be especially vulnerable. Thus, salmonellae may be transmitted nosocomially, especially in geriatric or psychogeriatric wards, and in such outbreaks it may be a waste of time to pursue a food source. Growing antibiotic resistance in salmonellae is proving to be a problem.

Characteristic sequence of events Various scenarios are described here:

A chicken dish is undercooked and then left in a warm environment for some hours before consumption. Alternatively, the chicken may be thoroughly cooked but is then replaced in an unwashed container or plate, or cut with a knife that was used for raw chicken, and allowed to stand. The contaminated utensil may be used on another dish, thus contaminating it.

A dried herb or spice, such as black pepper, is added to a dish after cooking but while still warm, and the dish is then left to stand.

Raw egg is added to a product without cooking, as with mayonnaise or mousse, or only lightly cooked. When the light cooking involves several hundred eggs, 1 contaminated egg and time in the warmth are enough to create many infective doses. In one outbreak, 800 eggs were used and left for a considerable period before being lightly cooked to make a hollandaise sauce. More than 100 guests at the wedding were affected. Subsequent examination of leftover unused eggs from the same batch suggested that the rate of contamination of eggs was very low, perhaps less than 1 per 1000. Low rates of contamination of a common food that is generally eaten after light cooking or raw can cause a large number of salmonella infections.

Clinical features The incubation period of salmonella infection is 12–36 h but can range from 6 to 72 h. Clinical features of salmonella infection range from asymptomatic to mild and enteric fever. Enteric fever (typhoid) is usually caused by *S. typhi* or *S. paratyphi A*. More commonly, salmonellae cause severe diarrhea with fever and abdominal pain. Vomiting is uncommon. Some salmonellae, such as *S. cholerae-suis*, may cause multiple abscesses, and people with sickle cell disease may have bone abscesses with any salmonella. Septicaemia (blood poisoning), meningitis, and other localised infections are also occasional complications of salmonellosis. Patients with AIDS and other immunosuppressive conditions are particularly vulnerable to severe complications.

Salmonellae and hens eggs In the late 1980s, *S. enteritidis* rapidly became the most common cause of salmonella infections in the United Kingdom. Previously, *S. typhimurium* had been by far the most frequently reported salmonella species. Between 1984 and 1987, the number of human *S. enteritidis* infections increased by approximately 50% per year. In 1988, the number more than doubled and by 1993 it was virtually 10 times that diagnosed in 1984. By 1993, *S. enteritidis* accounted for approximately five times the number of *S. typhimurium* infections. Most of this was due to eggs, although some of it was also attributable to chicken. Many European countries and countries elsewhere experienced similar trends.

Diagnosis The diagnosis of a salmonella infection is usually made by isolation of the organism from stool or food. Some salmonellae, such as *S. typhimurium* and *S. enteritidis*, are so common that further differentiation is necessary for epidemiological purposes. Further characterization of the organism can be undertaken by phage typing and antibiotic resistance profiles. Plasmid analysis may also be useful in differentiating strains of the same phage type.

Campylobacter Infections

Background The importance of campylobacter as a cause of GE was only recognized in the mid-1970s. They are now the most common known bacterial cause of GE in most developed countries. (In less developed countries, asymptomatic infection is more common.) *Campylobacter jejuni* is the most common species, but *C. coli* is common in some areas.

Campylobacter spp. are found in the intestines of many animals and birds, including cattle and horses, household pets, and chickens. Rates of contamination of chicken carcasses vary from >75% in the United Kingdom and The Netherlands to <30% in Sweden and Norway. Some of these differences may be due to the method of isolation used.

The reported incidence of human infection in Western Europe is high. In a survey of 15 countries, the annual incidence varied from 2.9 to 166.8 per 10^5 population, with a mean of 71 (1999 data). Because these are laboratory-confirmed infections, the true incidence will be considerably higher. The wide range of incidences almost certainly reflects rates of laboratory diagnosis and reporting rather than variation in incidence.

Growth and survival The reason for the late recognition of campylobacters is their fastidiousness: They grow best in an O_2 concentration of 5%, in a

special medium, and at a temperature of 42 °C. They are also sensitive to heat, being destroyed readily by cooking, and do not survive for long (probably a few hours only) on the surfaces of foods. They nevertheless are highly successful in causing infection, probably because of their ubiquity in the environment, domestic animals, and birds and the small dose required for infection (possibly no more than 200 organisms may be enough).

Characteristic sequence of events and clinical features Although campylobacters undoubtedly cause FP, the source of infection in most instances, especially sporadic cases, is unknown. It is highly probable that many cases, perhaps even most cases, are caused by direct contact with animals, birds, the environment (both domestic and outside), meat carcasses, and possibly other people. Food-borne outbreaks in the past have been traced to untreated water and milk and also milk from bottles whose tops have been pecked by birds. Undercooked poultry is undoubtedly a risk factor, and meat prepared at barbecues, which includes pork, veal, and beef as well as chicken, has also been implicated. In one study, consuming organic products, both meat and vegetables, and eating in a restaurant were risk factors. In another, eating grapes was found to be a risk factor, and salads have also been implicated, but it is possible that some of these foods were contaminated from another source or directly by a food handler.

Other risk factors include travel to foreign countries; handling and cooking of food, especially raw meat; contact with animals and pets (especially those with diarrhea) and visiting an animal farm; swimming; and sailing.

The incubation period of 3–5 days is long compared to that of most other FP bacteria. As with most gastrointestinal (GI) infections with a long incubation period, symptoms are mostly associated with the lower GI tract. Thus, vomiting is uncommon, and abdominal pain and diarrhea are the main symptoms. An accompanying fever is usual, and the diarrhea is often bloody. The illness may last a few days, and the antibiotic ciprofloxacin is now the treatment of choice for severe or prolonged illnesses.

Septicemia or other localized infections are rare complications. One of the well-known complications of campylobacter infection is Guillain–Barre syndrome, in which a symmetrical paralysis affects the body some weeks after the infection. Recovery is usually spontaneous but may take several months. In the acute phases of the illness, respiratory support may be needed.

Diagnosis The organism can be grown from stools, rectal swabs, and food. Special media and O_2 concentrations of 5–10% are needed for campylobacter. Two typing systems are available—Penner and Lior.

Escherichia coli

Background *Escherichia coli* are a remarkable group of organisms with a wide range of infections, including meningitis, septicaemia, and urinary infections. They are often also nonpathogenic. Those that cause GE also have a wide range of pathogenic mechanisms and are divided into various fairly distinct groups: enteropathogenic (EPEC), enterohemorrhagic (EHEC), enteroinvasive (EIEC), and enterotoxigenic (ETEC) are the main ones, although some groups—diffusely adherent (DAEC) and enteroaggregative (EAEC)—have recently been described. Some EHEC strains produce a shiga (or verocyto-) toxin, STEC, which includes *E. coli* O157:H7 as well as other strains. However, because the O157 strains are much more common, STEC strains are classified as O157 and non-O157. Shiga toxin is produced by other bacteria also, including *S. dysenteriae* type 1. Only these verocytotoxin-producing strains are considered in detail here because they are commonly foodborne and can cause serious illness and death.

Escherichia coli GE is not a notifiable infection, so there are few if any data on its impact on communities. Moreover, ETEC is not identified routinely by the stool culture methods commonly used. Infections with ETEC strains are common worldwide at all ages. These strains are the most common known cause of travellers' diarrhea but can also be spread by food. This toxigenic group includes strains that produce heat-labile and heat-stable enterotoxins. Heat-labile enterotoxin is closely related to cholera toxin and causes profuse watery diarrhea. EPEC strains are common infections in neonates and infants, tend to spread from person to person, and are not commonly known to be associated with food. EIEC and the two newer strains are rare. EIEC outbreaks related to food have been occasionally described, including one caused by French cheese exported to the United States.

In the United States, *E. coli* O157:H7 is estimated to cause 20 000 cases and 250 deaths annually, 67% of outbreaks are foodborne, 8% waterborne, and 22% transmitted case to case. Swimming in contaminated water can also transmit the infection. *Escherichia coli* O157:H7 was recognized as a cause of FP only in 1982. Some strains with the verocytotoxin (VT) gene produce a toxin that causes

the hemolytic–uraemic syndrome (HUS). Other *E. coli* strains also produce VT.

Escherichia coli, including *E. coli* O157:H7, is a normal inhabitant of the intestines of many mammals, including cattle, sheep, and goats. Contamination can occur directly from the intestines to carcass to meat or via the faeces of these animals to raw vegetables and other foods.

Growth and survival The organism can survive for a considerable length of time on contaminated meat and vegetables. In two outbreaks caused by apple juice, the organism was present on the surface of apples that had fallen to the ground. The orchard was frequented by deer that were subsequently found to be carrying the organism. Manure was also used. The apples were not processed adequately to kill most organisms, and waxing may have sealed the organisms onto the surface of the fruit. The cider was not pasteurized. The organism is more resistant than salmonella to acid: *E. coli* O157:H7 has been shown to survive for 21 days in cider at a pH of 3.7–3.9 at 4 °C, with only approximately a 5% kill-off. It can grow very successfully over several weeks in manure slurries. The infectious dose is thought to be small, so case-to-case infection may occur. Like most vegetative organisms, it is destroyed by heat.

Characteristic sequence of events In a town in North Cumbria, England, 61 patients had diarrhea, many with blood, over three weeks. A total of 114 people were found to be infected, ranging in age from 3 months to 85 years. Investigations implicated a farm supplying pasteurized milk. Nine days before the first case, a problem had occurred in the heat-exchanger plates of the pasteurization unit. No tests were undertaken after new plates were fitted, and temperature monitoring was inadequate. The unit was one that a few months before had been the subject of a food hazard warning. *Escherichia coli* O157 was isolated from 66 environmental and animal feces samples on the farm but not from the milk or the pasteurization plant.

In an outbreak in the United States, 501 patients became ill after eating inadequately processed hamburgers from a restaurant chain. HUS developed in 45 cases, and 3 died.

Undercooked hamburgers and ground beef are a common cause of *E. coli* O157:H7 infection. The process of grinding beef can spread the organism from the surface of the meat to the inside. Other vehicles of infection include raw milk, unchlorinated water, apple juice, unwashed fruits and vegetables including alfalfa sprouts and radish tops, or swimming in unchlorinated pools.

Clinical features The infectious dose for *E. coli* O157:H7 is thought to be fewer than 700 organisms. The incubation period of 3–5 days is long compared with that of most other FP bacteria. As with most GI infections with a long incubation, symptoms are mostly associated with the lower GI tract. Vomiting is uncommon, and abdominal pain and diarrhea, often bloody, are the main symptoms. Fever is usual. The illness may last a few days, and the antibiotic ciprofloxacin is now the treatment of choice for severe or prolonged illnesses. HUS is characterized by hemolytic anemia, thrombocytopenic purpura, renal failure, and a death rate of 3–5%.

Diagnosis The usual method of diagnosis is to isolate the organism from stools or food, which is straightforward. However, because most of the *E. coli* in the intestine is part of the normal flora and nonpathogenic, it is necessary to demonstrate virulence by further tests or assigning it to a serotype, which normally requires more sophisticated techniques in specialist laboratories. Serotyping is performed on the somatic cell wall antigens (O antigen) and the flagellar antigen (H). On the basis of the serotyping of the O antigens, the organisms can be classified as EPEC, ETEC, etc. DNA tests are increasingly being used. Thus, *E. coli* O111 is an EPEC strain, O115 with an H antigen is an ETEC strain, O115 without an H antigen is an EIEC strain, and O157:H7 is an EHEC strain. Toxins are now tested for using enzyme-linked immunosorbent assay or DNA probes. For EIEC strains, the conjunctival sac of a guinea pig is used. Serology tests are also used, but they are not reliable indicators of recent infection.

Other Organisms

Shigella

Shigella requires a very low dose to cause infection and does not grow very well in food. Thus, it is more commonly spread case to case, especially among kindergarten and primary school children. Affected patients may excrete the organisms for weeks. Nevertheless, some large and important outbreaks have been caused by food contaminated by sewage-polluted water or food handlers. In 1995, an extensive *S. sonnei* outbreak caused by lettuce imported from Spain affected people in many countries in northern Europe. In another outbreak caused by shrimp, infection was transmitted by a food handler who mixed the shrimp by hand with mayonnaise and tomato sauce. The incubation period is 24–48 h, and although bloody or mucoid diarrhea

is the usual symptom, it is characteristically accompanied by tenesmus—a feeling of wanting to defecate without being able to do so.

Listeria

Listeriosis, caused by the bacterium *Listeria monocytogenes*, is an unpleasant and rare infection that affects the more vulnerable, such as fetuses, infants, pregnant women, the elderly, and the immunocompromised. It causes septicaemia and meningitis, which is unusual for a FP organism. Fatality rates for invasive disease are high, as many as one in three. GI symptoms may be absent or mild. Also unusual, it can grow (albeit slowly) at normal refrigeration temperatures (0–4 °C). It is also very resistant in the environment, both to cold and to heat, so that it can survive for long periods. Normal pasteurization processes will inactivate it, but some organisms can survive the high-temperature/short-time process. The incubation period for invasive disease tends to be long (up to 3 weeks), but for GI symptoms very short periods of 1 day have been recorded. Dairy products, including soft cheese and butter, and pate are the most common sources of listerial FP, and a large and sustained outbreak in England and Wales between 1987 and 1989 was thought to be due to Belgian pate. The list of foods also includes hot dogs and other ready-to-eat delicatessen meats.

Yersinia enterocolitica

Like Listeria, *Y. enterocolitica* can reproduce at refrigeration temperatures. It is often missed in the laboratory because it requires special media and grows best at 25 °C. Many strains are nonpathogenic, but it is difficult to predict which strains are pathogenic and which not using current laboratory methods, although serotypes 3, 8, and 9 are most commonly associated with illness. The organism is found in many pets and other animals, and it may survive pasteurization, especially high-temperature/short-time milk treatment. Outbreaks have been associated with raw milk and dairy products. Undercooked pork and tofu have also caused outbreaks, and in one incident a caregiver who handled pork sausages passed the infection on to some infants. These infections appear to be more common in Scandinavia than elsewhere. The incubation period is 24–48 h to 5 days. Infants and young children are most often affected. Clinical features are characteristically fever and profuse watery diarrhea, but it may mimic acute appendicitis, risking an unnecessary operation. Occasionally, in vulnerable patients, septicaemia may occur.

Vibrio parahaemolyticus

Like *V. cholerae* (and several other aquatic organisms described later), *V. parahaemolyticus* is an aquatic organism that thrives in shallow coastal waters. Deep-sea fish do not tend to harbor the organism and usually become contaminated in fish markets. Precooked frozen shrimp may be contaminated and cause FP if served without further cooking, as in a seafood cocktail. *Vibrio parahaemolyticus* FP is associated with raw, undercooked, or contaminated seafood and is especially common in Japan and probably other countries in which seafood is a staple of the diet. Contamination from raw to cooked seafood is a common cause. The incidence of *V. parahaemolyticus* FP has increased in many Asian countries and the United States since 1996, and this is thought to be caused by a pandemic clone. Diarrhea, abdominal pain, and nausea are the predominant symptoms. The diarrhea can be severe, with blood or mucus in the stool. Vomiting is a less common feature, but fever can occur. The incubation period ranges from 4 h to 4 days, but most cases occur between 12 and 24 h. Death is uncommon.

The diagnosis is made by culture of the organism from feces or food. *Vibrio parahaemolyticus* can be easily isolated from most aquatic environments, but such strains are predominantly Kanagawa negative. Only the Kanagawa-positive strains (i.e., those producing a thermostable hemolysin that can be confirmed in a laboratory) cause GE, and it is thought that they multiply selectively in the human intestine. The infectious dose can be fairly small, 2×10^5 to 3×10^7.

Vibrio vulnificus

Like the other vibrios, infection with this organism is acquired from seafood. The epidemiology is similar but the organism appears to be the most common vibrio causing FP in the United States. It also causes septicaemia by ingress through a skin lesion in the food handler and in people with chronic liver disease through consumption of raw seafood. Gastroenteritis can also occur.

Aeromonas and *Plesiomonas shigelloides*

Aeromonas is another aquatic organism that prefers brackish and fresh water. It is generally accepted as a cause of FP, after initial doubts, in both adults and children. A profuse watery diarrhea is typical, although a dysentery-like syndrome is sometimes associated with it. The incubation period is 18–24 h. Sporadic infections are more common than full-blown outbreaks. Consumption of raw shellfish should be avoided (not only for aeromonas). *Plesiomonas shigelloides* is also an aquatic organism, and FP from it is rare. Its role in FP has not been fully

elucidated. Diarrhea is the usual symptom, and the incubation period is approximately 24 h.

Bacillus subtilis and *Bacillus licheniformis*

Bacillus subtilis is a member of the *Bacillus* genus and is similar to *B. cereus*, except that its natural habitat is slightly different, and so the foods causing illness also differ. It has been recognized increasingly as a cause of GE, characterized mainly by vomiting. The incubation period is short, 2 or 3 h, although many cases occur within 1 h. Foods implicated include meat and vegetable products such as meat pies, sausage rolls, curries with accompanying rice dishes, and even bread, crumpets, and pizza. The organism is present at high levels in implicated food (10^5–10^9 cfu/g) and can be isolated easily from both food and feces. Another member of this genus, *Bacillus licheniformis*, tends to cause diarrhea. Cooked meats and vegetables have been implicated. The median incubation period is approximately 8 h. Other members of this genus can also cause FP.

Bacillus anthracis

Rare in developed countries, anthrax FP is caused by the consumption of severely infected meat that has been insufficiently cooked. Bloody diarrhea is characteristic, accompanied by nausea, vomiting, and acute abdominal pain. The incubation period is from 2 days to many weeks.

Brucellosis

Although not usually considered as FP, brucellosis deserves mention because it is commonly caused by food. *Brucella melitensis* in particular is nearly always foodborne, and cheese, milk, and other dairy products made from unpasteurized milk are common vehicles. Occasionally, contaminated meats may be responsible. *Brucella abortus* is associated with cows and cow products, *B. melitensis* with goats, and *B. suis* with pigs. Brucellosis is a serious and prolonged systemic illness, with fever, night sweats, headache, aches and pains, and, sometimes, profound depression. Many developed countries have eradicated brucella from livestock.

Streptococcal Pharyngitis

Notwithstanding the definition of FP as causing GE, streptococcal sore throat with fever has been well documented to spread in this way. Usually, a food handler has a streptococcus group A in his or her throat, which may or may not be causing symptoms, and transfers this to a food that is then left in a warm environment for some time before consumption. Foods implicated include cheese, milk, eggs, and meat. The incubation period is 24–48 h. To confirm a source, typing of strains is important, as is sound epidemiological evidence, because many people carry these streptococci in their throats.

Prevention of Bacterial Food Poisoning

With the increasing trend toward the manufacturing of foods in large quantities for distribution not only nationally but also internationally, the potential for vast outbreaks of foodborne disease is considerable. Outbreaks of salmonellosis and *E. coli* FP caused by cheese, salami, chocolate, beef jerky, infant dried milk, minced beef, hamburgers, and even potato crisps have all been documented. In one outbreak of *E. coli* O157:H7 infection, 34 lots of 281 000 lb of beef patties were manufactured in one plant, and 7 of 21 lots tested were found to be contaminated. The introduction of HACCP (hazard analysis and critical control point) in food manufacturing processes has been a significant advance in the production of safer food and the prevention of FP. Microbiological guidelines now exist for ready-to-eat foods. The establishment of Enternet in countries in Europe and elsewhere is an important step in the early detection of such outbreaks and the curtailment of their effects. This is a voluntary surveillance system that shares information on organisms causing FP. For example, an outbreak of FP affecting several tourists from different countries after staying at a hotel on the Mediterranean coast will be detected more quickly and enable an early warning to be instituted. If a contaminated food is distributed through several countries, the country that first detected a problem can issue an early warning.

Fortunately, most outbreaks of FP are more localized, although large numbers of people may still be affected. The most common problems in the preparation of food are inadequate cooking, leaving prepared food too long at too high a temperature, and allowing cross-contamination from raw to cooked food.

All foods entering the kitchen should be considered to be potentially hazardous. In any investigation, it is important not to assume that a food cannot be the cause just because it is unlikely or not known to have caused FP in the past. Salads and other vegetables or fruit eaten raw may be contaminated, and outbreaks have been caused by lettuce (*S. sonnei* and *E. coli* VTEC 0157), raspberries and strawberries (*Cyclospora cayetanensis* and hepatitis A), alfalfa sprouts (*S. enteritidis*), and radish sprouts grown hydroponically (*E. coli* VTEC

0157). Some of these foods were contaminated at the source by water or sewage, others during processing by infected food handlers (NLV and hepatitis A), and others by food handlers during preparation. It is difficult to avoid or prevent such infections in the kitchen short of cooking everything, and more stringent codes for hygiene at the growing farms and processing plants are required.

In the kitchen, it is important to keep raw and ready-to-eat foods entirely separate. Salad and fruit fall into the ready-to-eat category. Raw meats especially should have their own utensils, surfaces, and cutting boards. For cooked food entirely different utensils, surfaces, and cutting boards should be used, unless washed thoroughly in very hot water and detergent or a dishwasher and then left to dry. Otherwise, FP organisms will transfer from raw to cooked food and grow.

Cooking food, especially meat, thoroughly will destroy vegetative organisms, including salmonellas, although spores will survive. If the cooling down period is too long—normally approximately 1 h is considered the limit before refrigeration is necessary—*C. perfringens* or *B. cereus* that have survived as spores will grow. So will salmonellas and many other FP bacteria if the food was inadequately cooked. Cooking will not normally destroy preformed toxins of *S. aureus*. Infected food handlers may occasionally cause outbreaks of FP, but with the exception of staphylococci, bacterial FP from this source is rarer than is generally thought. Salmonellae almost always originate in a food, and *B. cereus* and *C. perfringens* always arise from the food. Food handlers whose hands have been contaminated usually transmit shigella, hepatitis A, or norovirus.

Thus, moist food needs to be kept either hot (above approximately 60 °C) or cold (below 8 °C, preferably 4 °C). Cooling food, even freezing it, will not destroy organisms (except for some helminths). Undercooked chicken that has been refrigerated will still need thorough cooking before it is fit to eat. A large bulk of frozen meat or poultry will need to be thawed before cooking. Large frozen turkeys may need several days in a refrigerator to thaw fully. The inside of the meat is the last to thaw and the last to cook.

Grinding meat will disperse organisms through it. Thus, hamburgers and sausages need thorough cooking.

Drinking raw milk is hazardous: A large number of organisms, from tuberculosis to *Streptococcus zooepidemicus*, can be spread in this way. Hens' eggs caused many cases of salmonella FP (mainly *S. enteritidis*) in the 1980s and 1990s throughout much of Europe and the United States. The rate of contamination was low, probably not more than 2 or 3 per 1000 eggs, but the number of cases was large because of the popularity of eggs as a food and because it is normal to eat them less than fully cooked, not only on their own but also in other dishes such as sauces and mousse. Fortunately, screening and vaccination of flocks in recent years have made this a less hazardous source of salmonellosis. Irradiation of food is effective but is not popular with the public.

Education of food handlers may be straightforward, but, especially in countries in which food handlers have low status and pay, compliance is more difficult. Nevertheless, education of the general public has been slow but has progressed: Most people now realize the importance of thawing poultry and meat thoroughly before cooking, and the large outbreaks of salmonella FP that used to occur at Christmas time in England and Wales caused by inadequately defrosted and cooked turkeys are now very rare.

Other Contaminants

C K Winter, University of California at Davis, Davis, CA, USA

Food may be contaminated with many chemicals that pose the potential for toxicological consequences in humans consuming the contaminated food items. In addition to the presence of contaminants such as mycotoxins, pesticide residues, and heavy metals, food may contain numerous organic contaminants that enter the food supply from environmental sources or as a result of chemical reactions that occur during food processing. This article focuses on three types of food contaminants: dioxins (including dibenzofurans and polychlorinated biphenyls), acrylamide, and perchlorate. Each of these classes has been subject to considerable regulatory scrutiny, scientific study, and popular media coverage. It is likely that concerns regarding the presence of these contaminants in the food supply will continue throughout the next decade or longer, and that significant efforts will be made to reduce human exposure to these substances from food. This article discusses how these types of food contaminants enter the food supply, the types of food items in which they are most likely to occur, and the potential toxicological consequences resulting from exposure to these contaminants.

Dioxins

Dioxins are organic chemicals that comprise a family of ubiquitous environmental contaminants. Technically speaking, the dioxins of potential toxicological concern are polychlorinated dibenzo-*p*-dioxins (PCDDs). They are related, both structurally and toxicologically, to polychlorinated dibenzofurans (PCDFs) and polychlorinated biphenyls (PCBs). Structures of generic PCDDs, PCDFs, and PCBs are shown in **Figure 1**. Due to their structural and toxicological similarity and to avoid confusion, all three related groups of chemicals are considered to represent "dioxins" for the purposes of this article. Specific chemicals belonging to this family are referred to as congeners. Collectively, there are more than 200 dioxin-related congeners, and each possesses unique toxicological and chemical properties.

Occurrence in the Environment and in Food

PCDDs and PCDFs are primarily introduced into the environment as by-products of combustion processes. These by-products have been identified in the exhaust gases from sources such as cigarette smoke; industrial and municipal waste incinerators; power plants burning coal, oil, or wood; and automobiles. In addition to these human sources, PCDDs and PCDFs are also produced naturally by combustion in forest fires and from volcanic eruptions.

Historically, PCDDs and PCDFs have also been produced as impurities during organic chemical synthesis. The most notable and most toxic dioxin congener, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), has been shown to be produced in the synthesis of the herbicide 2,4,5-T, one of the herbicide components of Agent Orange, notoriously used in the Vietnam War. Although 2,4,5-T is now banned for use in the United States because of TCDD and other dioxin impurities, health concerns over the exposure of military veterans to Agent Orange and to TCDD continue to be raised. PCDDs and PCDFs can also be produced through the use of chlorine

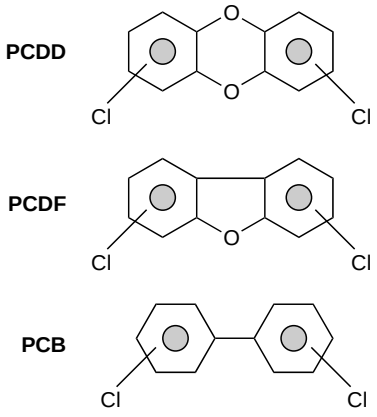

Figure 1 Chemical structures of generic PCDDs, PCDFs, and PCBs.

to bleach wood pulp, although most bleaching processes now use nonchlorine agents such as hydrogen peroxide.

PCBs have been produced synthetically since the 1930s and have been widely used for industrial applications, such as dielectric fluids in transformers (due to their inflammability) and capacitors in electrical machinery. Like their PCDD and PCDF counterparts, PCBs are extremely persistent in the environment and are of toxicological concern. As a result, the synthesis and industrial use of PCBs were significantly curtailed in the 1970s, although environmental residues of PCBs are still commonly detected today.

Although dioxin release into the environment has been known to occur for several decades, data are still limited with respect to the degree to which dioxins contaminate the food supply. Dioxin analysis in the laboratory is extremely expensive because methods must identify hundreds of different congeners, detection limits are required in the sub-part per trillion range, and significant precautions must be taken to minimize exposure of laboratory personnel to the analytical standards used for dioxin congeners.

Dioxins are highly fat soluble and have been shown to accumulate in the fat of birds, fish, and food animals. The US Environmental Protection Agency (EPA) has estimated that more than 95% of human exposure to dioxins results from dietary intake of animal fats. The major food sources for dioxin exposure include fish, poultry, meats, milk, and milk products. Dioxins are excreted in human breast milk and result in exposures to nursing infants.

Historically, it has been shown that human dioxin exposures, as determined by analyzing human tissues and environmental samples, have decreased significantly since 1987 due to engineering controls to limit dioxin emissions during combustion processes and to increased regulatory control over other sources of dioxin exposure. Dietary dioxin exposures to UK consumers were reduced by nearly two-thirds from 1982 to 1992, and subsequent studies showed even lower exposures in 1997. Nevertheless, dioxins are still ubiquitous in the environment and human exposure still occurs.

Toxicological Considerations

Dioxin exposure at significant dose levels has been linked to a large number of adverse health effects. Large acute exposures, resulting from chemical accidents and/or occupational exposure to dioxins, have caused a severe skin condition known as chloracne. A variety of other skin effects, such as rashes and discoloration, have also been attributed to acute dioxin exposures, as has liver damage.

Concerns from chronic exposure to dioxins include cancer, reproductive effects, and developmental effects. The most toxic dioxin congener, TCDD, was classified by the International Agency for Research on Cancer as a human carcinogen.

From a biochemical standpoint, PCDDs, PCDFs, and PCBs appear to cause their toxic effects through chemical binding to a specific cellular receptor known as the Ah receptor. Specific dioxin congeners vary dramatically with respect to their abilities to bind with the Ah receptor; TCDD binds extremely effectively, whereas other congeners are more limited in their binding capabilities. The degree to which various dioxin congeners bind with the Ah receptor seems to be directly related to the number and location of chlorine atoms on the congeners.

Assessing the potential human health risks from exposure to dioxins presents significant challenges. Dioxin levels in specific food items can be quite variable, and, as discussed previously, data concerning dioxin levels on foods are frequently not available.

Another difficulty encountered in assessing dioxin risks is to appropriately account for exposures to the various congeners and to account for the toxicological differences among congeners. This is most appropriately achieved through a toxic equivalency factor (TEF) approach that assigns a potency factor to each of the congeners relative to that of the most toxic dioxin TCDD. For example, the TEF for TCDD is 1 and the TEF for 1,2,3,4,7,8-hexachlorodibenzo-*p*-dioxin (with chlorines added to the 1 and 2 positions and otherwise similar to TCDD) is 0.1 based on findings that 1,2,3,4,7,8-hexachlorodibenzo-*p*-dioxin is 10 times less capable of binding to the Ah receptor than is TCDD. To calculate a total dioxin exposure, the dietary contributions of each of the dioxin congeners are multiplied by their corresponding TEFs and summed to determine a TCDD equivalent exposure.

According to the World Health Organization (WHO), a tolerable daily intake (TDI) for TCDD was established at 10 pg TCDD per kilogram bodyweight per day in 1990, although revisions by WHO reduced the TDI range to 1–4 pg/kg/day in 1999. A 1997 UK survey of dioxin consumer exposure provided an upper bound of 1.8 pg TCDD equivalent/kg/day. Surveys from other countries, using slightly different TEF approaches, yielded exposures of 0.7 pg/kg/day in Italy, 1.4 pg/kg/day in Norway, 2.4–3.5 pg/kg/day in Spain, and 0.2 pg/kg/day in New Zealand.

The US Food and Drug Administration (FDA) has been monitoring finfish, shellfish, and dairy products for dioxins since 1995 and initiated dioxin analysis of foods analyzed in its Total Diet Study in 1999. Specific findings from the FDA's annual Total Diet Study can be obtained from the FDA, although human exposure estimates, in terms of the amount of TCDD equivalent exposure per kilogram of body weight per day, have not been published by the FDA.

The EPA recommends that consumers follow the existing Federal Dietary Guidelines to reduce fat consumption and, subsequently, dioxin exposure. Such guidelines suggest that consumers choose fish, lean meat, poultry, and low- or fat-free dairy products while increasing consumption of fruits, vegetables, and grains. Dioxin exposure can be further minimized by trimming visible fat from meats, removing the skin of fish and poultry, reducing the amount of butter or lard used in cooking, and replacing cooking methods such as frying with methods such as boiling or oven broiling.

Acrylamide

Acrylamide is a widely used and versatile industrial chemical. Its most common use is as a coagulant in water treatment and purification. It is also used as a soil conditioner, in the sizing of paper and textiles, in ore processing, and as a construction aid for the building of tunnels and dam foundations.

Acrylamide is considered by the International Agency for Research on Cancer to be "probably carcinogenic to humans" based on the results of several animal carcinogenicity studies. As a result, there has been widespread concern about the potential risks from exposure to acrylamide among industrial, manufacturing, and laboratory workers. Consumer exposure to acrylamide in treated drinking water has posed a much lower concern since drinking water is subject to special treatment techniques that control the amount of acrylamide in drinking water.

Swedish researchers developed laboratory techniques that allowed for the detection of biological reaction products (hemoglobin adducts) of acrylamide in human blood samples; results from their studies allowed correlations to be made between occupational activities and acrylamide exposures. The findings that acrylamide occurred in tobacco smoke and that smokers had increased levels of hemoglobin adducts relative to nonsmokers provided a suggestion that acrylamide may be formed during incomplete combustion of organic matter or during heating. Interestingly, the researchers found significant levels of hemoglobin adducts in blood samples of nonsmoking humans not exposed occupationally to acrylamide. This led to speculation that the human diet could contain significant quantities of acrylamide. In April 2002, Swedish researchers published results of research that demonstrated the presence of acrylamide in several common foodstuffs, with the highest levels found in fried and baked foods. These findings stimulated worldwide interest in identifying the potential mechanisms for acrylamide formation in foods, in assaying a wide variety of foods for acrylamide levels, and in developing risk assessment and risk mitigation procedures.

Occurrence in Food

The findings from the initial Swedish study indicated that the highest levels (150–4000 μg/kg) of acrylamide were detected in carbohydrate-rich foods such as potatoes and in heated commercial potato products (potato chips) and crispbread. Moderate levels (5–50 μg/kg) were measured in protein-rich foods that were heated, whereas unheated or boiled foods showed no detectable acrylamide (<5 μg/kg).

The governments of several countries throughout the world performed similar analyses of acrylamide in foods and findings were fairly consistent with those reported in the Swedish study. The FDA analyzed dozens of foods for acrylamide levels and concluded that the highest levels were observed in french fries (29 samples; range, 117–1030 μg/kg) and in potato chips (40 samples; range, 117–2762 μg/kg). Multiple samples from different lots of the same commercial food products showed significant variability, with the highest levels often several times greater than the lowest levels. Commercial potato products that could be prepared by baking or by other methods showed much higher levels of acrylamide in the baked products. Acrylamide levels in baby food ranged from below the detection level (<10 μg/kg) to 130 μg/kg. All infant formula samples had levels below 10 μg/kg, and acrylamide levels in dairy products were also low.

The widespread findings of acrylamide in foodstuffs throughout the world provided the basis for numerous studies designed to elucidate the mechanisms for acrylamide formation in foods. It has been demonstrated that acrylamide can be formed from classical Maillard reactions as well as from reaction of the fatty acid oxidation product acrolein with ammonia and subsequent oxidation steps. The most plausible explanation for the relatively high acrylamide levels in fried potato products derives from a mechanism involving the reaction of the amino group of the amino acid asparagine with the

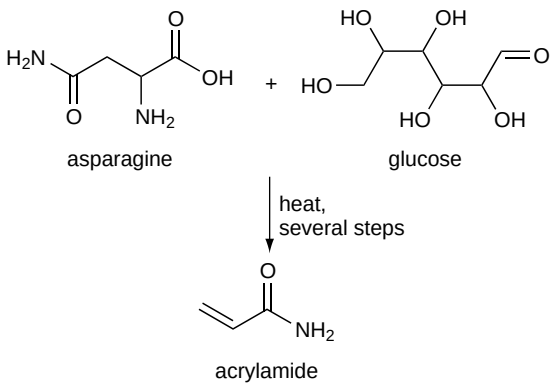

Figure 2 Proposed mechanism for acrylamide formation in foods.

carbonyl group of a reducing sugar such as glucose during baking and frying. This mechanism is shown in **Figure 2**. Potatoes are high in asparagine and in reducing sugars, and they are commonly prepared for consumption by frying or baking; all of these factors help explain the relatively high levels of acrylamide in heated potato products.

Toxicological Considerations

Laboratory toxicology studies have indicated that acrylamide is carcinogenic and also has been associated with the development of reproductive toxicity, genotoxicity, and neurotoxicity. Epidemiological and analytical studies of people exposed to acrylamide in the workplace have indicated that acrylamide does indeed enter the bloodstream of workers and can be detected and quantified as hemoglobin adducts, thus indicating both exposure and absorption of acrylamide. Such studies have not, however, indicated increases in cancer rates among those exposed occupationally to acrylamide. To date, the only documented toxicological effect observed in epidemiological studies of workers exposed to acrylamide is neurotoxicity. This effect is primarily an acute effect caused by large exposures to acrylamide for relatively short periods of time, leading to nervous system damage, weakness, and incoordination of limbs.

From a biochemical standpoint, it is likely that the health effects caused by high levels of exposure in humans and in laboratory animals may result from a Michael-type nucleophilic addition reaction of amino acids (both amino and sulfhydryl groups), peptides, and proteins to acrylamide because of the presence of the α,β-unsaturated conjugated structure in acrylamide. This is a common toxicological pathway for many reactive compounds. It is likely that high doses of acrylamide may overwhelm the defensive mechanisms of the body such as glutathione conjugation and may cause reaction with biologically significant nucleophiles, leading to mutations and possible carcinogenicity.

Although it is clear that humans have been consuming significant amounts of acrylamide in their diets for a long time, the relatively new discovery of acrylamide as a food contaminant has raised several questions. Significant efforts are currently being made to better understand the levels of acrylamide throughout the food chain and to estimate dietary exposure to acrylamide. In addition, there is much emphasis on developing food processing approaches that can reduce acrylamide formation.

Regulatory limits for acrylamide in food have yet to be established since dietary acrylamide risk assessments are still being developed. In the meantime, the FDA recommends that consumers eat a balanced diet that includes a wide variety of foods low in trans fat and saturated fat and rich in high-fiber grains, fruits, and vegetables.

Perchlorate

Perchlorate exists as an anion (ClO_4^-) with a central chlorine atom surrounded by four oxygen atoms arranged in a tetrahedron. Perchlorate is manufactured in the United States and is used as the primary ingredient of solid rocket propellant. Perchlorate wastes from the manufacture and/or improper disposal of perchlorate-containing chemicals are frequently detected in the soil and water. Levels of perchlorate have been detected in 58 California public water systems and in water samples from 18 states.

The widespread water contamination by perchlorate and its potential to cause health effects in those consuming contaminated drinking water have led four US agencies—the EPA, Department of Defense, Department of Energy, and National Aeronautics and Space Administration—to request that the US National Academy of Sciences convene a study on "Toxicological Assessment of Perchlorate Ingestion."

Occurrence in Food

Although the primary concerns from perchlorate contamination result from drinking water consumption, recent evidence has indicated that perchlorate may contaminate food items as well. A small survey of 22 lettuce samples purchased in northern California showed perchlorate contamination in 4 samples. A subsequent study of California lettuce showed detectable perchlorate levels in all 18 samples tested. The toxicological

significance of such findings has not been established, but the studies clearly indicate that perchlorate can enter lettuce, presumably from growing conditions in which perchlorate has contaminated water or soil.

Milk has also been shown to be subject to perchlorate contamination. A small survey of seven milk samples purchased in Lubbock, Texas, indicated that perchlorate was present in all of the samples at levels ranging from 1.12 to 6.30 μg/l. To put such findings in perspective, the State of California has adopted an action level of 4 μg/l for perchlorate in drinking water, whereas the EPA has yet to establish a specific drinking water limit.

Toxicological Considerations

Perchlorate is thought to exert its toxic effects at high doses by interfering with iodide uptake into the thyroid gland. This inhibition of iodide uptake can lead to reductions in the secretion of thyroid hormones that are responsible for the control of growth, development, and metabolism. Disruption of the pituitary–hypothalamic–thyroid axis by perchlorate may lead to serious effects, such as carcinogenicity, neurodevelopmental and developmental changes, reproductive toxicity, and immunotoxicity. Specific concerns relate to the exposures of infants, children, and pregnant women because the thyroid plays a major role in fetal and child development.

The ability of perchlorate to interfere with iodide uptake is due to its structural similarity with iodide. In recognition of this property, perchlorate has been used as a drug in the treatment of hyperthyroidism and for the diagnosis of thyroid or iodine metabolism disorders.

Ammonium perchlorate was found to be nongenotoxic in a number of tests, which is consistent with the fact that perchlorate is relatively inert under physiological conditions and is not metabolized to active metabolites in humans or in test animals.

Workers exposed to airborne levels of perchlorate absorbed between 0.004 and 167 mg perchlorate per day. These workers showed no evidence of thyroid abnormality, and a No Observed Adverse Effect Level was established at 34 mg absorbed perchlorate/day. Perchlorate does not accumulate in the human body, and 85–90% of perchlorate given to humans is excreted in the urine within 24 h.

Heavy Metals

G L Klein, University of Texas Medical Branch at Galveston, Galveston TX, USA

Food that we are culturally habituated to consume is usually thought to be safe. However, some foods are naturally contaminated with substances, the effects of which are unknown. Crops are sprayed with pesticides while they are being cultivated; some animals are injected with hormones while being raised. Meanwhile, other foods are mechanically processed in ways that could risk contamination. This article discusses food contamination with heavy metals, the heavy metals involved, their toxicities, and their sources in the environment. A brief consideration of medical management is also included. Five metals are considered in this category: lead, mercury, cadmium, nickel, and bismuth.

Lead

How Does Lead Contaminate Food?

Although lead is primarily known as an environmental contaminant that is ingested in paint chips by young children in urban slums or from contaminated soil or inhaled in the form of house dust or automobile exhaust, it may also enter the food and water supply. Ways in which this can occur include fuel exhaust emissions from automobiles that may contaminate crops and be retained by them, especially green leafy vegetables. Animals used for food may graze on contaminated crops and thus may also be a potential source of lead. Moreover, lead from soldered water pipes may contaminate tap water used for drink or for food production.

Permissible Intakes

In the United States, the maximum quantity of lead in the water supply that is permitted by the Environmental Protection Agency is 15 μg (0.07 μmol l^{-1}). The Food and Drug Administration (FDA) Advisory Panel recommends that no more than 100 μg (50 μmol) of lead per day should be ingested from food products.

Dietary Lead: Absorption and Consequences

People with certain macronutrient and micronutrient deficiencies are prone to experience increased absorption of lead in the diet. Thus, depletion of iron, calcium, and zinc may promote lead absorption through the gastrointestinal tract. Whereas adults may normally absorb approximately 15% of their lead intake, pregnant women and children may absorb up to 3.5 times that amount, and the explanation for this difference is not clear.

