchily, distributed in soil and aquatic environments. Second, the spores have to survive cooking, which again is not difficult because they can survive heating at 100 °C for 2 h. Third, they have to be allowed to germinate and grow in anaerobic conditions. This accounts for the rarity of botulism, although accidents have occurred, and occasionally still occur, with home canning (once popular in the United States), and it occasionally occurs in preserved meat in Europe (the term botulism is derived from *botulus*, the Latin term for sausage) and in preserved rotting or fermenting food in the Arctic and areas of the Far East. Large bulks of certain types of food (e.g., canned hazelnut puree) may also be susceptible to growth and toxin formation. Commercial canning, except for the occasional accident, destroys spores by the heating processes used. The vegetative forms of *C. botulinum* are as susceptible as most other vegetative bacteria to heat, and the toxin is also destroyed by boiling—the human types A, B, and E in 2 min at 70 °C and all toxins for 5 min at 80 °C. The pH is also important: The lower the pH, the less resistant are the spores to heat, and a low pH (<4.5) affects the ability of the spores to form toxin. Hence, bottled pickled vegetables in vinegar tend to be safe. High concentrations of salt also affect the viability and toxin-forming properties of *C. botulinum*.

Clinical features The incubation period is 12–36 h (range, 6 h–10 days).The toxin destroys the cholinergic nerves in the motor end plates (MEPs). These are the junctions of the nerves with muscle, preventing the release of acetylcholine from the cholinergic nerves in the MEP and paralysing the muscle. Once this has happened, no amount of antitoxin or antibiotic is going to help. The combination of nausea, vomiting, or diarrhea followed by symmetrical descending paralysis of cranial and autonomic nerves is almost diagnostic. Thus, the characteristic neurological symptoms are blurred vision, dry mouth, difficulty swallowing, dysarthria, diplopia, and descending paralysis. Recovery has to wait until new MEPs form. There is a high fatality rate, but with modern technology patients can often be kept alive artificially until new nerve terminals have formed new MEPs, which may take several months.

Baby botulism

Some babies, usually younger than 6 months of age, acquire a form of botulism that is usually mild. It is thought to be caused by ingested spores multiplying in and colonizing the baby's intestine, forming toxin. The initial symptom is often constipation, leading to poor feeding, irritability, neck paralysis, and generalized weakness. Honey is thought to be one cause of baby botulism.

Diagnosis The diagnosis is made by the demonstration of botulinus toxin in food, stool, or serum. Growing the organism from food is suggestive but not diagnostic, whereas fecal isolates are rare except in affected individuals.

Clostridium perfringens

Background Food poisoning caused by *C. perfringens* is also toxin mediated. It differs, however, from those described previously in that toxin is formed in the intestine after ingestion of the bacteria. Like other clostridia, it is anaerobic, gram positive, and spore forming. There are five types, classified A–E

according to the enterotoxin formed; type A is the one that causes FP. Some strains, but not generally those that cause FP, can cause gas gangrene. *Clostridium perfringens* is primarily found in soil and is transmitted to animals and man by ingestion of vegetables and other plants. It is thus commonly found in the intestine of man and animals. When animals are eviscerated, the organism contaminates the inside of the carcass. Flies can transmit the organism to food.

Clostridium perfringens FP is common. Fortunately, it is rarely fatal except in those who are debilitated or immunocompromised.

Growth and survival *Clostridium perfringens* does not tend to multiply on the surface of raw meat. It grows optimally at warm temperatures of approximately 43–47 °C (range, 20–50 °C) and low oxygen levels found in the interior of a cooked dish. The cooking process will have driven off oxygen and thus facilitated sporulation and subsequent growth of the organism. Vegetative cells are not resistant to heat, but spores of the FP strains of *C. perfringens* can survive boiling for several hours. If cooling is slow, vegetative cells reform and grow rapidly. After ingestion, toxin is formed from multiplying cells in the intestine, although both toxin and vegetative cells appear to be necessary to produce symptoms.

Clinical features and characteristic sequence of events A casserole is prepared containing, among other ingredients, cubed meat. It is heated to boiling and allowed to cook for 1 or 2 h until ready. However, it is not needed immediately, and because of its bulk and lack of refrigeration facilities it is left overnight in a warm kitchen. It is warmed the next day before serving. Symptoms of diarrhea with abdominal pain begin 8–24 h later. The illness may last only a few hours, and there are no sequelae, except in those who are already debilitated.

Diagnosis The organism can be cultured from the stools of affected people and should be compared with that isolated from food for toxin production. Enterotoxin detection in stools is important confirmatory evidence. The organism has to be detected in high numbers in food to be significant. Molecular typing methods are available to compare isolates from food and feces.

Vibrio cholerae

Background Cholera appears to have originated in India. It first spread to Asia in 1817–1823, the first pandemic. The second pandemic reached Europe in 1826–1837, and subsequent to this there were five additional pandemics. The most recent began inexplicably in 1961 with a mild strain, the el Tor biotype, which had been endemic in Indonesia since 1937. More recently, it has become endemic in areas of South America. *Vibrio cholerae* 0139 is a new strain that emerged in the Indian subcontinent in 1992.

It is mainly to cholera that we owe the introduction of sanitation and the development of 'public health.' Although not a common cause of FP or GE in developed countries, the vibrios, especially *V. cholerae*, still cause large, mainly waterborne outbreaks in the developing world. It is the only gastrointestinal infection that is internationally notifiable. Because large numbers of organisms are required for infection, case-to-case transmission is uncommon.