The effects of the entry of lead into the circulation depend on its concentration. Thus, the inhibition of an enzyme active in hemoglobin synthesis, δ-amino levulinic acid dehydratase (ALAD), occurs at blood lead concentrations of 5–10 μg dl^{-1} (0.25–0.5 μmol l^{-1}). Another enzyme active in heme biosynthesis, erythrocyte ferrochelatase, is inhibited at a blood lead level of 15 μg dl^{-1} (0.75 μmol l^{-1}). Reduction of the renal enzyme 25-hydroxyvitamin D-1-α hydroxylase, which converts circulating 25-hydroxyvitamin D to its biologically active steroid hormone, 1α,25-dihydroxyvitamin D (1,25$(OH)_2$D) or calcitriol, is observed at a blood lead concentration of 25 μg dl^{-1} (1.25 μmol l^{-1}). Behavioral changes and learning problems may begin to occur at blood levels previously thought to be normal, 10–15 μg dl^{-1} (0.5–0.75 μmol l^{-1}).

Manifestations of Lead Toxicity

Perhaps due to their increased absorption of lead from the diet, children appear to be more susceptible to the toxic effects of lead. These involve the nervous system, including cognitive dysfunction; the liver; the composition of circulating blood; kidney function; the vitamin D endocrine system and bone (**Table 1**); and gene function, possibly with resultant teratogenic effects. Chronic exposure results in high blood pressure, stroke, and end-stage kidney disease in adults.

Neurologic Full-blown lead encephalopathy, including delirium, truncal ataxia, hyperirritability, altered vision, lethargy, vomiting, and coma, is not common. Although peripheral nerve damage and paralysis may still be reported in adults, the most common toxicity observed is learning disability and an associated high-frequency hearing loss occurring in children with blood lead levels previously assumed to be safe. At low blood levels of lead (less than 10 μg dl^{-1}), children may lose IQ points, possibly due to the interference of lead in normal calcium signaling in neurons and possibly by blocking the recently reported learning-induced activation of calcium/phospholipid-dependent protein kinase C in the hippocampus.

The physicochemical basis of these changes derives largely from small animal data. Rats exposed to lead from birth develop mitochondrial dysfunction, neuronal swelling, and necrosis in both the cerebrum and the cerebellum. Exposure on day 10 of life elicited only the cerebellar pathology, and lead exposure after $3\frac{1}{2}$ weeks of life failed to produce any of these changes. In combination with manganese, lead has also produced peroxidative damage to rat brains and has been shown to inhibit nitric oxide synthase in the brains of mice. Additionally, an increase in blood arachidonic acid and in the ratio of arachidonic to linoleic acid following lead exposure in several species, including humans, may provide evidence in support of a peroxidative mechanism of damage to neural tissue following lead exposure.

Lead has also produced necrosis of retinal photoreceptor cells and swelling of the endothelial lining of retinal blood vessels in rats. Lead may also damage the auditory nerves in rats, and it may be partially responsible for the high-frequency hearing loss observed in humans. Finally, organic lead compounds may also disturb brain microtubular assembly.

Liver Although there are no outwardly recognizable manifestations of lead toxicity to the liver, studies in

Table 1 Heavy metal toxicities by tissues

Tissue	*Heavy metal*	*Dietary source(s)*	*Toxicity*
Neurologic	Lead	Green, leafy vegetables, canned food with lead solder, water	Learning disability, ataxia, encephalopathy, irritability
	Mercury	Seafood, agricultural crop contamination	Psychomotor retardation, paralysis, microcephaly, convulsions, choreoathetotic movements
	Bismuth	Medications	Paraesthesias, tremors, ataxia, reduced short-term memory
Bone	Lead	See above	Reduced conversion of vitamin D to active form, ?reduced osteoclast function
	Mercury	See above	?Reduced bone formation and bone density
	Cadmium	Seafood, plant roots in contaminated soil	?High bone turnover, secondary hyperparathyroidism
Bone marrow	Lead	See above	Decreased hemoglobin synthesis, decreased erythrocyte survival
	Mercury	See above	Increased hemolysis, alteration of T helper and T suppressor lymphocytes
	Cadmium	See above	?Reduced erythrocyte count
	Nickel	Vegetables, especially legumes, spinach and nuts	Decreased helper T cells and increased suppressor T cells
Gastrointestinal	Lead	See above	Decreased binding of L-tryptophan to hepatocellular nuclei
	Mercury	See above	Anorexia, fetal hepatic cell damage
	Cadmium	See above	Abdominal pain, vomiting, diarrhea
Renal	Lead	See above	Proximal tubular dysfunction: glycosuria, aminoaciduria, hyperphosphaturia, decreased renal conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D, the biologically active form
	Mercury	See above	Renal tubular dysfunction, proteinuria, autoimmune damage
	Cadmium	See above	Proteinuria, glycosuria

rats indicate that amino acid binding to hepatocyte nuclei may be altered by lead. Thus, liver function may be subtly or subclinically affected and further studies are needed to elucidate this possibility.

Blood composition The major consequences of lead toxicity to the blood are microcytic anemia and decreased erythrocyte survival. The anemia is largely due to the inhibition of ALAD and erythrocyte ferrochelatase, which are critical to heme biosynthesis. Although the pathogenesis of the decreased red blood cell survival is not clear in humans, animal data indicate that the pentose phosphate shunt and glucose-6-phosphate dehydrogenase (G6PD) are inhibited by lead, suggesting that increased hemolysis may also contribute to the reduction in erythrocyte survival.

Kidney function Studies from the US National Institute of Occupational Safety and Health have reported that lead exposure reduced glutathione *S*-transferase expression in the kidneys of rabbits, indicating increased susceptibility to peroxidative damage. Renal proximal tubular dysfunction is described with lead intoxication and can result in glycosuria, aminoaciduria, and hyperphosphaturia as well as a reduced natriuretic response to volume expansion. This latter effect of lead exposure may possibly offer an explanation of how lead accumulation may contribute to hypertension.

Vitamin D endocrine system and bone As previously mentioned, lead can contribute to the reduced conversion of 25-hydroxyvitamin D to $1,25(OH)_2D$. The extent to which this action may contribute to vitamin D deficiency is not known, but there is at least the potential for lower circulating levels of $1,25(OH)_2D$ to play a role in reduced intestinal calcium absorption. This in turn may result in further lead absorption. Additionally, lead accumulating in bone has been reported to cause osteoclasts to develop pyknotic nuclei and manifest inclusion bodies, possibly lead, in the nucleus and cytoplasm. Although it has yet to be proven, these findings suggest a reduction in the resorptive function of osteoclasts. This may be a protective mechanism by the body to prevent the liberation of lead stored in bone, but at the same time lead may prevent the uptake by bone of additional calcium.

Genetic/teratogenic effects Lead has been reported to alter gene transcription by the reduction of DNA

binding to zinc finger proteins. This interruption of transcription has the potential to produce congenital anomalies in animals or humans. Studies have reported that lead crossing the placenta has produced urogenital, vertebral, and rectal malformations in the fetuses of rats, hamsters, and chick.

Management

Chelation therapy with dimercaprol succinic acid is recommended for anyone with a blood lead level higher than $25\,\mu g\,l^{-1}$ ($1.2\,\mu mol\,l^{-1}$), as shown in Table 2.

Mercury

How Does Mercury Contaminate Food?

The primary portal of mercury contamination of food is via its industrial release into water, either fresh or salt water, and its conversion to methyl mercury by methanogenic bacteria. As the marine life takes up the methyl mercury, it works its way into the food chain and is ultimately consumed by humans. This is the scenario that occurred following the release of inorganic mercury from an acetaldehyde plant into Minimata Bay in Japan in 1956 and 1965 and is responsible for the so-called 'Minimata disease.' Furthermore, acid rain has increased the amount of mercury available to be taken up by the tissues of edible sea life and can enhance the toxicity of certain fish. An unfortunate consequence of seafood contamination with methyl mercury is the contamination of fish meal used to feed poultry, resulting in mercury accumulation in the poultry as well as in the eggs. Additionally, mercury-containing pesticides can contaminate agricultural products. In Iraq in 1971 and 1972, wheat used in the baking of bread was contaminated with a fungicide that contained mercury.

Permissible Intakes

Limits of mercury intake set by the UN Food and Agriculture Organization (FAO) and the World Health Organization (WHO) are 0.3 mg per person per week, of which no more than 0.2 mg should be methyl mercury. Furthermore, FAO and WHO have set limits of mercury contamination of foods as not to exceed 50 parts per billion wet weight ($50\,\mu g\,l^{-1}$). Hair mercury content is used as a marker of methyl mercury burden.

Dietary Mercury: Absorption and Consequences

Although the precise mechanism of mercury absorption and transport has not been clarified, one possibility is its use of molecular mimicry. Studies of methyl mercury show that it binds to reduced sulfhydryl groups, including those in the amino acid cysteine and glutathione. Methyl mercury-1-cysteine is similar in conformation to the amino acid methionine and may be taken up by the methionine transport system in the intestine. Also, inasmuch as it has been shown that deep-frying of fish, with or without breading, will increase the mercury content, it has been postulated that mercury may be absorbed with the oil from the frying process.

A Swedish study reported a direct correlation between the amount of seafood consumed by pregnant mothers and the concentration of methyl mercury in their umbilical cord blood. Although fetal tissue mercury concentration is generally lower than the maternal concentration, the exception to this is liver. According to a Japanese study, mercury is stored in the fetal liver, bound to metallothionein. With development, the amount of metallothionein decreases and the mercury in liver is redistributed primarily to brain and kidney. In studies of offspring of animals exposed to mercury vapors, behavioral changes have been detected.

With regard to toxicity, mercury affects the skin, kidneys, nervous system, and marrow, with

Table 2 Recommended management of toxic symptoms caused by heavy metal contaminants in food

Element	*Agent*	*Comments*
Lead	Dimercaptosuccinic acid	Blood lead levels greater than $25\,\mu g$ ($1.2\,\mu mol$) l^{-1}; treatment of children with blood levels exceeding $10\,\mu g$ ($0.5\,\mu mol$) l^{-1} advocated due to learning problems
Mercury	Dimercaptosuccinic acid	Dimercaprol and D-penicillamine have also been used, but dimercaprol complicated by increased amount of mercury in brain
Cadmium	Diethyldithiocarbamate	Also used: dimercaprol, D-penicillamine, and dicalcium disodium EDTA
Nickel	Insufficient studies for recommended agent	Parenteral administration of diethyldithiocarbamide for acute toxicity may be helpful but unproven
Bismuth	Insufficient studies for recommended agent	Dimercaprol has been used anecdotally and reversed the symptoms of myoclonic encephalopathy; many choose to stop bismuth-containing drugs with a gradual resolution of symptoms

consequent effects on the blood cells, immune system, and bone formation.

Manifestations of Mercury Toxicity

Skin Mercury produces a symptom complex called acrodynia. Its main features are redness of the lips and pharynx, a strawberry tongue, tooth loss, skin desquamation, and pink or red fingertips, palms, and soles. The eyes are also affected, and photophobia and conjunctivitis are seen. In addition, there is enlargement of the cervical lymph nodes, loss of appetite, joint pain, and, occasionally, vascular thromboses, possibly by the induction of platelet aggregation, which has been shown in *in vitro* experiments. There is also a neurological component to this symptom complex: irritability, weakness of the proximal muscles, hypotonia, depressed reflexes, apathy, and withdrawal.

Kidneys Mercury has been hypothesized to stimulate T lymphocytes to produce a glomerular antibasement membrane antibody, which produces sufficient damage to lead to the proteinuria observed with mercury toxicity (**Table 1**). The basis for this theory derives from studies in rats in which mercuric chloride injection produced these antibodies, both as IgG and IgM. There was also an observed increase in $CD8^+$ (suppressor) T cells in the glomeruli. In addition, the rats developed proximal tubular necrosis. However, it is not clear that this theory is correct because methyl mercury can induce apoptosis, or programmed cell death, of the T lymphocytes, possibly by damaging mitochondria and inducing oxidative stress.

Nervous system In the large epidemics of methyl mercury ingestion reported in both Japan and Iraq, infants were reported to have psychomotor retardation, flaccid paralysis, microcephaly, ataxia, choreoathetotic motions of the hands, tonic seizures, and narrowing of the visual fields (**Table 1**). Studies of neonatal rats injected with methyl mercuric chloride reported postural and movement changes during the fourth week of life. These were associated with degeneration of cortical interneurons, which produce γ-aminobutyric acid (GABA) as a neurotransmitter. In the caudate nucleus and putamen, these GABAergic and somatostatin immunoreactive interneurons manifested the abnormalities. Pregnant rats given methyl mercury by intraperitoneal injection demonstrated rapid (within 2 h) effects on their fetuses, including mitochondrial degeneration of cerebral capillary endothelial cells, which led to hemorrhage. In turn, the bleeding disrupted normal neuronal migration.

In addition, methyl mercury may disrupt neuronal microtubular assembly and, perhaps by molecular mimicry (as described previously), may bind to the sulfhydryl groups of glutathione, causing peroxidative injury to the neurons. Following intracerebral injection in the rat, methyl mercuric chloride distributes in the Purkinje and Golgi cells of the cerebellum as well as in three different layers of cerebral cortical cells—III, IV, and VI.

Mercury exposure in humans can result in deficits in attention and concentration, especially under pressure of time deadlines. One report suggests that this may be due to mercury damage to the posterior cingulate cortex, where these functions are regulated.

Finally, *in vitro* studies of rat cerebellar granular cells suggested that incubation with methyl mercury caused an increased, although delayed, phosphorylation of certain proteins. The 12- to 24-h time course from mercury exposure to phosphorylation was believed to be consistent with the alteration of gene expression by mercury. Thus, the effects of mercury on the nervous system are multiple.

Bone marrow: Immune cells, blood cells, and bone formation A toxic effect of mercury on bone marrow would explain the abnormalities in red cell production, immune cell production, and bone formation (**Table 1**); all of the cells involved arise from stem cells found in the marrow and are presumably affected by mercury.

With regard to the immune cells, mercury induces an autoimmune response manifested by an increase in $CD4^+$ (helper) and $CD8^+$ (suppressor) T lymphocytes and in B lymphocytes in peripheral lymphoid tissue. This may explain in part the autoimmune nephropathy as well as the enlarged lymph nodes of acrodynia, previously described. Additionally, mercury may impair integrin signaling pathways in neutrophils, which may give rise to neutrophil dysfunction.

Hemolysis of red blood cells resulting from mercury exposure may be at least in part due to peroxidative damage inasmuch as studies on workers chronically exposed to mercury vapors demonstrate a reduction in erythrocyte enzyme activity of glutathione peroxidase and superoxide dismutase, as well as in G6PD.

Finally, although the effects of mercury exposure on bone have not been studied in humans, experiments in mice indicate that the administration of an anti-metallothionein antibody and mercury results in

decreased biochemical markers of bone formation and decreased bone mineral density. The mechanism for this is unknown, but mercury interference with differentiation of osteogenic precursor cells is postulated.

Genetic/teratogenic effects The uptake and redistribution of mercury by fetal hepatic tissue have been previously discussed. Abnormalities described with in utero exposure to mercury during the epidemics in Japan and Iraq have included low birth weight, malformation of the brain (both cerebrum and cerebellum), an abnormal migratory pattern of neurons, mental retardation, and failure to achieve developmental milestones. This remains a problem today for pregnant women who consume seafood. The FDA recommends that intake of large predator fish, such as swordfish and shark, be limited since they contain large amounts of mercury. Even tuna is considered to contain more mercury than most other seafood.

Management

Chelation with dimercaptosuccinic acid is recommended (**Table 2**).

Cadmium

How Does Cadmium Contaminate Food?

Cadmium enters the food chain in much the same way that lead and mercury do—by means of industrial contamination. Cadmium is often used as a covering of other metals or in the manufacture of batteries and semiconductors; it readily transforms into a gas as the metal ores are smelted. The cadmium then condenses to form cadmium oxide, which deposits in soil and water near the source. Cadmium accumulates in lower marine life, such as plankton, mollusks, and shellfish, and continues through the food chain as these organisms are consumed. However, contamination of the human food supply is limited by this route since cadmium is toxic to fish and fish embryos. In contrast to seafood, vegetables are affected differently because cadmium is taken up by the leaves and roots of plants, so those near industrial sources may be very high in cadmium.

Permissible Intakes

A 1991 study of adults consuming rice contaminated with cadmium in the Kakehashi River Basin of Ishikara, Japan, correlated cadmium intake with renal tubular dysfunction and established a maximum allowable intake of 110 μg per day. Canadian studies have estimated daily intake in study populations to be approximately half that, and the French have estimated cadmium exposure in the diet as being only 3 or 4 μg per day. The Provisional Tolerable Weekly Intake (PTWI) established by FAO/WHO is $7\,\mu g\,kg^{-1}$ body weight per week, a slightly more conservative estimate than the Japanese study but still in general agreement with it.

Dietary Cadmium: Absorption and Consequences

Fortunately, only 2–8% of dietary cadmium is absorbed and significant cadmium ingestion is accompanied by vomiting. Therefore, the gastrointestinal route is not as significant as inhalation of dust particles as a source of significant exposure.

Manifestations of Toxicity

Toxic manifestations of cadmium ingestion include renal dysfunction, osteoporosis and bone pain, abdominal pain, vomiting and diarrhea, anemia, and bone marrow involvement (**Table 1**).

Gastrointestinal toxicity The mechanisms for cadmium's effects on the gastrointestinal tract are not certain. Whether these toxicities stem from an irritative effect of the metal or whether there is cellular damage has not been resolved in animal or *in vitro* studies. One possibility is that *in vitro* studies of neural tissue suggest that cadmium blocks adrenergic and cholinergic synapses. Therefore, it is possible that cadmium interferes with autonomic nervous system influence on gastrointestinal motility.

Renal toxicity Renal tubular dysfunction is manifest in patients with itai itai disease as glycosuria and proteinuria, including excessive excretion of α- and β-microglobulin. Approximately 50–75% of cadmium accumulation in the body occurs in the liver and kidneys. Urinary cadmium excretion of $200\,\mu g$ $(1.78\,\mu mol)\,g^{-1}$ of renal cortical tissue has been associated with tubular dysfunction. In the kidney, cadmium is bound to metallothionein. When the amount of intracellular cadmium accumulation exceeds metallothionein binding capacity, this is the point at which renal toxicity is hypothesized to occur.

Bone marrow and bone In short-term accumulation of cadmium in the marrow, there is a proliferation of cells in the myeloid/monocyte category. However, with longer term burden, marrow hypoplasia is reported, including decreased production of

erythropoietin. Although a reduction in marrow cells may indicate that the osteogenic precursors in the marrow may also be reduced (**Table 1**), this is not borne out by studies both in humans and in rats. In these cases, biochemical markers of bone formation (osteocalcin) and resorption (deoxypyridinoline) are both increased, indicating a high turnover state. In rats, circulating parathyroid hormone levels are also elevated, suggesting that the high turnover is due to secondary hyperparathyroidism and subsequent inability of the bone matrix to mature and bind calcium and phosphate. Parenteral administration of 1,25-dihydroxyvitamin D has been reported to decrease circulating parathyroid hormone in the rat and to reduce bone turnover. Moreover, other animal studies report that cadmium interferes with hydroxyapatite nucleation and growth, thus making it difficult for bone matrix to bind to calcium.

Management

Chelation therapy is recommended using calcium, disodium ethylene diaminetetraacetic acid, dimercaprol, D-penicillamine, or diethyldithiocarbamate (**Table 2**).

Nickel and Bismuth

Dietary Contamination

Nickel and bismuth are not considered to be common dietary contaminants. Nickel is mainly inhaled as a dust by workers, whereas bismuth is mainly ingested in bismuth-containing medications such as Pepto-Bismol. Vegetables contain more nickel than other foods, and high levels of nickel can be found in legumes, spinach, lettuce, and nuts. Baking powder and cocoa powder may also contain excess nickel, possibly by leaching during the manufacturing process. Soft drinking water and acid-containing beverages can dissolve nickel from pipes and containers. Daily nickel ingestion can be as high as 1 mg (0.017 mmol) but averages between 200 and 300 μg (3.4 and 5.1 μmol).

Permissible Intakes

The maximum permissible intake of nickel is not known. Bismuth intake is related to whole blood bismuth levels. If these levels exceed $100\,\mu g\,l^{-1}$, bismuth-containing medication should be discontinued.

Toxicity

Nickel ingestion by women resulted in an increase in interleukin-5 levels 4 h after ingestion and a decrease in $CD4^+$ and an increase in $CD8^+$ lymphocytes 24 h following the nickel intake. Thus, alterations in the immune response may be associated with excessive nickel ingestion, consistent with reports of tumor production in animals and humans by inhalation of nickel-containing dust or powders. The mechanism for nickel-associated toxicity is purported to be oxidative. For bismuth, neurotoxicity, including irritability, numbness and tingling of the extremities, insomnia, poor concentration, impairment of short-term memory, tremors, dementia masquerading as Alzheimer's disease, and abnormal electroencephalograms, has been reported. Discontinuation of the bismuth may result in restoration of normal neurological function. Production of these symptoms in animals was associated with a brain bismuth concentration of $8\,\mu g\,g^{-1}$ brain tissue; a brain bismuth concentration of $4\,\mu g\,g^{-1}$ brain tissue was not associated with these neurotoxic manifestations. However, hydrocephalus was reported. At 1 μg bismuth g^{-1} brain tissue, no neurotoxic features were observed in animals. Nephropathy, osteoarthropathy, and thrombocytopenia have also been reported with bismuth toxicity.

Management

Insufficient controlled clinical trials have been performed to make clear-cut recommendations for pharmacotherapy for toxicity from either nickel or bismuth. Diethyl dithiocarbamide chelation therapy when promptly administered intravenously has been reported to be effective in acute nickel carbonyl poisoning. In addition, there have been anecdotal case reports of the reversal of myoclonic encephalopathy caused by bismuth with use of dimercaprol. However, no recommendations can be given at the present time.

Published by Elsevier Ltd.

Fructose, a monosaccharide, is naturally present in fruits and is used in many food products as a sweetener. This article reviews the properties and sources of fructose in the food supply, the estimated intake of fructose in Western diets, the intestinal absorption of fructose, and the metabolism of fructose and its effect on lipid and glucose metabolism. The health implications of increased consumption of fructose are discussed, and inborn errors of fructose metabolism are described.

Properties and Sources of Fructose

Fructose has a fruity taste that is rated sweeter than sucrose. Sweetness ratings of fructose are between 130% and 180% (in part dependent on the serving temperature) compared to the standard, sucrose, rated at 100%. Both sucrose and fructose are used extensively in foods to provide sweetness, texture, and palatability. These sugars also contribute to the appearance, preservation, and energy content of the food product.

Natural sources of dietary fructose are fruits, fruit juices, and some vegetables. In these foods, fructose is found as the monosaccharide and also as a component of the disaccharide, sucrose (**Table 1**). However, the primary source of fructose in Western diets is in sugars added to baked goods, candies, soft drinks, and other beverages sweetened with sucrose and high-fructose corn syrup (HFCS). HFCS is produced by hydrolyzing the starch in corn to glucose using α-amylase and glucoamylase. This is followed by treatment with glucose isomerase to yield a mixture of glucose and fructose. The process typically produces a HFCS composed of 42% fructose, 50% glucose, and 8% other sugars (HFCS-42). By fractionation, a concentrated fructose syrup containing 90% fructose can be isolated (HFCS-90). HFCS-42 and HFCS-90 are blended to produce HFCS-55, which is 55% fructose, 41% glucose, and 4% other sugars. HFCS-55 is the preferred sweetener used by the soft drink industry, although HFCS-42 is also commonly used as a sweetener in many processed food products. Concentrated

fruit juices, such as apple juice and white grape juice, are also used to sweeten beverages. The amount of fructose in fruit juices varies, as does its proportion with glucose, but clearly the use of concentrated apple juice provides more fructose relative to glucose (**Table 1**), compared to either sucrose or HFCS-55. Nevertheless, considering the variety of sweeteners commonly available, it is likely that fructose constitutes approximately 50% of energy from added sweeteners.

As a result of the addition of sweeteners and sugars to so many food products, the consumption of fructose has increased from the mid-1970s to the mid-1990s. Sugars added to the diet are difficult to quantify accurately, but based on food intake survey data, total fructose consumption provides approximately 12% of adult energy intake or ~60 g/day based on a 2000-kcal diet. Individuals who are avid consumers of soft drinks, such as adolescent males, typically consume more than two times the average intake or more than 100 g/day of fructose from added sweeteners. Considering the US population as a whole, and based on both food disappearance data and food survey data, total fructose consumption has increased approximately 25% during the past three decades.

Absorption of Fructose

Dietary fructose is ingested as the simple monosaccharide and also as part of the disaccharide sucrose. Sucrose is hydrolyzed by sucrase at the intestinal brush border to yield one molecule of glucose and one of fructose. Glucose is rapidly absorbed via a sodium-coupled cotransporter and arrives at the liver via the portal circulation. Fructose absorption is accomplished primarily by a fructose-specific hexose transporter, GLUT-5. This transporter is found in the jejunum on both the brush border and the basolateral membranes. Expression of GLUT-5 increases within hours of exposure to a fructose-enriched diet, indicating that the transporter is regulated by luminal signals. However, consumption of a large amount of pure fructose can exceed the capacity of intestinal fructose absorption, resulting in diarrhea. Several studies have shown that when a single dose of 50 g of fructose is consumed by healthy adults, more than half experience malabsorption, and in some studies malabsorption is also observed with a 25-g dose. Fructose malabsorption results in abdominal bloating, flatulence, and diarrhea. However, the intestinal absorptive capacity for fructose increases when

glucose is consumed along with fructose. Thus, coingesting glucose to roughly balance fructose, as occurs when most fruits or sucrose is consumed, largely alleviates problems of fructose malabsorption. In addition, fructose absorption increases during sustained fructose consumption, suggesting adaptation to increased fructose intake.

Fructose Metabolism

The predominant site of fructose metabolism is the liver, where fructose enters the intermediary pathways of carbohydrate metabolism. Fructose is readily extracted by the liver because of the presence of an active hepatic enzyme system for metabolizing fructose, and the majority of ingested fructose is cleared in a single pass through the liver. Thus, the concentration of fructose circulating in blood is low after consumption of moderate amounts of fructose. Other tissues that take up small quantities of fructose include the kidney, skeletal muscle, and adipose tissue. The GLUT-5 transporter is expressed in these tissues but at relatively low levels.

In the liver, fructose is phosphorylated and forms fructose-1-phosphate. This reaction requires ATP and is catalyzed by fructokinase (EC 2.7.1.4), an enzyme with high affinity and specificity for fructose. Fructose-1-phosphate is then cleaved by hepatic aldolase (aldolase B; EC 4.1.2.13) to form dihydroxyacetone phosphate (DHAP) and glyceraldehyde. DHAP is an intermediate metabolite in both the gluconeogenic and glycolytic pathways. Thus, a portion of the original fructose carbon structure forms glucose, and, in fact, a small increase in circulating glucose occurs after ingestion of fructose. The glyceraldehyde intermediate is phosphorylated by triokinase (EC 2.7.1.28) to form glyceraldehyde-3-phosphate, another intermediate in the glycolytic pathway. The triose phosphate compounds provide substrate for glycolysis and oxidative metabolism, formation of glycogen, and synthesis of glucose and fatty acids. With the formation of the triose phosphates, the metabolism of fructose and glucose converges. However, prior to this step, there are important differences in fructose and glucose metabolism that impact both carbohydrate and lipid metabolism. The initial reaction that primes fructose for entry to the glycolytic pathway allows it to bypass the critical rate-limiting step of glycolysis. This critical step precedes the formation of triose phosphates; glucose carbons pass through an intermediate step in which fructose-6-phosphate is converted to fructose-1,6-bis-phosphate. This reaction is catalyzed by the allosterically regulated enzyme phosphofructokinase (PFK; EC 2.7.1.11) and is the most important control point in the glycolytic sequence. Among the multiple effectors of PFK are ATP and citrate; these products of glucose oxidation exert an inhibitory effect on the enzyme (**Figure 1**). The

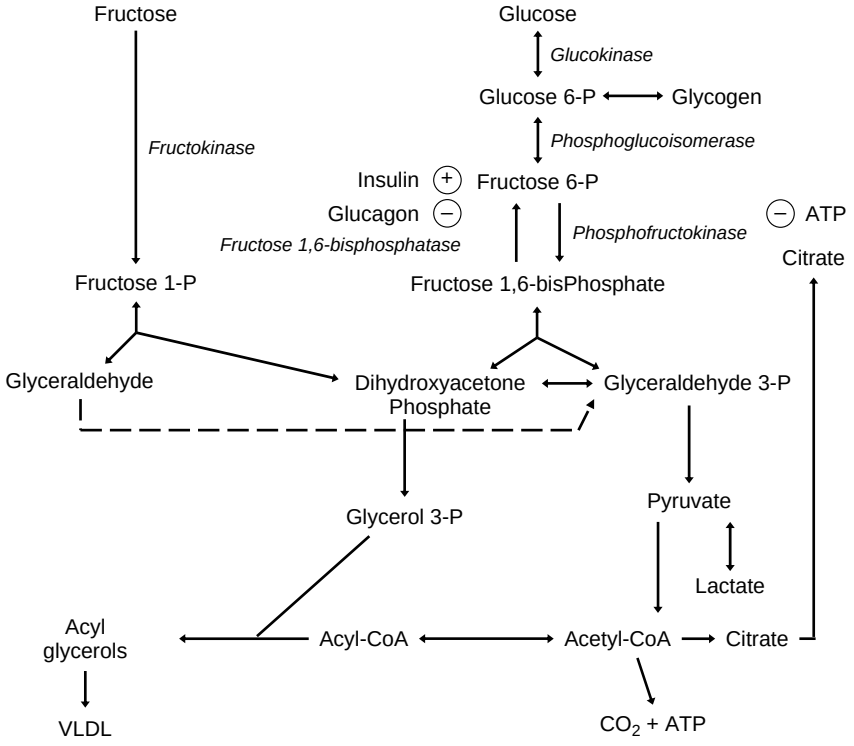

Figure 1 The intermediary pathways and fructose metabolism. Reproduced with permission by the American Journal of Clinical Nutrition. Copyright *Am J Clin Nutr.* American Society for Clinical Nutrition.

allosteric inhibition of PFK effectively reduces the rate of glycolysis and decreases hepatic glucose uptake overall. In contrast, the entry of fructose carbons through the pathway proceeds without this limitation.

Fructose and Lipid Metabolism

When large amounts of fructose are ingested, the glycolytic pathway becomes saturated with intermediates. In these circumstances, the intermediates become substrates for triacylglycerol synthesis: DHAP can be converted to glycerol, and acetyl-CoA can enter the lipogenic pathway to form fatty acids that are then esterified to the glycerol molecule to form triacylglycerols. During the initial step of lipogenesis, malonyl-CoA is formed. This intermediate serves to inhibit the transport of fatty acids into the mitochondria, where they are oxidized. By this regulatory mechanism, esterification of the newly synthesized fatty acids is reinforced. Studies have shown that the ingestion of fructose results in increased synthesis of fatty acids compared to ingestion of a comparable amount of glucose. The increased availability of fatty acids and subsequent triacylglycerol synthesis results in the production and secretion of triacylglycerols from the liver in the form of very low-density lipoproteins. Studies in animals have demonstrated that when large quantities of fructose or sucrose are consumed, an increase in blood triacylglycerol concentration occurs. Similar findings have been observed in humans, although some humans appear to be more susceptible to fructose consumption than others. For example, the lipogenic sequence may be accentuated in humans with preexisting hypertriacylglycerolemia or in those who are insulin resistant. Since high circulating triacylglycerol levels have been identified as a risk factor for coronary heart disease, long-term exposure to high levels of dietary fructose may contribute to a chronic, unfavorable lipid profile and increase risk of coronary heart disease.

Fructose and Glucose Metabolism

With fructose ingestion, there is an increased flux through the glycolytic pathway, with formation of pyruvate and lactate. As fructose-1-phosphate is formed, at the initial priming stage of glycolysis, it feeds forward and enhances the activation of pyruvate kinase (EC 2.7.1.40), thereby facilitating the passage of fructose carbon to pyruvate and lactate. With fructose ingestion, it is common to observe increases in blood lactate concentrations.

In the postprandial state, fructose serves to promote the formation of glycogen, but only when it is consumed along with glucose. This occurs through the activation of glycogen synthase (EC 2.4.1.11) and the inhibition of glycogen phosphorylase (EC 2.4.1.1).

In the starved state, fructose actively serves as a substrate for gluconeogenesis and glucose production. The gluconeogenic pathway and the glycolytic pathway share many common intermediates and enzymes, but the direction of the carbon flux through these pathways is controlled by several allosteric enzymes unique to each pathway. Since fructose enters the glycolytic pathway beyond the major gluconeogenic–glycolytic pivotal point (the interconversion between fructose-6-phosphate and fructose-1,6-bisphosphate), it does not exert an inhibitory effect on the gluconeogenic rate-limiting enzyme, fructose-1,6-bisphosphatase (EC 3.1.3.11). Consequently, there is no inhibition of gluconeogenesis by fructose as fructose carbons proceed through the glycolytic pathway. When a large quantity of fructose is infused intravenously, hepatic glucose production and output increase.

Consumption of large amounts of fructose is also associated with an impairment of glucose disposal. Prolonged feeding of fructose or sucrose to animals impairs insulin signaling and induces insulin resistance. Less is known about the effect of fructose ingestion on glucose tolerance and insulin resistance in humans because the scientific literature contains conflicting results. However, the lipogenic effects of fructose may contribute to insulin resistance indirectly since increased blood levels of triacylglycerols and fatty acids and deposition of lipid in liver and skeletal muscle have been implicated in the etiology of insulin resistance.

Fructose and Diabetes

Historically, in the nutritional management of diabetes mellitus, the ingestion of fructose was recommended as a sweetener for diabetics because it causes smaller increases in blood glucose following ingestion compared to similar amounts of glucose, sucrose, or starches. In fact, fructose, in small quantities, increases the hepatic uptake of glucose and promotes glycogen storage, probably by stimulating the activity of hepatic glucokinase (EC 2.7.1.2). Also, in individuals with type 2 diabetes mellitus, the addition of a small amount of fructose to an oral glucose tolerance test improves the glycemic response, indicating improved glycemic control. It must be emphasized, however, that the consumption of large quantities of fructose is not recommended, particularly for diabetics who, as a group, are at increased risk for cardiovascular disease, because of

potentially adverse effects of fructose on lipid metabolism, body weight regulation, and oxidative stress that may contribute to diabetic complications.

Fructose Consumption, Body Weight, and Obesity

With the increase in fructose intake, primarily as sugar-sweetened beverages, occurring coincidently with the increase in prevalence of overweight and obesity during the past two decades, it is important to examine the evidence that links fructose consumption and body weight gain. In epidemiological studies, consumption of larger amounts of soft drinks and sweetened beverages is associated with greater weight gain in women and increased energy intake and higher body mass index in children. In experimental studies, when fructose- or sucrose-sweetened beverages are added to the diet, subjects do not compensate for the additional energy provided by these beverages by reducing energy intake from other sources, and total energy intake increases. Possibly, this lack of compensation may be explained by the lack of a significant effect of fructose ingestion on the secretion of hormones involved in the long-term regulation of food intake.

Data comparing the effects of ingesting fructose- and glucose-sweetened beverages with meals indicate that fructose ingestion results in smaller increases in blood glucose and insulin concentrations following the meals. In addition, circulating leptin concentrations are lower, and the normal suppressive effect of meal consumption on ghrelin concentrations is attenuated with fructose beverages. Glucose, insulin, leptin, and ghrelin are all involved in the long-term control of food intake and body weight regulation through the central nervous system. Since these key signals are absent or weakened with fructose consumption, chronic consumption of a diet high in fructose could contribute, along with dietary fat and inactivity, to increased energy intake, weight gain, and obesity.

Inborn Errors of Fructose Metabolism

Several genetically based abnormalities in fructose metabolism have been described in humans. Fructokinase deficiency leads to high levels of fructose in the blood and urine. In the absence of fructokinase, fructose can be metabolized to fructose-6-phosphate by hexokinase (EC 2.7.1.1), although at a low rate. Consequently, no serious health problems are associated with this abnormality.

The aldolase A, B, and C enzymes catalyze the reversible conversion of fructose-1-diphosphate into glyceraldehyde-3-phosphate and dihydroxyacetone phosphate, and deficiencies in the A and B enzymes have been identified. Aldolase A is expressed in embryonic tissues and adult muscle. Possibly owing to the importance of this enzyme in fetal glycolysis, its deficiency results in mental retardation, short stature, hemolytic anemia, and abnormal facial appearance. There is no known treatment for aldolase A deficiency. Aldolase B is expressed in liver, kidney, and intestine, and a deficiency of this enzyme is more common and can be exhibited at first exposure to fructose during infancy or can have its onset in adulthood. Upon ingestion of fructose-containing foods, vomiting and failure to thrive are apparent. Hypoglycemia (in some cases severe), increased blood uric acid, and liver dysfunction also occur. Fortunately, this disorder can be treated effectively by completely eliminating fructose from the diet.

Deficiency of fructose-1,6-bisphosphatase is also considered a genetic disorder of fructose metabolism. This enzyme has a critical role in the enzyme complex regulating glycolysis and gluconeogenesis. Deficient individuals exhibit hypoglycemia, acidosis, ketonuria, hyperventilation, and often hypotonia and hepatomegaly. The urinary excretion of many organic acids is altered; notably, urinary glycerol is elevated and is useful in the diagnosis of this disease. The treatment includes avoidance of dietary fructose, sorbitol, and prolonged fasting.

D-Glyceric aciduria is caused by D-glycerate kinase (EC 2.7.1.31) deficiency. Only 10 cases have been documented, with symptoms ranging from none to metabolic acidosis, failure to thrive, psychomotor retardation, spastic tetraparesis, and seizures. The absence of significant symptoms in some suggests that this enzyme deficiency is essentially benign, and other associated enzyme deficiencies may underlie the more severe symptoms.

FRUITS AND VEGETABLES

A E Bender, Leatherhead, UK

This article is a revision of the previous edition, article by A E Bender, pp. 902–906, © 1999, Elsevier Ltd.

Fruits and vegetables have considerable potential as a source of nutrients but the amounts eaten vary enormously both within and between countries. Some 3000 species are known to be edible and there are said to be more than 1500 species of wild tropical plants. In the foreword to *Traditional Plant Foods*, published by the Food and Agriculture Organization of the United Nations, it is stated that "rural Africa is rich in nutritious plant foods but in recent decades social and economic changes have militated against their propagation and use." This is because the promotion of major cereals has led to the eclipse of traditional plants. Furthermore, in developing regions many plant foods are regarded as being 'merely' children's food or poor man's food. Indeed, more fruits and vegetables are eaten in industrialized countries where there is an abundance of foods of all kinds than in developing countries, where any addition to the food supply is valuable.

For example, the average daily intake of fruit and vegetables in some underdeveloped regions is only 10–12 g per day compared with the recommendation in Western countries of five (and even up to nine) helpings (at least 375 g per day).

Definition

Plant foods are usually divided into seeds (including cereals), nuts, and a third combined group of fruits and vegetables.

Fruits are the fleshy seed-bearing parts of plants, while stems, roots, shoots, leaves, some seeds (including peas, beans, and lentils), tubers (underground storage organs such as potato, Jerusalem artichoke, sweet potato, yam), underground stems (taro, onion), and flower buds and flowers (cauliflower, broccoli) are all classed as vegetables.

However, through popular usage some fruits such as tomato and cucumber are classed as vegetables, and rhubarb, a stem, as fruit. So the group includes a large number of very diverse foods which differ considerably in nutritional value.

Macronutrients

Fruits and vegetables contain a very high proportion of water (e.g., up to 96% in cucumber) and so, with some exceptions, supply only small amounts of

macronutrients. The exceptions are those few eaten in sufficiently large amounts as to constitute a staple food, such as potato, plantain, cassava, and taro (colocasia, also known as eddo, dasheen, and old cocoyam). These are also lower in water content than many other members of the group and make a significant contribution to the carbohydrate and so the energy intake, and a small contribution of protein. For example, a 1000 kcal (4200 kJ) portion of plantain (*Musa* spp.) supplies 10 g protein. Cassava (manioc, *Manihot utilissima*) is extremely hardy and prolific and is a valuable staple in some communities, although a poor source of protein (1%).

Even in Western countries the potato (*Solanum tuberosum*) makes a contribution to the carbohydrate and protein of the diet, as well as supplying significant amounts of thiamin and ascorbic acid, because several hundred grams are often eaten per day.

One fruit, avocado (*Persea americana*), is a source of fat—17–27%—two-thirds of which is monounsaturated. Olives (*Olea europea*) contain 10–12% fat, two-thirds of which is monounsaturated, and of course are a commercial source of oil. Leafy vegetables are very watery (80–90%) and make an insignificant contribution to the intake of macronutrients. However, such proteins that are supplied are relatively rich in the amino acid lysine and to some extent, depending of course on the amount eaten, complement the relative deficiency of lysine in cereals (see Leaf Protein below).

The legumes—peas, beans, and lentils—play a special role in the diet since, as eaten, they contain more dry matter than most fruits and vegetables, around 30%. Unlike fresh fruits and vegetables they are usually stored for long periods in the dry state. After rehydration and cooking most of them including 'baked beans' (mature haricot beans, *Phaseolus vulgaris*) supply 5–8 g protein, 10–15 g carbohydrate, 300–400 kJ (80–100 kcal), and 4–5 g dietary fiber per 100 g. Legumes are sometimes described as rich sources of protein, but this is based on the dried product, not as eaten. When rehydrated and cooked their protein content is less than that of cereal products.

Garden peas (*Pisum sativum*) are commonly cooked from the fresh or frozen state, i.e., wet, but the macronutrient content is similar to that quoted above.

Green beans/French beans (pods and seeds of *Phaseolus vulgaris*) contain only 10% dry matter and 2 g protein, 100 kJ (25 kcal), and 2 g dietary fiber per 100 g.

Sprouted beans, commonly mung beans (*Vigna radiata*) but also alfalfa (lucerne, *Medicago sativa*) and adzuki beans (*Vigna angularis*), are also low in dry matter content and supply macronutrients in amounts similar to those in French beans.

Micronutrients

The major contribution of fruits and vegetables to the diet lies in their content of vitamins and minerals, but there are enormous variations between different types and between varieties of the same type.

Vitamins

The vitamin C content of different types of fruits ranges between some thousands of milligrams per 100 g in the instance of the West Indian cherry (acerola/Barbados cherry, *Malpighia punificolia*) to a few milligrams in apples (species of *Malus sylvestris*) and pears (varieties of *Pyrus communis*). The yellow–orange colored fruits (e.g., apricots, *Prunus armeniaca*, pawpaw, *Carica papaya*) supply carotene, as also do all green vegetables, while it is absent from white types. Leafy vegetables are rich sources of vitamin K and many fruits and vegetables are significant sources of folate.

Growing conditions including soil, fertilizer (type, amount, and time of application) and the state of maturity influence the vitamin content, particularly of vitamin C. In some foods, such as citrus fruits and tomato, the vitamin C is influenced by exposure to sunshine. One further cause of variation in vitamin content, again applying particularly to vitamin C and to a lesser extent to folate, is the loss after cropping, particularly from leaves that are bruised or wilted. Consequently it is not possible, apart from very broad generalizations, to state the vitamin content of a particular fruit or vegetable. Furthermore, new varieties have been and are being developed that are particularly rich in some vitamins.

Comparisons between food composition tables from various national authorities are unrealistic. Thus among six such tables (Australia, Germany, Great Britain, Spain, Italy, and the USA) the range of carotene in pumpkins is quoted from 0.24 to 19 mg per 100 g; for thiamin between 0.15 and 0.5 mg per 100 g; and for vitamin C between 10 and 50 mg per 100 g. For tomato the carotene ranges between 0.8 and 4 mg per 100 g. Even within one set of tables, in which the same sampling and analytical techniques are presumably used, there is a range of carotene in sweet potatoes (*Ipomea batatas*) from 0.3 to 4.6 mg per 100 g; and for lettuce (*Lactuca sativa*) from 0.16 to 1.6 mg per 100 g.

Mineral Salts

These are stable compared with some of the vitamins but the amounts can vary with different growing conditions, though to a lesser extent than described above for vitamins. Chemical analysis can be misleading since part of the mineral may be present

in the food in a bound, unavailable form which is not liberated during digestion. In addition there may be other substances present in the same food or eaten at the same meal that interfere with absorption. Substances such as oxalates, phytates, tannins, and dietary fiber reduce the amount absorbed.

Generally, vegetables are good sources of potassium with a very high potassium/sodium ratio, but rather poor sources of iron of low availability, although the amount absorbed is a balance between enhancement by the vitamin C present and various factors that reduce absorption. Vegetables are also a minor source of iodine depending on the content in the soil water.

Both fruits and vegetables are often described as sources of calcium but they are minor sources, i.e., many supply around 50 mg per 100 g compared with milk at 120 mg (which is consumed in much larger quantities) and cheese at several hundred mg per 100 g. Some common fruits and vegetables do not contain any calcium and the richer sources such as parsley at 330 mg and watercress at 220 mg per 10 g are eaten in relatively small amounts. Spinach stands out with 600 mg calcium per 100 g, but this is partly unavailable.

Dietary Fiber

All fruits and vegetables are sources of dietary fiber—more precisely nonstarch polysaccharides—but in different amounts. Thus, taken from the same food composition tables, they vary in fruits from around 0.5 g per 100 g in grapes, lychees, melons, and cherries, through 1.5 g per 100 g in oranges, peaches, pineapple, plums, rhubarb, and apples, 2.5 g per 100 g in mangoes, olives, and pears, to nearly 4 g per 100 g guava, blackberries, and blackcurrants (Englyst method of analyis). Similarly vegetables vary from 1–1.5 g (potatoes, cauliflower, celery, lettuce) to 2 g (aubergine, French beans, cabbage), 4 g (baked beans, lentils, Brussels sprouts), and 6–7 g per 100 g (broad beans, kidney beans).

Leaf Protein

Leafy vegetables contain so little protein that excessive amounts would have to be consumed to make a significant contribution to the diet: Such amounts would include unacceptable intakes of dietary fiber (chiefly cellulose). This problem has been overcome by extracting the protein from leaves, including grass; the soluble proteins are separated from the fibrous parts and concentrated by heat coagulation. This product can be added on the domestic scale without further purification to foods such as stews or can be further refined to remove color and dried for storage, which adds to the cost and the technology required. Since grass and many leaves provide a continuing crop leaf protein offers considerable possibilities in developing countries but has been little exploited.

Developing Regions

As quoted in the introduction, there are numerous species of wild plants that could make useful contributions to the diet. The Food and Agriculture Organization has frequently drawn attention to the possibility of collecting wild plant foods, of growing them under protection, or of cultivating them. It has been calculated, for example, that adding 100 g of leafy vegetables to the diet of a 6-year-old child whose staple is cereal or cassava could supply three times the daily need for vitamins A and C, all the folate, calcium, and iron, 15% of the B vitamins, and 15% of the protein. Regular consumption of amaranth leaves and leaves of the drumstick tree (*Moringa olifera*) is recommended for children as a public health measure in many areas of the world, particularly to overcome the widespread problem of vitamin A deficiency.

Vegetarians

Although there is little evidence that the avoidance of animal products results in malnutrition, indeed, in some instances the reverse may be true, the intake of some nutrients may be at risk if all animal foods (including fish, eggs, and milk products) are shunned. Vitamin B_{12} is present only, with very few exceptions (e.g., some yeasts), in animal foods, so supplementation of the diet is virtually essential.

The average intake of carnitine by strict vegetarians is only one-tenth of that of people eating a mixed diet but plasma levels are within 'normal' limits. However, dietary carnitine may be required by premature infants and possibly by full-term infants and may be required by adults taking certain drugs.

There are very few plant sources of taurine and it is not known to what extent this may be a dietary essential. However, plasma levels in strict vegetarians are close to the 'normal' range.

Toxins and Contaminants

Fruits and vegetables contain large numbers of nonnutrients, some of which are toxic, but they are rarely harmful under ordinary conditions. Antinutritional substances in plant foods include antienzymes that interfere with digestion, antivitamins, and substances such as oxalates, phytates, tannins,

and dietary fiber that can interfere with the absorption of some minerals. Glucosinolates, which are responsible for the characteristic flavor of vegetables of the families Cruciferae and Brassicaceae, are goitrogenic but appear to be an insignificant hazard to human health in the amounts usually eaten. In addition some legumes contain lectins in amounts sufficient to have been the cause of occasional cases of food poisoning when incompletely destroyed by cooking.

Most of these substances are destroyed by heat and have been found harmful to animals when included in feed in the raw state. Some are present in salad vegetables that are eaten raw, but in amounts too small to be harmful.

Cassava, especially the bitter variety, contains cyanide. This is usually removed in traditional food processing but not infrequently is a source of harm when the food is not properly treated.

Plantains eaten as a staple provide sufficient 5-hydroxytryptamine to affect central and peripheral nervous systems. Unripe ackee fruit (*Blighia sapida*) contains a toxin (hypoglycin) which causes vomiting sickness and hypoglycaemia. Rhubarb contains oxalate, and although the amounts in stems are harmless, poisoning has resulted from eating the leaves which contain a much higher concentration.

Potatoes contain small, usually harmless, amounts of solanine, but this is increased to toxic levels by exposure to light and subsequent 'greening.'

Some plant foods have been the cause of occasional outbreaks of poisoning in special circumstances. For example Jimson weed, *Datura stramonium*, contains alkaloids including scopolamine which produce hallucination; and the hemp plant, *Cannabis indica*, and the peyote, containing mescaline, have been consumed deliberately for their psychic effects.

Contamination

Some vegetables accumulate environmental toxins such as lead and radioactive fallout but the main cause for concern is from residues of agricultural chemicals, pesticides, and weedkillers. The danger of these chemicals is mainly to those handling them in production and manufacture, but there is concern over the small amounts remaining in the crops since these may be consumed over a long period, and the toxins may possibly be cumulative. Among these are the organochlorine insecticides including DDT and dieldrin. Both the substances and their degradation products persist in crops and so find their way into the human food chain. The fact that they are fat soluble and accumulate in the adipose tissue has given rise to concern but there is no evidence that these quantities merit alarm. Nevertheless, they are restricted in use and are under continuous observation.

Role in Diet

There is considerable epidemiological evidence that a high intake of fruits and vegetables is protective against certain forms of cancer. Vitamins C, E, and β-carotene, when individually subjected to trials by dietary supplementation, have not been shown to be protective and it has been suggested either that there may be a synergistic effect between the various anti-oxidants found in plant foods or that some of the numerous other substances in the food may be the protective agent(s). These include lycopene, lutein, indoles, and phenols. Overall there are many hundreds of nonnutrients in plant foods whose functions in the diet, if any, have been little investigated.

Health Effects

Cardiovascular Disease

Observational studies during the past decade have shown consistent associations between consumption of fresh fruits and vegetables (FF&V) and reduction in cardiovascular disease (CVD) outcomes. An inverse correlation between fruits and vegetables intake and CVD mortality has also been shown in two studies. Similarly, a few, well-controlled randomized clinical trials have shown positive effects on CVD events or biomarkers of risk. The DASH trial (Dietary Approaches to Stop Hypertension), in which a high intake of fresh fruits and vegetables was a major component of the intervention, showed a significant decrease in systolic blood pressure after only 8 weeks. It is less clear whether these beneficial effects are primarily related to antioxidant effects of substances present in fresh fruits and vegetables or to the increased potassium intake associated with high consumption of fruits and vegetables.

Table 1 Sources of vitamin C in the average British diet

Food	*% Average intake*
Potatoes	16
Other vegetables	19
Fruit juices	18
Fruit	17
Salad vegetables	8
Milk products	5
Meat	4
Soft drinks	4
Enriched cereal products	3

From Gregory *et al.* (1990).

Diabetes

Cohort and cross-sectional studies indicate a protective effect of FF&V for type 2 diabetes. The European EPIC study reported an inverse association between FF&V intake and Hgb A1C levels. Other studies have shown a similar inverse correlation with fasting glucose and with glucose levels during an oral glucose tolerance test.

Cancer

The evidence of a protective effect of FF&V on several forms of cancer has been summarized by the International Agency for Research in Cancer (IARC), the World Health Organization, and the World Cancer Research Fund. The IARC report concluded that there is strong evidence of the protective effects of FF&V for cancers of the I gastrointestina tract (including colon) and lungs, but not for others. Some studies have suggested that the intake level necessary for cancer protection may be higher than the traditional recommendation five of servings per day.

FUNCTIONAL FOODS

Contents

Health Effects and Clinical Applications

L Galland, Applied Nutrition Inc., New York, NY, USA

Introduction

Functional foods are foods with health benefits that exceed those attributable to the nutritional value of the food. The term is usually applied to foods that have been modified or combined in order to enhance the health benefits but may include any food that naturally possesses components with demonstrable pharmacologic activity. Functional foods are most often selected because they contain ingredients with immune-modulating, antioxidant, anti-inflammatory, antitoxic, or ergogenic effects. The most widely studied functional ingredients are plant-derived phenolic chemicals, probiotic bacteria, and fiber or other poorly digested carbohydrates, but colostrum, egg yolk, and other

nonplant foods may also serve as functional food sources. Although pharmacologic activity of most of these substances is well established *in vitro* or in small mammals, establishing clinical effects in humans poses a challenge for functional food research.

Concept and Definition

The concept of functional foods derives from the observation that certain foods and beverages exert beneficial effects on human health that are not explained by their nutritional content (i.e., macronutrients, vitamins, and minerals). The definition of functional foods varies among countries for reasons that are historical, cultural, and regulatory. In its broadest use, functional foods are food-derived products that, in addition to their nutritional value, enhance normal physiological or cognitive functions or prevent the abnormal function that underlies disease. A hierarchy of restrictions narrows the definition. In most countries, a functional food must take the form of a food or beverage, not a medication, and should be consumed the way a conventional food or beverage is consumed. If the ingredients are incorporated into pills, sachets, or other dosage forms they are considered dietary supplements or nutraceuticals, not functional foods. In Japan and Australia, the functional food appellation has been applied only to food that is modified for the purpose of enhancing its health benefits; in China, Europe, and North America, any natural or preserved food that enhances physiological function or prevents disease might be considered a functional food. If food is modified, there is lack of international consensus as to whether a vitamin or mineral-enriched food (e.g., folate-fortified flour or calcium-fortified orange juice) should be considered a functional food, or whether functional foods are described by the presence of their nonnutritive components (e.g., fiber or polyphenols). Future development of functional foods is likely to be driven by scientific research rather than government regulation, so it is likely that the concept (if not the definition) of functional foods will remain fluid and flexible.

History

If the broadest, least restrictive definition is employed, the use of functional foods for promoting health and relieving symptoms is as old as the practice of medicine. Specific dietary recommendations for treating or preventing various types of illness have been documented in Hippocratic and Vedic texts and the canons of traditional Chinese medicine. Traditional Chinese remedies frequently contain recipes for combining specific foods with culinary and nonculinary herbs to produce healing mixtures. Folk medicine, East and West, has always depended upon functional foods. Peppermint (*Mentha piperita)* tea has a long history of use for digestive complaints. Peppermint oil contains spasmolytic components that block calcium channels in smooth muscle. Cranberry (*Vaccinium macrocarpon*) juice contains proanthocyanidins that inhibit the attachment of *E.coli* to the epithelium of the urinary bladder, explaining its efficacy in prevention of bacterial cystitis and its traditional use for treatment of urinary infection.

Herbs and spices are added to food to enhance flavor and initially were used to inhibit spoilage. Many of these have documented medicinal uses that render them functional foods, broadly defined. Thyme (*Lamiaceae* spp.) was used to treat worms in ancient Egypt. Thyme oils possess potent antimicrobial properties. Ginger (*Zingiber officinale* root), cinnamon (*Cinnamomum* spp. bark), and licorice (*Glycyrrhiza glabra* root) are common ingredients in Chinese herbal tonics and have been widely used in Western folk medicine for treating digestive disorders. Ginger contains over four hundred biologically active constituents. Some have antimicrobial, anti-inflammatory, or anti-platelet effects; others enhance intestinal motility, protect the intestinal mucosa against ulceration and dilate or constrict blood vessels. Cinnamon oil contains cinnamaldehyde and various phenols and terpenes with antifungal, antidiarrheal, vasoactive, and analgesic effects. Recent research has identified phenolic polymers in cinnamon with actions that increase the sensitivity of cells to insulin, leading to the recognition that regular consumption of cinnamon may help to prevent type 2 diabetes. The most studied component of licorice, glycyrrhizin, inhibits the enzyme11 beta-hydroxysteroid dehydrogenase type 2, potentiating the biological activity of endogenous cortisol. Glycyrrhizin also inhibits the growth of *Helicobacter pylori*. Glycyrrhizin and its derivatives may account for the anti-inflammatory and anti-ulcerogenic effects of licorice.

Fermentation is a form of food modification initially developed for preservation. The health-enhancing effects of fermented foods have a place in folk medicine. Several fermented foods have health benefits that exceed those of their parent foods and can be considered functional foods, broadly defined. These include red wine, yogurt, and tempeh. Red wine is a whole fruit alcohol extract that concentrates polyphenols found primarily in the seed and skin of the grape. Its consumption is associated with protection against heart disease, perhaps because red wine polyphenols inhibit the production of free radicals and lipid peroxides that result from the simultaneous ingestion of

cooked meat. Fresh yogurt contains live cultures of lactic acid-producing bacteria that can prevent the development of traveler's diarrhea, antibiotic-induced diarrhea, rotavirus infection, and vaginal yeast infection, decrease the incidence of postoperative wound infection following abdominal surgery and restore the integrity of the intestinal mucosa of patients who have received radiation therapy. Tempeh is made from dehulled, cooked soy beans fermented by the fungus *Rhizopus oligosporus*. Not only is its protein content higher than the parent soy bean, but it also has antibiotic activity *in vitro* and the ability to shorten childhood diarrhea *in vivo*.

Modification of a food to make it less harmful by removing potential toxins or allergens may create a functional food. Using this criterion, infant formula, protein hydrolysates, low-sodium salt substitutes, low-fat dairy products, and low-erucic-acid rapeseed oil (canola oil) might be considered functional foods.

If the most restrictive definition of functional foods is employed, the functional food movement began in Japan during the 1980s, when the Japanese government launched three major research initiatives designed to identify health-enhancing foods to control the rising cost of medical care. In 1991, a regulatory framework, Foods for Special Health Uses (FOSHU), was implemented, identifying those ingredients expected to have specific health benefits when added to common foods, or identifying foods from which allergens had been removed. FOSHU products were to be in the form of ordinary food (not pills or sachets) and consumed regularly as part of the diet. Initially, 11 categories of ingredients were identified for which sufficient scientific evidence indicated beneficial health effects. The Japanese Ministry of Health recognized foods containing these ingredients as functional foods. They were intended to improve intestinal function, reduce blood lipids and blood pressure, enhance calcium or iron absorption, or serve as noncariogenic sweeteners (see **Table 1**). In addition, low-phosphorus milk was approved for people with renal insufficiency and protein-modified rice for people with rice allergy.

Interest in the development of functional foods quickly spread to North America and Europe, where the concept was expanded to include any food or food component providing health benefits in addition to its nutritive value. In Europe, functional food proponents distinguished functional foods from dietetic foods, which are defined by law. European dietetic foods are intended to satisfy special nutritional requirements of specific groups rather than to enhance physiologic function or prevent disease through nonnutritive influences. They include infant formula, processed baby foods (weanling foods), low-calorie foods for weight reduction, high-calorie foods for weight gain, ergogenic foods for athletes, and foods for special medical purposes like the treatment of diabetes or hypertension. In the US, functional food proponents have distinguished functional foods from medical foods, defined by law as special foods designed to be used under medical supervision to meet nutritional requirements in specific medical conditions. In both domains, functional foods have been viewed as whole foods or food components with the potential for preventing cancer, osteoporosis, or cardiovascular disease; improving immunity, detoxification, physical performance, weight loss, cognitive function, and the ability to cope with stress; inhibiting inflammation, free-radical pathology and the ravages of aging; and modulating the effects of hormones. Researchers have sought to validate biomarkers that demonstrate functional improvement in response to dietary intervention, identify the chemical components of functional foods responsible for those effects, and elucidate the mechanism of action of those components. The scientific substantiation of claims is a major objective.

In China, functional foods (referred to as health foods) have been viewed as part of an unbroken

Table 1 Some ingredients conferring FOSHU status on Japanese functional foods

Ingredient	*Physiological function*
Dietary fiber	Improve gastrointestinal function
Psyllium seed husk	
Wheat bran	
Hydrolyzed guar gum	
Oligosaccharides	Improve gastrointestinal function and mineral absorption
Xylo-, fructo-, isomalto-	
Soy-derived	
Polydextrose	
Bacterial cultures	Improve gastrointestinal function
Lactobacilli	
Bifidobacteria	
Soy protein isolates	Reduce cholesterol levels
Diacylglycerols	Reduce triglyceride levels
Sugar alcohols	Prevent dental caries
Maltitol	
Palatinose	
Erythritol	
Green tea polyphenols	Prevent dental caries
Absorbable calcium	Improve bone health
Calcium citrate malate	
Casein phosphopeptide	
Heme iron	Correct iron deficiency
Eucommiacea (tochu) leaf glycosides	Reduce blood pressure
Lactosucrose, lactulose, indigestible dextrin	Improve gastrointestinal function

medical tradition that does not separate medicinal herbs from foods. Over 3000 varieties of health foods are available to Chinese consumers, most derived from compound herbal formulas for which the active ingredients and their mechanism of action are unknown, all claiming multiple effects on various body systems, with little experimental evidence for safety and efficacy but widespread acceptance due to their history of use.

Edible Plants and Phytochemicals

Because their consumption is known to enhance health, vegetables, fruits, cereal grains, nuts, and seeds are the most widely researched functional foods. The health benefits of a plant-based diet are usually attributed to the content of fiber and of a variety of plant-derived substances (phytonutrients and phytochemicals) with antioxidant, enzyme-inducing, and enzyme-inhibiting effects. Some phytochemicals may also exert their health effects by modifying gene expression. Carotenoids, for example, enhance expression of the gene responsible for production of Connexin 43, a protein that regulates intercellular communication. The protective effect of carotenoid consumption against the development of cancer is more strongly related to the ability of individual carotenoids to upregulate Connexin 43 expression than their antioxidant effects or conversion to retinol. Dietary supplementation with beta-carotene reduces the blood levels of other carotenoids, some of which are more potent inducers of Connexin 43 than is beta-carotene. The unexpected and highly publicized increase in incidence of lung cancer among smokers taking beta-carotene supplements may be explained by this mechanism.

Phytochemicals associated with health promotion and disease prevention are described in **Table 2**. The most studied food sources of these phytonutrients are soy beans (*Glycine max*) and tea (*Camellia sinensis* leaves), but tomatoes (*Lycopersicon esculentum*), broccoli (*Brassica oleracea*), garlic (*Allium sativum*), turmeric (*Curcuma longa*), tart cherries (*Prunus cerasus)*, and various types of berries are also receiving considerable attention as functional food candidates. An overview of the research on soy and tea illustrates some of the clinical issues encountered in the development of functional foods from edible plants.

Soy protein extracts have been found to lower cholesterol in humans, an effect that appears to be related to amino acid composition. Soy protein extracts frequently contain nonprotein isoflavones, which have received considerable attention because of their structural similarity to estrogen. Soy isoflavones are weak estrogen agonists and partial estrogen antagonists. Epidemiologic and experimental data indicate that isoflavone exposure during adolescence may diminish the incidence of adult breast

Table 2 Phytochemicals associated with health promotion and disease prevention

Group	*Typical components*	*Biological activities*	*Food sources*
Carotenoids	Alpha- and beta-carotene cryptoxanthin, lutein, lycopene, zeaxanthin	Quench singlet and triplet oxygen, increase cell–cell communication	Red, orange and yellow fruits and vegetables, egg yolk, butter fat, margarine
Glucosinolates, isothiocyanates	Indole-3-carbinol sulphoraphane	Increase xenobiotic metabolism, alter estrogen metabolism	Cruciferous vegetables, horseradish
Inositol phosphates	Inositol hexaphosphate (phytate)	Stimulate natural killer cell function, chelate divalent cations	Bran, soy foods
Isoflavones	Genistein, daidzein	Estrogen agonist and antagonist, induce apoptosis	Soy foods, kudzu
Lignans	Enterolactone, enterolactone	Estrogen agonists and antagonists, inhibit tyrosine kinase	Flax seed, rye
Phenolic acids	Gallic, ellagic, ferulic, chlorogenic, coumaric	Antioxidant, enhance xenobiotic metabolism	Diverse fruits, vegetables
Phytoallexins	Resveratrol	Antioxidant, platelet inhibition, induce apoptosis	Red wine, grape seed
Polyphenols	Flavonoids, chalcones, catechins, anthocyanins, proanthocyanidins	Antioxidant, enhance xenobiotic metabolism, inhibit numerous enzymes	Diverse fruits, vegetables, red wine, tea
Saponins	Glycyrrhizin, ginsenosides	Antimicrobial, immune boosting, cytotoxic to cancer cells	Legumes, nuts, herbs
Sterols	Beta-sistosterol, campestrol	Bind cholesterol, decrease colonic cell proliferation, stimulate T-helper-1 cells	Nuts, seeds, legumes, cereal grains
Sulfides	Diallyl sulfides	Antimicrobial, antioxidant	Garlic, onions

cancer. *In vitro* studies show conflicting effects. On the one hand, soy isoflavones induce apoptosis of many types of cancer cells; on the other hand, estrogen receptor-bearing human breast cancer cells proliferate in tissue culture when exposed to isoflavones. Although the widespread use of soy in Asia is cited in support of the safety of soy foods, the intake of isoflavones among Asian women consuming soy regularly is in the range of 15–40 mg day^{-1}, significantly less than the isoflavone content of a serving of soymilk as consumed in the US. In clinical trials, soy isoflavones have not been effective in relieving hot flashes of menopausal women but do diminish the increased bone resorption that causes postmenopausal bone loss. In premenopausal women, soy isoflavones may cause menstrual irregularities. The successful development of soy derivatives as functional foods will require that these complex and diverse effects of different soy components in different clinical settings be better understood.

Regular consumption of tea, green or black, is associated with a decreased risk of heart disease and several kinds of cancer. These benefits are attributed to tea's high content of catechin polymers, especially epigallocatechin gallate (ECGC), which has potent antioxidant and anti-inflammatory effects, that may lower cholesterol in hyperlipidemic individuals and alter the activity of several enzymes involved in carcinogenesis. Catechin content is highest in young leaves. Aging and the fermentation used to produce black tea oxidize tea catechins, which polymerize further to form the tannins, theaflavin and thearubigen. Although ECGC is a more potent antioxidant than theaflavin, theaflavin is far more potent an antioxidant than most of the commonly used antioxidants, like glutathione, vitamin E, vitamin C, and butylated hydroxytoluene (BHT). Both ECGC and theaflavin are partially absorbed after oral consumption, but a clear dose–response relationship has not been established. Tea-derived catechins and polymers are being intensively studied as components of functional foods, because the results of epidemiologic, *in vitro*, and animal research indicate little toxicity and great potential benefit in preventing cancer or treating inflammation-associated disorders. Clinical trials have shown a mild cholesterol-lowering effect and perhaps some benefit for enhancing weight loss.

Probiotics and Prebiotics

Probiotics are live microbes that exert health benefits when ingested in sufficient quantities. Species of lactobacilli and bifidobacteria, sometimes combined with *Streptococcus thermophilus*, are the main bacteria used as probiotics in fermented dairy products. Most probiotic research has been done with nutraceutical preparations, but yogurt has been shown to alleviate lactose intolerance, prevent vaginal candidosis in women with recurrent vaginitis, and reduce the incidence or severity of gastrointestinal infections.

Prebiotics are nondigestible food ingredients that stimulate the growth or modify the metabolic activity of intestinal bacterial species that have the potential to improve the health of their human host. Criteria associated with the notion that a food ingredient should be classified as a prebiotic are that it remains undigested and unabsorbed as it passes through the upper part of the gastrointestinal tract and is a selective substrate for the growth of specific strains of beneficial bacteria (usually lactobacilli or bifidobacteria), rather than for all colonic bacteria, inducing intestinal or systemic effects through bacterial fermentation products that are beneficial to host health. Prebiotic food ingredients include bran, psyllium husk, resistant (high amylose) starch, inulin (a polymer of fructofuranose), lactulose, and various natural or synthetic oligosaccharides, which consist of short-chain complexes of sucrose, fructose, galactose, glucose, maltose, or xylose. The best-known effect of prebiotics is to increase fecal water content, relieving constipation. Bacterial fermentation of prebiotics yields short-chain fatty acids (SCFAs) that nourish and encourage differentiation of colonic epithelial cells. Absorbed SCFAs decrease hepatic cholesterol synthesis. Fructooligosaccharides (FOSs) have been shown to alter fecal biomarkers (pH and the concentration of bacterial enzymes like nitroreductase and beta-glucuronidase) in a direction that may convey protection against the development of colon cancer.

Several prebiotics have documented effects that are probably independent of their effects on gastrointestinal flora. Whereas the high phytic acid content of bran inhibits the absorption of minerals, FOSs have been shown to increase absorption of calcium and magnesium. Short-chain FOSs are sweet enough to be used as sugar substitutes. Because they are not hydrolyzed in the mouth or upper gastrointestinal tract, they are noncariogenic and noninsulogenic. Bran contains immunostimulating polysaccharides, especially beta-glucans and inositol phosphates, which have been shown to stimulate macrophage and natural killer cell activity *in vitro* and in rodent experiments. The poor solubility and absorption of beta-glucans and inositol phosphates are significant barriers to clinical effects in humans.

Immune Modulators

Several substances produced by animals and fungi have been investigated for immune-modulating effects. Fish oils are the most studied. As a source of *n*-3 fatty acids, fish oil consumption by humans has been shown to influence the synthesis of inflammatory signaling molecules like prostaglandins, leukotrienes, and cytokines. In addition to direct effects on prostanoid synthesis, *n*-3 fats have also been shown to directly alter the intracellular availability of free calcium ions, the function of ion channels, and the activity of protein kinases. Generally administered as nutraceuticals rather than as functional foods, fish oil supplements have demonstrated anti-inflammatory and immune suppressive effects in human adults. A high intake of the *n*-3 fatty acids eicosapentaenoic (20:5*n*-3) and docosahexaenoic (22:6*n*-3) acid (DHA) from seafood or fish oil supplements has also been associated with prevention of several types of cancer, myocardial infarction, ventricular arrhythmias, migraine headaches, and premature births, and with improved control of type 2 diabetes mellitus, inflammatory bowel disease, rheumatoid arthritis, cystic fibrosis, multiple sclerosis, bipolar disorder, and schizophrenia. 20:5*n*-3 but not 22:6*n*-3 is effective for schizophrenia and depression; 22:6*n*-3 but not 20:5*n*-3 improves control of blood sugar in diabetics. The benefits of fish oil supplements have prompted efforts at increasing the *n*-3 fatty acid content of common foods by adding fish oil or flax oil extracts. Consumption of these has been associated with decreased levels of some inflammatory biomarkers, including thromboxane B2, prostaglandin E2, and interleukin 1-beta.

Feeding flax seed meal or fish meal to hens enriches the *n*-3 fatty acid content of the yolks of the eggs they lay. Consumption of these eggs increases the *n*-3 fatty acid content of plasma and cellular phospholipids and produces an improved blood lipid profile when compared with consumption of standard eggs. Egg yolk is not only a source of fatty acids, but also of carotenoids and immunoglobulins. The xanthophyll carotenoids zeaxanthin and its stereoisomer lutein are readily absorbed from egg yolk. Their consumption is associated with a decreased incidence of macular degeneration and cataract. Immunizing hens to specific pathogens and extracting the antibodies present in their egg yolks yields a functional food that has been shown to prevent enteric bacterial or viral infection in experimental animals.

Bovine colostrum, the milk produced by cows during the first few days postpartum, has a long history of use as a functional food. Compared to mature milk, colostrum contains higher amounts of immunoglobulins, growth factors, cytokines, and various antimicrobial and immune-regulating factors. Consumption of bovine colostrum has been shown to reduce the incidence of diarrheal disease in infants and the symptoms of respiratory infection in adults. Specific hyperimmune bovine colostrums, produced by immunizing cows to pathogenic organisms like *Cryptosporidium parvum*, *Helicobacter pylori*, rotavirus, and *Shigella* spp., may prevent or treat infection by these organisms.

Human studies have also shown that consumption of bovine colostrum can improve anaerobic athletic performance and prevent the enteropathy induced by use of nonsteroidal anti-inflammatory drugs.

Mushrooms play a major role in traditional Chinese medicine and as components of contemporary Chinese health foods. Many *Basidiomycetes* mushrooms contain biologically active polysaccharides in fruiting bodies, cultured mycelium, or culture broth. Most belong to the group of beta-glucans that have both beta-(1→3) and beta-(1→6) linkages. Although they stimulate macrophages and natural killer cells, the anticancer effect of mushroom polysaccharide extracts appears to be mediated by thymus-derived lymphocytes. In experimental animals, mushroom polysaccharides prevent oncogenesis, show direct antitumor activity against various cancers, and prevent tumor metastasis. Clinical trials in humans have shown improvement in clinical outcome when chemotherapy was combined with the use of commercial mushroom polysaccharides like lentinan (from *Lentinus edodes* or shiitake), krestin (from *Coriolus versicolor*), or schizophyllan (from *Schizophyllum commune*). Mushroom extracts may fulfill their potential more as medicines than as functional foods.

Designer Foods

An important direction in the development of functional foods is the combination of numerous ingredients to achieve a specific set of goals, rather than efforts to uncover the potential benefits of a single food source. Infant formula was probably the first area for designer foods of this type, because of the profound influence of nutrients on the developing brain and immune system. The addition of DHA to infant formula for enhancing brain and visual development, the alteration of allergenic components in food, and the possible use of probiotics and

nucleotides to enhance immune response are important developments in this area.

Sports nutrition is another established arena for designer foods. Specific nutritional measures and dietary interventions have been devised to support athletic performance and recuperation. Oral rehydration products for athletes were one of the first categories of functional foods for which scientific evidence of benefit was obtained. Oral rehydration solutions must permit rapid gastric emptying and enteral absorption, improved fluid retention, and thermal regulation, to enhance physical performance and delay fatigue. Carbohydrates with relatively high glycemic index combined with whey protein concentrates or other sources of branched chain amino acids have been shown to enhance recovery of athletes. Caffeine, creatine, ribose, citrulline, L-carnitine, and branched chain amino acids have each been shown to improve exercise performance or diminish postexercise fatigue. Whether combinations of these ingredients, blended into foods or beverages, will perform better than the individual ingredients will help to determine the design of future sports foods.

Optimal cardiovascular health involves prevention of excessive levels of oxidant stress, circulating homocysteine, cholesterol, triglycerides and fibrinogen, and protection of the vascular endothelium. A mix of ingredients supplying all of these effects could consist of soy protein powder, oat beta-glucan, plant sterols and stanols, folic acid, L-arginine, 22:6*n*-3, magnesium, and red wine or green tea polyphenols. Evidence suggests that addressing multiple nutritional influences on cardiovascular health will be more beneficial than addressing only one influence, but more definitive studies are needed. Genetic factors may need to be incorporated for designer foods to achieve their full potential. Polyunsaturated fatty acids, for example, raise the serum concentration of HDL-cholesterol among individuals who carry the Apo A1-75A gene polymorphism, but reduce HDL-cholesterol levels of individuals who carry the more common Apo A1-75G polymorphism.

Regulatory Aspects

H H Butchko, Exponent, Inc., Wood Dale, IL, USA
B J Petersen, Exponent, Inc., Washington DC, USA

Although there is no universally accepted definition of functional food, the International Life Sciences Institute of North America (ILSI NA) defines such foods as those that provide a health benefit beyond basic nutrition through the presence of physiologically active food components. Health Canada considers functional food as "similar in appearance to a conventional food, consumed as part of the usual diet, with demonstrated physiological benefits, and/

or to reduce the risk of chronic disease beyond basic nutritional functions." The Institute of Medicine of the US National Academy of Sciences has a more limited definition of functional foods as those in which the concentrations of one or more ingredients have been manipulated or modified to enhance their contribution to a healthful diet.

Under a broad definition, functional foods may include conventional foods; fortified, enriched, or enhanced foods; and dietary supplements because they provide essential nutrients often beyond quantities necessary for normal maintenance, growth, and development and/or other biologically active components that impart health benefits or desirable physiological effects. Thus, fruits and vegetables, such as broccoli, carrots, and tomatoes, are the simplest forms of functional foods because they provide physiologically active components such as sulforaphane, β-carotene, and lycopene, respectively.

Although functional foods can play a key role in promoting a healthier population, the government regulation of such foods is important to ensure protection of consumers from fraud and to ensure that any claims provide accurate information, are not misleading, and are scientifically valid. Governments have developed or are developing regulatory frameworks of nutrition and health claims to assist consumers in choosing foods for health promotion. The regulation of functional foods, the types and wording of claims communicated to consumers, and their place in national regulatory frameworks is evolving globally.

Regulation of Functional Foods in Japan

In the 1980s, the Japanese government funded large-scale research programs for systemic analysis of food functions and the physiological regulation of the function of food and the molecular design of functional foods. In 1991, the government established the Japanese Foods for Specified Health Use (FOSHU) to define foods with potential health benefits to help stem the rising cost of health care in Japan.

Under the FOSHU system, health claims are approved for specific products. Companies make an application for FOSHU approval to the Ministry of Health and Welfare (MHW). FOSHU are those foods that have a specific health benefit due to the presence of certain constituents or foods. Allergens cannot be present. Scientific substantiation, including the scientific evidence of safety and efficacy of the food and the medical or nutritional basis for the claim, must be provided to the MHW for consideration. To be classified as FOSHU, it must be demonstrated that the final food product, not just individual components, is likely to have a beneficial health effect when consumed as part of the normal diet. FOSHU must be in the form of food and not pills or capsules.

The labeling of FOSHU foods must not be misleading and must include the approved health claim, the recommended daily intake, relevant nutrition information, guidance on healthful eating, and any necessary warnings regarding excessive intake. Domestic products have an 'approved' mark from the MHW, whereas imported products have a "permitted" mark.

Regulation of Functional Foods in the United States

Current US food regulations do not specifically address functional foods but, rather, include them in several categories within conventional foods, food additives, dietary supplements, medical foods, or foods for special dietary use. All of these fall under the amended Federal Food, Drug and Cosmetic Act (FDCA) of 1938 and are implemented under regulations from the Food and Drug Administration (FDA). Four types of claims can be used to communicate the usefulness of functional foods to consumers: health claims, qualified health claims, structure–function claims, and nutrient content claims.

Health Claims

The Nutrition Labeling and Education Act (NLEA) of 1990 authorizes the FDA to allow approved disease risk-reduction claims, known as health claims, to appear on food labeling. NLEA allows claims that "characterize the relationship of any substance to a disease or health-related condition." For example, "diets low in sodium may reduce the risk of high blood pressure." Health claims may not be false or misleading in any respect and must not suggest that a food will diagnose, treat, mitigate, cure, or prevent any disease, or they would be considered drug claims under the FDCA. If a manufacturer fails to comply with all of the requirements for an approved health claim, the FDA would consider that the food is either misbranded (mislabeled and therefore illegal) or an illegal drug because it would not comply with all applicable drug requirements.

The scientific standard for authorization of a health claim under NLEA mandates that there be significant scientific agreement among qualified

experts about the validity of the relationship described in the proposed claim. The FDA has approved 12 health claims that meet the significant scientific agreement standard (**Table 1**).

The FDA Modernization Act of 1997 (FDAMA) provides an additional expedited process for manufacturers to use health claims. FDAMA allows health claims if they are based on current, published, authoritative statements from certain federal government official scientific bodies, such as the National Institutes of Health, the Centers for Disease Control and Prevention, and the National Academy of Sciences. Under FDAMA, manufacturers are required to notify and provide specific wording of the claim to the FDA 120 days in advance of use of the claim. During this time period, the FDA is expected to review the claim and may prohibit or modify the claim. If the FDA fails to act within the 120-day period, the claim is authorized by statue; the FDA is not required to issue a regulation. Since July 6, 1999, when the first health claim under the FDAMA was authorized, only one additional health claim has been allowed (**Table 2**).

Qualified Health Claims

Qualified health claims allow disease risk-reduction statements but, unlike health claims, must be qualified to indicate that the level of scientific support is not conclusive. Qualified health claims for dietary supplements were first authorized under a 1999 court decision in the case of *Pearson versus Shalala* regarding health claims for dietary supplements. In December 2002, the FDA announced the institution of a new labeling scheme for qualified health claims. The FDA indicated that it will depart from its standard of significant scientific agreement for health claims in evaluating qualified health claims. Qualified health claims may be based on the weight of the scientific evidence. In July 2003, the FDA announced a ranking system and proposed language for qualified health claims. Under the new scheme, claims are ranked by strength of scientific evidence. A claim designated as 'A' is actually an unqualified health claim with the standard of significant scientific agreement. Claims 'B,' 'C,' and 'D' would have progressively less supportive scientific evidence, and the FDA has suggested appropriate qualifying language for these claims (**Table 3**). To date, the FDA has allowed qualified health claims regarding certain foods, food components, and dietary supplements and the risk of cancer, cardiovascular disease, cognitive function and dementia, and neural tube defects (**Table 4**).

Structure–Function Claims

Structure–function claims for conventional foods focus on effects derived from nutritive value, whereas such claims for dietary supplements may focus on nutritive as well as nonnutritive effects. Structure–function claims describe the role of a nutrient or dietary ingredient that affects normal structure or function of the body (e.g., "calcium builds strong bones") without linking it to a specific disease. Structure–function claims may also characterize the mechanism by which a nutrient or dietary ingredient acts to maintain such structure or function (e.g., "fiber maintains bowel regularity"). They may also relate general well-being to consumption of a nutrient or dietary ingredient or describe a benefit related to a nutritional deficiency disease (e.g., deficiency of vitamin C and the occurrence of scurvy), which must be accompanied by a statement that describes the prevalence of such a disease in the United States. Structure–function claims on conventional foods are not preapproved by the FDA; it is the manufacturer's responsibility to ensure the accuracy and truthfulness of its claims and that such claims are not misleading.

The Dietary Supplement Health and Education Act of 1994 established special regulatory procedures for structure–function claims for dietary supplements. When such claims are used with a dietary supplement, the label must include a disclaimer that the FDA has not evaluated the claim and also that the product is not intended to "diagnose, treat, cure, or prevent any disease." Manufacturers of dietary supplements that make structure–function claims on labels or in labeling are required to submit a notification to the FDA no later than 30 days after marketing the dietary supplement. Although this notification must include the text of the structure–function claim, there is no requirement that the manufacturer include the scientific evidence supporting the claim with this notification.

Nutrient Content Claims

A nutrient content claim either expressly or implicitly characterizes the level of a nutrient in a product (e.g., "high in vitamin C" or "low in sodium"). In general, nutrient content claims cannot be used in food labeling unless the claim is made in accordance with existing FDA regulations or an authoritative statement by a scientific body. The FDA has allowed nutrient content claims for certain substances for which it has established Daily Reference Values or Reference Daily Intakes (RDIs). In general, the FDA allows nutrient content labeling for "high in," "rich in," or an "excellent source of" a vitamin or mineral

Table 1 FDA-approved health claims that meet the significant scientific agreement standard

Food or dietary component	*Disease claim*	*Model claim*
Calcium 21 CFR 101.72	Osteoporosis	"Regular exercise and a healthy diet with enough calcium helps teens and young adult white and Asian women maintain good bone health and may reduce their high risk of osteoporosis later in life."
Dietary fat 21 CFR 101.73	Cancer	"Development of cancer depends on many factors. A diet low in total fat may reduce the risk of some cancers."
Dietary saturated fat and cholesterol 21 CFR 101.75	Coronary heart disease	"While many factors affect heart disease, diets low in saturated fat and cholesterol may reduce the risk of this disease."
Dietary noncariogenic carbohydrate sweeteners 21 CFR 101.80	Dental caries	**Full claim**: "Frequent between-meal consumption of foods high in sugars and starches promotes tooth decay. The sugar alcohols in [name of food] do not promote tooth decay." **Shortened claim** (on small packages only): "Does not promote tooth decay."
Fiber-containing grain products, fruits, and vegetables 21 CFR 101.76	Cancer	"Low-fat diets rich in fiber-containing grain products, fruits, and vegetables may reduce the risk of some types of cancer, a disease associated with many factors."
Folate 21 CFR 101.79	Neural tube birth defects	"Healthful diets with adequate folate may reduce a woman's risk of having a child with a brain or spinal cord defect."
Fruits and vegetables 21 CFR 101.78	Cancer	"Low-fat diets rich in fruits and vegetables (foods that are low in fat and may contain dietary fiber, vitamin A, or vitamin C) may reduce the risk of some types of cancer, a disease associated with many factors. Broccoli is high in vitamin A and C, and it is a good source of dietary fiber."
Fruits, vegetables, and grain products that contain fiber, particularly soluble fiber 21 CFR 101.77	Coronary heart disease	"Diets low in saturated fat and cholesterol and rich in fruits, vegetables, and grain products that contain some types of dietary fiber, particularly soluble fiber, may reduce the risk of heart disease, a disease associated with many factors."
Sodium 21 CFR 101.74	Hypertension	"Diets low in sodium may reduce the risk of high blood pressure, a disease associated with many factors."
Soluble fiber from certain foods 21 CFR 101.81	Coronary heart disease	"Soluble fiber from foods such as [*name of soluble fiber source, and if desired, name of food product*], as part of a diet low in saturated fat and cholesterol, may reduce the risk of heart disease. A serving of [*name of food product*] supplies __ grams of the [necessary daily dietary intake for the benefit] soluble fiber from [*name of soluble fiber source*] necessary per day to have this effect."
Soy protein 21 CFR 101.82	Coronary heart disease	(1) "25 grams of soy protein a day, as part of a diet low in saturated fat and cholesterol, may reduce the risk of heart disease. A serving of [*name of food*] supplies __ grams of soy protein." (2) "Diets low in saturated fat and cholesterol that include 25 grams of soy protein a day may reduce the risk of heart disease. One serving of [*name of food*] provides __ grams of soy protein."
Stanols/sterols 21 CFR 101.83	Coronary heart disease	(1) "Foods containing at least 0.65 gram per serving of vegetable oil sterol esters, eaten twice a day with meals for a daily total intake of at least 1.3 grams, as part of a diet low in saturated fat and cholesterol, may reduce the risk of heart disease. A serving of [*name of food*] supplies __ grams of vegetable oil sterol esters." (2) "Diets low in saturated fat and cholesterol that include two servings of foods that provide a daily total of at least 3.4 grams of plant stanol esters in two meals may reduce the risk of heart disease. A serving of [*name of food*] supplies__ grams of plant stanol esters."