Growth and survival The bacteria are aquatic and prefer briny waters. They can be found in many warm plankton-rich coastal waters, including the Mediterranean, Gulf of Mexico, and those of Southeast Asia and South America. Bivalved molluscs concentrate them, as they do many other bacteria. Other fish and shellfish can be contaminated, and inadequate cooking and storage will allow growth sufficient to cause FP. They prefer moist, slightly salty foods. Unfortunately, the el Tor strain is more likely to produce asymptomatic infections, persist longer in the environment, multiply more rapidly in food, and produce less immunity than the classical type. The organism produces an enterotoxin in the intestine.

Clinical features Cholera, in its most dramatic form, is characterized by an acute outpouring of watery diarrhea (rice water stools) and vomiting causing death within 24 h by acute loss of fluid and electrolytes. However, the clinical syndrome ranges from the symptomless to the mild and less dramatic forms. The organism is not invasive, and if the loss of fluid and salts can be counterbalanced by infusion of equal amounts of fluid supplemented by electrolytes, the patient will survive. Patients with an absence of acid in the stomach, and those with blood group O, are especially prone to severe disease. The incubation period is 1–3 days (range, 12 h–5 days).

Characteristic sequence of events Sewage-contaminated seafood or water is by far the most common source of infection. The vibrio can grow successfully in cooked rice and other grains contaminated by food handlers, and salad vegetables can be

contaminated by water. However, the organism often seems to find an 'environmental niche' and may persist in some communities for years.

Diagnosis The organism is usually isolated from the stool using special media. It can also be distinguished by light microscopy, and specific antisera will halt motility of the organisms. Agglutination tests with serum will distinguish 01 from 0139 and other strains. The organism can also be isolated from the environment using enriched media. Toxin production or the presence of the toxin gene can, and should, also be demonstrated. A 4-fold or greater rise in antibody is also helpful in diagnosis.

Invasive Bacteria

Salmonella Infections

Background Salmonellae are the most common known cause of bacterial FP in developed (and possibly less well-developed) countries of the world. Other bacteria such as campylobacter commonly cause GE but not necessarily FP.

There are a large number of serotypes of salmonella. They are typed according to their somatic [O] or flagellar [H phases 1 and 2] antigens according to the Kauffman–White scheme and are generally named after a geographical location. Further typing, usually by phages, can be done to distinguish the more common serotypes. Some serotypes are pathogenic for man, some for animals, others for birds including poultry, and some for humans as well as animals and birds. They are gram-negative bacilli that do not form spores but can survive for remarkably long periods on dried foods.

Salmonellae are widely distributed in and excreted by living creatures so that environmental contamination is inevitable. Protein foods processed in bulk for animals and poultry can cause widespread infection in them and subsequently in humans. In the United Kingdom, for example, fishmeal imported from Peru and fed to poultry caused a large outbreak of *Salmonella agona* infection in humans that lasted for several years through the late 1960s and early 1970s. Since then, there have been outbreaks of *S. hadar* infection in turkeys, and more recently various phage types of *S. enteritidis* infection in poultry and hens' eggs have caused outbreaks in many countries. In eggs, transmission is mainly 'vertical' (i.e., through oviducts). Before this, salmonellae gained entry to the insides of eggs mainly through the shell. If eggs were shelled in bulk, contamination of just one or two shells would be enough to contaminate the whole bulk of eggs and then grow given the right conditions. However, mayonnaise, paradoxically, is best kept at room rather than refrigerator temperatures if contaminated with salmonella. This is because acid, in the form of lemon juice or vinegar, kills salmonella more efficiently at warm than cool temperatures.

Other potent sources of contamination are sewage, polluted water, or direct fecal contamination of foodstuffs. Thus, many foods are bought already contaminated. Recent examples include mung beans, black pepper, dried herbs and spices, chocolate, spent yeast (used as a flavoring vehicle in packet potato crisps), infant dried milk, salamis, and sausages. Indeed, it is important to note that almost any food can be contaminated given the right circumstances. A multistate outbreak of salmonellosis in the United States was traced to tomatoes that had been washed in a contaminated water bath. An extensive outbreak in the United Kingdom was shown to be caused by lettuce. These episodes are particularly worrying because they show that any vegetable eaten raw may cause a salmonella infection. Cross-contamination from raw meat to relishes and dressings in a kitchen may also occur. Direct contamination of a food by a food handler, at any rate enough to cause an outbreak, is rarely documented. Indeed, infected food handlers are nearly always victims of the food they have prepared, not the source of contamination. Cases of human carriers with prolonged carriage occur.

Growth and survival Although salmonellae do not form spores, and are fairly easily destroyed by heat, they survive for a remarkably long period in the environment. An outbreak of *S. virchow* and *S. saint-paul* infection was caused in several countries in Europe by green lentils (mung beans) imported from Queensland. They were used to make bean sprouts, which required overnight growth in a warm waterbath. Slow drying of salmonellae makes them more resistant to dry heat. Moisture is important when using heat to kill bacteria.

Salmonellae grow best at 37 °C, and the danger temperatures are 30–45 °C. Growth stops below approximately 7 °C and above approximately 63 °C. Antibiotic-resistant strains are becoming more common.

The infective dose of salmonellae in humans is quite large—approximately 10^7 organisms. However, in certain circumstances, much lower doses may cause symptoms. Fatty foods such as chocolate, cheese, salami, and mayonnaise seem to require much smaller doses, and patients with immunosuppression, low acid levels in their stomach (achlorhydria), as well as the elderly and debilitated may also