Table 2 Health claims allowed under the FDAMA

Food or dietary component	*Disease*	*Basis*
Potassium	High blood pressure and stroke	National Academy of Sciences report *Diet and Health: Implications for Reducing Chronic Disease Risk*
Whole grain foods	Heart disease and certain cancers	National Academy of Sciences report *Diet and Health: Implications for Reducing Chronic Disease Risk*

From *Label Claims, FDA Modernization Act of 1997 (FDAMA) Claims*. Available at www.cfsan.fda.gov/~dms/labfdama.html.

for which the agency has established an RDI if the food provides 20% or more of the RDI per reference amount customarily consumed. The FDA has also published regulations authorizing and establishing detailed requirements for "good source," "more," and "light" (or "lite") claims, and certain claims about calorie content, sodium content, and fat, fatty acid, and cholesterol content.

If a manufacturer wants to make a claim about a food as a good source of a nutrient for which no FDA nutrient content claim regulation exists, such a claim would not be allowed, even if the claim is truthful and not misleading, unless and until the FDA issues a regulation approving the use of the claim.

Table 3 Standardized language for qualified health claims by category

FDA category	*Level of scientific evidence*	*Proposed qualifying language*
B	Second level: Moderate/good level of comfort	"Although there is scientific evidence supporting this claim, the evidence is not conclusive."
C	Third level: Low level of comfort	"Some scientific evidence suggests ... however, FDA has determined that this evidence is limited and not conclusive."
D	Fourth level: Extremely low level of comfort	"Very limited and preliminary scientific research suggests ... FDA concludes that there is little scientific evidence supporting this claim."

European Regulations for Functional Foods

The concept of functional foods was first evaluated in Europe in the 1990s when the International Life Sciences Institute in Europe (ILSI Europe) developed a project on functional foods that became a European Commission (EC) concerted action, Functional Food Science in Europe. Approximately 100 experts in nutrition and medicine in Europe reviewed the scientific literature about foods and food components and their effects on body functions, and they developed a global framework that included a framework for the identification and development of functional foods and for the scientific substantiation of their health-related effects. From this evaluation, two types of claims for functional foods were suggested: enhanced function claims and reduction of disease risk claims. From this evaluation, the "Concepts of Functional Foods" was produced by ILSI followed by publication of "Scientific Concepts of Functional Foods in Europe: Consensus Document." According to this concept document, "a food can be regarded as functional if it is satisfactorily demonstrated to beneficially affect one or more target functions in the body, beyond adequate nutritional effects, in a way which is relevant to either an improved state of health and well-being, or reduction of risk of disease." As in the United States, this definition of a functional food specifically excludes the treatment of disease. However, unlike the case in the United States, where functional foods can include dietary supplements in pill or capsule form, in Europe functional foods must be foods that have a positive health benefit in amounts normally consumed in the diet.

There are currently no final regulations or legislation at the European Union (EU) level that define permissible nutrition and health claims on foods. However, various member states have adopted local legislation to regulate their use, which has resulted in numerous differences throughout the EU in the definition of terms and the circumstances when claims are warranted. In 2003, the EU Commission issued a "Proposal for a Regulation of the European Parliament and of the Council on Nutrition and Health Claims Made in Foods" for harmonization of claims throughout the EU. Under this proposed regulation, although functional food is not defined, both nutrition and health claims would be allowed. Nutrition and health claims must be based on, and substantiated by, generally accepted scientific data and not be false, ambiguous, or misleading or imply doubts about the safety or nutritional adequacy of other foods. This proposal is being evaluated by the member states.

Table 4 Qualified health claims permitted by FDA

Food or food component	*Disease*	*Eligible food*	*Required claim statement*
Selenium	Cancer	Dietary supplements containing selenium	(1) "Selenium may reduce the risk of certain cancers. Some scientific evidence suggests that consumption of selenium may reduce the risk of certain forms of cancer. However, FDA has determined that this evidence is limited and not conclusive." *or*, (2) "Selenium may produce anticarcinogenic effects in the body. Some scientific evidence suggests that consumption of selenium may produce anticarcinogenic effects in the body. However, FDA has determined that this evidence is limited and not conclusive."
Antioxidant vitamins	Cancer	Dietary supplements containing vitamin E and/or vitamin C	(1) "Some scientific evidence suggests that consumption of antioxidant vitamins may reduce the risk of certain forms of cancer. However, FDA has determined that this evidence is limited and not conclusive." *or*, (2) "Some scientific evidence suggests that consumption of antioxidant vitamins may reduce the risk of certain forms of cancer. However, FDA does not endorse this claim because this evidence is limited and not conclusive." *or*, (3) "FDA has determined that although some scientific evidence suggests that consumption of antioxidant vitamins may reduce the risk of certain forms of cancer, this evidence is limited and not conclusive."
Nuts	Heart disease	Whole or chopped nuts or foods containing nuts with at least 11 g per reference amount customarily consumed; types of nuts — almonds, hazelnuts, peanuts, pecans, some pine nuts, pistachio nuts, walnuts	"Scientific evidence suggests but does not prove that eating 1.5 ounces per day of most nuts [such as *name of specific nut*] as part of a diet low in saturated fat and cholesterol may reduce the risk of heart disease."
Walnuts	Heart disease	Whole or chopped walnuts	"Supportive but not conclusive research shows that eating 1.5 ounces per day of walnuts, as part of a low saturated fat and low cholesterol diet and not resulting in increased caloric intake, may reduce the risk of coronary heart disease. See nutrition information for fat [and calorie] content."
Omega-3 fatty acids	Coronary heart disease	Dietary supplements containing the omega-3 long-chain polyunsaturated fatty acids eicosapentanoic acid (EPA) and/or docosahexanoic acid (DHA)	"Consumption of omega-3 fatty acids may reduce the risk of coronary heart disease. FDA evaluated the data and determined that, although there is scientific evidence supporting the claim, the evidence is not conclusive."

Continued

Table 4 Continued

Food or food component	*Disease*	*Eligible food*	*Required claim statement*
B vitamins	Vascular disease	Dietary supplements containing vitamin B_6, B_{12}, and/or folic acid	"As part of a well-balanced diet that is low in saturated fat and cholesterol, Folic Acid, Vitamin B_6 and Vitamin B_{12} may reduce the risk of vascular disease. FDA evaluated the above claim and found that, while it is known that diets low in saturated fat and cholesterol reduce the risk of heart disease and other vascular diseases, the evidence in support of the above claim is inconclusive."
Phosphatidylserine	Cognitive function and dementia	Dietary supplements containing soyderived phosphatidylserine	(1) "Consumption of phosphatidylserine may reduce the risk of dementia in the elderly. Very limited and preliminary scientific research suggests that phosphatidylserine may reduce the risk of dementia in the elderly. FDA concludes that there is little scientific evidence supporting this claim." *or*, (2) "Consumption of phosphatidylserine may reduce the risk of cognitive dysfunction in the elderly. Very limited and preliminary scientific research suggests that phosphatidylserine may reduce the risk of cognitive dysfunction in the elderly. FDA concludes that there is little scientific evidence supporting this claim."
Folic acid (0.8 mg)[a]	Neural tube birth defects	Dietary supplements containing folic acid	"0.8 mg folic acid in a dietary supplement is more effective in reducing the risk of neural tube defects than a lower amount in foods in common form. FDA does not endorse this claim. Public health authorities recommend that women consume 0.4 mg folic acid daily from fortified foods or dietary supplements or both to reduce the risk of neural tube defects."

[a]FDA has approved a health claim for folic acid in food and does not endorse that the 0.8 mg is more effective than lower amounts found in food.
From *Summary of Qualified Health Claims Permitted*. Available at www.cfsan.fda.gov/~dms/qhc-sum.html.

Nutrition Claims

A nutrition claim is defined as "any claim which states, suggests, or implies that a food has particular nutrition properties due to" energy or nutrients or other substances (i.e., provides, provides at a reduced or increased rate, or does not provide). The proposed regulation calls for establishment of a list of permitted claims and their specific conditions of use, which would be regularly updated. In the current proposed regulation, the list of nutrients includes fat, saturated fat, unsaturated fat, monounsaturated fat, polyunsaturated fat, omega-3 fatty acids, sugar, sodium, fiber, protein, vitamins/minerals, or other substances.

Health Claims

A health claim is defined in the proposed regulation as "any claim that states, suggests, or implies that a relationship exists between a food category, a food, or one of its constituents and health." A reduction in disease risk claim is defined as "any health claim that states, suggests, or implies that the consumption of a food category, a food, or one of its constituents significantly reduces a risk factor in the development of a human disease." As in the United States, medicinal products in Europe are those that treat, prevent, or diagnose disease or restore, correct, or modify physiological functions. In the European Directive 2000/13/EC on labeling, presentation, and advertising of foods, there is a specific prohibition on attributing prevention, treatment, or cure of a human disease or any reference to such properties to a food. However, there is a distinction made between prevention and significant reduction of a major disease risk factor, and the directive acknowledges that diet and certain foods are important for supporting and maintaining health and can affect certain disease risk factors.

Under the proposed regulation, health claims will only be allowed if the following information is included on the label: (i) a statement describing the importance of a varied and balanced diet and healthy lifestyle; (ii) the quantity of the food and pattern of consumption required to obtain the claimed beneficial heath effect: (iii) a statement addressed to people who should avoid the food, if appropriate; and (iv) a warning for products that may result in a health risk if consumed in excess. A reduction of risk claim must also include a statement that diseases may have many risk factors and that altering only one of these factors may or may not have a beneficial effect. Claims regarding a "slimming, slimness-producing, or weight-reducing" effect, those that refer to reducing hunger or increasing satiety, and those that claim a reduction in available energy from the diet would not be permitted.

The European Food Safety Authority (EFSA) is designated as the body that will be responsible for evaluating and authorizing health claims. EFSA would be required to make a decision within 6 months of receipt of an application. Once EFSA makes a decision, it would be forwarded to the Commission, which would be required to draft a decision within 3 months, followed by publication in the *Official Journal of the European Communities*. It is also anticipated that the Commission would establish and maintain a "community register of nutrition and health claims on food."

Nutrition and Health Claims at Codex

Many countries use decisions of the Codex Alimentarius Commission (Codex) as a basis for national regulations. Codex decisions are also used by the World Trade Organization (WTO) as the basis for resolution of trade disputes between nations. In May 2004, the Codex Committee on Food Labeling adopted draft guidelines for the use of nutrition and health claims; the commission officially adopted these draft guidelines in June 2004. Nutrition and health claims would not be allowed for foods for infants and young children unless specifically provided for in relevant Codex standards or national legislation.

Nutrition Claims

According to Codex, a nutrition claim "states, suggests, or implies that a food has particular nutritional properties, including but not limited to the energy and to the content of protein, fat, and carbohydrates, as well as the content of vitamins and minerals." The only nutrition claims permitted are those relating to energy, protein, carbohydrate, and fat and components thereof, fiber, sodium, and vitamins and minerals for which Nutrient Reference Values (NRVs) have been laid down in the Codex Guidelines for Nutrition Labelling. Two types of nutrition claims were defined. A nutrient content claim is defined as a nutrition claim that describes the level of a nutrient contained in a food—for example, "source of calcium," "high in fiber," and "low in fat." A nutrient comparative claim is one that compares the nutrient levels and/or energy value of two or more foods—for example, "reduced," "less than," "fewer," "increased," and "more than" (**Table 5**).

Table 5 Nutrient content claims at Codex

Food component	*Content claim*	*Requirements Not more than*
Energy	Low	40 kcal (170 kJ) per 100 g (solids) or 20 kcal (80 kJ) per 100 ml (liquids)
	Free	4 kcal per 100 ml (liquids)
Fat	Low	3 g per 100 g (solids), 1.5 g per 100 ml (liquids)
	Free	0.5 g per 100 g (solids) or 100 ml (liquids)
Saturated fat	Low[a]	1.5 g per 100 g (solids), 0.75 g per 100 ml (liquids) and 10% of energy
	Free	0.5 g per 100 g (solid) or 100 ml (liquids)
Cholesterol	Low[a]	0.02 g per 100 g (solids), 0.01 g per 100 ml (liquids)
	Free[a]	0.005 g per 100 g (solids), 0.005 g per 100 ml (liquids) and, for both claims, less than 1.5 g saturated fat per 100 g (solids), 0.75 g saturated fat per 100 ml (liquids) and 10% of energy of saturated fat
Sugars	Free	0.5 g per 100 g (solids), 0.5 g per 100 ml (liquids)
Sodium	Low	0.12 g per 100 g
	Very low	0.04 g per 100 g
	Free	0.005 g per 100 g
Protein	Source	10% of NRV per 100 g (solids), 5% of NRV per 100 ml (liquids) or 5% of NRV per 100 kcal (12% of NRV per 1 MJ) or 10% of NRV per serving
	High	2 times the values for 'source'
Vitamins and minerals	Source	15% of NRV per 100 g (solids), 7.5% of NRV per 100 ml (liquids) or 5% of NRV per 100 kcal (12% of NRV per 1 MJ) or 15% of NRV per serving
	High	2 times the values for 'source'

[a]*Trans* fatty acids should be taken into account where applicable.
NRV, nutrient reference value.
From Codex Alimentarius Commission (2004) *Joint FAO/WHO Food Standards Programme. Twenty-Seventh Session Rome, 28 June–3 July 2004. ALINORM 04/27/22 Report of the Thirty-Second Session of the Codex Committee on Food Labeling. Montréal, Canada, 10–14 May 2004.* Available at www.codexalimentarius.net.

Any comparisons are to be based on a relative difference of at least 25% in the energy value or macronutrient nutrient content and a 10% difference in the NRV for micronutrients between the compared foods. The use of the word "light" follows the same criteria as for "reduced" and should include an indication of the characteristics that make the food "light."

Health Claims

Health claims are defined by Codex as "any representation that states, suggests, or implies that a relationship exists between a food or a constituent of that food and health." Health claims must be based on the current relevant scientific data and be sufficient to substantiate the claimed effect and the relationship to health; Codex also envisions a re-review of claims as additional data may become available. Health claims should include information on the physiological role of the nutrient or the diet–health relationship as well as information on the composition of the product relevant to the physiological role of the nutrient or the accepted diet–health relationship. Codex defined three types of health claims: nutrient function claims, other function claims, and reduction of disease risk claims.

A nutrient function claim describes the physiological role of a nutrient in growth, development, and normal functions of the body. For example, "Nutrient A (naming a physiological role of nutrient A in the body in the maintenance of health and promotion of normal growth and development). Food X is a source of/high in nutrient A."

Other function claims convey specific beneficial effects of the consumption of foods or their constituents in the context of the total diet on normal functions or biological activities of the body. Such claims relate to a positive contribution to health, to the improvement of a function, or to modifying or preserving health. For example, "Substance A (naming the effect of substance A on improving or modifying a physiological function or biological activity associated with health). Food Y contains x grams of substance A."

Reduction of disease risk claims convey that consumption of a food or food constituent, in the context of the total diet, is related to a reduced risk of developing a disease or health-related condition. Risk reduction is defined as "significantly altering a major risk factor(s) for a disease or health-related condition." Because diseases have multiple risk factors and altering one of these risk factors may or may not have a beneficial effect, the risk reduction claims must have appropriate language and reference to other risk factors to ensure that consumers do not interpret them as prevention claims. For example, reduction of risk claims may include statements such as "A healthful diet low in nutrient or substance A may reduce the risk of disease D. Food X is low in nutrient or substance A" or "A healthful diet rich in nutrient or substance A may reduce the risk of disease D. Food X is high in nutrient or substance A."

Claims Related to Dietary Guidelines or Healthy Diets

Claims describing a food as part of a healthy diet should be permitted only if they are related to the pattern of eating contained in dietary guidelines officially recognized by the appropriate national authority, contain a statement relating the food to the pattern of eating to that in the guidelines, and are consistent with such guidelines. Such claims should not describe the food itself as healthy or imply that the food in and of itself will impart health. Foods that are allowed such claims should meet certain minimum criteria for major nutrients in the dietary guidelines. Codex stated that there should be some flexibility in the wording of such claims as long as they "remain faithful to the pattern of eating outlined in the dietary guidelines."

Conclusion

With the growing recognition of the connection between diet and health along with soaring health care costs, both consumers and governments have had great interest in capitalizing on the benefits of functional foods for health promotion. Although there is no standard accepted definition of functional food, most regulations and guidelines incorporate the concept that such foods, food components, and supplements provide a benefit to health beyond basic nutrition. There has been considerable progress by governments and Codex to develop systems to allow such products and to communicate their benefits to consumers through labeling claims. Some national regulatory agencies have laid down scientific standards for demonstrating the safety and efficacy of functional foods for different types of nutrition and health claims. Regulatory agencies are especially concerned that claims on foods or supplements are truthful and not misleading and aid consumers in making informed choices for health promotion. In the future, it is expected that functional foods will gain in importance, and regulatory agencies will need to continue to ensure that any claims on such products meet consumer needs.

G

GALACTOSE

A Abi-Hanna and J M Saavedra,
Johns Hopkins School of Medicine, Baltimore, MD, USA

This article is reproduced from the previous edition, pp. 915–922, © 1999, Elsevier Ltd.

Lactose, a disaccharide composed of glucose and galactose, is the principal sugar of mammalian milk and the principal carbohydrate energy source for infants and children; thus galactose plays a central metabolic role in human nutrition. Lactose is hydrolyzed in the intestine into glucose and galactose, which together with other sources of these monosaccharides are absorbed and metabolized and used as energy. Galactose additionally is an important constituent of complex polysaccharides, galactolipids, and other glycoconjugates of structural and functional importance. Both absorptive as well as metabolic defects affecting galactose have been described.

Dietary Sources of Galactose

Lactose is by far the most abundant source of galactose in the diet of most humans. However, lactose can also be found in a considerable number of sources. These include drugs and medications, which use lactose as an excipient, in part because of its excellent tablet-forming capacity. Additionally, small amounts of galactose can be present in many fruits and vegetables, and considerable amounts can also be found in legumes (beans and peas) and in other food plants. Galactose polysaccharides with various glycolytic linkages such as $\alpha(1–6)$, $\beta(1–3)$, and $\beta(1–4)$ are ubiquitous in animals and plants. The bioavailability of galactose in these linkages found in foods is not well known. Some galactosidasis in plants can liberate galactose, and foods fermented by microorganisms for preparation or preservation may also contain free galactose. The role of free and bound galactose in cereals, fruits, legumes, nuts, and other vegetables may contribute to sources of galactose that are not readily obvious. Bound galactose is also present in raffinose oligosaccharides and other sugars.

Galactose Absorption

Lactose is hydrolyzed in the intestine by the enzyme lactase-phlorizin hydrolase to glucose and galactose. In humans, D-glucose and D-galactose are the only nutritionally significant monosaccharides that are actively absorbed. Although glucose and galactose can cross the intestinal mucosa down a diffusion gradient, the slowness of this method is such that water would diffuse in the opposite direction leading to a lessening in the concentration gradient. Thus, a rapid transport mechanism exists for glucose and galactose, particularly in infants. The 'coupled carrier' hypothesis is generally accepted as the main mechanism. In the small intestine and proximal tubule of the kidney, D-glucose is absorbed by epithelial cells via a sodium-dependent cotransport system existing at the luminal membrane level and a sodium-independent transport system at the basolateral membrane level. It is suggested that the potential difference across the brush border membrane of the cell also plays an important role in the mechanism which concentrates sugar in the cell.

The genetic functional defects of this cotransport system are expressed in two main clinical entities; selective congenital glucose and galactose malabsorption by the intestine discussed below, and familial renal glycosuria. Once galactose is absorbed, it must be converted to glucose for utilization. This occurs primarily by the pathways explained below. Three distinct enzymatic defects are responsible for the conditions generally described as galactosemia.

Glucose–Galactose Malabsorption

Pathophysiology and Clinical Manifestation

Glucose and galactose malabsorption is a rare congenital disease resulting from a selective defect in the

intestinal transport of glucose and galactose. It is characterized by the neonatal onset of severe, watery, acidic diarrhea. The diarrhea is profuse and contains sugar. In children given lactose, fecal sugar mainly consists of glucose and galactose with only small amounts of lactose, since lactase activity is usually adequate. Hyperosmotic dehydration and metabolic acidosis are the rule. Related gastrointestinal signs and symptoms include increase of abdominal gas, distension, and vomiting. Intermittent or permanent glycosuria after fasting or after a glucose load is frequent. Thus the combination of reducing sugar in the stool and slight glycosuria despite low blood glucose levels is highly suggestive of glucose–galactose malabsorption.

The major characteristic in glucose–galactose malabsorption is the lack of intracellular glucose or galactose accumulation against a concentration gradient. The transport of other molecules such as alanine or leucine via a sodium cotransporter is typically intact.

The abnormality of carbohydrate metabolism is confined to glucose transport in the small intestine and the proximal renal tube. The main defect appears to be the absence of a functional sodium-dependent glucose contransporter. Electrolytes can be secreted in the jejunal mucosa together with fluids, suggesting that the combined glucose–sodium water absorption process is effective. Sucrose can undergo normal hydrolysis and fructose can be absorbed typically without problems. Glucose entry into the erythrocytes is normal and so are fasting blood glucose levels. Oral glucose tolerance tests usually yield a flat glucose curve while breath hydrogen tests done separately for glucose and galactose are consistent with malabsorption.

The functionality of the cotransporter at the brush border membrane is either absent or reduced. Additionally, the participation of a mutarotase in sugar transport has recently been suggested in the absence of this enzyme and has been demonstrated in glucose–galactose malabsorption. However, full understanding of this condition requires additional information on the liquid composition of the membrane and on other characteristics and genetic control of this transport system.

Diagnosis

Children affected with glucose–galactose malabsorption are of diverse origin. There is high consanguinity rate and no clear-cut vertical transmission, suggesting an autosomal recessive mode of inheritance.

The diagnosis can be established by a clinical history of watery diarrhea with glucose–water solution or milk and rapid cessation of the problem when these are discontinued. Oral glucose or galactose tolerance tests and breath hydrogen analysis can aid in the diagnosis. The differential diagnosis includes congenital lactase deficiency, sucrose–isomaltose deficiency, and congenital chloride-secreting diarrhea. Most other monosaccharide malabsorption and intolerance is secondary to mucosal injury and responds to adequate nutritional management with complete resolution.

Management

Treatment consists of immediate rehydration, adequate maintenance of hydration, and initiation of a glucose- and galactose-free diet. Since fructose is tolerated, most of the carbohydrate initially can be given as fructose, using other dietary modular products of protein and fat as well as micronutrients.

Biochemistry and Physiology of Galactose

The main pathway of galactose metabolism in humans is the conversion of galactose to glucose, without disruption of the carbon skeleton. The name 'galactosemia' has been associated with a syndrome of toxicity associated with the administration of galactose to patients with an inherited disorder of galactose utilization, leading to multiple clinical manifestations, including malnutrition, mental retardation, liver disease, and cataracts. The clinical manifestations are linked to specific enzymatic defects. Thus the term 'galactosemia' should be qualified by the specific defect. Three enzymatic steps are required to metabolize galactose to UDP-glucose. Two alternate pathways, oxidation and reduction, are used in the absence of enzymes of the main route.

Step 1: Galactokinase

Galactose is phosphorylated by galactokinase with ATP to form galactose 1-phosphate. The equilibrium is far in the direction of sugar phosphorylation, but the reaction is reversible. Galactokinase has been studied in detail in human red cells, leucocytes, fibroblasts, placenta, liver, and various human fetal tissues. It is detectable in fetal liver from 10 weeks of gestation onwards and the activity of the enzyme in liver and red cells is higher in the second and third trimester. Its activity is higher in red blood cells from human infants than in cells from adults, and in reticulocytes than with aged

red cells. Cultured human fibroblasts show enhanced galactokinase activity when grown in the presence of galactose, whereas in the liver the activity does not appear to be regulated by dietary galactose. The red cell enzyme, like that of the liver, undergoes substrate and product inhibition.

The assignment of the gene for galactokinase has been made to human chromosome 17, and its regional localization of the chromosome has been assigned to band q21–22.

Step 2: Transferase

Galactose 1-phosphate reacts with UDP-glucose to produce UDP-galactose and glucose 1-phosphate. This step is catalyzed by galactose-1-phosphate uridyltransferase, an enzyme present in bacteria and most mammalian tissues. Like galactokinase, galactose-1-phosphate uridyltransferase is detectable in fetal liver from 10 weeks of gestation, with the liver enzyme-specific activity being highest at 28 weeks of gestation. The rate of reaction may be regulated by substrate concentration and limited by UDP-glucose substrate inhibition of transferase. Glucose 1-phosphate is a potent inhibitor of the enzyme. Uridine nucleotides such as uridine di- and triphosphate are powerful competitive inhibitors of substrate UDP-glucose.

Galactose-1-phosphate uridyltransferase deficiency is the most commonly reported defect in galactosemic patients. In the young infant galactose is a major energy source and its metabolism to glucose 1-phosphate is essential, but this is not the case in the fetus in whom glucose is the main energy source. However, the metabolism of galactose in the fetus is important to prevent accumulation of toxic galactose metabolites. Thus in galactose-1-phosphate uridyl-transferase deficiency the fetus could be at a disadvantage as early as the 10th week of gestation. Dietary and hormonal influences on the liver enzyme have not been reported. In the rat a galactose-rich diet increases transferase activity.

Galactose-1-phosphate uridyltransferase is localized on chromosome 9p13. At least 32 variants in the nucleotide sequence of the galactose-1-phosphate uridyltransferase gene have been identified, with the most frequent being change in amino acid codon position 188 in which an arginine is substituted for a glutamine, the Q188R mutation. This Q188R mutation is associated with 'classical' galactosemia with virtually no galactose-1-phosphate uridyl-transferase activity detectable. However, there are other variant forms of the enzyme which have diminished but detectable activity, known as Duarte, Indiana, Rennes, Los Angeles, Münster, and Chicago. Heterozygotes for normal and Duarte alleles are presumed to have 75% of normal galactose-1-phosphate uridyltransferase activity. Homozygotes for the Duarte allele could have 50% activity, and compound heterozygotes for the Duarte allele and the classical galactosemia allele have 25% activity in peripheral erythrocytes.

Step 3: Epimerase

The UDP-galactose is converted to UDP-glucose by UDP-galactose 4′-epimerase. The UDP-glucose thus formed can then enter the reaction again in a cyclical fashion until all the free galactose coming into the pathway is converted to glucose 1-phosphate. This enzyme is responsible for the inversion of the hydroxyl group at the C-4 carbon of the hexose chain to form glucose from galactose; it is also important for the conversion of UDP-glucose to UDP-galactose when only glucose is available and galactose is required as a constituent of complex polysaccharides. The epimerase maintains a cellular equilibrium of UDP-glucose to UDP-galactose in a ratio of about 3:1.

The purified enzyme is a dimer of identical subunits that consists of a mixture of catalytically active subunits (epimerase-NAD^+) and inactive subunits (epimerase-NADH-uridine nucleotide). The NAD binds to the enzyme and induces a conformational change resulting in enzymatic activity. For liver enzyme activity, exogenous NAD is required and NADH is a potent inhibitor of the enzyme. Any process disturbing the NAD/NADH ratio, such as ethanol metabolism which generates NADH, will impair galactose utilization. Cellular levels of UDP-glucose and other uridine nucleotides may also exert rate-regulating effects. Cells not exposed to free galactose form the sugar from glucose in adequate amounts to satisfy normal growth and development. Epimerase activity of the intestinal mucosa increases with age, whereas human red cells have a higher activity in newborns than adults. The intestinal enzyme activity can be enhanced by feeding diets high in glucose or galactose content. Less information is available on fetal levels of UDP-galactose 4′-epimerase, but one fetus of 16 weeks' gestation had liver enzyme activity comparable with that of children and adults. In epimerase deficiency, when the amount of entering galactose is low, an elevated level of galactose 1-phosphate in red blood cells may be reduced to normal but the UDP-galactose level stays elevated. The gene for epimerase has been assigned to human chromosome 1.

Alternative Pathway: Reduction

The polyol pathway was first identified in placenta and seminal vesicles and is responsible for the fructose content of seminal fluid. Two enzymatic reactions involving aldose reductase and sorbitol dehydrogenase catalyze the conversion of glucose to fructose with sorbitol as the intermediate. In certain cells, such as renal collecting duct cells, retinal pigment epithelial cells, and renal glomerular endothelium, and under certain conditions, aldose reductase functions to produce sorbitol which acts as an intracellular osmolyte. The acyclic polyols such as sorbitol, galactitol, and mannitol are the end product of metabolism and have osmotic properties. The presence of galactitol in the urine and plasma of patients with transferase-, galactokinase-, and epimerase-deficiency galactosemia is suggestive of the importance of the reduction of galactose as an alternative pathway. However, the high K_m of this enzyme indicates that reduction will occur only when galactose levels in tissues are very high.

Patients with classical galactosemia have markedly elevated levels of galactitol in plasma and urine, which remain above age-matched control levels after treatment with galactose-free diet, whereas high urinary galactose levels return to normal in all patients. Aldose reductase has been localized to the Schwann cells of peripheral nerves and to renal paptillae cells. Kinetic studies suggest that neither glucose nor galactose are preferred substrates. Only when tissue levels of galactose are much elevated would reduction be important. Aldose reductase activity of lens and other tissue is stimulated by sulfate ions and ATP and is inhibited by various keto acids, fatty acids, and ADP. Increased production of galactitol is felt to play an important role in the pathogenesis of cataracts in the infant with galactose-1-phosphate uridyltransferase, galactokinase, and UDP-galactose epimerase deficiency. The toxicity of polyols in the ocular lens is probably related to their ability to act as osmotically active particles within the lens cells, which leads to accumulation of water and eventually cell dysfunction.

Cataracts are the primary manifestation of disease in untreated patients with galactokinase deficiency, who manifest accumulation of galactitol but not galactose 1-phosphate in tissues. Thus the galactose 1-phosphate and not galactitol toxicity is probably a necessary mediator in both transferase and epimerase deficiencies for expression of hepatic disease, renal tubular dysfunction, and increased red blood cell turnover.

Alternative Pathway: Oxidation

In the absence of galactose-1-phosphate uridyltransferase activity, galactose 1-phosphate and galactose accumulate behind the block. The second alternate pathway, besides reduction of galactose to sugar alcohol, galactitol, is the oxidation of galactose to sugar acid, galactonate. Galactonate, for example, appears in the urine of transferase-deficient individuals. Galactonate can be further metabolized to xylulose, a sugar capable of further metabolism. This pathway accounts for about 50% of oxidation of galactose by galactosaemic patients. Patients with transferase-deficient galactosemia excrete galactonate in urine after galactose is administered, and galactonate has been found in the liver of a transferase-deficient subject.

Disorders of Galactose Metabolism

Clinical Manifestations

Galactose is an important constituent of the complex polysaccharides which are part of cell glycoconjugates, key elements of immunologic determinants, hormones, cell membranes structures, endogenous animal lectins, and numerous other glycoproteins. In addition galactose is incorporated in galactolipids, important structure elements of the central nervous system. It is not difficult to assume that the abnormal galactose metabolism in galactosemic patients could have profound and widespread effects on glycoconjugate structures and their biological function.

Classically, the term 'galactosemia' was associated with an inherited disorder of galactose utilization characterized by malnutrition, liver disease, cataracts, and mental retardation, resulting from the specific deficiency of galactose-1-phosphate uridyltransferase. However, other enzymatic defects with variations of clinical presentation can also lead to galactosemia (**Table 1**). Thus it is preferably better to refer to these abnormalities of metabolism by the specific enzymatic deficiencies which are described below.

Transferase deficiency Failure to thrive is the most common initial clinical sign of galactose-1-phosphate uridyltransferase deficiency, and it is present in all cases. Vomiting or diarrhea is present in almost all patients, usually starting within a few days of milk ingestion. Jaundice, hepatomegaly, or both are present almost as frequently after the first week of life. The jaundice of intrinsic liver disease may be accentuated by severe hemolysis in some

Table 1 Disorders of galactose metabolism

Enzyme deficiency	*Primary clinical manifestations*
Galactose-1-phosphate uridyltransferase	Failure to thrive Emesis/diarrhea Jaundice, hepatomegaly Cataracts Galactosuria Gonadal dysfunction Developmental delay, neurologic symptoms Cataracts
Galactokinase	Similar manifestations as transferase deficiency, but with no liver, kidney, or gonadal dysfunction
UDP-galactose 4′-epimerase	Mostly asymptomatic Rarely same manifestations as transferase deficiency but with no gonadal dysfunction

patients. Abnormal liver function tests and ascites may develop. The reason for liver toxicity remains obscure. The liver of affected patients has a characteristic acinar formation, and liver biopsy on occasion has been helpful in establishing the diagnosis. There is high frequency of neonatal death due to *Escherichia coli* sepsis, possibly caused by the inhibition of leucocyte bactericidal activity.

Galactose 1-phosphate and galactitol have been detected in the kidneys of patients with galactosemia. Renal toxicity may manifest as renal tubular dysfunction and a defect in urine acidification mechanisms. Galactosuria, hyperchloremic acidosis, albuminuria, and aminoaciduria may also occur. Hyperchloremic acidosis could be also secondary to the gastrointestinal disturbance and poor food intake. Galactosuria may be intermittent, depending on oral intake, and can disappear within 3–4 days with the use of intravenous glucose. The finding of urinary reducing substances which do not react in a glucose oxidase test should raise the suspicion of galactosemia. This finding, however, does not establish the diagnosis, since galactosuria can also occur in intestinal lactase deficiency and in severe liver disease due to other causes.

Ovarian atrophy appears to be an important manifestation of galactose toxicity, with clinical and biochemical evidence of ovarian dysfunction present in nearly all affected females. The basis of the toxicity has not been defined. The consequences of the gonadal dysfunction range from failure of pubertal development, through primary amenorrhea to secondary amenorrhea or premature menopause (75–76% of affected females). Although gonadal function has been described as early as infancy based on elevations of follicle stimulating hormones (FSH) and abnormal stimulation testing, no predisposing factor for gonadal dysfunction can be found. Previous recommendations that dietary lactose restriction from birth may be beneficial have in fact not prevented gonadal dysfunction. In the galactosemic male, a complete understanding of gonadal dysfunction has not yet been described. The majority—but not all—of male galactosemic patients had normal pubertal development, and a few individuals have been found to have normal semen.

Cataracts have been observed within a few days of birth. These may be found only on slit-lamp examination and can be missed with an ophthalmoscope, since they consist of punctate lesions in the fetal lens nucleus. Several hypotheses have been postulated to account for their formation and are mentioned above. It seems conclusive that the initiator of the process in rats is galactitol and not galactose 1-phosphate. Galactose 1-phosphate accumulates only late in the process and is absent in patients with galactokinase deficiency who present with cataracts.

Development of mental retardation may be apparent after the first months of life. Signs of increased intracranial pressure and cerebral oedema have been observed as a presenting feature.

Many of the toxicity symptoms can rapidly resolve with institution of dietary lactose restriction. However, a substantial percentage of children have subnormal IQs and speech and language deficits, but rarely devastating neurological sequelae. Most galactosemic patients with lactose restriction are deficient of cognitive functioning in one or more areas. The deficits are variable and do not appear to be related to the age, diagnosis, or the severity of illness at presentation. The pathophysiology of these impairments in galactosemia remains unknown. Several hypotheses are suggested, including toxic oedema due to increased brain galactitol concentrations, changes in the second messenger pathway, and changes of the energy status of the brain.

Galactokinase deficiency Galactokinase deficiency is characterized by the occurrence of cataracts without liver, kidney, or ovarian dysfunction and no increased risk of infections. A number of infants are reported to have pseudotumor cerebri, with very rare neurological involvement, suggesting that retardation is not a feature. The absence of liver and kidney damage in galactokinase deficiency and the presence of damage to these organs in transferase deficiency make it likely that toxicity in the later condition is in some way associated with galactose 1-phosphate formation.

Epimerase deficiency Elevated red cell levels of galactose 1-phosphate with absence of UDP-galactose 4′-epimerase have been described in a patient with normal growth, development, and normal ability to metabolize ingested galactose. Several cases of biochemical deficiency have been described but symptomatic cases are extremely rare. A few had cataracts, sepsis, liver, kidney, and brain abnormalities, including a few with neurosensory deafness. There appears to be no ovarian dysfunction. The absence of ovarian dysfunction suggests that elevated UDP-galactose levels may protect the ovary from damage observed in transferase deficiency. Screening programs have been established in Japan, where the incidence is reported to be 1 in 23 000. In epimerase deficiency, when dietary galactose is low, galactose 1-phosphate concentrations in red blood cells may be reduced to normal, but UDP-galactose concentrations remain elevated. Despite the many phenotypic similarities between transferase and epimerase deficiency, the latter is characterized by elevated red cell levels of UDP-galactose even with modest galactose intake.

Diagnosis

The presence of reducing substance in urine which does not react with glucose oxidase reagents is consistent with galactosuria; however, occasionally some infants (particularly premature babies) also develop galactosuria. It is important to note that the presence of lactose, fructose, and pentose in the urine may give the same results. The presence of cataracts in infants without other systemic symptoms suggests the possibility of galactokinase deficiency. The presence of cataracts in older patients with the absence of gastrointestinal dysfunction or failure to thrive in galactosemic patients helps to differentiate between galactokinase deficiency and transferase deficiency.

The diagnosis of transferase deficiency is suggested by abnormally high amounts of red cell galactose 1-phosphate and confirmed by direct assay of red cell transferase activity. The red cell UDP-glucose consumption test may help to differentiate homozygous patients with a complete absence of transferase in red cells from heterozygous patients who have intermediate levels. Normal red cell values are of 6 mmol UDP-glucose consumed per hour per millilitre of red blood cells. In galactokinase deficiency the diagnosis can be made by the presence of normal amounts of galactose-1-phosphate uridyltransferase and the absence of galactokinase in the red blood cells.

Galactose-1-phosphate uridyltransferase deficiency can be diagnosed prenatally, by assay of galactose-1-phosphate uridyltransferase activity in cultured amniotic fluid cells or chorionic villi, and by galactitol measurement in amniotic fluid supernatant. The perinatal diagnosis is undertaken rarely, because the transferase deficiency is seen as a treatable condition.

Methods for mass screening of newborns for galactosemia are available, although galactosemia is rare. The incidence in Norway is 1 in 96 000, in Sweden 1 in 81 000, in the USA 1 in 62 000, in Switzerland 1 in 58 000, in Germany 1 in 40 000, and the worldwide incidence is about 1 in 70 000. Newborn screening has not been introduced in Great Britain, the Netherlands, or in some states of the USA. Most newborn screening programs designed for the detection of anomalies of galactose metabolism use tests to measure either blood galactose or the activity of galactose-1-phosphate uridyltransferase. Beutler and Baluda developed a fluorescence test in which the activity of uridyltransferase in the dried blood spot is required for the reduction of NADP, yielding fluorescence under long-wave ultraviolet light; the intensity of the fluorescence corresponds to the activity of uridyltransferase. The main advantage of this test is that it can be completed in short time, although false positive results do occur. The disadvantage of this test is that patients with galactokinase deficiency are not detected by this method. Guthrie and Paigen described a more efficient test using the principle of metabolite inhibition; galactose inhibited the growth of an *E. coli* mutant strain lacking uridyltransferase. Later, Paigen used an *E. coli* mutant strain which lacks UDP-galactose 4′-cpimerase activity. Using the Paigen test it is possible to detect galactokinase and uridyltransferase deficiencies. Epimerase deficiency can also be detected by the Paigen test if alkaline phosphatase is added to hydrolyze galactose phosphatase. In many screening laboratories the Beutler test is combined with the microbiological Paigen test.

Management

A galactose-free diet is the current treatment for galactosemia. It is important to know that galactose is present not only in milk but in other sources of food. A strict galactose-free diet in galactosemic patients with transferase deficiency is not harmful. The quality of the galactose-free diet and patient compliance are usually monitored by measuring free galactose in plasma and galactose 1-phosphate in erythrocytes.

Growth retardation, cognitive impairment, speech impediment, tremor, ataxia, and ovarian failure are frequent complications in spite of a strict galactose-free diet. Elevated galactose phosphate levels may occur in erythrocytes of even well-treated galactosemic patients. This elevation is attributed to endogenous production of the metabolite. A galactose-free diet is recommended from birth. It is recommended to restrict galactose in the diet of pregnant mothers diagnosed perinatally with transferase deficiency; a galactose-free diet should be started as soon as the diagnosis is made in the infant regardless of any preexisting manifestation of toxicity. The strict galactose-free diet will cause regression of symptoms and findings. It is important for the families to be aware of the high incidence of verbal dyspraxia even on a very strict diet. The speech intervention program and language stimulation are recommended as early as the first year of life. Many patients with normal IQ values who were treated from birth have learning disabilities, speech and language deficit, and psychological problems. Neurological sequelae have been described also in patients on strict galactose-free diets. These sequelae include cerebellar ataxia, tremor, choreoathetosis, and encephalopathy. Gonadal dysfunction in female galactosemic patients is an almost universal finding, even with a strict galactose-free diet. There is no current therapy for ovarian dysfunction except palliative replacement of oestrogen and progesterone. This is suggested in galactosemic females to develop secondary sexual characters and establish regular menses. There is no universal recommendation for the management of newborns screened positive nor for galactosemic heterozygotic patients.

In patients with epimerase deficiency, UDP-glucose cannot be converted to UDP-galactose. Thus a complete absence of galactose from the diet and the lack of formation of UDP-galactose via transferase would have serious consequences. There would be an inability to form complex polysaccharides and an inability to provide an adequate galactose component for brain cerebrosides. The treatment of epimerase deficiency relies on providing a small amount of dietary galactose.

GALL BLADDER DISORDERS

B Nejadnik and L Cheskin, Johns Hopkins University, Baltimore, MD, USA

The incidence of gall bladder disease in the United States exceeds 20 million cases annually. The total cost of gall bladder disease in the United States is more than that of any other gastrointestinal illness, including colorectal cancer and peptic ulcer disease.

Gall bladder disease has an intimate relationship with diet and nutrition. On the one hand, there has been a great deal of interest in the role of dietary constituents and nutritional habits in the etiology of gall bladder disease. On the other hand, an individual's nutritional status has a direct impact on the risk of acquiring gall stones. For instance, obesity as well as rapid weight loss and total parenteral nutrition (TPN) predispose the patient to a higher risk of gall bladder disease. Of course, there are multiple other risk factors that play an important role in the formation and manifestations of gall bladder disease, including female gender, family history of first-degree relative with gall stone disease, pregnancy, and drug use. Approximately three-fourths of gall stones detected in the general population are cholesterol gall stones.

According to a large study of the Danish population published in 1991, the 5-year incidence of gall stones in men and women aged 30 years was 0.3% and 1.4%, respectively. At age 60, the incidence had increased to 3.3% and 3.7% for men and women, respectively. It seems that the difference in incidence between men and women disappears with age. This may be related to the difference in estrogenic hormones between the two genders, which follows the same pattern.

Normal Biliary Physiology

Bile, which is formed in the hepatic lobules, is secreted into the canaliculi, small bile ductules, and larger bile ducts that drain it into portal tracts. Interlobular bile ducts join to form larger septal bile ducts that coalesce to form the right and left hepatic ducts, which in turn join to form the common hepatic duct. The common hepatic duct is joined by the cystic duct of the gall bladder to form the common bile duct, which enters the duodenum (often after joining the main pancreatic duct) through the ampulla of Vater.

The largest bile components are water (82%), bile acids (12%), lecithin and other phospholipids (4%), and unesterified cholesterol (0.7%). The total daily basal secretion of hepatic bile is approximately 500–600 ml. The primary bile acids, cholic acid and chenodeoxycholic acid, are synthesized from cholesterol in the liver, conjugated with glycine or taurine, and excreted into the bile. Secondary bile acids, including deoxycholate and lithocholate, are formed in the colon as bacterial metabolites of the primary bile acids. The normal bile acid pool size is approximately 2–4 g. Bile salts play an important role not only in facilitating the biliary excretion of cholesterol but also in intestinal absorption of dietary fats. They are absorbed passively in the entire gut and actively absorbed by the terminal ileum. The bile acid pool circulates approximately 5–10 times daily.

Cholesterol is poorly soluble in water, and its solubility in bile depends on its lipid concentration and the quantity of bile acids and lecithin. Usually, cholesterol is solubilized and forms mixed micelles. Supersaturation of cholesterol provokes the precipitation of cholesterol crystals in bile.

Cholecystokinin (CCK) is the most powerful stimulator of gall bladder contraction. It is released from the duodenal mucosa in response to the ingestion of fats and amino acids. CCK plays its role through contraction of the gall bladder, reducing resistance of the sphincter of Oddi, increasing hepatic secretion of bile, and therefore enhancing flow of biliary contents into the duodenum.

Pathophysiology of Stone Formation

Morphology and Composition

There are three kinds of gall stone: cholesterol, black pigment, or brown pigment stones. Cholesterol stones constitute 75–90% of all gall stones. They are composed purely of cholesterol or have cholesterol as the major chemical constituent. Most cholesterol gall stones are of mixed composition. Pigmented stones get their color and their name from precipitated bilirubin. Increased production of unconjugated bilirubin causes black pigmentation. Formation of black pigment stones is typically associated with chronic hemolysis, cirrhosis, and pancreatitis. Brown pigment stones are usually associated with infection. Cytoskeletons of bacteria can be seen microscopically in brown pigment stones,

and bacterial infection seems to be a prerequisite for brown stone formation.

Pathogenesis

Three factors have been recognized in gall stone formation: cholesterol supersaturation, accelerated nucleation, and gall bladder hypomotility. Among these, the degree of cholesterol saturation in gall bladder bile is the most important factor in crystal formation.

Cholesterol supersaturation Cholesterol is hydrophobic and not easily soluble in water. Its solubility is dependent on the presence of bile salts and lecithin. It is easy to imagine that as the ratio of cholesterol to bile salts and lecithin increases, cholesterol precipitation, crystal formation, and therefore stone formation ensue.

Nucleating and antinucleating factors Pronucleators include mucin glycoproteins, immunoglobulin G (IgG) and IgM, aminopeptidase N, haptoglobin, and α_1 acid glycoprotein; the most prominent of these is mucin glycoproteins. The hydrophobic centers of these proteins can bind to cholesterol, phospholipids, and bilirubin.

Gall bladder hypomotility The gall bladder concentrates and acidifies the bile. The most powerful stimulant of gall bladder contraction is CCK. CCK release is stimulated by (in order of decreasing potency) long-chain fatty acids, amino acids, and carbohydrates.

Risk Factors Associated with Cholesterol Gall Stone Formation

Major risk factors predisposing to gall stones are age, sex, genetic profile, nutritional status (including the route of nutrition), hormones, drugs, and some other diseases such as diseases of the terminal ileum. A summary of these elements is provided in **Table 1**.

Table 1 Risk factors associated with cholesterol gall stone formation

Age
Female gender
Genetics
Prima Indians
Chileans
Family history of gall stone
Pregnancy
Small bowel diseases
Crohn's disease
Terminal ileum resection
Drugs
Estrogens
Ceftriaxone
Lipid-lowering agents (Clofibrate)
Octreotide
Nutritional status
Obesity
Rapid weight loss
Total parenteral nutrition
Diabetes
Other conditions
Immobility
Cirrhosis
Spinal cord injury

Age, sex, and genetic profile As mentioned previously, women are affected more than men, and the incidence of gall stone increases with age. A positive family history of gall bladder disease increases risk to more than twice that of the general population. Native Americans and Scandinavians are more predisposed to this disease than other ethnic groups.

Obesity, weight loss, and total parenteral nutrition Obesity is a well-known risk factor for cholelithiasis. A large prospective study of obese women found a strong linear association between body mass index and the reported incidence of cholelithiasis. In this study, those with the highest body mass index ($>45\,kg/m^2$) had a 7-fold increased risk of development of gall stones compared to non-obese controls. This relationship is somewhat weaker in men than in women. The association between obesity and gall stone formation may result from increased secretion of cholesterol into the bile as a result of higher 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA).

In studies of gall bladder motility in obese patients, no impairment in gall bladder contraction has been documented. Abnormal processing of the cholecystokinin receptor gene has been reported in one obese patient who had gall stones. Such an abnormality could lead to gall bladder stasis and ultimately to cholelithiasis.

Rapid weight loss is a recognized risk factor for cholesterol gall stone formation. As many as 30% of obese patients on restricted calorie intake may develop (usually asymptomatic) gall stones. This rate is higher, up to 50%, for obese patients who undergo gastric bypass surgery. It has been shown that hepatic cholesterol secretion increases in patients with low calorie intake. Other predisposing factors for the same patients are increased mucin secretion and decreased gall bladder motility. Gall stone formation may be prevented in this high-risk population possibly through prophylactic administration of a bile salt, ursodeoxycholic acid.

Low-fat diet by itself seems to be a predisposing factor. Cholecchia *et al*. studied 32 gall-stone-free obese patients and concluded that during a significant weight loss period, 54% of subjects following the low-fat diet, but none in the high-fat intake group, formed asymptomatic gall stones.

Total parenteral nutrition (TPN) is associated with the development of acalculous cholecystitis as well as cholelithiasis, cholecystitis, and gall bladder sludge. The latter can occur as early as 3 weeks after initiation of TPN. After 3 or 4 months of TPN, approximately 45% of patients will develop gall stones. Prolonged fasting resulting in gall bladder hypomotility seems to be the major cause of the bile stasis. Cholecystokinin–octapeptide 50 ng/kg intravenous infusion for 10 minutes once daily has been shown to prevent gall bladder sludge and gall stone formation in patients on TPN.

Hormones and drugs Hormones such as estrogen and progesterone have a significant effect on the risk of gall stone formation. One interesting illustration of these effects is seen in pregnant woman. Increased estrogen levels during pregnancy cause increased cholesterol secretion and supersaturation of bile, which results in more lithogenic bile. Progesterone, on the other hand, reduces gall bladder motility, resulting in stasis and sludge formation in 30% of cases.

Among lipid-lowering drugs, Clofibrate seems to have the greatest association with increased gall stone formation. The role of statins in gall bladder disease remains to be elucidated. Approximately one-third of patients treated with octreotide, a somatostatin analog, develop new gall stones. Ceftriaxone (Rocephin) has been shown to cause sludge formation in children. A large fraction of ceftriaxone is secreted in bile (40%) and forms complexes with calcium, resulting in an insoluble salt. The sludge disappears when ceftriaxone is discontinued.

Diet and lipid profile The ingestion of refined sugars has been shown to be associated with gall stone disease. However, no such association has been shown for alcohol or tobacco. It is not clear if high serum cholesterol predisposes to gall stone formation. In fact, the contrary has been shown in some studies. This is also the case for dietary cholesterol ingestion, which was shown to be a protective factor for gall stone formation in one study. Hypertriglyceridemia, on the other hand, is positively associated with an increased incidence of gall stones.

Dietary antioxidant deficiency, particularly of α-tocopherol, as well as low intakes of linoleic acid and essential amino acids may increase the incidence of gall stone disease. One study showed that there is an inverse correlation between the incidence of gall stone disease and the amount of certain foods, particularly fish and fruits, consumed per day. The gall stone subjects ate fewer meals per day but ate more cereals, oils, sugars, and meats. They also had more fluctuation in their weight. They consumed less fiber, folate, magnesium, vitamins, and minerals.

Other conditions predisposing to gall bladder disease Insulin-resistant diabetes predisposes to cholelithiasis. A Swedish study showed that the prevalence of gall stones in Crohn's disease was twice that seen in the general population. Cirrhosis is another major risk factor for gall stones. The incidence of gall stone formation in cirrhosis is 10 times that seen in the general population. The incidence increases with the severity of cirrhosis, being worse in Child's class B and C disease and in patients with higher body mass index. High estrogen level and reduced hepatic synthesis and transport of bile salts are reasons for the increased risk in cirrhosis. The Physicians' Health Study showed that 30 minutes of endurance-type exercise five times per week prevents approximately one-third of cases of symptomatic gall stones in men. The Nurses' Health Study confirmed the same trend in women.

Clinical Manifestations and Diagnosis of Gall Stone Disease

Approximately 80% of people with gall stones are asymptomatic. The presentation of gall bladder disease can be episodic pain when a brief cystic duct obstruction occurs or acute cholecystitis when the obstruction lasts longer and results in local and relatively extensive inflammation and edema. The complications include infection of the biliary system (cholangitis) and pancreatitis.

Symptoms and Signs

Pain related to the gall bladder is usually felt in the right upper quadrant or in the epigastrium. It may radiate to the back, going around the right flank. In some cases, it may radiate to the shoulder area or be felt in the chest. In acute cholecystitis, the pain is steady, as opposed to cramping or colicky. It typically occurs after a meal and may be accompanied by nausea and vomiting. Continuous obstruction of the cystic duct causes gall bladder distention and inflammation. Extension of the inflammation into the common bile duct area may cause edema and obstruction of the duct, resulting in jaundice. The

physical signs of acute cholecystitis include right upper quadrant tenderness and Murphy's sign, which refers to severe right upper quadrant tenderness and inhibition of inspiration on deep palpation under the right subcostal margin.

Laboratory Findings

In acute cholecystitis, liver enzymes are normal or mildly elevated. Marked increase in liver enzymes should raise the possibility of bile duct obstruction concomitant with, or instead of, acute cholecystitis. In the case of bile duct obstruction, alanine aminotransferase and aspartate aminotransferase increase rapidly to levels 10 times normal and then decrease quickly toward normal, even if the obstruction persists. Alkaline phosphatase, on the other hand, will continue to increase unless the obstruction resolves. Mild to moderate leukocytosis is common in acute cholecystitis. Bile levels may increase if the obstruction lasts long enough.

Imaging

Ultrasonography, with a sensitivity of 96%, is a major diagnostic tool in gall bladder disease. The sonographic evidence of acute cholecystitis includes gall bladder size, its wall thickness, and pericholecystic fluid conformation. Among these signs, the latter is the most sensitive. Computed tomography is less sensitive and more expensive than ultrasonography. Its main role is to rule out other intra-abdominal processes. Magnetic resonance imaging has become an important means of detecting bile duct stones. Its sensitivity is approximately 85% for bile duct stones. Oral cholecystography has almost completely been replaced by ultrasonography. Endoscopic retrograde cholangiopancreatography (ERCP) is mostly used for its diagnostic and especially its therapeutic capability for removing bile duct stones. Hepatobiliary scintigraphy consists of the uptake by the gall bladder of an intravenously administered, ^{99m}Tc-labeled iminodiacetic acid derivative. The liver excretes the isotope into the bile ducts. A normal hepatobiliary scan using diisopropyliminodiacetic acid effectively rules out acute cholecystitis. If, on the other hand, the isotope does not appear in the bile ducts within 4 h, the likelihood of acute cholecystitis is very high.

Management

The decision about the treatment of gall stones will depend strongly on the presentation of the patient. Asymptomatic gall stones should not be treated surgically. This recommendation is based on multiple studies, including several prospective studies, that showed that patients with asymptomatic gall stones, observed over many years, develop symptoms or biliary complications only on rare occasions. In one study of 123 people with asymptomatic gall stones followed for 11–24 years, biliary pain developed in 2% during each of the first 5 years, followed by a decreasing incidence thereafter. Complications were seen in only 3 people and were preceded by warning signs of pain in all cases.

Prophylactic cholecystectomy has been performed in diabetic patients because of concern of higher rates of complications from acute cholecystitis and also in patients with sickle cell disease. In the latter group, the main reason for prophylactic cholecystectomy is that the pain of sickle crises is not easily distinguished from acute cholecystitis. Cholecystectomy should be undertaken in patients with 'porcelain' gall bladder and Native Americans with gall stones because these groups have a higher incidence of gall bladder carcinoma. However, the risk of gall bladder carcinoma is not high enough to justify cholecystectomy in other asymptomatic patients. Symptomatic gall stones should be treated surgically unless contraindicated. More than 60% of patients with symptomatic gall stones will have recurrent episodes within 1 or 2 years. Moreover, approximately 3% will develop biliary complications annually.

Nutritional Considerations

Prevention of gall stone formation The importance of nutritional factors in the formation of gall stones was discussed previously. Thus, modification of those risk factors (obesity, rapid weight loss, TPN, etc.) or application of a remedy to correct the underlying offensive mechanism will perhaps reduce the chance of gall stone formation.

Some studies have shown beneficial effects of dietary fiber in the prevention of gall bladder disease during weight loss in obese patients. However, this effect seems to be limited. During rapid weight loss, patients are occasionally given a small amount of dietary fat in order to reduce the risk of gall stone formation. Some studies have confirmed this technique, especially when a lower amount of fat has been used (2 vs. 10 g fat/day); others have shown that this strategy is not effective when the comparison was made between higher amounts (16 vs. 30 g fat/day). However, some studies support the concept that factors other than gall bladder motility are involved in gall stone formation in patients undergoing rapid weight loss. The weight loss by itself will eventually be beneficial in the prevention of future gall stones.

In one study, fish oil (n-3-polyunsaturated fatty acids) was shown to prevent cholesterol gall stone formation in obese women during rapid weight loss.

A high-calcium diet has also been prescribed in order to change the output of deoxycholic acid. This diet has a modest beneficial effect on gall stone formation.

Multiple small meals as opposed to one or two larger meals per day will empty the gall bladder on a regular basis and prevent stasis. It also prevents long interruptions of the enterohepatic circulation of bile acids.

Cholecystokinin increases bile acid synthesis and, more important, promotes gall bladder contraction. Therefore, CCK is theoretically an effective agent in the prevention of gall stones in patients with TPN. In practice, though, this effect seems to be quite variable.

The Third National Health and Nutrition Examination Survey found that a history of clinical or asymptomatic gall stones was inversely correlated with serum ascorbic acid levels in women but not in men. Coffee consumption has been found to be associated with a reduced risk of symptomatic gall stones. Consumption of two or three cups of regular coffee per day reduces the risk of symptomatic gall stones by approximately 40% over 10 years. **Table 2** summarizes the different preventive measures available to reduce the risk of gall stone formation.

Complementary and alternative medicine Factors reducing hyperinsulinemia, such as dietary unrefined carbohydrates and aerobic exercise, have been suggested to reduce the risk of cholelithiasis. Holistic health providers have been prescribing herbal medicines, such as turmeric, Oregon grape, bupleurum, and coin grass, with the belief that they may reduce gall bladder inflammation and relieve liver congestion.

Medical Treatment

Ursodeoxycholic acid is approved for gall stone dissolution in appropriate patients. This drug is a bile acid that forms soluble vesicles and prolongs the nucleation time of bile. Moreover, it inhibits HMG-CoA reductase and secondarily reduces cholesterol saturation. A year of treatment with ursodeoxycholic acid will result in complete dissolution of 50% of gall stones. This agent works on the surface of the stones; thus, the larger the stone, the less the efficacy of ursodeoxycholic acid. This drug is used in patients who refuse surgery or have a high risk for cholecystectomy. Shiffman *et al.* studied the efficacy of ursodeoxycholic acid in patients undergoing dietary-induced weight reduction and found it to be highly effective in preventing gall stone formation. The cost of this drug ($4 per day) is an important impediment for its long-term use.

Nonsteroidal antiinflammatory drugs may have some beneficial effect in the prevention of gall stone formation, but studies have not been conclusive. Extracorporeal shock wave lithotripsy has been used for fragmentation of gall stones by high-amplitude

Table 2 Prevention of gall stone formation

Dietary fiber	Limited efficacy
During rapid weight less	
Small amount of dietary fats	Depends on the amount of fat
Fish oil	Prevents cholesterol gall stone formation in obese women
Nonsteroidal antiinflammatory drugs	Studies have not been conclusive
Ursodeoxycholic acid	Effective in secondary prevention
Reduce insulin resistance	
Exercise	
Gradual weight loss	
During total parenteral nutrition	
Cholecystokinin	Increases bile acid synthesis and promotes gall bladder contraction; efficacy variable
Nutritional factors	
Ascorbic acid	Inverse correlation with gall stone formation in women but not in men
Reduce ingestion of refined sugars	Prevents insulin resistance and secondarily prevents gall bladder immobility
Dietary antioxidants, fiber, folate, magnesium, vitamins, minerals, linoleic acid, and essential amino acids	Unknown mechanism
Multiple small meals as opposed to few large meals	Prevents gall bladder stasis
High-calcium diet	Preventive
Coffee consumption	May reduce risk of symptomatic gall stone

shock waves generated by external piezoelectric devices. The waves are guided toward the stones by ultrasound imaging. This procedure was first used for kidney stones. Its efficacy in gall bladder stone treatment has been much less impressive. Its complications are the consequence of migration of stone fragments and include postprocedure biliary colic and pancreatitis. The availability of laparoscopic cholecystectomy has limited the need for lithotripsy.

Surgical Treatment

Patients admitted with suspected acute cholecystitis should initially be made NPO (nothing by mouth) and intravenously hydrated. Administration of broad-spectrum antibiotics early in the course is recommended because secondary infection often supervenes in what is initially a noninfectious process. If the diagnosis of acute cholecystitis is made within 24–48 h of onset of symptoms, early surgery leads to reduced morbidity and mortality rates.

Laparoscopic cholecystectomy The first successful laparoscopic cholecystectomy in Europe in 1987 transformed gall bladder surgery very rapidly. The minimal injury to the abdominal wall tissues resulted in faster discharge and rapid return to normal activities. In approximately 1 in 10 patients, laparoscopic cholecystectomy must be converted to open surgery. The rates of complications in both procedures are approximately 5%.

Laparotomy (open cholecystectomy) Today, open cholecystectomy is almost always a consequence of conversion of a laparoscopic procedure. On rare occasions, such as when there is suspicion of gall bladder cancer, a history of prior extensive abdominal surgery resulting in adhesions, or in patients with common bile duct stones that cannot be removed by ERCP, surgeons will perform open cholecystectomy at the outset of the operation.

Conclusions

Gall bladder disease is intimately tied to nutrition with respect to its etiology, treatment, and prevention. Attention to nutritional considerations can have a meaningful impact in particular on the prevalence and incidence of asymptomatic and symptomatic gall stones. Certain nutriments can change the likelihood of gall stone formation or change the course for preexisting stones. Nutritional status, including obesity and rapid weight loss, is an important predisposing factor. TPN increases the risk of gall stones considerably. Diagnosis of gall stone disease is based on history and physical examination as well as the laboratory and ultrasonographic evidence. Therapeutic decisions depend on the patient's presentation. Asymptomatic patients should not be treated surgically, except those with sickle cell disease or if there is a higher risk of gall bladder carcinoma (as in Native Americans and in patients with porcelain gall bladder). Laparoscopic surgery is the treatment of choice in symptomatic patients.

Nutritional interventions, such as fish oil, ascorbic acid, and coffee, seem to be protective against gall stone formation. Dietary fiber and the administration of small amounts of dietary fat have shown limited preventative efficacy for patients at higher risk of gall stone formation. CCK may be useful in patients receiving TPN. Ursodeoxycholic acid is effective in preventing gall stone formation in patients undergoing diet-induced weight reduction. Some authors have recommended the use of nonsteroidal antiinflammatory drugs in the prevention of gall stones, but studies have not been conclusive.

GLUCOSE

Contents

Chemistry and Dietary Sources

D J A Jenkins, R de Souza, L S A Augustin and C W C Kendall, University of Toronto, Toronto, ON, Canada

Glucose and its polymers are important energy sources for living organisms and structural components of plants. Because of the diversity of compounds in which glucose occurs, it may be helpful to first discuss nomenclature.

Nomenclature and Chemical Structure

Glucose

The compound D-glucose (Greek *gleucos*, 'sweet wine') or dextrose is 2,3,4,5,6-pentahydroxyhexaldehyde, more conventionally expressed as $C_6H_{12}O_6$, with a molecular weight of 180.16 kDa. Glucose is readily soluble in water in a powder form. Below 50 °C, α-D-glucose hydrate is the stable form; at 50 °C the anhydrous form is obtained; and at higher temperatures, α-D-glucose is obtained. Glucose is also present in the diet as part of the disaccharides sucrose (glucose and fructose), lactose (glucose and galactose), and maltose (glucose).

Glucose Oligosaccharides

Oligosaccharides (Greek *oligo*, 'few') are sugar polymers; the term usually refers to compounds containing 2–9 units but may include polymers containing up to 19 units. The dimer, trimer, and tetramer forms in which glucose molecules are joined by (1–4) linkages are referred to as maltose, maltotriose, and maltotetrose, respectively, since these substances are the products of starch digestion in the malting process. Sucrose, maltose, and lactose are common dietary disaccharides.

Starches

Starches are large-molecular-weight, α-linked polymers of glucose $(C_6H_{10}O_5)n$. Most starches show a mixture of α(1–4) and α(1–6) linkages. The α(1–4)-linked polymer forms a linear structure that allows for hydrogen bonding between polymer chains and a more compact starch structure. Introduction of (1–6) linkages results in branch points and a more open structure that allows the (1–4)-linked backbone with the hemiacetal bond in the alpha configuration to coil like a spring into a helical form. Branched starches with the (1–6) linkage are more readily hydrated and digested compared to the (1–4)-linked linear starch. The (1–4)-linked starches are referred to as amylose starch, and (1–6)-linked starches are amylopectin starches.

Resistant Starch

Resistant starches are defined by their resistance to digestion in the human upper gastrointestinal tract. As with the term 'dietary fiber,' the definition is largely physiological. One proposed classification divides resistant starches into three classes: RS_1, RS_2, and RS_3. The first class, RS_1, is starch that escapes small intestinal digestion owing to the food form and incomplete enzymatic attack (e.g., large particle size or compact nature of food, or starch entrapment by dietary fiber). The second, RS_2, includes the more crystalline starches that resist digestion (e.g., high-amylose starches that resist gelatinization). The RS_3 starches are retrograded starches (e.g., high-amylose starches that upon

cooling after cooking form a compact, hydrogen-bonded crystalline structure that excludes water).

Cellulose

Like starch, cellulose is a (1–4)-linked glucose polymer $(C_6H_{10}O_5)n$, but in this instance the glucose molecules are β-linked, allowing the development of a linear polymer with strong intrachain hydrogen bonding. Cellulose polymers may consist of as many as 10 000 glucose monomer units. Cellulose is both resistant to small intestinal digestion and insoluble in cold or hot water and most dilute acids and alkali. It is partially degraded by colonic bacteria; the proportion degraded is dependent on the source, with cellulose from vegetables broken down to a greater extent than cellulose from cereals such as wheat.

β-Glucans

In many ways, these predominantly (1–4)-linked glucose polymers are the cellulose equivalent of the starch amylopectin. Here, it is the (1–3) linkages interspersed throughout the polymer that prevent the compact structure achieved with the cellulose polymer where only the (1–4) linkages exist. As a result of the more open molecular structure of the β-glucan, unlike cellulose, it is readily hydrated and soluble in water, forming a solution of high viscosity. The viscosity, in turn, is dependent on the molecular weight and the presence of the (1–3) linkages. The greater the molecular weight, the greater the viscosity. Thus, reduction of molecular weight by acid or enzymatic hydrolysis, which may also occur during food processing, may greatly reduce viscosity. The common feature shared by cellulose and the β-glucans is that both are resistant to digestion by small intestinal enzymes. However, whereas cellulose is only partially fermented by the colonic bacteria, β-glucans are completely fermented.

Hemicellulose

The term 'hemicellulose' should not be taken to imply a class of (1–4)-linked glucose polymers. The similarity with cellulose lies not in the chemical structure but in the fact that hemicellulose is also insoluble in hot or cold water or hot dilute acid. It is, however, soluble in dilute alkali. The polymeric structure is heterosaccharitic with two or more sugars (e.g., arabinoxylans found in cereals), with a relatively small molecular size (50–200 saccharide units).

Occurrence

Glucose is the primary carbohydrate energy source of vertebrates. In healthy humans, fasting blood glucose levels are approximately 3.5–5.5 mmol/l (depending on the laboratory) and increase postprandially to values considerably less than 10 mmol/l (the renal threshold for complete reabsorption, above which glucose 'spills' over into the urine). Blood levels higher than 7.8 mmol/l 2 h after a 75-g glucose load are one of the diagnostic criteria for diabetes. Glucose is stored as glycogen, an α-linked polymer, predominantly in the liver and muscles ('animal starch'). On average, a 70-kg man may store 500 g of glycogen. Glucose can also be synthesized de novo by gluconeogenesis from the gluconeogenic amino acids lactate, glycerol, and pyruvate.

Erythrocytes, renal tissue, and nervous tissue require glucose as an energy source. In erythrocytes and renal tissue, the glucose is not oxidized but is returned to the liver as part of the Cori cycle for glucose synthesis. The brain oxidizes glucose and requires 140 g per day. From this figure the carbohydrate requirement was derived in the recent DRI assessment (**Table 1**). Despite this requirement, carbohydrate is still recommended to comprise between 45 and 65% of dietary calories.

Glucose is present in fruit and vegetables and, although less sweet on a per gram basis than fructose or sucrose, it is responsible together with fructose and sucrose for the sweet taste of vegetables and fruit. With the exception of fruit such as green banana, seeds (grain and dried legumes), and tubers, in which starch is the major carbohydrate form, foods containing glucose, fructose, and sucrose in various ratios comprise the major available (i.e., absorbable in the small intestine) carbohydrate sources. The relative proportions of the sugars have not been generally determined, and data are not available for many foods.

The main sources of dietary starch are cereal grains, dried legumes, and tubers. The major part of the available carbohydrate in these foods is

Table 1 Estimation of brain glucose requirements of adult humans

Glucose consumption (μmol/100 g brain/min)	*Estimated brain weight (g)*	*Brain glucose consumption*	
		mg/min	*g/day*

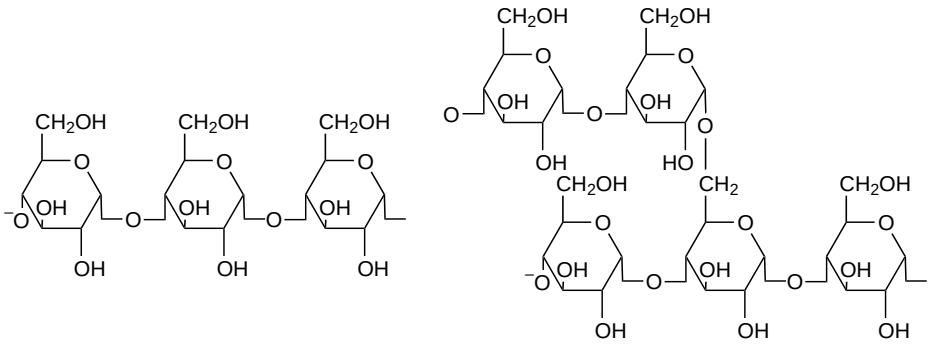

Figure 1 Partial structures of amylose (linear) and amylopectin (branched) starches.

starch. Starches contain both α(1–4) and α(1–6) linkages (i.e., amylose and amylopectin) (**Figure 1**). In most studies amylose predominates, with a ratio of amylose to amylopectin of 2–3:1. In general, legumes contain higher amylose levels than do cereals. Cultivars of corn have been bred with high amylose levels.

Resistant starches comprise a small proportion of most industrialized Western diets. Increased starch malabsorption may be induced by coarse milling or large particle size of cereal grains (e.g., whole-grain pumpernickel or bulgur wheat). Such foods may be said to contain resistant starch (RS_1). Resistant starches that are crystalline in nature and resist hydration (RS_2) are found in green banana, high-amylose corn, and relatively high-amylose legumes (peas, beans, and lentils). Starches, especially high-amylose starches that are cooked and then allowed to cool, undergo retrogradation with more crystalline realignment. These starches (RS_3) are produced in common foods such as potato, rice, and bread. Resistant starches in this category are produced commercially from high-amylose cornstarch by enzymatically debranching the remaining (1–6) linkages and allowing the resulting (1–4)-linked starch to 'retrograde' into a highly crystalline, digestion-resistant starch.

Cellulose is an important structural component of plant cell walls. In human nutrition, it forms an important part of the 'insoluble' dietary fiber component reported in food composition tables. However, values for the actual proportion of the total dietary fiber that is composed of cellulose are only available in special food composition tables for a relatively small number of foods.

From the standpoint of human nutrition, β-glucans are found predominantly in cereals, notably oats and barley, with trace amounts in wheat. In oats, the β-glucan is concentrated in the outer bran layer and may comprise 50% of the dietary fiber value and possibly 8 or 9% of the so-called oat bran derived from standard milling practices. In barley, the β-glucan is more dispersed through the endosperm, and thus a bran concentrate is less easy to achieve. In both cases, high β-glucan cultivars may greatly increase the yield of β-glucan. In addition, 'wet' processing techniques may yield a high-concentration β-glucan bran and purified β-glucan oat gum.

Analysis

Analysis of glucose may involve chemical, enzymatic, electrochemical, and high-performance liquid chromatography (HPLC) systems. Prior to the introduction of enzyme-based analyses, chemical techniques were based on the reducing ability of glucose, and techniques employing copper sulfate were popular. Such techniques were influenced by other reducing sugars and reducing substances, including uric acid and vitamin C. With the introduction of the more specific glucose oxidase-based tests, the chemical tests were abandoned, although there was debate over the potential carcinogenicity of the early chromogens, *O*-dianizadine and *O*-toluidine. Later, more specific, hexokinase-based enzyme assays were introduced. Current methods for rapid determination of blood glucose, which no longer require prior precipitation of plasma proteins, involve electrochemical detection. These methods rely on silver electrodes to detect electrons generated by the oxidation of glucose by glucose oxidase contained in membranes on the surface of the electrodes. For determination of glucose and α-limit dextrins resulting from starch digestion, HPLC techniques have proved useful.

Much attention has been given to the analysis of the glucose polymers—starches, resistant starches,

cellulose, and β-glucans—in the context of dietary fiber. The ultimate assessment depends on the use of specific enzymes or enzyme systems to break the macromolecules down to their component glucose and other sugars when mixtures containing other polymers (dietary fibers) are being analyzed. These are then assessed by gas chromatography or HPLC and the ratios of the sugars determined. More routine assessment may involve a variety of chemical techniques combined with enzymatic digestion and, in the case of a popular Association of Official Analytical Chemists (AOAC)-approved technique for dietary fiber analysis, with a gravimetric determination. However, there is debate as to whether the resistant starch, which in the gravimetric AOAC technique is analyzed as dietary fiber, should be included as fiber or whether it is physiologically distinct. It is also debated whether a determination of β-glucan is sufficient without knowledge of its viscosity and molecular weight—factors that determine its physiological effect.

Physiology

The physiology of the gastrointestinal absorption of (and the energy retrieved from) the glucose molecule along the length of the gastrointestinal tract in its various forms is discussed in the following sections, together with the influence of other dietary factors (**Figure 2**).

Absorption

In its simplest form, glucose ingested by mouth is rendered isotonic in the stomach by the gastric juices and expelled through the pylorus into the duodenum, where active transport takes place at the brush border by way of a sodium-linked glucose transporter. The absorbed glucose that is taken up by way of the portal vein suppresses hepatic glucose output but does not markedly alter the glucose balance across the liver. The major part of the absorbed glucose is taken up by muscle and also adipose tissue under the action of insulin. Similarly, sucrose, maltose, and lactose are both split and absorbed at the brush border by the brush border enzymes sucrase–isomaltase, maltase, and lactase. Although sucrose deficiency is exceedingly rare, hypolactasia is common in adult life in most of the world's populations, with the exception of those of northern European origin. Thus, unlike sucrose malabsorption, small-intestinal lactose malabsorption is common, with significant amounts of lactose entering

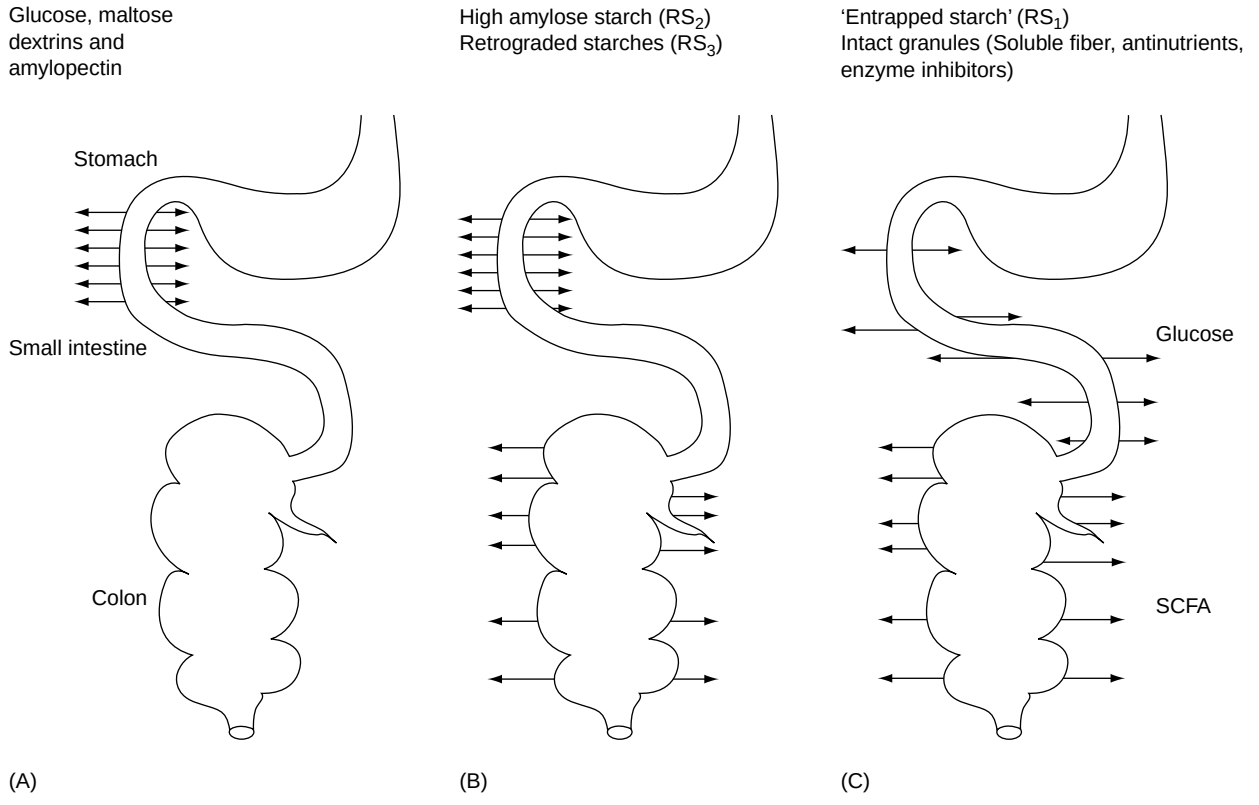

Figure 2 Effect of different forms of glucose on glucose absorption and short-chain fatty acid (SCFA) production and uptake from the gut.

the colon, resulting in gas production, short-chain fatty acid (SCFA) synthesis, and, in some instances, diarrhea.

On the other hand, purified, fully hydrated, cooked amylopectin starch commences digestion in the mouth under the action of salivary amylase. Enzyme activity ceases under the acidic conditions of the stomach and resumes in the duodenum under the action of pancreatic amylase. Amylolytic digestion in both mouth and stomach results predominantly in the production of free glucose, maltose, maltotriose, and the α-limit dextrins of greater polymeric length. The free glucose is taken up by the brush border glucose transporter, and the uptake of maltose and maltotriose is effected by brush border enzymes, notably the sucrase–isomaltase complex. In both situations, absorption in the small intestine is considered to be complete.

However, foods as eaten do not usually comprise pure glucose and pure amylopectin starch as their carbohydrate components. Many factors influence small-intestinal absorption in terms of both rate and amount (**Table 2**). Some of these factors were previously discussed in connection with amylose and resistant starch.

Food Components

Insoluble fiber may form a coat around starchy foods, limiting the penetration of enzymes and thus reducing the rate and amount digested. Viscous soluble fibers may also reduce the rate of

absorption through prolonging gastric emptying and by acting as a barrier to diffusion in the small intestine. Starch–protein interactions (as seen with gluten in wheat products) and starch–fat interactions have been shown to reduce the rate of digestion, and fat is known to slow gastric emptying. A number of the so-called 'antinutrients' present in foods, notably lectins, phytates, and tannins, have been shown to reduce the digestibility of foods. For example, it is considered that phytate, by binding calcium ions that catalyse starch digestion by amylase, reduces the rate of small-intestinal starch digestion.

Food processing may influence the rate of digestion by removing or reducing the level and activity of inhibitory food components. It may also modify the structure of the food or its components to make the food more available to digestive enzyme attack. Examples are cooking, resulting in starch gelatinization, and reducing the particle size (and hence increasing the surface area available to digestive enzymes) by milling, crushing, or flaking. On the other hand, processing may also reduce digestibility by parboiling, cooking with retrogradation of the starch, and extrusion, as in the production of pasta, producing a more compact physical structure.

Increasing the frequency of meals and reducing their size spreads the nutrient load over time and hence prolongs the time spent in the absorptive state. It is perhaps the 'clearest' model of slowing the rate of absorption and is referred to again to explain the metabolic consequences of reducing the absorption rate.

Finally, enzyme inhibitors of carbohydrate absorption have been developed for pharmacological use in the treatment of diabetes, and these work by reducing the rate of carbohydrate uptake from the small intestine. One example of this class of substances is acarbose, an α-glycoside hydrolase inhibitor that has antiamylase and anti-sucrase–isomaltase activity and thus inhibits both intraluminal and brush border carbohydrate digestion and absorption of starch, sucrose, and maltose.

Possible Effects of Prolonging Absorption Time of Carbohydrate

The question remains as to what physiological effects are produced when carbohydrate is absorbed more slowly (**Table 3**). Studies have demonstrated the effectiveness of carbohydrate-absorption enzyme inhibitors in treating diabetes but also in preventing the development of diabetes in high-risk subjects treated with acarbose over a 3-year period. A further way to reduce the rate of absorption of carbohydrate without altering its composition is to change the rate of ingestion of carbohydrate substrates.

Table 3 Possible effects of prolonging absorption time of carbohydrates

Flatter postprandial glucose profile
Lower mean insulin levels postprandially and throughout the day
Reduced gastric inhibitory polypeptide response
Reduced 24-h urinary C peptide output
Prolonged suppression of plasma free fatty acids
Reduced urinary catecholamine output
Lower fasting and postprandial serum total and LDL cholesterol levels
Reduced hepatic cholesterol synthesis
Lower serum apolipoprotein B levels
Lower serum uric acid levels
Increased urinary uric acid excretion

A number of effects appear to be beneficial when glucose is sipped slowly rather than drunk as a bolus or when starchy meals are eaten more frequently but in smaller amounts. Studies by Ellis in the 1930s first demonstrated a reduction in insulin requirements in patients with diabetes when glucose and insulin were administered in small, frequent doses. Since then, a range of metabolic benefits have been ascribed to increased meal frequency (the 'nibbling versus gorging' phenomenon). Early studies reported lower total cholesterol levels with increased meal frequency. Subsequent studies showed low-density lipoprotein (LDL) cholesterol reduction in subjects eating 3 meals a day compared to those eating from 6 to as many as 17 meals daily for periods of 2–8 weeks. An extreme model of slowing absorption, in which 17 meals daily were fed, demonstrated lower levels of apolipoprotein B in addition to total and LDL cholesterol. Population studies also indicated that total cholesterol levels were lower in those who ate more meals daily. Studies using stable isotopes showed that cholesterol synthesis was reduced at greater meal frequencies. Furthermore, mevalonic acid excretion (a water-soluble marker of cholesterol synthesis) suggested that the change in cholesterol levels was also related to the change in urinary mevalonic acid output. Since insulin is known to stimulate HMG-CoA reductase activity, a rate-limiting enzyme in cholesterol synthesis, the depressed cholesterol synthesis was attributed to the lower insulin levels observed. In addition, the reduction in serum cholesterol levels on 'nibbling' may have resulted from increased bile acid losses due to more frequent bile acid cycling through the gut following increased meal frequency.

Studies of non-insulin-dependent diabetes have shown depressed glucose and insulin levels during the day with increased meal frequency. In non-diabetic subjects, the major effect of reducing the absorption rate (by sipping glucose over 3 h instead of taking the same amount of glucose as a bolus within 5 minutes) was to reduce insulin secretion. In addition, insulin suppression of free fatty acids and branched-chain amino acid levels was prolonged, and following glucose challenge no counter-regulatory response was observed.

Finally, serum uric acid, an independent risk factor for coronary heart disease, was reduced and increased urinary uric acid excretion was seen with increased food frequency. As with the reduction in serum cholesterol levels, the effects of lower insulin levels were used to explain these differences. It was suggested that insulin promoted renal reabsorption of uric acid, as demonstrated in the context of sodium reabsorption and hypertension in hyperinsulinemic states.

Further effects of food frequency on diabetes have been assessed. It has been suggested that increased food frequency may limit obesity by reducing adipose tissue enzyme levels. Acute studies in humans failed to show an increased thermogenic response with increased meal frequency. Nevertheless, when satiety was assessed in acute studies, fluctuations in satiety were less over the whole day; long-term studies have yet to be undertaken. Concern still remains that 'snacking' may increase body weight in susceptible individuals. Despite these concerns, the demonstration that increased meal frequency can improve certain aspects of lipid and carbohydrate metabolism makes it a valuable model for other methods of 'spreading the nutrient load' (e.g., reducing the rate of glucose absorption).

Colonic Function

A portion of the starch, together with dietary fiber including cellulose and β-glucan, enters the colon and is fermented by the colonic microflora with the growth of the fecal biomass and the production of SCFA, hydrogen, and methane. The extent to which this occurs varies from individual to individual and is based on the nature of the resistant starch and the source of the cellulose (e.g., vegetable cellulose is more readily fermented than cereal cellulose). Although some individuals may have starch in their feces, the majority of subjects show little or no fecal starch. Furthermore, all the β-glucan is broken down by bacterial action in the colon. A large proportion of the cellulose escapes colonic bacterial fermentation and contributes directly to fecal bulk. Thus, a significant proportion of glucose molecules are not absorbed in the small intestine but enter the colon and are salvaged after conversion to SCFAs. The SCFAs are rapidly absorbed and contribute to the host's energy metabolism. They are usually produced in the ratio of 60% acetate, 20% propionate, and 20% butyrate, but the relative ratios of these three fatty acids vary depending on the substrate and the rate of fermentation. Of the three SCFAs, only acetate appears in the peripheral circulation to any significant extent. Propionate is of interest since it is gluconeogenic and has been suggested to inhibit hepatic cholesterol synthesis. It is largely extracted by the liver at first pass. Butyrate, on the other hand, is taken up and used by colonocytes. The slower the fermentation, the higher the butyrate levels. Starches have been claimed to increase colonic butyrate and in some instances propionate production, and butyrate is said to have antineoplastic properties.

The Glycemic Index

The differing effects of different carbohydrate foods in raising the blood glucose concentration postprandially have long been recognized. The glycemic index classification was proposed to indicate the rates at which different starchy foods were digested. It was hoped that selection of foods with lower glycemic indices would contribute to prolonging the absorption of nutrients and thus improve the glycemic profile and reduce levels of fasting blood lipids.

However, a number of acute (up to 1 day) mixed meal studies during the mid- and late 1980s suggested that a glycemic index classification of foods had no clinical utility. Nevertheless, a number of subsequent reports have documented improved glycemic control in both type 1 and 2 diabetes as judged by serum fructosamine and glycosylated hemoglobin levels in studies lasting from 2 weeks to 2 months. Furthermore, some studies also noted reductions in serum lipids. Many high-fiber foods that lower LDL cholesterol levels also have low glycemic indices (barley, beans, etc.). Extensive glycemic index tables have been published that will help in food selection for therapeutic and study purposes.

Many of the traditional starchy foods from different cultures have a low glycemic index (**Table 4**). Finally, results of cohort studies suggest that consumption of foods with a low glycemic index, especially in the context of a high-fiber

Table 4 Glycemic foods of staples from different cultures

Food	*Average GI*[a]	*Culture*
White bread rolls	100	North American, European
Pumpernickel	70–90	North European
Pasta	50–70	Mediterranean
Cracked wheat (tabouli)	60–70	Mediterranean, Middle Eastern
Beans, lentils, dried peas	40–70	Southern United States, Latin American, Middle Eastern, Indian, Oriental
Parboiled long-grain rice	70	Asian, North African

[a]Glycemic index (GI) is rounded to the nearest 10%.

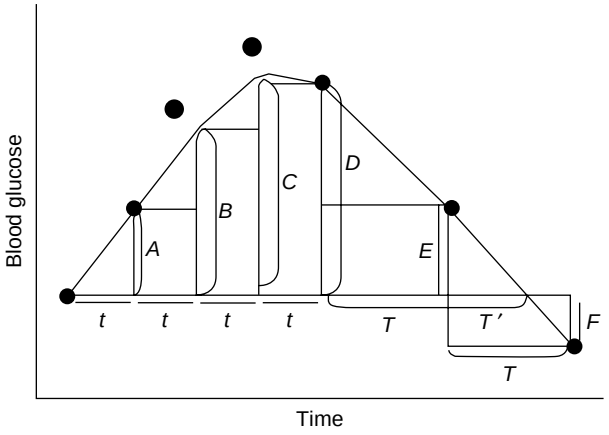

Figure 3 Schematic representation of postprandial blood glucose response (From Wolever TMS and Jenkins DJA (1986) The use of the glycemic index in predicting the blood glucose response to mixed meals. *American Journal of Clinical Nutrition* **43**:167–172.)

diet, protects from the development of type 2 diabetes. Therefore, the question is whether the rapid increase in diabetes in cultures in transition from traditional to Western lifestyle patterns is in part due to the high glycemic index of the diets eaten, in addition to the excess consumption of energy and reduced physical activity.

Calculation of the Glycemic Index

The glycemic index (GI) has been defined as the area under the blood glucose response curve for 50 g carbohydrate from the test food divided by the area under the blood glucose response curve for 50 g carbohydrate from the standard source, multiplied by 100. The standard carbohydrate source for modern assessments is white bread. In early studies, however, 50 g glucose was used rather than bread. On the 'bread scale' the glucose GI is approximately 130%. Other food GI values can be adjusted accordingly to allow direct comparison of the two scales.

The area under the blood glucose curve includes the area above the fasting level only. Any area beneath the fasting level is ignored. The incremental area under the blood glucose response curve is the sum of the areas of the triangles and rectangles. In **Figure 3**, *A*, *B*, *C*, *D*, *E*, and *F* represent the blood glucose increments above the baseline value (fasting level) at sequential time points, where *t* and *T* represent different time intervals between blood samples.

When the blood glucose concentration at *F* falls below the fasting concentration (**Figure 3**), only the area above the fasting level is included in the total area represented by the triangle *ET*, where *T′* represents the portion of the time interval *T* when the blood glucose level between *E* and *F* is above the fasting level.

The overall equation simplifies to

$$\text{Area} = \left(A + B + C + \frac{D}{2}\right)t + \frac{(D + E)T}{2} + \frac{E^2T}{2(E + F)}$$

If the last blood glucose concentration *F* is above the fasting level, then the term $(E+F)T/2$ is substituted for the last term in the equation, namely $E2\,T/2(E+F)$. An example of the incremental area calculation is shown in **Table 5**.

Calculation of mixed meal or total day's GI Each carbohydrate component is expressed as a percentage of the total carbohydrate in the meal or day and multiplied by the relevant GI. The sum of these values represents the meal's or the day's GI.

Table 5 Example of calculation of incremental area under the blood glucose response curve for glycemic response when the last glucose value falls below baseline

Time (min)	*Corresponding letter on* ***Figure 3***	*Blood glucose (mg dl^{-1})*	*Blood glucose increment (mg dl^{-1})*
0	—	100	—
15	*A*	120	20
30	*B*	140	40
45	*C*	160	60
60	*D*	150	50
90	*E*	120	20
120	*F*	90	−10

Calculation: Area $= (20 + 40 + 60 + 25) \times 15 + (25 + 10) \times 30 + (20^2 \times 30/2 \times (20 + 10)) = 3425$ mg min dl From Wolever TMS and Jenkins DJA (1986) The use of the glycemic index in predicting the blood glucose response to mixed meals. *American Journal of Clinical Nutrition* **43**: 167–172.

Calculation of glycemic load Glycemic load is the diet GI multiplied by daily dietary carbohydrate intake in grams per day.

Metabolism and Maintenance of Blood Glucose Level

V Marks, University of Surrey, Guildford, UK

This article is a revision of "Glucose: Maintenance of Blood Glucose Level" in the Encyclopedia of Food Science and Nutrition (Second Edition. pp. 2911–2916 © 2003 Elsevier Ltd).

Glucose is the only simple sugar found in most body fluids in anything more than trace amounts and for all practical purposes is confined to extracellular water. Lactose and fructose are the major sugars in milk and semen, respectively. This article reviews the major factors determining the concentrations of glucose in blood under everyday physiological and pathological conditions.

The Body Glucose Pool

The body of an adult subject seldom contains less than 8 g, or more than 28 g, of glucose at any one time (corresponding to blood glucose concentrations of 3.5–10 mmol l^{-1}), despite enormous fluctuations in demand and supply. This quantity of glucose can be considered as constituting a hypothetical body pool (**Figure 1**) confined within a glucose space equal in volume to the combined water in blood and the interstitial fluid (i.e., approximately 35% of total body water).

Glucose enters the cells by facilitated transport utilizing one or more of the genetically determined glucose transporter proteins that have been identified, depending on the tissue and which proteins are inducible. Upon entering a cell, glucose is immediately phosphorylated and consequently removed from the glucose pool.

Although its subsequent conversion into carbon dioxide and water or other metabolites (most notably glycogen, glycerol, fatty acids, and the glyco-moieties of mucopolysaccharides and glycoproteins) is the only way that glucose ordinarily leaves the glucose pool, its loss in the urine may become a major factor in diabetes mellitus. Glucose enters the glucose pool from food in the intestine after a meal via the portal vein or, in the postabsorptive subject, by release of glucose from preformed glycogen or molecules newly synthesized by liver cells into the hepatic veins.

Glucose Space

The glucose space (i.e., the extracellular water volume) is constant in any individual and

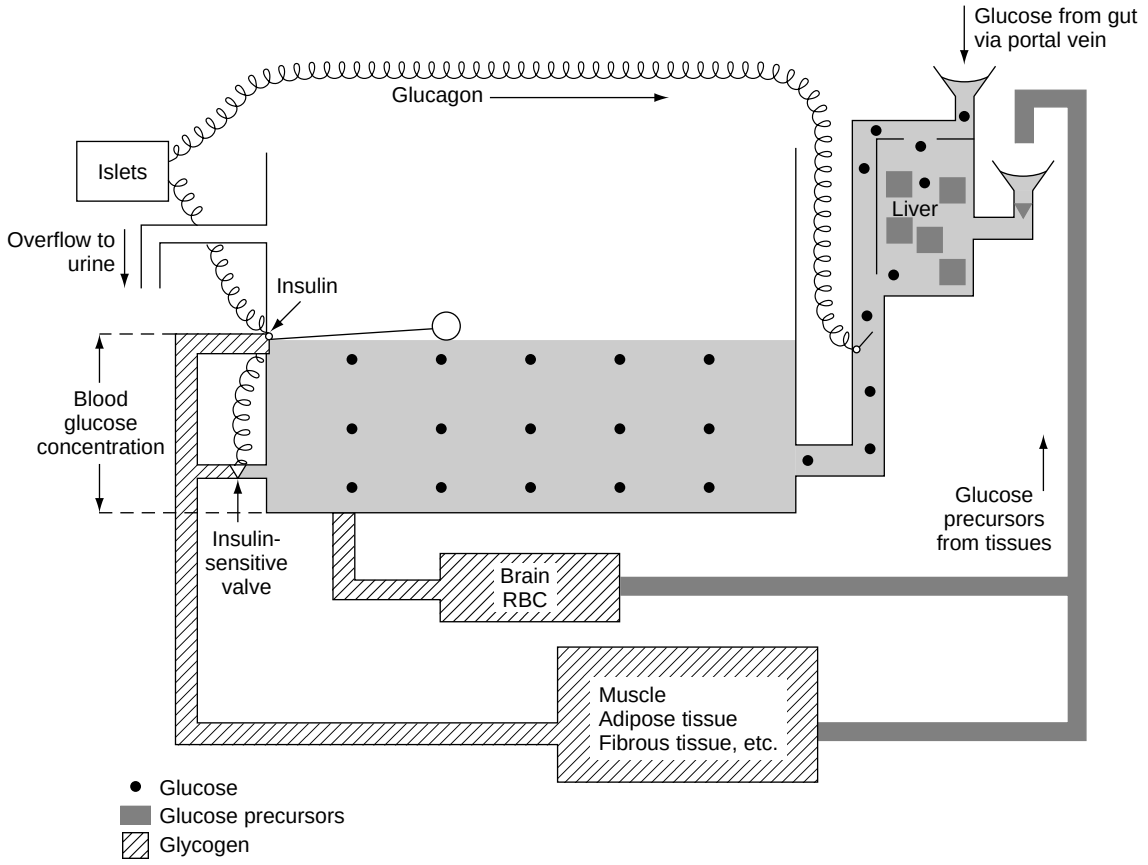

Figure 1 Schematic representation of blood glucose concentration and its relationship to the body glucose pool. The central system represents the hypothetical glucose pool, the actual size of which is represented by the horizontal axis (i.e., volume of distribution multiplied by blood (and extracellular fluid) glucose concentration). The postulated homeostatic switch is the cells of the endocrine pancreas, which respond to blood glucose concentration modulated by intestinal hormonal (incretin) and neural factors, which are themselves controlled by messages received from the gut (enteroinsular axis) and the autonomic nervous system. RBC, red blood cells.

consequently the amount of glucose in the body (the glucose pool) is directly proportional to its concentration in the blood. This is controlled through a series of complicated control mechanisms, the most important of which involve individual pancreatic islets of Langerhans. These function semiautonomously and release either insulin or glucagon according to need.

When pool size increases above a threshold, corresponding to a concentration in blood of approximately 10 mmol l^{-1}, glucose filtered at the glomeruli exceeds tubular capacity to reabsorb it and consequently spills over into the urine, producing glycosuria. Temporary increases in glucose pool size (hyperglycemia) are not immediately harmful but in the long term give rise to the so-called complications of diabetes. Decreases in glucose pool size (hypoglycemia), on the other hand, are immediately harmful and potentially so dangerous that many defence mechanisms have evolved to prevent or overcome them.

Blood Glucose

The brain, which can remove glucose from the extra-cellular fluid (ECF) in the absence of insulin, is the only important drain on the glucose pool in the fasting subject when plasma insulin levels are minimal. It consumes glucose at the rate of approximately 78 mg per gram of tissue per day. This amounts to approximately 110 g per day in an adult man or 75 g per day in a 1-year-old child. Estimates of glucose turnover suggest that approximately 9 g of glucose enters and leaves the glucose pool every hour in the average overnight fasting healthy subject.

The concentrations of glucose in venous and arterial blood are similar in the fasting subject because peripheral tissues, such as muscle, skin, and connective tissue, do not extract significant amounts of glucose from the blood in these circumstances. In the recently fed subject, however, glucose uptake by peripheral tissues increases markedly under the

influence of insulin released in response to the ingestion of a meal. This can produce a difference in arterial and venous blood glucose concentrations of $2\,mmol\,l^{-1}$ or more. This fact, known for more than 80 years, is still often forgotten or ignored by both experimentalists and clinicians. It not only has implications with regard to our understanding of the physiology of glucose homeostasis but also sometimes has unfortunate consequences for patients who may, if only venous blood is sampled, be misdiagnosed as suffering from hypoglycemia (i.e., blood glucose $<3.0\,mmol\,l^{-1}$).

It is, after all, arterial and not venous blood glucose that is homeostatically controlled and relevant to brain physiology, but because venous blood is more easily obtained, it is often used in studies of glucose homeostasis and clinical practice. Arterialized venous blood, collected from heat-distended veins on the back of the hands, is the best substitute for arterial blood in studies of glucose homeostasis. Finger-prick or earlobe capillary blood can also be used, although it is difficult to obtain in more than small amounts.

Blood glucose concentrations are generally $3.5–6.0\,mol\,l^{-1}$ in healthy fasting adult subjects and seldom rise above $11\,mmol\,l^{-1}$ in arterial or $10\,mmol\,l^{-1}$ in venous blood, even after a large carbohydrate-rich meal. Glucose and other simple sugars given in solution produce more rapid and greater increases in blood glucose than equal or larger amounts of glucose-yielding carbohydrate taken as part of a solid mixed meal. Conversely, prolonged starvation for as long as several weeks rarely causes the blood glucose concentration to fall below $3\,mmol\,l^{-1}$, except in children and adults with metabolic defects associated with impaired gluconeogenesis.

The remarkable ability of the body to regulate the size of the glucose pool under such widely diverse conditions depends mainly on two organs, the liver and the pancreas, although during prolonged starvation the kidneys become important generators of new glucose molecules.

The Effects of Feeding on Blood Glucose

Glucose

Glucose and the two lesser dietary monosaccharides, fructose and galactose, enter the circulation through the intestinal mucosa. The speed with which glucose can be absorbed is limited by the rate of transfer from the intestine but rarely exceeds 50 g (0.28 mol) per hour. This comparatively massive influx of glucose into a pool of less than 20 g ordinarily produces a remarkably small perturbation in blood glucose because the rate of removal from the glucose pool increases to match glucose input.

In healthy people, arterial blood glucose concentrations generally return to fasting levels within 2 h of eating a carbohydrate-rich meal and before all of it has been absorbed. This remarkable feat of homeostasis is achieved through the prompt and appropriate release of insulin into the circulation. This is a consequence of stimulation of pancreatic B cells (the source of insulin) by a rising arterial blood glucose concentration augmented by the insulinotropic hormones, GIP and GLP-1, released by endocrine cells in the intestinal mucosa. Nervous impulses originating in the brain in response to anticipation of eating (the cephalic phase) and from the mouth, gut wall, and portal vein may also play a role.

Under the influence of the rise in plasma insulin so produced and a simultaneous reduction in glucagon secretion, the liver reduces its rate of glucose input into the pool and increases its rate of extraction. Peripheral insulin-sensitive tissues, such as connective tissue, skin, fat, and especially striatal muscle, also start removing glucose. As a result of these duel actions, arterial blood glucose concentration decreases and the stimulus to insulin secretion declines until all of the food has been absorbed.

Ordinarily, the rates of change of glucose inflow from the gut into the glucose pool and the outflow of glucose into the tissues are so well aligned that arterial blood glucose levels rarely fall below fasting levels after a meal, and then only temporarily. Venous blood glucose levels do so more often. The somewhat unnatural conditions resulting from ingestion of large amounts of a glucose solution on an empty stomach may produce a 'reactive hypoglycemia' due to persistence of insulin action after plasma insulin has fallen to basal levels and all of the glucose has been absorbed from the gut. Such a reactive hypoglycemia may be, but rarely is, sufficiently severe to produce (neuroglycopenic) symptoms even in perfectly healthy individuals.

Disposal of an Oral Glucose Load

The exact disposition of glucose absorbed from the gut after a carbohydrate-rich meal by healthy subjects varies widely from individual to individual, and it depends on the size, composition, and physical nature of the meal. Within 4 h of ingestion, approximately 70% of a 70-g oral glucose load given in solution is removed by peripheral tissues, where most of it is used to generate energy by oxidation to carbon dioxide and water or turned into metabolites. The remaining 30% is removed by the liver

during its passage from the gut to the periphery and converted into glycogen, triglycerides, and other metabolites.

Volunteers given a meal consisting of glucose (1 g per kilogram bodyweight) as a 45% solution on an empty stomach reduced their normal basal release of glucose from preformed glycogen in the liver from $9\,g\,h^{-1}$ to approximately $2.2\,g\,h^{-1}$ (i.e., approximately 75%). This persists for the period (3 or 4 h) during which glucose is absorbed from the gut. In other words, although there is a small net uptake of glucose by the liver following a carbohydrate-rich meal, the liberation of glucose from preformed glycogen does not cease completely. Glycogenolysis and gluconeogenesis take place simultaneously but at different rates, depending on whether glucose is being absorbed as well as on the amount and nature of the hormones released by the pancreas and intestine in response to the presence of food.

Fructose and Galactose

Before being absorbed, sucrose is cleaved into glucose and fructose, and lactose is cleaved into glucose and galactose. Galactose shares a transporter mechanism with glucose, whereas fructose uses a less efficient one of its own. Fructose and galactose, and a percentage of absorbed glucose, are removed on their first pass through the liver and converted into glycogen. This provides a store of carbohydrate that is released as glucose into the body pool when absorption from the gut is no longer occurring and gluconeogenesis has not yet become fully reestablished.

Starches and their partial hydrolytic products are converted enzymatically into glucose in the gut lumen and mucosal brush border at a rate that depends on their composition and physical form. Some starches are absorbed as rapidly as preformed glucose, whereas others are absorbed much more slowly. This is reflected in the rate and magnitude of the increase in blood glucose concentration that follows their ingestion and is referred to as the glycemic index.

The Postabsorptive Stage

The exact duration of the absorptive phase following ingestion of a meal depends on many factors, including the size of the meal, its composition, physical nature, and energy density as well as the rate of gastric emptying. Studies based on measurement of intestinal hormones that are released only in response to the absorption of food indicate that the average adult who eats three meals per day is rarely truly postabsorptive except during the night. During this comparatively brief fasting period, glucose lost from the glucose pool by its constant drain into the brain is replaced by glucose derived from the breakdown of liver glycogen. This can come either from reserves built up during the absorptive phase of a meal or by synthesis from glucose precursors, such as lactate, pyruvate, glycerol, and alanine, brought to it in the blood from peripheral tissues during fasting. Glucose synthesis, or gluconeogenesis, is increased by rising levels of glucagon and fatty acids in the blood, which are a consequence of decreasing plasma insulin levels.

The amount of glycogen in the liver varies with the nature of the diet and the size, composition, and timing of the last meal. The average amount of glycogen in the liver after an overnight fast is approximately 44 g (range, 15–80 g) and surprisingly does not increase very much after a meal. Nevertheless, after 36 h without food, liver glycogen stores may decline to as low as 4–8 g. Paradoxically, more prolonged fasting has little additional effect: Indeed, hepatic glycogen stores may actually be replenished as the brain shifts from using glucose to β-hydroxybutyrate as its main source of energy.

Glycogen probably never disappears from the liver completely, except *in extremis*, and there is evidence that it may be an intermediary in the production of glucose by the gluconeogenic pathway. Striatal muscles, which lack glucose-6-phosphatase, cannot convert the glycogen they contain into glucose and release it into the blood. Instead, they release its main breakdown products, lactate and pyruvate (and the latter's transamination partner, alanine), into the blood for conversion into glucose in the liver.

Gluconeogenesis

Gluconeogenesis is the process wherein the liver and, to a smaller but often significant extent, the kidneys make new glucose molecules from chemically simpler compounds. In humans, lactate is probably the most important glucose precursor, especially during exercise. Others, in order of importance, are alanine, pyruvate, glycerol, and some glucogenic amino acids, including glutamate. Glutamate is especially important in gluconeogenesis in the kidney. Fatty acids, apart from propionate formed in the colon by bacterial fermentation of nonabsorbable carbohydrates, do not serve as glucose precursors to any significant degree but do provide the conditions under which it can take

place. So too do specific hormones, such as glucagon and cortisol.

The contribution by alanine to gluconeogenesis has probably been exaggerated. Although formed along with other amino acids by proteolysis of non-structural muscle proteins during periods of prolonged fasting and starvation, its main role under normal conditions is to transport, after transamination, three-carbon skeletons (e.g., pyruvate) derived from muscle glycogen to the liver, where it is converted into glucose during fasting.

Eating inhibits gluconeogenesis mainly through an increase in insulin and decrease in glucagon action. Fasting produces the opposite effect. Alcohol specifically inhibits gluconeogenesis from lactate but not other substrates, such as alanine. It does so by adversely changing the redox potential within the hepatocytes and reducing the availability of nicotinamide adenine dinucleotide, which is an essential component in the formation of glucose from lactate. The inhibition of gluconeogenesis by quite modest amounts of alcohol can sometimes be so profound that people, especially children, with reduced liver glycogen stores may develop hypoglycemia of a severity that can be fatal.

Hormones and Glucose Homeostasis

Insulin is the only major hormone capable of lowering blood glucose levels (**Table 1**). It does so by inhibiting glycogen breakdown in the liver and inhibiting gluconeogenesis and by encouraging glucose uptake by peripheral tissues. It achieves this mainly by activating the glucose transporter protein, GLUT-4, an action that is enhanced by exercise and hyperglycemia. Consequently, insulin lowers

Table 1 Hormones that affect blood glucose concentrations

Hormones concerned with glucose homeostasis

Hormone	*Source*	*Stimuli*	*Inhibitors*	*Main effect on glucose homeostasis*
Insulin	B-cells of islets	Hyperglycemia, incretins (i.e., GIP & GLP-1), glucagon, some amino-acids e.g., arginine, leucine: parasympathetic nervous system i.e., vagus	Hypoglycemia, sympathetic nervous system and adrenaline, somatostatin	Reduced blood glucose concentration by Inhibition of hepatic glycogenolysis and gluconeogenesis, permitting peripheral glucose uptake
GIP	K-cells of duodenum, jejunum, ileum	Actively absorbed sugars e.g., glucose and galactose, actively absorbed fats, especially polyunsaturated	Glucagon; insulin	Incretin: stimulates insulin secretion only in presence of hyperglycemia
GLP-1	L-cells of the ileum and colon	Ingested food; whether absorbed or not	Glucagon; insulin	Incretin: stimulates insulin secretion only in presence of hyperglycemia: inhibits glucagon secretion. Inhibits gastric emptying: reduces appetite
Glucagon	A-cells of islets	Hypoglycemia, adrenaline, some amino-acids e.g., arginine	Insulin, hyperglycemia.	Increases glycogenolysis in liver (not peripheral tissues), enhances gluconeogenesis
Adrenaline	Adrenal medulla	Hypoglycemia, through sympathetic nervous stimulation, physical and mental stress.		Increases glycogenolysis in liver and peripheral tissues, inhibits insulin secretion, stimulates glucagon secretion, impairs peripheral glucose utilization and increases lipolysis (i.e., raises plasma NEFA levels)
Cortisol	Adrenal cortex	Hypoglycemia through hypothalamic release of ACTH		Decreases peripheral glucose uptake, induces insulin resistance, permits hepatic glycogenesis
Growth Hormone	Anterior pituitary	Hypoglycemia, through hypothalamus, ghrelin released from stomach following ingestion of food	Hyperglycemia, Somatostatin, alcohol	Decreases peripheral glucose uptake; increases adipocytes lipolysis
Vasopressin	Hypothalamus and posterior pituitary	Hypoglycemic stress; dehydration	Hypo-osmolality: alcohol	Stimulates hepatic glycogenolysis

blood glucose by two independent mechanisms. Which of the two actions predominates depends on the circumstances, including the actual concentration of insulin in the blood. Another is whether it is of exogenous or endogenous (pancreatic) origin. Exogenous insulin reaches peripheral tissues at a concentration in blood equal to or greater than that in blood perfusing the liver and is unaccompanied by C-peptide. Endogenous insulin, on the other hand, reaches the liver at a higher concentration than peripheral tissues and is accompanied by C-peptide, for which there is increasing evidence of synergism with insulin action.

Insulin released into the portal circulation is partially or, when its concentration in portal blood is low, almost completely removed by the liver. Not all tissues on which insulin acts are equally sensitive to its actions.

At the concentration at which insulin normally circulates in peripheral blood of fasting subjects ($<30\,\text{pmol}\,\text{l}^{-1}$) it depresses, but does not completely suppress, the release of fatty acids from adipocytes and completely inhibits glucose uptake by striatal muscle. At insulin concentrations seen in peripheral blood in the absorptive phase of a meal ($\sim$150–600 $\text{pmol}\,\text{l}^{-1}$) it enhances peripheral glucose uptake and is responsible for the marked arteriovenous glucose difference observed at this time.

The release of insulin from the B cells of the pancreatic islets depends on the concentration of glucose in the blood perfusing them. At blood glucose levels less than approximately 3.5–4.0 $\text{mmol}\,\text{l}^{-1}$, insulin secretion is minimal (constitutive). This means that as the arterial blood glucose declines toward its basal level in the postabsorptive state, plasma insulin levels also decline. However, they never decline low enough in the nondiabetic subject to permit uncontrolled liberation of glucose by the liver or fatty acids by adipocytes. This does, of course, happen when the B cells are destroyed, as in C-peptide negative type 1 diabetes, and is the cause of the hyperglycemia and ketosis that are the hallmark of this illness.

During prolonged starvation (20–50 days without food), small amounts of insulin still reach the liver. However, the amount reaching the adipocytes is sufficiently small to permit lipolysis by adipocytes, and their release of fatty acids into the circulation is sufficient to produce hyperketonemia (10–20 $\text{mmol}\,\text{l}^{-1}$) comparable to that seen in diabetic ketoacidosis. The situation differs, however, from that in diabetes, in that the restraining effect of insulin on hepatic gluconeogenesis and glycogenolysis remains. Consequently, blood glucose levels remain normal rather than grossly elevated and few ill effects develop except weight loss.

An important consequence of reduced insulin secretion as blood glucose levels decline after absorption of a meal is emancipation of the A cells, which are 'down stream' of B cells in the islet, from its suppressive effect on their own release of glucagon. Glucagon reaching its target organ, the liver, promotes both glycogenolysis and gluconeogenesis, thus reversing the effect exerted by insulin during the absorptive phase. In other words, each of the approximately 1 million pancreatic islets functions independently as a miniature glucostat.

Counterregulatory Hormones

Although it is possible to explain the control of blood glucose largely by means of the servoregulatory control of insulin and glucagon secretion described previously, the body has many other neural and hormonal mechanisms to correct or overcome a decline in blood glucose below the critical level (approximately 3.5 $\text{mmol}\,\text{l}^{-1}$) necessary to maintain normal brain function. The sensors for this regulatory function are located in at least two anatomically distinct sites—within the brain and in the portal vein.

The following are the most important mechanisms involved:

Stimulation of the sympathetic and parasympathetic nervous systems, which in turn leads, respectively, to release of adrenaline from the adrenal medulla and noradrenaline from nerve terminals in the liver, and glucagon from the pancreas

Secretion of growth hormone, prolactin, and adrenocorticotrophic hormone by the anterior pituitary gland, cortisol by the adrenal cortex, and vasopressin by the posterior pituitary gland

None of these hormones, apart from cortisol, appears to be absolutely essential for the maintenance of normal glucose homeostasis, but all are brought into play under adverse conditions. They produce their hyperglycemic effects in a variety of ways that can be summarized as follows:

1. Increasing the liberation of glucose by the breakdown of preformed glycogen in the liver (e.g., glucagon, adrenaline, noradrenaline, and vasopressin)
2. Increasing gluconeogenesis in the liver (e.g., glucagon and cortisol)
3. Decreasing peripheral glucose utilization by peripheral tissues (e.g., growth hormone, cortisol, and prolactin)

Hyperglycemia and the Glycemic Index

In contrast to the numerous processes that protect against blood glucose falling too low, there is only one that protects the body from hyperglycemia—the release of insulin into the blood in response to the ingestion of food. Plasma insulin concentration, although neither its rate of increase nor its effectiveness (which depend on intrinsic physiology of the B cells and peripheral insulin sensitivity, respectively), is in large part determined by the increase in arterial blood glucose concentration that follows ingestion of a carbohydrate-containing meal. People who develop type 2 diabetes often have a delayed B cell response to intravenous glucose before showing overt evidence of impaired glucose tolerance in response to a meal. This is because their B cells, although relatively insensitive to hyperglycemia alone, remain sensitive to the hormones GIP and GLP-1, collectively known as incretins and that are released into the circulation from endocrine cells in the intestine in response to actively absorbed carbohydrates and fats. The incretins are able to stimulate insulin secretion only in the presence of hyperglycemia and do not do so when the meal contains little or no carbohydrate, thereby avoiding the risk of hypoglycemia following ingestion of a high-fat meal that does release GIP but virtually no insulin.

Other hormones released from the intestine in response to dietary constituents indirectly affect disposal of absorbed nutrients into the tissues and appetite as well as regulate gastrointestinal functions, such as the rate of gastric emptying and secretion of digestive enzymes.

There is a school of thought that maintains that the rate and magnitude of increase in blood glucose following ingestion of a carbohydrate-containing food compared to those of a comparable amount of glucose in solution or white bread eaten alone can usefully be expressed as its glycemic index. It further avers that low glycemic index foods are nutritionally preferable to high glycemic index foods, the ingestion of which various chronic illnesses are attributed. This has been disputed, and there is little evidence that the concept has much relevance to people with healthy pancreatic endocrine function eating combinations of diverse foods in their everyday life. There is indirect evidence that it may have value in determining dietary choices by people with diabetes whose pancreatic endocrine function is faulty or absent.

Glycosuria

Approximately 100 g of glucose is normally filtered from the blood at the glomeruli of the kidneys each day, more than 99% of which is reabsorbed by the kidney tubules. As a result, healthy people lose less than 150 mg of glucose in their urine each day, an amount too small to be detected by most simple screening procedures for glycosuria. When, for any reason—the most common cause of which is a blood glucose concentration of 10 mmol l^{-1} or higher—the amount of glucose filtered at a glomerulus is more than can be reabsorbed by its tubule, glucose appears at high concentration in the urine. The osmotic diuresis so produced is associated with an increased excretion of water, sodium, chloride, and potassium and is often the first clue to the existence of hyperglycemia, the characteristic hallmark of diabetes. Moreover, it is their loss and not that of glucose that leads to the fatal outcome of diabetic ketoacidosis in patients with untreated type 1 diabetes.

Because their concentration in blood is ordinarily extremely low, except in certain rare diseases, neither fructose nor galactose occur in the urine of healthy people.

Glucose Tolerance

B Ahrén, Lund University, Lund, Sweden

Definition and Impact of Glucose Tolerance

The prevalence of type 2 diabetes is steadily increasing and it has been estimated that the prevalence will increase during the next 25 years to reach epidemic levels. It is assumed that within 25 years, if the trend is not altered, more than 25% of the global adult population older than 65 years of age will be affected by diabetes. The prevalence also shows ethnic differences, with prevalence ranging by a factor of 10 between different populations. Also, the prevalence of diabetic complications is high, resulting in high and significant morbidity. Diabetes is also a major risk factor for cardiovascular diseases, and the majority of deaths in those with diabetes are due to cardiovascular or cerebrovascular disorders. Altogether, this makes diabetes a major burden for global health and health economy.

A most important factor underlying the morbidity in diabetes, its complications and concurrent cardiovascular diseases, is hyperglycemia. Importantly, even at such a low degree as not to reach the limit criteria for diabetes, hyperglycemia is related to morbidity. Lifestyle changes and pharmacological interventions to reduce or even normalize the hyperglycemia exist, and consistent adherence to such regimen will reduce the morbidity. However, hyperglycemia is initially without symptoms and therefore usually remains undetected for a long period of time. Therefore, it is important to have reliable methods for the detection of hyperglycemia in its initial stages for proper actions to be taken. Such detection relies on analysis of the circulating glucose in the fasting state or after a challenge. Thus, it is important to recognize that hyperglycemia is subdivided into two different entities. The first entity is fasting hyperglycemia. This is mainly due to inappropriately high release of glucose from the liver, which is in turn caused by excessive glucagon levels in combination with low insulin levels and/or deficient action of insulin to restrain glucose release from the liver. Standardization of the sample is usually defined as 8- or 12-h fast. The second entity of hyperglycemia is postchallenge hyperglycemia, which occurs after meal or glucose ingestion. This is called 'glucose intolerance' and is equivalent to an impairment to dispose glucose after a challenge. Several modes to diagnose glucose intolerance exist. However, the gold standard for its diagnosis is the oral glucose tolerance test (OGTT). This article describes this test, its advantages and limitations, and its potential role for early detection of patients with increased risk for developing type 2 diabetes and cardiovascular diseases. The article also summarizes the basic mechanisms determining glucose tolerance as well as epidemiological and clinical aspects of glucose intolerance, including the potential of treating the condition for prevention of diabetes and cardiovascular diseases.

Glucose Tolerance Tests

History and Definition of Oral Glucose Tolerance Tests

A major breakthrough in the understanding of glucose intolerance as a basis and risk factor for development of type 2 diabetes and cardiovascular diseases was the introduction of a worldwide standardization of the OGTT in the 1970s. By this introduction, glucose tolerance became a standardized entity, which enabled studies in metabolism, physiology, and clinical medicine with detection of risk factors as well as progressive follow-up studies using a standard recognized worldwide. At the same time, and also of significant importance for the generation of present-day knowledge within the field, was the introduction of the clinical entity impaired glucose tolerance (IGT), which replaced the term "borderline" diabetes. A problem with the term borderline diabetes was that its definition was not uniform, which was partly due to inconsistencies in the procedure of performing a glucose tolerance test, with the amount of glucose ingested varying from 50 to 100 g or given on a kilogram basis. IGT as an entity was thus introduced simultaneously with the suggestion that glucose tolerance in a clinical test should be determined following ingestion of 75 g glucose, with a blood sample for the measure of glucose to be taken 2 h later.

The evaluation of the standardized OGTT in the clinical setting relies on the 2-h glucose value. This value during the 75 g OGTT usually displays a normal distribution slightly skewed to the right. **Figure 1** shows the distribution pattern of 2-h glucose levels obtained from 802 Caucasian subjects in the Malmö Prevention Study, an epidemiological study from Sweden. From this distribution, normal values may be defined statistically from mean and variance values for statistical definition of the distribution. The mean value, as in most studies, is $\approx$7 mmol/l and standard deviation is $\approx$1 mmol/l. By defining reference values as 95% confidence intervals, the cutoff value for normality would be

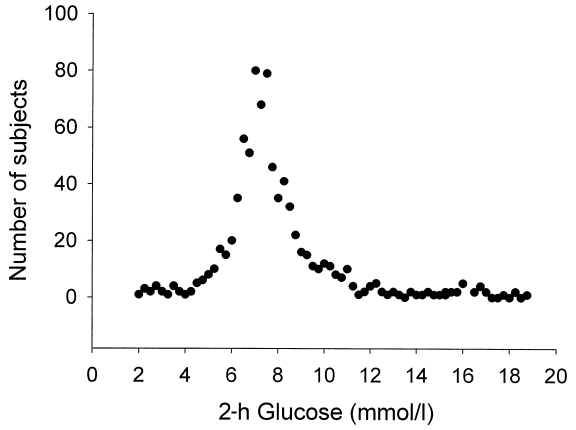

Figure 1 Distribution of the 2-h glucose value in an OGTT performed in 802 Caucasian subjects from the Malmö Prevention Study (unpublished data).

approximately 9 mmol/l and, hence, values higher than 9 mmol/l would indicate diabetes. By using such a definition of diabetes, a large number of subjects would have the disease, the clinical relevance of which is doubtful. Therefore, the definition of diabetes has instead been based on prospective studies evaluating the risk for microvascular disease and the cutoff-levels have been defined as levels increasing this risk. Therefore, a cutoff value of 11.1 mmol/l glucose has been used for the definition of type 2 diabetes.

OGTT was frequently used during the 1980s and 1990s for the clinical diagnosis of type 2 diabetes and in epidemiological studies, which markedly increased our knowledge of these conditions. By the end of the 1990s, however, definitions of IGT and clinical tests to be performed were again discussed. This resulted in revised cutoff levels and the introduction of a new entity called impaired fasting glycemia (IFG), which is defined as high fasting glucose. **Table 1** shows the new cutoff values for the three diagnostic entities—IFG, IGT, and diabetes. It was also suggested that fasting glucose was sufficient for the diagnosis of glucose intolerance and type 2 diabetes.

Table 1 Cutoff values for fasting and 2-h glucose values (mmol/l) of impaired glucose tolerance (IGT), impaired fasting glucose (IFG), and type 2 diabetes (T2D) in an oral glucose tolerance test according to guidelines by the American Diabetes Association

	Plasma	*Whole blood*	
	Venous	*Venous*	*Capillary*
T2D			
Fasting glucose	≥7.0	≥6.1	≥6.1
2-h glucose	≥11.1	≥10.0	≥11.1
IGT			
2-h glucose	7.8–11.0	6.7–9.9	7.8–11.0
IFG			
Fasting glucose	6.1–6.9	5.6–6.0	5.6–6.0

The suggestion that a fasting sample is sufficient for the diagnosis of abnormal glycemia has been questioned, however, mainly because studies have shown that such a strategy will reduce the numbers at risk who are diagnosed and detected. This is because a large proportion of subjects with IGT have a normal fasting glucose but an elevated 2-h glucose value. In fact, there are populations with IFG alone, IGT alone, and IFG and IGT together, and these populations may represent different risks for diabetes and cardiovascular diseases. Consequently, those having a high 2-h glucose value but a normal fasting glucose, who also have increased risk for cardiovascular diseases, will be missed by the suggested strategy. A study by Larsson and collaborators from Sweden identified this dilemma since it was demonstrated that out of 414 subjects with abnormal fasting or 2-h glucose values during an OGTT, only 140 (34%) had elevation of both values. The largest group comprised subjects with high 2-h glucose values but normal fasting glucose values (i.e., IGT but not IFG), which were seen in 235 subjects (57%), whereas only 39 subjects (9%) had high fasting but normal 2-h glucose values (i.e., true IFG). The individual subgroups were shown to have similar risk factor patterns in terms of degree of obesity, blood pressure, and lipid levels. Therefore, it is now obvious that for a proper strategy to detect early cases at risk for diabetes and cardiovascular diseases, an OGTT needs to be performed since this test includes both fasting and postchallenge glucose determination.

Procedures and Evaluation of the Oral Glucose Tolerance Test

Glucose tolerance is defined as the ability to dispose a glucose load, and therefore glucose intolerance is defined as an impaired ability for glucose disposal. The gold standard technique is to challenge with an oral glucose load, with measurement of circulating glucose before and after the challenge—the OGTT. As routinely performed, this test determines the ability to dispose glucose after oral administration of 75 g glucose. The test is standardized such that it is performed in the morning after a 12-h overnight fast and blood samples are taken before the glucose load and after 2 h. Furthermore, the diet during the 3 days preceding the test should contain at least 250 g carbohydrates per day and the subjects should rest during the test in a semirecumbant position

without smoking. The glucose given should be dissolved in 250–300 ml fluid, and sometimes fruit-flavored water is used to improve the taste. There has been much debate about how to take the blood sample. The original diagnostic criteria used values obtained from plasma derived from blood taken venously in tubes containing additives for prevention of coagulation. However, valid results are also obtained when glucose is measured in whole blood and when capillary samples are taken, although cutoff levels need to be adjusted for the different glucose concentrations in these samples. Arterial samples are also theoretically possible but rarely, if ever, used. Sometimes, mainly for research purposes, more frequent samples are taken and the test may last 3 h; however, for clinical purposes, the routine OGTT lasts 2 h, with a sample taken at that time point.

As shown in **Figure 2**, in a normal person, circulating levels of glucose increase within the first 15 min after the oral ingestion of glucose to reach a peak after 30 min. Thereafter, a progressive decline occurs, with the 2-h value usually approximately 25% higher than the fasting value. Usually, it takes 3 h for a return to baseline glucose levels. In subjects with IGT, there is usually also a peak at 30 min, albeit at a higher level than in normal subjects, but the main difference versus normal subjects is that the glucose disposal is impaired, which results in a higher 2-h glucose value. In diabetics, there is usually not a peak at 30 min but a continuous rise throughout the 2-h study period. The currently used cutoff values are shown in **Table 1**. Note that the mode of measuring glucose is important with regard to the cutoff values used.

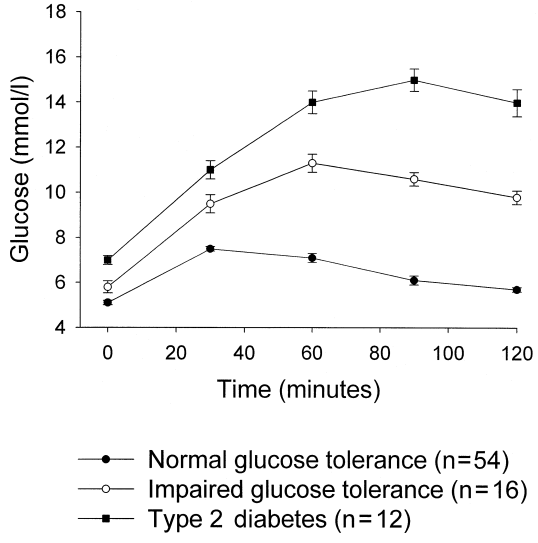

Figure 2 Venous plasma glucose levels during OGTT in subjects with normal impaired glucose tolerance, impaired glucose tolerance, and diabetes. From Ahrén B, unpublished data. Means ± SEM are shown.

Limitations of the Oral Glucose Tolerance Test

An important limitation of the OGTT is the variability in results when the test is repeated. Actually, the coefficiency of variance (CV) is usually 15% and in some studies 20%, which is higher than that for most other clinical tests. It is not clear why OGTT has such a high CV. The variance is not, however, dependent on CV in the measurement of glucose, which is a procedure with very small error and CVs usually below 3%. Therefore, biological variation probably explains the high CV of OGTT. Factors explaining this variation may be preceding diet, exercise, emotions, stress, drugs taken for various diseases, and gender, which are all factors influencing gastric emptying, carbohydrate absorption, islet hormone secretion, hepatic glucose production, and peripheral glucose uptake (i.e., all processes contributing to the 2-h glucose value). Because of the high variability in the 2-h glucose value, a diagnosis of IGT or diabetes, particularly if intervention is planned, should not be based on a single OGTT. Instead, a clinical recommendation is to perform two OGTTs and use the mean of the two 2-h glucose values as the diagnostic value. The time interval between the two OGTTs should not exceed 3 months.

Metabolic Basis for Oral Glucose Tolerance

Oral ingestion of glucose initiates a series of metabolic perturbations, which comprise the 2-h glucose value. These metabolic perturbations are complex and involve glucose entering the bloodstream, changes in neural activity and islet hormone secretion, suppression of hepatic glucose production, and stimulation of peripheral glucose uptake. From a quantitative standpoint, of most importance with regard to the 2-h value are the changes in islet hormone secretion, which include stimulation of insulin secretion and inhibition of glucagon secretion, and the suppression of hepatic glucose production. In fact, there is an inverse linear relation between the inhibition of hepatic glucose production and the 2-h glucose value and, similarly, a linear inverse relation between stimulation of the early (first 30 min) insulin secretion and 2-h glucose. This section briefly summarizes these processes.

A first series of events in the OGTT is initiated during the anticipation of the oral glucose ingestion, through olfactory stimuli and through receptors located in the oral cavity. This response is called

the cephalic phase and activates sensory nerves, which give input to the central nervous system. This information is integrated in the hypothalamus for initiation and adjustment of a vagal nerve response to release insulin from the pancreatic islets. Therefore, when analyzed in detail, there is an increase in circulating insulin after glucose or meal ingestion already before glucose levels become elevated. After passage of glucose through the oral cavity, glucose passes to the stomach and through a regulated mechanism delivered into the gut. Since glucose is a monosugar, it is readily absorbed in the small intestine and reaches the splanchnic venous drainage. Glucose then passes to the portal vein and the liver. In the portal vein, glucose activates glucosensitive receptors, which through afferent sensory nerves send signals centrally to the brain for further integration with the previous signals in the hypothalamus for adjustment of efferent nerve activity. Furthermore, glucose in the liver inhibits hepatic glucose production, which is high after the overnight fast. Then, glucose passes to the general circulation to reach the pancreatic islets and the peripheral cells. The glucose load to the gut also stimulates the release of intestinal hormones, such as glucose-dependent insulinotropic polypeptide and glucagon-like peptide-1 (GLP-1). These hormones then pass through the circulation to reach the pancreas, where they stimulate insulin secretion and, as for GLP-1, inhibit glucagon secretion. In the pancreatic islets, vagal activation, intestinal hormones, and glucose stimulate insulin secretion, and glucose, GLP-1, and insulin inhibit glucagon secretion. These islet responses are of major importance for a normal glucose tolerance, and defects in these islet responses are major determinants of IGT and type 2 diabetes. Following passage of insulin into the venous drainage of the pancreas, the islet hormones reach the portal vein and the liver, and a main function of insulin is to potently suppress hepatic glucose production. This is a major process with regard to the degree of hyperglycemia during the test; in subjects with inappropriately high hepatic glucose production, the glucose level after oral glucose is high. This suppression of hepatic glucose production is augmented by the reduction in circulating levels of glucagon, which is initiated by the direct action of glucose and GLP-1 on the glucagon-producing cells and also by the action of insulin to inhibit glucagon secretion. After the liver, glucose and insulin reach the peripheral circulation and peripheral cells, where glucose is transported across the cell membranes and therefore leaves the circulation. In most cells, a major proportion of glucose uptake is sensitive to insulin; therefore, the amount of insulin, in relation to the insulin sensitivity of the cell, is of major importance for the delivery rate of glucose. However, insulin-independent mechanisms also exist, even in tissues, which are also insulin sensitive, and glucose uptake is thus also dependent on glucose. Of most importance for glucose disposal after oral glucose is the muscle cells, which have a high capacity for glucose uptake. From all these processes, the glucose level at 2 h can be determined.

It is important to realize that the metabolic processes underlying glucose tolerance are different from those underlying the fasting glucose value. Fasting glucose is mainly determined by hepatic glucose delivery during the night, which in turn is governed by the ability to maintain normal basal insulin and glucagon levels. Therefore, mechanisms underlying IFG include defective insulin secretion, defective suppression of glucagon secretion, defective sensitivity in the liver for the action of insulin, and defective peripheral glucose disposal at low glucose levels, which is a sign of insulin resistance. Although mechanisms underlying fasting and 2-h glucose values differ, there is a high correlation between fasting and 2-h glucose values in normal subjects, as shown in **Figure 3**. Nevertheless, there is a limited overlap between IGT and IFG in a population; in fact, most subjects with IGT have normal fasting glucose, and most subjects with IFG have a normal 2-h glucose value. This suggests that different pathophysiological processes underlie IGT and IFG, which in turn suggests that OGTT should be undertaken more frequently than performed today.

Differential Tests for Glucose Tolerance

Diagnoses of type 2 diabetes or stages preceding its occurrence can be undertaken by other means

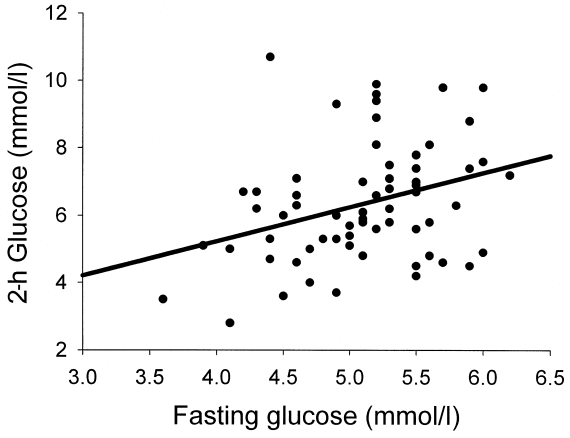

Figure 3 Correlation between fasting glucose and 2-h glucose during an OGTT in nondiabetic subjects. The regression is significant ($r = 0.32$, $p = 0.008$). From Ahrén B, unpublished data.

besides OGTT. As previously stated, the use of fasting glucose has been suggested as the gold standard for diagnosis during recent years. Although it has a lower CV than the 2-h glucose value after OGTT and is simpler and more convenient for both the subject and the staff, the problem with this method is that a large number of subjects with IGT, namely those with a normal fasting glucose, will be missed.

As an alternative to OGTT, glucose tolerance may also be determined by administering glucose intravenously. In the intravenous glucose tolerance test (IVGTT), glucose is injected intravenously, usually at a dose of 0.3, 0.5, or 1 g/kg, and circulating glucose is determined before and 8, 10, 15, 20, 30, 40, 50, 60, and 80 min after injection. Glucose tolerance is estimated from the elimination rate, where a glucose elimination constant (k_g) is calculated. The theory behind this is that the glucose elimination after intravenous glucose displays an exponential function (i.e., after logarithmic transformation of the data, the elimination is linear. k_g is thus calculated as the slope for the glucose curve following logarithmic transformation of the individual glucose values and is calculated from the formula $k_g = (0.693 \times 100)/t_{1/2}$, where $t_{1/2}$ is the half-time of glucose elimination (in minutes). The unit for k_g is percentage of glucose decay per minute. **Figure 4** shows this condition. Before OGTT was routinely used, IVGTT was undertaken more frequently. Unless very specific questions are asked, it is currently not used in clinical practice because it is more cumbersome to perform and it identifies only some of the metabolic processes underlying glucose tolerance, mainly insulin secretion, insulin sensitivity, and glucose uptake. Thus, other important aspects, such as glucagon secretion, release of incretin hormones, and hepatic glucose output, which are involved in the overall glucose tolerance and included in the 2-h glucose value after OGTT, contribute only marginally to the k_g after IVGTT.

It has been suggested that measurement of HbA_{1c} (i.e., the fraction of hemoglobin being glycosylated) may be used for the diagnosis of IGT and type 2 diabetes. The rationale is that hemoglobin is irreversibly glycosylated in proportion to the glucose level, and therefore the proportion of HbA_{1c} should reflect the mean of the glucose levels during the preceding 2 or 3 months. However, although this theoretical assumption is true, measurements of HbA_{1c} are not precise, have not been standardized at levels near the normal levels, and, consequently, slight elevations of HbA_{1c} will not distinguish normal from impaired glucose tolerance with fairly high precision. In addition, most subjects with IGT have HbA_{1c} levels within the normal distribution.

Linear regression curve for the logarithmic values from minutes 8 to 60. k_g value = 1.61 ± 0.08%/min. From Ahrén B, unpublished data. Means ± SEM are shown.

Clinical Aspects of IGT

Epidemiology of IGT

During the 1980s, studies on the prevalence of IGT and type 2 diabetes were performed in several different populations. It became apparent that the prevalence of these conditions, although high in many populations, varied markedly between different populations. Thus, for some populations, mainly in Africa, data from only a few percent were published, whereas an exceedingly high prevalence (60%) was reported in some populations, such as Pima Indians. **Figure 5** shows a collaborative study from 1993 in which data from several populations throughout the world are summarized. Studies during the past 10 years have further increased our knowledge since they have included additional populations and demonstrated that the

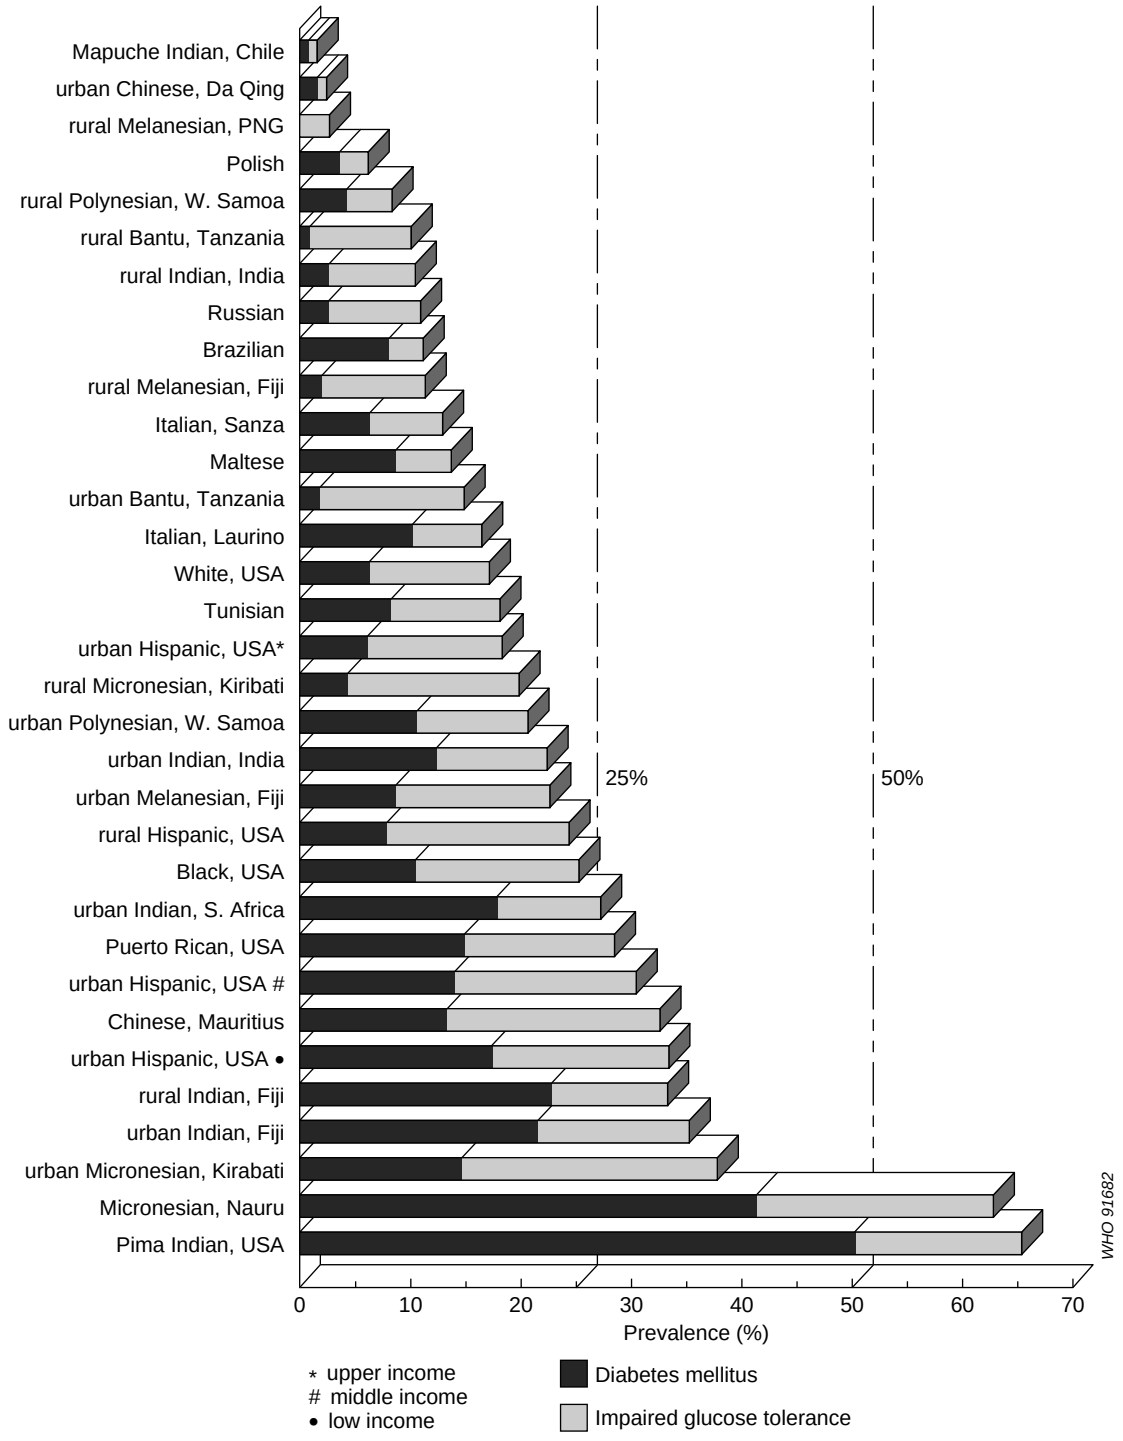

Figure 5 Prevalence (%) of diabetes and IGT in selected populations in the age range of 30–64 years; genders combined. Copyright © 1993 American Diabetes Association. From *Diabetes Care* volume 16, page 170. Reprinted with permission from the American Diabetes Association.

prevalence of IGT and type 2 diabetes is steadily increasing. Hence, the prevalence reported in 1993 is an underestimation of the prevalence today. It has to be emphasized, however, that the difference in reported prevalence rates between different populations may be partially explained by methodological differences. For example, the prevalence of IGT and type 2 diabetes is increased by age,

and in many populations there is also a higher prevalence in women than in men, at least in younger age groups. Different studies have not controlled for these confounders. Furthermore, due to migration patterns in some populations, generalization of study results is questionable, and there may also be differences in the likelihood of subjects attending a study between different populations. Nevertheless, a true ethnic difference seems to exist, with extremely high values in some Pacific island and North American Indian populations and a low prevalence in South American Indian and Bantu populations. An interesting observation is that the increase in prevalence of IGT and type 2 diabetes seems to be higher in populations with low prevalence rates and vice versa, which probably will result in diminished differences in prevalence rates between different populations in the future.

Clinical Consequences of IGT

IGT is an important risk factor for development of type 2 diabetes. However, prospective and long-term studies report different predictive values for the development of type 2 diabetes in different populations. In general, the risk of transition of IGT into type 2 diabetes ranges from 1–2% to 5% and as high as 15–20% per year. The risk is higher for those older than 50 years of age. There is also evidence that hyperglycemia, even at levels not reaching the threshold for type 2 diabetes, is associated with a substantial risk for the development of cardiovascular diseases. One explanation for this is that glucose initiates metabolic perturbations of importance for developing angiopathy, such as tissue peroxidation, production of plasminogen activation inhibition-1, and impairment of endothelial function, such as nitric oxide production. Another explanation is that hyperglycemia is associated with a number of risk factors for cardiovascular diseases, such as high blood pressure, hyperinsulinemia, dyslipidemia, and microalbuminuria, which all are included in the metabolic syndrome. In fact, if hyperglycemia is present, the risk for developing cardiovascular diseases for each of the other risk factors is augmented. Attempts to define cutoff values of glucose for cardiovascular risks have been problematic, however, probably due to the fact that the risk is continuously increased across the glucose ranges. Hence, the use of defined cutoff values is more a convenient practical issue, which is important in a clinical setting, but offers limitations from a theoretical standpoint.

Since IGT is a risk factor for type 2 diabetes and cardiovascular diseases, it is also a risk factor for overall mortality. Alberti and coworkers attempted to quantify this by performing a meta-analysis on 13 prospective studies, and they identified a hazard ratio of 1.34 (95% confidence interval, 1.14–1.57) by comparing subjects with IGT to those with normal glucose tolerance. The hazard ratio is higher for subjects with IGT than for subjects with IFG, suggesting that the 2-h glucose value is more predictive of mortality than the fasting glucose value. This shows that an individual with IGT has an increased risk not only for type 2 diabetes but also for cardiovascular diseases and hence mortality. This indicates that attempts should be made to prevent IGT from progressing to cardiovascular diseases and type 2 diabetes.

Treatment of IGT

During recent years, the issue of whether IGT may be treated to prevent progression to type 2 diabetes or cardiovascular diseases has gained considerable interest. On the one hand, it has been argued that it is important to prevent progression of IGT. On the other hand, it has been argued that treating such a large population group as those with IGT would be risky. **Table 2** lists criteria that need to be fulfilled to justify prevention of a condition. In fact, most of these criteria are met for IGT; therefore, it may be argued that treating IGT is now justified. The optimal preventive intervention for IGT is not known, however. The intervention may include lifestyle changes, notably increased physical activity and dietary regulations. Such interventions have been shown to be efficient in highly motivated populations and study centers. However, whether generalization of these results to the general population is possible is not known. A clinical experience is that the outcome of advice on lifestyle changes is often disappointing in the long term. Another mode of

Table 2 Criteria for recommending population-based intervention for preventing a disease[a]

Criterion 1:	The disease (IGT and type 2 diabetes) should pose a major health problem.
Criterion 2:	Early development and natural history of the disease (IGT and type 2 diabetes) should be understood to identify parameters that measure its progression.
Criterion 3:	Tests should exist for diagnosing the presumptive population (OGTT).
Criterion 4:	Preventive methods should be safe, efficient, and reliable.
Criterion 5:	Effort to find subjects and cost of intervention should not be burdensome and should be cost-effective.

[a]Based on recommendations from the American Diabetes Association (2004).
IGT, impaired glucose tolerance; OGTT, oral glucose tolerance test.

intervention is pharmacological treatment using compounds to stimulate insulin secretion, suppress hepatic glucose production, and/or enhance insulin sensitivity. These may be efficient, perhaps more efficient than advice on lifestyle changes, but may in turn pose other questions concerning long-term efficiency and potential adverse events. These two strategies are not mutually exclusive, however, and introducing pharmacological intervention without giving lifestyle advice is not appropriate in a clinical setting.

Recently, interesting data from large population studies on the prevention of progression of IGT have been obtained. Two studies, the Finnish diabetes prevention study and the Diabetes Prevention Program, have shown that lifestyle changes (i.e., individualized diet and exercise counseling) in subjects with IGT reduced the incidence of diabetes by more than 50%. In addition, in the Diabetes Prevention Program, it was shown that metformin (which reduces glucose output from the liver) reduces the risk by approximately 30%. This suggests that pharmacological treatment of IGT prevents development of type 2 diabetes. Several large studies are ongoing and results are expected within a few years.

Whether interventional programs on IGT are valid also for the prevention of cardiovascular diseases is not clearly established, mainly because long-term studies have not been performed. The STOP-NIDDM study, however, showed that acarbose, which reduces glucose absorption from the gut, reduced cardiovascular events by more than 30% during a 3-year study period. This suggests that cardiovascular diseases may be prevented by treating IGT. It should be noted, however, that for prevention of cardiovascular diseases and mortality, more studies and longer follow-up periods are required.

Conclusion

Because of the risk of developing type 2 diabetes and cardiovascular diseases in subjects with IGT, and also in those with IFG albeit at a lower level, it is important to diagnose and treat these conditions. This means that OGTT should be undertaken more frequently, at least in subjects found to have high fasting glucose. These subjects should be regarded similarly as other subjects with risk factors for cardiovascular diseases (i.e., those with hypertension and dyslipidemia). This implies that subjects with IGT should be given lifestyle advice and be checked regularly. Ongoing large and long-term prevention trials will also provide information on whether pharmacological treatment should be added.

GLYCEMIC INDEX

G Frost and A Dornhorst, Imperial College at Hammersmith Hospital, London, UK

In the past 10 years, a number of important epidemiological and experimental studies have linked glycemic index to postprandial glucose metabolism, insulin resistance, and cardiovascular risk factors. The World Health Organization (WHO) and the Food and Agriculture Organization (FAO) recommended that the physiological effects of dietary carbohydrates be classified according to their glycemic index. This review examines the historical and scientific background of the glycemic index.

Background and Definition

In 1939, Conn and Newburgh noted how different carbohydrate-containing foods could have the same macronutrient composition but different glycemic responses. Insulin responses elicited by different carbohydrates also vary. These observations led to the first classification of carbohydrate foods according to their glycemic response, which then allowed different dietary carbohydrates to be exchanged within a meal without altering postprandial glucose levels. The 'glycemic index' was introduced as a means of quantifying the glycaemic response of different dietary carbohydrates.

Glycemic indices of several foods are published in international nutritional tables, the most recent of which was published in 2002. Methodology on their derivation is available from previous reviews. Glycemic index of a food is a measure of postprandial glucose response after a 50-g load of available carbohydrate from the food (**Figure 1**) and provides a standardized comparison of a carbohydrate's 2-h postprandial glucose response with that of glucose (**Table 1**). Low glycemic index carbohydrates have lower 2-h incremental areas under the glucose curve than glucose, whereas high glycemic index foods have higher areas. Although the insulin response is not used to define glycemic index, the lower the glycemic index of a food, the more attenuated is the insulin response to a standard test meal. It has been argued that it is the insulin response to foods and not the glycemic response that is important in the pathogenesis of insulin resistance and related metabolic disturbances and disease risk. Although still an area of debate in general, glycemic index is a surrogate marker of the insulin response to different carbohydrates, with the possible exception of diary products. Indeed, the insulin response in nondiabetic subjects to a wide range of foods (glycemic indices between 32 and 100) are highly correlated. The exception to this is possibly diary products which have an insulin response high than predicted but the glycemic index. This remains unexplained at present. Dietary carbohydrates stimulate insulin secretion both directly by stimulating the pancreatic β cell and indirectly through their secretion effect. The pattern of insulin secretion caused by different

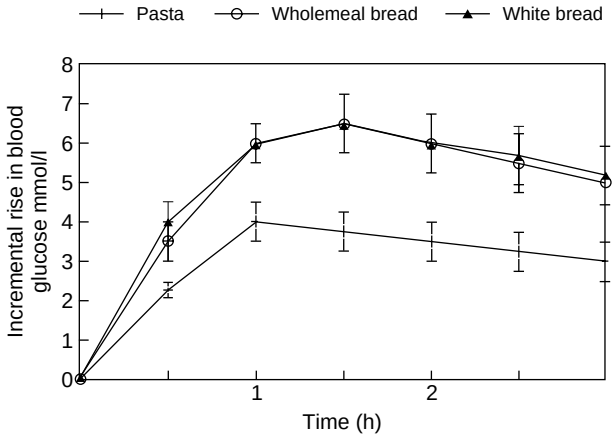

Figure 1 Mean blood glucose increment after equi-available carbohydrate meals. (Data from Jenkins DJ, Wolever TM and Jenkins AL (1988) Starchy foods and glycemic index. *Diabetes Care* **11:** 149–159.)

Table 1 The glycemic index model

Calculation of the glycemic index of a mixed meal containing three separate carbohydrate-containing foods

$$\text{Glycemic index/mixed meal} \quad (GI_1)(PCF_1) + (GI_2)(PCF_2) + (GI_3)(PCF_3)$$

Where
The three carbohydrate-containing foods are 1, 2, and 3
The glycemic index for each carbohydrate-containing food is GI_1, GI_2, and GI_3
The carbohydrate content is **C** 1, **C** 2, and **C** 3 g
The total meal carbohydrate (TMC) is [**C** 1 + **C** 2 + **C** 3] g
The proportion of carbohydrate from each food (PCF) is PCF1 **C** 1/TMCg, PCF2 **C** 2/TMCg, and PCF3 **C** 3/TMCg

carbohydrates reflects their different intestinal transit times.

Type of Dietary Carbohydrate and the Glycemic Index

The glycemic index of a carbohydrate is influenced by its rate of intestinal absorption, which in turn is influenced by its composition, tertiary structure, type of starch, and susceptibility to enzymic digestion.

Chain Length and Composition

Complex carbohydrates are polymeric chains of repeating monosaccharide units. Starches comprise repeating glucose units. The glycemic indexes of different starches are determined by their susceptibility to enzymic digestion, not chain length. White bread and pasta have similar chain lengths, but bread has a higher glycemic index due to its tertiary structure and solubility that ensures greater exposure to salivary and pancreatic amylases.

Short-chain carbohydrates are rapidly absorbed; however, when they contain nonglucose sugars, the glycemic index is lowered proportionally. The disaccharides sucrose and lactose consist of 50% glucose and 50% fructose or galactose, respectively, and both have a lower glycemic index than maltose, the disaccharide formed from two molecules of glucose.

Amylose and Amylopectin

The starches in cereal grains, rice, potatoes, and all green plants are composed of repeating glucose units arranged in straight (amylose) and branched-chained (amylopectin) polysaccharides. The absorption rate, and hence the glycemic index, of these starches is influenced by the ratio of amylose to amylopectin. The more compact structure of amylose than amylopectin results in a smaller surface area being available for amylase digestion. Amylose-enriched starches therefore have lower glycemic indexes than those enriched in amylopectin.

Relationship of Insoluble and Soluble Nonstarch Polysaccharides (Fiber) to Glycemic Index

Nondigestable complex carbohydrates are commonly known as dietary fiber; the more correct terminology is nonstarch polysaccharides (NSPs). NSPs are either soluble or insoluble. Clinical studies have shown that diets rich in soluble fiber/NSPs, such as guar gum, pectin, and sugar beet fibers, lower postprandial blood glucose and insulin levels. Guar gum, a β-glactomannan from the Indian locust bean, also reduces postprandial lipemia. Nonsoluble NSPs have no effect on dietary glycemic index.

Soluble NSPs, such as pulse vegetables, whole fruits, oats, and barley, form gelatinous gels within the stomach that delay gastric emptying and enzymic digestion, the latter by forming a physical barrier around the carbohydrate. Insoluble NSPs have little effect on gastric emptying and no effect on glucose absorption. High-fiber/high-NSP diets are therefore not necessarily synonymous with low glycemic foods. Cellulose is the most widely used NSP in household cereals, whole meal bread, and brown rice, and since it is insoluble, these foods have the same glycemic index whether replete or deplete of their dietary fiber/NSPs. For unknown reasons, Albran is an exception, and despite its high insoluble fiber content, it has a low glycemic index.

The solubility of dietary fiber/NSPs have benefits on postprandial glycemia and hyperinsulinemia. The reason for this are multifactorial including slowing of gastric emptying, a physical barrier to amylase, possible thickening of the unstirred lear and possative effects on gut incretin hormones such as GLP-1 and GIP. The lack of effect on increasing nonsoluble fiber NSPs on glucose and insulin should not detract from important effects on bowel function and bowel pathology.

Cell Structure, Food Preparation, and Processing

Cooking and food preparation can modify the glycemic index. Highly processed convenience foods tend to have high glycemic indexes. When cooking and processing disrupt the cell wall, the starch granules are broken open, optimizing amylase digestion and increasing the glycemic index. Cooked pulse vegetables have low glycemic indexes because their cell walls are resistant to cooking. The intact cereal grains of pumpernickel rye bread, granary bread, and bulgur wheat all have low glycemic indexes. However, when granary bread is processed to wholemeal bread, these grains are disrupted and the glycemic index rises. Cooling can paradoxically lower the glycemic index of certain starches, such as potatoes, due to the formation of retrograde starches that are resistant to amylase digestion.

Effects of the Upper Gastrointestinal Tract

For many foods, their glycemic index is determined by the process of chewing and swallowing. Chewing can reduce food particle size, which increases absorption rates. This explains why boiled and mashed potatoes have different glycemic indexes. Chewing can also change the constituency of the food such that with bread the particle size is reduced

to such an extent that it behaves more as a fluid on swallowing and is therefore very rapidly absorbed. In contrast, pastes retain their structure on swallowing and are more slowly absorbed. The rate of gastric emptying also influences the glycemic index, with lower glycemic index foods being retained in the stomach for longer periods than high glycemic index foods.

Concerns Related to the Glycemic Index

Whereas the 1998 WHO/FAO dietary carbohydrate guidelines and the 1998 European dietetic guidelines advocate greater use of the glycemic index, the American Diabetes Association's evidence-based guidelines are more cautious, suggesting a "B"-level evidence grade. This is basically due to the lack of long-term studies, there is only one randomized control trial which had a study period of longer than 6 months. Also there remains concerns regarding the effects of mixed meals are difficult to predict. Against this is the observation in well conducted randomized control trials, blood glucose during the low glycemic index diet is lower than the high glycemic index diet. Studies of the long-term efficacy of low glycemic index diets in diabetes, obesity, and coronary risk groups using randomized control methodology are under way and will report during the next 5 years. The issue regarding the predictability of the glycemic index of mixed meals remains a matter of debate, but evidence suggests that the glycemic index of a mixed meal is reasonable when the fat content is low and deteriorates as the fat content of the meal rises. However, this academic debate should not detract from the fact the evidence from randomized control trial suggests positive benefits on glucose, insulin and lipids from low glycemic index diets.

Reproducibility

Within-subject variation The variability of the glycemic response for a given food for any individual is similar to that seen for the oral glucose tolerance test. In one study, a 25% coefficient of variation (CV) within individuals was seen when 11 healthy subjects had their glycemic response to different carbohydrates tested on eight separate occasions. In another study, the CV of the glycemic response in 22 healthy subjects given 50 g of white bread was 22%. This variability is reduced when the glycemic response is expressed in terms of the 'glycemic index.'

Between-individual variation The variability of the glycemic responses between individuals is larger than that within individual subjects. In a study that included 11 nondiabetic individuals, 10 non-insulin-treated type 2 diabetic subjects, 12 insulin-treated type 2 diabetic subjects, and 14 type 1 diabetic subjects, the CV between individuals within each group was 26, 34, 23, and 34%, respectively. From this it can be seen that comparing the absolute glycemic responses both within and between subjects is unreliable. However, this problem is considerably lessened when the glycemic response to any given food is expressed as a percentage of that individual's glycemic response to a standardized food substance, which in the case of the glycemic index is usually 50 g of glucose. By expressing the glycemic response of a test food against an equal amount of a standard carbohydrate in an individual, variations that occur with age, sex, body mass index, and ethnicity as well as medical conditions such as diabetes are minimized. By using the glycemic index, the between-individual CV of the glycemic response is reduced from approximately 40 to 10%.

Reproducibility of the Glycemic Index

The glycemic index measurement of certain foods can vary between individuals. For example, one study reported that the glycemic index of lentils ranged between 23 and 70 for different subjects. However, this large variability can be minimized to approximately 10% when both the food to be tested and the standard, usually white bread, are each measured in triplicate.

Problems arising from Different Methodologies Used to Calculate the Glycemic Index

Prior to the 1998 WHO nutritional report that standardized the methodology of assessing the glycemic index, different groups used different techniques to calculate the area under the glucose curve and to assess the postprandial glycemic response. The biggest change has been the standardization of the standard used from white bread to glucose. To allow comparison to historic data published glycemic index tables provide conversion factors or present tables using different methods.

Mixed Meals and Other Nutrients

Carbohydrate foods are frequently taken as part of a mixed meal, and the addition of fat and protein to a carbohydrate-containing meal tends to lower the glycemic response. Although the addition of protein or fat to carbohydrate foods reduces the glycemic response, the relative response of one carbohydrate to another remains, such that lentils

will always have a lower response than white bread when part of a mixed meal.

The glycemic index of a mixed meal can be calculated from the different proportions of each of the carbohydrate-containing foods and their individual glycemic index values. For example, when bread and beans are mixed in equal portions, the resulting glycemic response is midway between that of bread alone and that of beans alone. A formula for calculating the glycemic index of mixed meals has been derived by Wolever and Jenkins (**Table 1**). For accuracy, this method requires all individual carbohydrate components of a mixed meal to be pretested. Other methods of calculating the glycemic responses of mixed meals relying on a single measurement of the area under the glycemic curve for the mixed meal or an estimation that does not account for all the carbohydrate-containing foods will be less accurate. To be fair, this remains an area of debate; a recent study suggested that the ability to predict the glycemic index of a mixed meal is poor, particularly those with a high fat content.

The Second Meal Effect

Dietary carbohydrates can influence the glycemic response of a second meal consumed during the postprandial period. The blood glucose response to a lunchtime meal is lower when taken after a low glycemic index breakfast than after a high glycemic index breakfast. Similarly, the glycemic response of a second meal taken during the postprandial period after lunch or dinner is influenced by the glycemic index of the preceding meal.

Wolever attributed the differences in the glycemic response to a second meal during the postprandial period to differences in intermediary metabolism and insulin action associated with rapidly and slowly absorbed carbohydrates. Rapidly absorbed carbohydrates produce large increases in blood insulin levels that result in blood glucose levels decreasing sufficiently quickly to stimulate several counterregulatory hormones that inhibit insulin action and glucose disposal. Both carbohydrate drinks and meals consumed rapidly rather than sipped or eaten slowly are associated with significantly higher serum concentrations of glucagon, catecholamines, growth hormone, and nonesterified fatty acid (NEFA) levels postprandially. The addition of guar to a meal, which slows glucose absorption and lowers the glycemic response, reduces postprandial NEFA and β-hydroxybutyrate levels and improves insulin action. In contrast, nibbling high glycemic index foods between meals increases the glycemic response of a subsequent meal.

Clinical Significance of Postprandial and Fasting Hyperglycemia in Diabetic and Nondiabetic Populations

As with fasting blood glucose levels, postprandial hyperglycemia in nondiabetic populations is a predictor of insulin resistance and cardiovascular disease (CVD). The combined 20-year mortality data on men from the Whitehall, Paris prospective, and Helsinki policemen studies showed that the highest quintile compared with the lowest for the 2-h postplasma glucose load was associated with a 2.7 increased risk of CVD mortality. The fasting glucose values were less predictive for CVD, with only the top 2.5% conferring a 1.8-fold increased mortality risk. During a 7-year period, elderly women with isolated postprandial hyperglycemia and a 2-h value more than 11.1 mmol/l and fasting value less than 7.0 mmol/l on a 75-g oral glucose tolerance test had an approximately threefold increased risk of heart disease compared with women whose 2-h values were less than 11.1 mmol/l.

In established diabetes, postprandial glycemia appears to have a stronger relationship with microvascular and macrovascular disease than fasting blood glucose. Similarly, in gestational diabetes adverse pregnancy outcome is more closely related to postprandial glycemia than fasting and premeal glycemic values.

Benefits of Low Glycemic Index Carbohydrates on Diabetic Control

This is the area in which there is most evidence of clinical efficacy. Two independent systematic reviews of the world evidence demonstrated the efficacy of low glycemic index diets on glycemic control in both type 1 and type 2 diabetes. Clinical studies have shown that after 3 months of a diet containing low glycemic index carbohydrates, glycemic control is improved in both type 1 and type 2 diabetes. With low glycemic diets, postprandial glucose and insulin concentrations decrease in type 2 diabetic subjects, whereas both postprandial glucose values and insulin requirements decrease in type 1 diabetic subjects. Good glycemic control and favorable lipid and fibrinolytic profiles have also been reported in individuals with either type 1 or 2 diabetes who habitually consume low glycemic index dietary carbohydrates. It remains to be shown whether these diets bestow

long-term benefits on micro- or macrovascular complications.

Benefits of Low Glycemic Index Carbohydrates on Cardiovascular Disease Risk Factors

High glycemic index foods induce postprandial hyperinsulinemia, which is a powerful predictor for metabolic risk factors and CVD in epidemiological studies. Both cross-sectional and prospective population studies have shown favorable lipid profiles in association with high carbohydrate diets. Initially, these benefits were attributed to a high fiber content. However, when the glycemic index is controlled for, it is the low glycemic index diets rather than high fiber content that have the greatest influence on high-density lipoprotein (HDL) cholesterol, insulin sensitivity, and fibrinolytic parameters. In a cross-sectional study on more than 2000 middle-aged subjects, the glycemic index was a stronger determinant of HDL cholesterol than any other dietary factor, be it carbohydrate or fat. In this study, the HDL cholesterol of the women whose habitual diet was within the lowest quintile for glycemic index was 0.25 mmol/l higher than that for women whose dietary carbohydrate was within the highest quintile. Extrapolating from the Framingham data that showed a 3% decrease in female and a 2% decrease in male cardiovascular morbidity to be associated with a 0.026 mmol/l increase in HDL cholesterol, one would predict a 29% difference in CHD morbidity between women in the lowest and highest quintile for dietary glycemic index. A similar calculation for men with dietary carbohydrates in the lowest and highest quintile for glycemic index found a 7% decrease in CHD morbidity associated with the 0.09 mmol/l difference in HDL cholesterol concentrations. Low glycemic index diets have also been shown to lower serum cholesterol and triglyceride levels in hyperlipidemic subjects.

Glycemic Index and the Prevention of Type 2 Diabetes

Changes in diet and physical activity levels, both alone and in combination, reduce the progression of impaired glucose tolerance to diabetes. Two large US prospective population studies have demonstrated a doubling of the relative risk of developing type 2 diabetes for both men and women when the habitual diet is characterized by a high glycaemic index and high fat content. A similar protective effect against diabetes has been reported in populations consuming high-fiber foods and high quantities of fruit, and one would predict that these diets would also have a low glycemic index.

Obesity and Glycemic Index

Obesity contributes to the pathogenesis and morbidity of type 2 diabetes. Obesity is associated with changes in carbohydrate and fat metabolism that are central to the development of insulin resistance. Although low glycemic index diets enhance insulin sensitivity and improve metabolic cardiovascular risk factors, they will not reduce weight unless part of an energy-deficient diet. However, in obese subjects, when low glycemic carbohydrates are incorporated into a hypocaloric diet, there is a greater decrease in insulin resistance than can be accounted for by weight loss alone. Evidence from both animal and human studies demonstrates a change in body composition (decrease in fat but no change on overall weight) when exposed to a low glycemic index diet.

Pregnancy and Glycemic Index

Throughout pregnancy in well-nourished urbanized women consuming typical Western diets, glucose tolerance deteriorates. During pregnancy, African women living in traditional rural populations and consuming high-carbohydrate/low glycemic index diets do not invariably experience deterioration in their glucose tolerance. Clinical studies in the West show that women consuming similar high-carbohydrate/low glycemic index diets throughout pregnancy also have no deterioration of glucose tolerance despite the physiological increase in insulin resistance that occurs secondary to maternal and placental hormones. When the proportion of dietary carbohydrate increases above 50% in women with gestational diabetes, if no emphasis on low glycemic index carbohydrates is given, glucose tolerance will deteriorate.

Proposed Mechanism by which Dietary Carbohydrates/Glycemic Index Influence Insulin Resistance

Adipocyte metabolism is central to the pathogenesis of insulin resistance and dietary carbohydrates influence adipocyte function. The previous simplistic view that insulin resistance resulted from the down-regulation of the insulin receptors in response to hyperinsulinemia is being replaced by the hypothesis that high circulating NEFA levels both impair insulin action and reduce pancreatic β cell secretion. It is plausible that low glycemic index carbohydrates

reduce insulin resistance by their ability to reduce adipocyte NEFA release. There is evidence of a loss of suppression of hormone-sensitive lipase (HSL), an enzyme that breaks down triglyceride to free fatty acids and glycerol, to small physiological amounts of insulin and, to a lesser extent, insulin insensitivity of lipoprotein lipase. HSL is normally very sensitive to small increases in insulin levels and is totally suppressed at much lower concentrations than those required for glucose uptake. In insulin-resistant subjects, HSL is less sensitive to small changes in insulin levels and adipocyte NEFA release is increased. A relationship between increased adipocyte NEFA release and insulin resistance has been shown in subjects with coronary heart disease. The metabolic consequences of increased circulating NEFA are multiple and are beyond the scope of this review, but they include adverse lipoprotein and coagulation changes and have been reported to affect insulin secretion and have a lipotoxic effect on the β cell. Accumulation of triglyceride within the β cell also impairs insulin secretion.

Many of the metabolic benefits associated with low glycemic index carbohydrates can be attributed to their ability to reduce adipocyte NEFA release. Low glycemic index foods have been consistently shown to reduce insulin resistance, and animal studies have shown that improvements in fat and muscle insulin sensitivity are accompanied by decreases in fatty acid synthatase activity, adipocyte size, and lipid storage. Although human studies have shown that low glycemic index diets consumed for 3 weeks increase adipocyte insulin sensitivity, no direct effect on adipocyte metabolism has been identified.

Low glycemic index diets attenuate the insulin response for approximately 4 h postprandially. This slightly high postprandial insulin is insufficient to affect glucose transport but does suppress the insulin-sensitive enzyme, HSL, and thus ensures prolonged suppression of postprandial NEFA output. The ability of low glycemic carbohydrates to do this is in stark contrast with high glycemic diets that can cause an elevation of NEFA release postprandially by stimulating the counterregulatory hormones, as discussed previously. Low glycemic meals taken in the evening can effectively suppress circulating NEFA concentrations and hepatic glucose output throughout the night. These metabolic effects are predicted to promote insulin sensitivity.

Our own work has shown that insulin-resistant adults with a history or who are at risk of CHD improve their adipocyte insulin sensitivity after consuming a low glycemic index diet for 3 weeks and their circulating NEFA levels decline. These human studies complement animal work showing that low glycemic index diets improve insulin sensitivity by modulating adipocyte metabolism.

Conclusion

The glycemic index of a diet is an indicator of postprandial metabolism, which is important in contributing to cardiovascular risk. Dietary carbohydrates are absorbed and metabolized differently and therefore influence postprandial glucose, insulin, and NEFA concentrations differently. In Western society, the proportion of the day that we spend in the postprandial state is increasing as the tendency to snack throughout the day replaces sit-down meals. The known detrimental consequences of high glycemic foods and snacks on postprandial metabolism should encourage us to advocate low glycemic diets to counter the current epidemic of insulin resistance-related diseases, notably CVD and diabetes. The relevance of the glycemic index to these two major preventable diseases of the Western world argues strongly for its greater acceptance in current nutritional guidelines.

GOUT

L A Coleman, Marshfield Clinic Research Foundation, Marshfield, WI, USA
R Roubenoff, Millennium Pharmaceuticals, Inc., Cambridge, MA, USA and Tufts University, Boston, MA, USA

A diagnosis of gout refers to a group of metabolic conditions resulting from the deposition of monosodium urate crystals around and in the tissues of joints. The precise mechanism by which uric acid leads to gouty arthritis remains somewhat unclear; various contributing factors are discussed. Clinically, gout typically involves an episodic monoarthritis; if untreated, acute gout can segue into a deforming, chronic polyarthritis that may be difficult to distinguish from rheumatoid arthritis. Improved prevention and treatment of gout have occurred during the latter half of the twentieth century; however, recent research has focused on the link between serum urate, coronary artery disease, and insulin resistance syndrome. Dietary management of gout no longer seems to be focused on restriction of foods with a high purine content but, rather, on the treatment of metabolic disorders commonly associated with gout: obesity, insulin resistance syndrome, and dyslipidemia.

Definition and Etiology

Gout, from the Latin *gutta* or drop (of evil humor), is an ancient disease that was included in Hippocrates' Aphorisms. In the first edition of his textbook, *Principles and Practice of Medicine* (1892), Osler defined gout as "a nutritional disorder associated with an excess formation of uric acid." Today, we recognize that this definition is partly true, but that most cases of gout are not due to excess formation of uric acid but, rather, to insufficient clearance of the substance. Hyperuricemia occurs when there is too much uric acid in the blood, a condition that is generally agreed to exist when the serum or plasma uric acid exceeds the saturation point at 37 °C, which is approximately 7.0 mg dl^{-1}. Hyperuricemia is a requirement for gout, but it is not always present when a patient presents with a first episode of gout, presumably because the acute deposition of uric acid in a joint reduces blood levels transiently. However, hyperuricemia is present at some point in virtually all gout patients. It is important to distinguish hyperuricemia, an asymptomatic condition, from gout, a painful disease that afflicts only a minority of people with elevated uric acid levels. Hyperuricemia can result from overproduction of uric acid in 10–15% of cases (generally because of enzyme deficiency or overactivity) or from underexcretion of uric acid, which accounts for 85–90% of cases of gout (due to decreased renal clearance of uric acid, even in the setting of a normal glomerular filtration rate).

Chemical Pathology

Uric acid is a by-product of purine metabolism in humans and certain apes who lack uricase, the enzyme that breaks down uric acid (**Figure 1**).

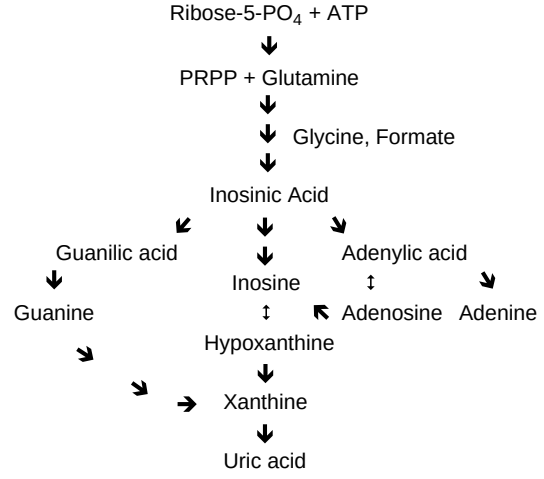

Figure 1 Simplified pathway of uric acid metabolism. PRPP, 5-phosphoribosyl-*l*-pyrophosphate. (Modified from Seegmiller JE, Rosenbloom FM and Kelly WN (1967) Enzyme defect associated with a sex-linked human neurological disorder and excessive purine synthesis. *Science* **155:** 1682–1684.)

When uric acid production is normal, and its clearance by the kidneys is normal, this metabolic quirk has no ill effects. However, this minor metabolic inconvenience becomes of pathological importance because uric acid is so poorly soluble in aqueous solutions that it can crystallize and cause the various conditions recognized as gout. Uric acid can be ingested directly in the diet (especially in organ meats such as liver, kidney, and sweetbreads), or it can be produced in the body by two pathways involved in purine metabolism (**Figure 1**). The de novo synthesis of uric acid proceeds directly from ribose-5-phosphate, whereas the salvage pathway consists of production of the uric acid precursors inosine from adenosine and xanthine from guanine. The medication allopurinol, which blocks the conversion of xanthine to uric acid by xanthine oxidase, is effective because xanthine is far more soluble in aqueous solutions than is uric acid.

The precise mechanism by which uric acid leads to gouty arthritis remains somewhat unclear. However, uric acid is known to be proinflammatory in that it can initiate an immune response with recruitment of white blood cells after uric acid crystals are phagocytosed by polymorphonuclear leukocytes or macrophages. These white blood cells also release tumor necrosis factor and interleukin-1, recruiting more white cells, which release lysosomal enzymes that lead to cartilage destruction and joint erosions with repeated attacks. In addition, ingestion of uric acid leads to death of the phagocytosing cells, leading to release of the uric acid and additional proteolytic enzymes, thus reinforcing the inflammatory condition. However, the crystals become progressively less phlogistic after several cycles of ingestion and release, and the inflammation relents over a period of 10–14 days. The natural history of untreated gout progresses through four stages from (i) asymptomatic hyperuricemia to (ii) acute gouty arthritis, (iii) intercritical gout, and (iv) chronic tophaceous gout. In addition, renal manifestations of gout develop in up to 50% of patients, depending on the amount of uric acid they excrete.

Prevalence and Risk Factors

Gout is the most common inflammatory arthritis in men; more than 2 million men and women in the United States are afflicted. The prevalence of gout in the United States tripled between 1969 and 1981 but recently seems to have stabilized. This increase is thought to be due to a combination of factors, including aging of the US population, increased prevalence of diuretic treatment of hypertension, better access to health care, and better diagnosis and reporting of gout. The incidence of gout (i.e., the development of new cases) is linked to serum uric acid levels, increasing from 0.9 cases per 1000 person-years for uric acid levels less than $7.0\,\mathrm{mg\,dl^{-1}}$ to 70 cases per 1000 person-years for levels higher than $10.0\,\mathrm{mg\,dl^{-1}}$. However, even in the highest category, only 30% of men developed gout during the 5 years after their uric acid level was determined, confirming that only a minority of hyperuricemic men develop acute gout.

Risk factors for acute gout other than hyperuricemia have been identified. All risk factors act either by increasing serum uric acid levels or by reducing the solubility of uric acid in the joints. For example, male sex, alcohol ingestion, obesity, and weight gain are associated with increased uric acid production, whereas diuretics (thiazides and loop diuretics), low-dose salicylates, and renal insufficiency lead to reduced clearance of uric acid. Hypertension has been associated with increased risk of gout, but this effect probably operates through renal insufficiency, which occurs as a result of hypertension and diuretic therapy. Lead, on the other hand, has been shown to directly reduce the solubility of uric acid in synovial fluid, whereas lead nephropathy also leads to reduced clearance of uric acid; the gout associated with lead toxicity is known as saturnine gout. Joint trauma and cooling of distal joints also reduce solubility of uric acid and increase the risk of an acute attack. Gout was known in the eighteenth century as 'pheasant hunter's toe' when aristocratic gentlemen developed *podagra* (acute inflammation of the first metatarsophalangeal (MTP) joint) after a day of hunting in the cold marshes and a night of drinking alcohol, especially sherry shipped in lead-lined casks. In more recent times, saturnine gout has been associated with drinking illegal 'moonshine' whiskey distilled through lead-lined stills. An independent association has been shown between kidney stone disease and gout, strongly suggesting that they share a common underlying pathophysiological mechanism.

Insulin resistance has been increasingly implicated in the pathogenesis of gout. The lipoprotein abnormalities described in subjects with hyperuricemia are similar to those found in individuals with insulin resistance, and insulin has an impact on renal urate excretion. Although the precise frequency of insulin resistance syndrome in patients with gout is not known, it is estimated to be as high as 76% for insulin resistance syndrome and 95% for hyperinsulinemia. It has been suggested that elevated serum urate may even serve as a surrogate marker for insulin resistance syndrome.

Clinical Features

Gout is typically an episodic monoarthritis, although polyarticular gout (involving three or more joints) occurs in approximately 10% of cases. The description of the pain of acute gout by Thomas Sydenham in the seventeenth century remains among the best:

> The victim goes to bed and sleeps in good health. About two o'clock in the morning he is awakened by a severe pain in the great toe; more rarely in the heel, ankle, or instep. This pain is like that of a dislocation ... then follow chills and a little fever. The pain ... becomes more intense. ... Now it is a violent stretching and tearing of the ligaments—now it is a gnawing pain and now a pressure and tightening. So exquisite and lively meanwhile is the feeling of the part affected, that it cannot bear the weight of the bed-clothes nor the jar of a person walking in the room. The night passes in torture.

More than half of patients present with podagra, and 75–90% of patients eventually develop podagra. This joint is thought to be most susceptible to gout because it is very prone to trauma and cooling, both of which reduce the solubility of uric acid. After the first MTP, acute gout most commonly involves the ankles, knees, instep, but it can also involve the wrists, elbows, and small joints of the hands and feet. Large axial joints, such as hips, shoulders, and vertebral joints, are rarely affected. Acute gout often involves a component of tenosynovitis (inflammation of tendon sheaths), and gouty cellulitis (sterile inflammation with urate crystals in the skin) and bursitis have also been described. As Sydenham stated, the onset is generally explosive, but many patients also describe a series of minor attacks leading up to the full-blown episode. Untreated gouty arthritis lasts from days to weeks, but minor bouts may resolve spontaneously in a few hours. At this stage, joint radiographs are normal except for soft tissue swelling. If untreated, acute gout can segue into a deforming, chronic polyarthritis that may be difficult to distinguish from rheumatoid arthritis.

Because a significant proportion of people, perhaps as many as one-third, who have a single acute gouty attack do not have another for 1 year or longer, no further therapy is indicated after the first attack has subsided. Once a patient has demonstrated recurrent attacks of acute gout, or if he or she has had a uric acid stone (or another type of stone in the setting of hyperuricosuria), treatment aimed at reducing serum uric acid below the point of solubility is indicated. In general, patients who develop a second attack and have a serum creatinine concentration less than 2.0 mg dl^{-1} should be evaluated further with a 24-h urine collection for creatinine clearance and uric acid output while consuming their regular diet. If the 24-h urinary uric acid totals more than 1000 mg, the patient is classified as an overproducer of uric acid and should be treated with allopurinol if he or she is not allergic. If the 24-h uric acid production is under 700 mg, then the patient is an underexcreter and may first be treated with a uricosuric agent, which is safer and less expensive than allopurinol. Renal insufficiency will reduce both creatinine clearance and urinary uric acid output, and allopurinol is the drug of choice in this situation, so the utility of a 24-h urine collection is reduced. Patients who produce between 700 and 1000 mg of uric acid are in a gray zone, and clinical judgment regarding optimal therapy is necessary, balancing issues of safety, cost, and convenience in the management of a chronic disease.

Chronic tophaceous gout occurs with an average of 10 years of untreated or inadequately treated gout. Over time, the acute attacks become less noticeable, and the patient develops a chronic, often deforming arthritis. This arthritis may mimic rheumatoid arthritis, although it should be less symmetric. At this time, the radiological hallmarks of gout, which include large, well-demarcated erosions in the absence of joint space narrowing ('rat-bite erosions'), are often visible. Tophi, which are subcutaneous deposits of uric acid, may be found in and around joints, bursae (especially the olecranon), tendons (Achilles and infrapatellar), and the extensor surfaces of the forearms. Less commonly, they may arise in the pinna of the ear, cardiac valves, cornea and sclera, and nasal cartilage. Needle aspiration or spontaneous rupture of tophi elicits a white, chalky material that is full of urate crystals under microscopy and is diagnostic of tophaceous gout. The presence of tophi is always an indication for allopurinol in nonallergic patients.

Dietary Management

There has been a substantial change in the predominant view regarding the relationship between diet and gout. It has even been said that "dietary considerations now play a minor role in the treatment of hyperuricemia, despite a fascinating history and abundant literature."

The relationship between gout and gluttony (overindulgence of food and alcohol) dates back to ancient times. In the fifth- century BC, Hippocrates attributed gout to dietary excesses of food and wine; he advised dietary restriction and reduction of alcohol consumption. Historically, the dietary management of gout has focused on two goals: (i) reducing the amount

of uric acid that may be deposited as crystals in joints or soft tissues, leading to the clinical syndrome of gout, and (ii) managing the disorders that occur with increased frequency among patients with gout, including diabetes mellitus, obesity, hyperlipidemia, hypertension, and atherosclerosis.

Although some practitioners may still advocate the traditional low-purine, low-protein, alcohol-restricted diet, there is increasing support for the more 'contemporary' view that dietary management should focus on weight reduction with a restricted intake of calories and carbohydrates along with proportional increases in both protein and unsaturated fats and no restriction of purine content.

Traditional Low-Purine Diet

The primary dietary modification that has traditionally been recommended to reduce uric acid production is a low-purine diet (<75 mg/24 h; **Table 1**). Uric acid is the end product of purine metabolism in humans, formed by oxidation of its precursors, the oxypurines, hypoxanthine and xanthine. With the advent of more powerful and effective urate-lowering drugs, however, dietary restriction of purine-rich foods is of decreasing importance. Although patients may be advised to avoid large quantities of food and alcoholic beverages that they know may precipitate a gouty attack (i.e., large amounts of organ meats or beer), a rigid purine-restricted diet is no longer viewed as a mainstay of dietary management.

Many patients with gout are overweight, and a combination of caloric reduction and exercise can have a beneficial impact on any associated hypertension, hyperlipidemia, and insulin resistance syndrome via enhanced renal excretion of urate and reduced serum urate levels. However, although weight reduction, purine restriction, and reduced alcohol consumption may transiently reduce serum urate, there are no long-term studies demonstrating the efficacy of such an approach. Any benefit that does occur is likely to be small, and any limited reduction in serum urate levels is likely to be offset by the difficulty of maintaining such an improvement over the long term.

Table 1 Foods to avoid on a purine-restricted diet

Meats, organ meats (sweetbreads, liver, kidney), fish, eggs, sausages, meat extracts and gravies
Beans, peas, spinach, asparagus, cauliflower, mushrooms
Oatmeal
Legumes
Chocolate
Yeast and yeast extracts
Tea, coffee, cola beverages, alcoholic beverages

Touger-Decker R (1996) Nutritional Care in Rheumatic Diseases. In: Mahan LK and Escott-Stumps S (eds.) *Krause's Food, Nutrition, & Diet Therapy*, 9th edn. pp. 889–898. Philadelphia, PA: W.B. Saunders Company.

Contemporary Low-Calorie, Carbohydrate-Restricted Diet

In view of the well-recognized link between insulin resistance syndrome, hyperuricemia, and gout, a diet emphasizing reduced calorie intake with moderate restriction of carbohydrates and liberalization of protein and unsaturated fat consumption has been espoused for patients with gout. Low-purine foods are often high in both carbohydrate and saturated fats; these foods tend to further decrease insulin sensitivity, thereby contributing to even higher levels of insulin, glucose, triglycerides, and low-density lipoprotein cholesterol and lower high-density lipoprotein cholesterol levels, all of which result in increased risk of coronary heart disease among these patients. Conversely, a calorie-restricted, weight-reduction diet that is low in carbohydrates (40% of total calories) and relatively high in protein (approximately 120 g per day compared to 80–90 g in the typical Western diet) and unsaturated fat content, with no limitation of purine content, has been studied and found to result in weight loss and reductions in serum urate, lipids, and gouty attacks. These benefits seem to relate to the coexistence of hyperlipidemia and glucose intolerance in patients with gout.

In summary, both the traditional and the contemporary approaches to dietary modification need to be studied over the long term, but it appears that the most benefit can be gained by focusing efforts on reducing calorie intake and carbohydrate consumption rather than on limiting the purine content of the diet. It appears that restriction of alcoholic beverages is advisable in the management of gout.

Prognosis

Gout is unusual among the rheumatic diseases in that its etiology, treatment, and prevention are well understood. Thus, the long-term sequelae of gout should be completely avoidable with adequate treatment, making the overall prognosis excellent. Noncompliance with medication, lack of access to adequate medical care, and inability to tolerate one or more of the medications used to treat gout can lead to a worse outcome. A number of dietary and lifestyle factors may contribute to the increased uric acid production among patients with gout. If these factors can be identified and appropriate changes made, the serum uric acid concentration may decline substantially. However, many patients require medication to control the hyperuricemia. The

predominant dietary approach to gout is that dietary advice, other than the restriction of overly excessive alcohol intake, is likely to be limited to weight reduction.

Introduction

Growth and development refers to the growth of the individual in size as determined by anthropometric measurements of body weight, length, circumference, and weight/length ratio, as well as changes in body composition. This article will focus on growth and development of the fetus, as most of the relevant concepts about growth and development apply to the fetal period of development and this period encompasses the greatest changes in body proportion and composition during the life of the individual. Fetal growth occurs by increases in cell number and size. In the first third of gestation, during the embryonic period, growth occurs primarily by increased cell number (hyperplasia); in the middle third of gestation, cell size also increases (hypertrophy), while the rate of cell division becomes stable. In the last third of gestation, the rate of cell division declines, while cell size continues to increase.

Many terms are used to describe variations in growth. For example, human newborns are classified as having normal birth weight (greater than 2500 g), low birth weight (less than 2500 g), very low birth weight (less than 1500 g), or extremely low birth weight (less than 1000 g). Obviously,

classification by weight alone says little about growth rate, as most infants with less than normal birth weights are the result of a shorter than normal gestation, i.e., they are preterm. Similarly, classifying newborns according to duration of gestation (e.g., preterm, term, or post-term) on the basis of birth weight also is erroneous, because infants with intrauterine growth restriction (IUGR) are smaller and macrosomic infants of diabetic mothers are larger than normal at any gestational age. Furthermore, it is inappropriate to label newborns as abnormally grown when their birth weight is less than some arbitrarily determined 'normal' birth weight, but their mother was quite small to begin with; such newborns are considered constitutionally small but not abnormal.

Spastics International Medical Publications (Clinics in Developmental Medicine No. 46), p. 17. London: William Heinemann Medical Books Ltd.)

Growth of Fetal Size

What should be considered more important for growth assessment than birth weight (at any gestational age) is the genetic growth potential of the infant, which may or may not be limited by maternal size. Under usual conditions, the fetus grows at its genetic potential. Small fetuses of small parents or large fetuses of large parents do not reflect fetal growth restriction or fetal overgrowth, respectively; in fact, their rates of growth are normal for their genome. If the mother is unusually small, however, she might limit fetal growth by 'maternal constraint,' which represents a limited uterine size (primarily endometrial surface area) and thus the capacity to support placental growth and nutrient supply to the fetus. A clear example of maternal constraint is shown in **Figure 1**, showing the reduced rate of fetal growth of multiple fetuses in a species, i.e., human, that optimally supports only one fetus.

Fetal weight tends to increase exponentially in the middle part of gestation, producing the typical S-shaped curve of fetal weight versus gestational age that is derived from cross-sectional measurements of newborn weights at different known gestational ages (**Figure 2**). The length of gestation is more strongly related to the growth of neural tissue (range 0.015–0.033 $g^{1/3}$/day – a 2.2-fold range) than to the growth of the fetal body (range 0.033 to 0.25 $g^{1/3}$/day – a 7.6-fold range). The physiological significance of this relationship is not known, but intrauterine development of a large brain/body mass ratio in humans is favored in a single fetus and is made possible by a slow rate of somatic growth.

Saunders.)

Developmental Change of Fetal Body Composition

Fetal growth during the last third of gestation requires large increases in nutrient supplies and

appropriate utilization of these nutrients. Nutrient substrate supply is coupled with increased development of anabolic hormones and growth factors in fetal tissues and fetal plasma to produce increased nitrogen and carbon deposition in protein, carbohydrate deposition in glycogen, and fatty acid, glycerol and triglyceride deposition in adipose tissue. Growth of these tissues gradually replaces water in the fetal extracellular space.

Chemical composition studies of normal human infants are limited. Based on data from 15 studies that included 207 infants, nonfat dry weight and nitrogen content (predictors of protein content) show a linear relationship with fetal weight and an exponential relationship with gestational age (**Figure 3**). As gestation proceeds, larger fetuses grow faster than smaller fetuses, and protein accretion follows accordingly.

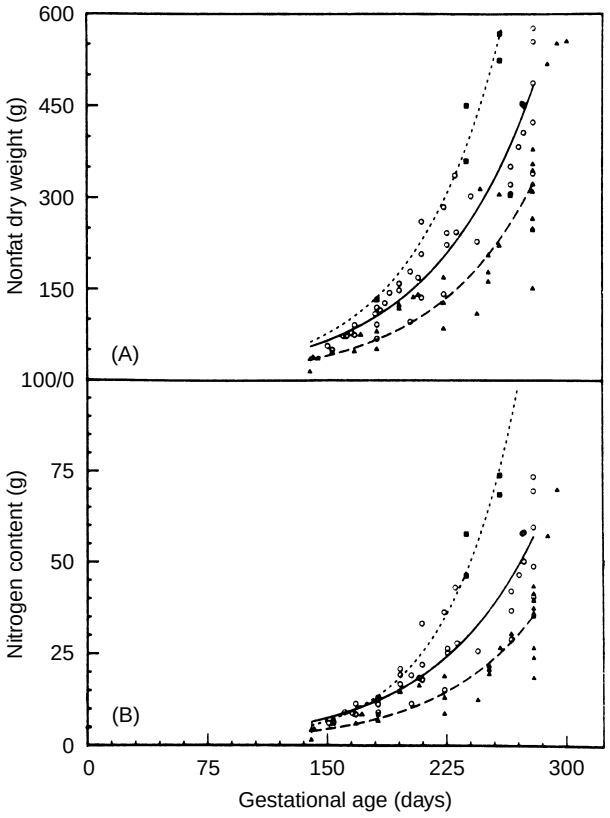

Figure 3 Nonfat dry weight (A) and nitrogen content (B) are plotted against gestational age for LGA (■, ····), AGA (O, —), and SGA (◆, – – –) infants. (Reproduced with permission from Sparks JW (1992) Intrauterine growth and nutrition. In: Polin RA and Fox WW (eds.) *Fetal and Neonatal Physiology*, p. 184. Philadelphia: W.B. Saunders.)

Water

Fetal water content increases directly with body weight, but not proportionally to body weight, as fetal body water, expressed as a fraction of body weight, decreases with advancing gestation. The relatively large growth of adipose tissue in the human fetus further dilutes the body concentration of water. Extracellular water, as a fraction of fetal body weight, also decreases more than intracellular water as gestation advances; this is mainly due to increasing cell number and increasing cell size, rather than the intracellular concentration of osmotic substances.

Nonfat dry weight

Comparative aspects of fetal chemical and physical growth in six species are summarized in **Table 1**. Despite growth rate variations up to 20-fold and weight-specific fat content variances at term up to 16-fold among these species, nonfat dry weight and protein weight-specific contents (as percentages of total weight at term) are constant. Protein concentration is about 12% in all species at term and fetal protein content is linearly related to fetal weight; thus, protein accretion in the fetal rat occurs about 23 times as fast as it does in the human. These species-related differences in growth rate are remarkable and require marked differences in the placental capacity to supply nutrients to the fetus.

Table 1 Growth characteristics and chemical composition at term of selected mammals and a representative human fetus

	Human	*Monkey*	*Sheep*	*Pig*	*Rabbit*	*Rat*
Gestation (days)	280	163	47	67	30	21.5
Number of fetuses	1	1	1	3–5	4–6	10–12
Growth rate ($g\,kg^{-1}\,day^{-1}$)	15	44	60	70	300	350
Fetal weight (g)	3500	500	4000	100	60	5
Dry weight (g/% body wt)	1050/30	125/25	760/19	25/25	9/15	0.2/4
Nonfat dry weight (g/% body wt)	490/14	–	640/16	14/14	–	–
Protein (g/% body wt)	420/12	–	480/12	12/12	7.2/12	0.6/12

Nitrogen Balance, Protein Turnover, and Protein Synthesis

According to animal data, only about 80% of the nitrogen content of the fetus is found in protein; the rest is found in urea, ammonia, and free amino acids. Additional nitrogen requirements for urea excretion and for other possible nitrogen excretion products are not known for human fetuses.

Radioactive and stable isotopic tracers of selected amino acids, especially essential amino acids such as leucine and lysine, have been used to measure fetal protein synthesis, breakdown, and accretion. Limited human data is consistent with data in the fetal sheep, the only species studied in significant detail. **Figure 4** shows results of experiments in fetal sheep over the second half of gestation, comparing fractional protein synthesis rates derived from tracer data and fractional body growth rates derived from body composition data. Whole body weight-specific protein turnover rate is higher in the early-gestation fetus primarily from increased rates of amino acid uptake from the placenta (exogenous entry of amino acids into the fetal circulation) and protein synthesis. These processes produce a 50% higher rate of net protein accretion in the mid-gestation fetus.

Mechanisms underlying the decrease in protein synthesis rate over gestation are not well understood, but they appear to be intrinsic to the fetus and not to a limitation of nutrient supply by the placenta. At least a partial explanation can be offered according to the changing proportion of body mass contributed by the major organs (**Table 2**). Based on the increased mass of skeletal muscle with advancing gestation, fetal whole body fractional synthesis rate should be lower, as skeletal muscle has a relatively lower fractional protein synthetic rate in late gestation than in earlier gestation. A direct relationship between anabolic growth-promoting substances acting as principal regulators of fetal protein synthesis rate, and thus fetal growth rate, cannot be made, however, as plasma concentrations or secretion rates of these substances increase in the fetus as gestation proceeds, while protein synthetic rates decline.

Glycogen

Many tissues in the fetus, including brain, liver, lung, heart, and skeletal muscle, produce glycogen over the second half of gestation. Liver glycogen content, which increases over the gestation period, is the most important store of carbohydrate for systemic glucose needs, because only the liver contains sufficient glucose-6-phosphatase for release of glucose into the circulation. Skeletal muscle glycogen content increases during late gestation and forms a ready source of glucose for glycolysis within the myocytes. Lung glycogen content decreases in late gestation with change in cell type, leading to loss of glycogen-containing alveolar epithelium, development of type II pneumocytes, and onset of surfactant production. Cardiac glycogen concentration decreases with gestation owing to cellular hypertrophy, but cardiac glycogen appears essential for postnatal cardiac energy metabolism and function. At term, fetal liver glycogen concentration in most species (80–120 $mg\,g^{-1}$) is at least twice the adult concentration, but in the relatively slow-growing human fetus, glycogen synthesis rates are low (about 2 $mg\,day^{-1}\,g^{-1}$), representing less than 2% of estimated whole body glucose utilization rate.

The principal source of fetal glycogen is glucose derived from placental transport of glucose from the mother. Smaller fractions come from lactate and amino acids such as glutamine. Glycogen content of the fetus and selected fetal organs is directly related to the maternal and thus fetal plasma glucose concentrations. Thus, macrosomic fetuses of diabetic mothers have very high body and organ contents of glycogen, while IUGR fetuses that result from sustained maternal hypoglycemia or placental insufficiency and decreased placental glucose supply to the fetus have markedly decreased glycogen contents.

Cortisol and glucose provide developmental regulation, while adrenaline (epinephrine) and glucagon provide acute and more variable regulation. Experimentally, cortisol infusion decreases glycogen content of the liver while deficiencies in hypothalamic-pituitary regulation of the adrenal gland leads to cortisol deficiency and glycogen deficiency. Insulin acts synergistically with glucose to increase hepatic glycogen stores. Glucose also acts independently to activate glycogen phosphorylase and glycogenolysis to keep hepatic glycogen content constant at higher glucose concentrations.

Fat

Fetal fat content as a fraction of fetal weight varies several fold among species (**Figure 5**). The fat content of newborns at term of almost all land mammals is 1–3% and is considerably less than that of the human (15–20%). Differences in body fat content among species are due primarily to the capacity of the placenta to transfer fat to the fetus and to the capacity of the fetus to synthesize triglycerides and fat. Even in those species that take up fat from the placenta and deposit fat in fetal tissues, the rate of fetal fatty acid oxidation is presumed low, because plasma concentrations of fatty acids (and keto acid products such as β-hydroxybutyrate and acetoacetate) are low, and because the carnitine palmitoyl transferase enzyme system is not sufficiently developed to deliver long-chain fatty acids to the respiration pathway inside the mitochondria.

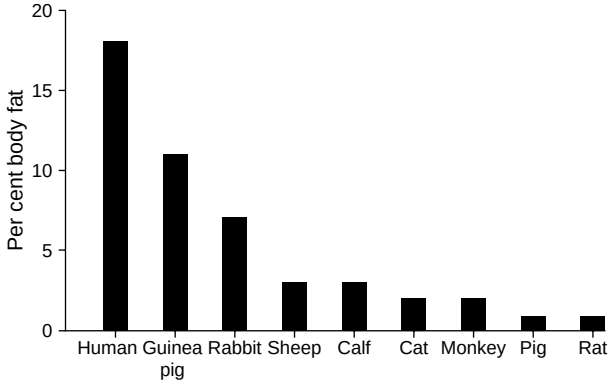

Figure 5 Fetal fat content at term as a per cent of fetal body weight among species. (Reproduced with permission from Hay WW Jr (1996) Nutrition and development of the fetus: carbohydrate and lipid metabolism. In: Walker WA and Watkins JB (eds.) *Nutrition in Pediatrics*, 2nd edn, p. 376. Hamilton: B. C. Decker.)

In the human fetus, calories produced by the complete oxidation of glucose and lactate can fully meet energy required for maintenance metabolism and for conversion of glucose and lactate to fatty acids. The portion of glucose converted into fat has been estimated to be $23\,\mathrm{kcal\,kg^{-1}\,day^{-1}}$. This would permit accumulation of $2.4\,\mathrm{g\,kg^{-1}\,day^{-1}}$ of fat. In the human fetus between 26 and 30 weeks' gestation, nonfat and fat components contribute equally to the carbon content of the fetal body. After that period, fat accumulation considerably exceeds that of the nonfat components. At 36 weeks' gestation, 1.9 g of fat accumulates for each gram of nonfat daily weight gain, and by term, the deposition of fat accounts for over 90% of the carbon accumulated by the fetus. The rate of fat accretion is approximately linear between 36 and 40 weeks' gestation, and by the end of gestation, fat accretion ranges from 1.6 to $3.4\,\mathrm{g\,kg^{-1}\,day^{-1}}$. At 28 weeks' gestation, it is slightly less and ranges between 1.0 and $1.8\,\mathrm{g\,kg^{-1}\,day^{-1}}$. By term, fat content of the human fetus is 15–20% of body weight, ranging from less than 10% in IUGR fetuses to 25% or more in macrosomic infants of diabetic mothers.

Energy Accretion in the Fetus

Fat has a high energy content ($9.5\,\mathrm{kcal\,g^{-1}}$) and a very high carbon content (approximately 78%). Thus, differences in fetal fat concentration among species lead to large differences in calculated energy accretion rates and carbon requirements of the fetal tissues for growth. The energy concentration of nonfat dry weight is fairly consistent across species and also within species at different developmental stages, indicating that the ratio of protein to nonprotein substrates in the tissues is relatively constant. Thus, energy accretion rate of any fetus can be estimated from the growth curve of the fetus in question and the changing fat and water concentrations.

Data for energy accretion and distribution in the human fetus are shown in **Table 3**. Because growth of fat and nonfat (protein plus other) tissues are metabolically linked through energy supply that is used for protein synthesis and the production of

Table 3 Calculation of the energy distribution in the term human infant

	Wet weight	*Fat*	*Nonfat wet weight*	*Nonfat dry weight*
Weight (g)	3450	386	3064	511
Total calories (kcal)	5950	3650	2300	2300
Energy concentration (kcal g^{-1})	1.73	9.45	0.75	4.5

anabolic hormones that promote positive protein, fat, and carbohydrate growth, restriction of nutrient supply is likely to produce growth deficits of all tissues, not just fat (i.e., growth retardation involves limitation of muscle growth as well as fat and glycogen). Indeed, chronic experimental selective energy (glucose) restriction in the fetal sheep leads to increased protein breakdown as well as to lower rates of fetal growth and lipid content. In contrast, as shown by the growth curves in **Figure 6** from human infants born prematurely at different times

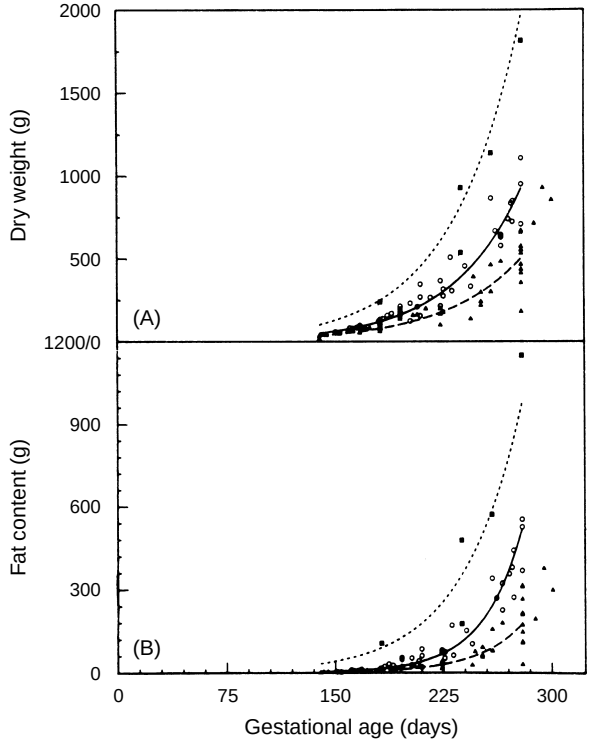

Figure 6 Dry weight (A) and fat content (B) plotted against gestational age in the same newborn human infants shown in **Figure 3** for LGA (■, ····), AGA (O, —), and SGA (◆, – – –) infants. (Reproduced with permission from Sparks JW (1992) Intrauterine growth and nutrition. In: Polin RA and Fox WW (eds.) *Fetal and Neonatal Physiology*, p. 184. Philadelphia: W. B. Saunders.)

over the last third of gestation, there is a bias towards thinner, SGA infants with less fat relative to nonfat weight and nitrogen content, raising the possibility that in a species that does lay down considerable fetal fat during late gestation, differences in intrauterine growth rate may reflect fat deposition more than the growth of nonfat, protein-containing tissues.

Mineral Accretion in the Fetus

Fetal calcium content is best correlated with fetal body length; this is true for both AGA and SGA infants. Using this index, fetal calcium content increases exponentially with a linear increase in length. Using this estimate, the human fetal rate of calcium accretion is about 85 mg kg^{-1} day^{-1}. Accretion of other minerals varies more directly with body weight, and according to the distribution of the minerals into extracellular (e.g., sodium) or intracellular (e.g., potassium) spaces.

Regulation of Fetal Growth

Fetal growth is the result of interaction among maternal, placental, and fetal factors, representing a mix of genetic mechanisms and environmental influences through which the genetic factors are expressed and modulated. The single most important environmental influence that affects fetal growth is the nutrition of the fetus. Nutrient supply to the fetus and the resulting increases in fetal tissue and plasma concentrations of anabolic hormones and growth factors are regulated by maternal health, maternal nutrition, uterine growth (including uterine blood flow and endometrial surface area), and placental growth and function.

Genetic Factors

Many genes contribute to fetal growth and birth weight of the normal term fetus. Maternal genotype is more important than fetal genotype in the overall regulation of fetal growth. **Table 4** presents estimates of the quantitative contribution of fetal and parental factors to fetal growth and birth weight at term. The more modest regulation by the paternal genotype, acting through the fetal genotype, is essential for trophoblast development. In fact, overexpression of the paternal genotype can produce trophoblast tumors. More specific gene targeting studies have shown the importance of genomic imprinting on fetal growth. For example, in mice normal fetal and placental growth require that the IGF_2 gene be paternal and the IGF_2 receptor gene be maternal, and paternal disomy producing IGF_2 gene overexpression results in fetal overgrowth while

maternal disomy producing IGF_2 underexpression results in fetal dwarfism. In humans, isopaternal inheritance of IGF_2 alleles is associated with the Beckwith-Wiedemann syndrome, which includes hyperinsulinism and fetal macrosomia.

Nongenetic Maternal Factors

There is a high correlation between birth weights of siblings that extends to cousins. The nongenetic, maternal nature of this effect is demonstrated by embryo transfer and cross-breeding experiments. For example, a small-breed embryo transplanted into a large-breed uterus will grow larger than a small-breed embryo remaining in a small-breed uterus. Furthermore, partial reduction in fetal number in a polytocous species such as the rat produces greater than normal birth weights in the remaining offspring. Conversely, embryo-transfer of a large-breed into a small-breed uterus will result in a newborn that is smaller than in its natural large-breed environment. Such evidence demonstrates that fetal growth is normally constrained, and that this constraint comes from the maternal environment. This is a physiological process and includes the maternal-specific capacity of uterine size, placental implantation surface area of the uterus, and uterine circulation, which together support the growth of the placenta and its function.

Maternal Nutrition

Normal variations in maternal nutrition have relatively little effect on fetal growth, because they do not markedly alter maternal plasma concentrations of nutrient substrates or the rate of uterine blood flow, the principal determinants of nutrient substrate delivery to and transport by the placenta. Human epidemiological data from conditions of prolonged starvation, as well as nutritional deprivation in experimental animals, indicate that even severe limitations in maternal nutrition only limit fetal growth by 10–20%. Restriction of caloric and protein intakes to less than 50% of normal for a considerable portion of gestation are needed before marked reductions in fetal growth are observed; such severe conditions often result in fetal loss before the impact on late gestation fetal growth rate and fetal size at birth are manifested. Similarly, fetal macrosomia is only common in pregnancies complicated by gestational diabetes mellitus in which maternal plasma hyperglycemia and hypertriglyceridemia, plus fetal hyperinsulinemia, combine to produce excessive fetal adiposity.

The Placenta

The placenta exerts strong control over fetal growth by providing nutrients directly or in metabolically altered form and amount. Naturally and experimentally, placental growth precedes fetal growth, and failure of placental growth is directly associated with decreased fetal growth. There is considerable variation in this control. For example, experiments in sheep that limited placental growth did not result in proportionately reduced fetal weight, indicating that either the capacity of the smaller placenta to transport nutrients to the fetus increased adaptively, or that the fetus developed increased capacity to extract nutrients from the placenta and direct those nutrients to growth. More characteristically, though, limitation in placental function to transfer nutrients to the fetus directly limits fetal growth. In fact, fetal growth retardation is seen as a natural and reproductively successful (though not perfect) adaptation to nutrient limitation. There is a direct relationship between fetal weight and placental weight in humans, indicating that placental size and fetal size are directly interrelated, although functional interrelationships between placenta and fetus also are important to fetal growth and development.

Maternal Endocrine Influences on Fetal Growth

Changes in maternal circulating growth hormone and growth hormone-like peptides such as placental lactogen, which increase during pregnancy, have combined effects that induce maternal insulin resistance and lead to higher circulating concentrations of glucose and lipids. These in turn are transported in increased amounts to the fetus where, combined with their stimulatory effects on fetal insulin and IGF_1 and IGF_2, promote fetal adiposity (or macrosomia, as in the infant of the diabetic mother) and

limit fetal protein breakdown, both of which promote fetal growth.

Influence of Fetal Endocrine and Autocrine/Paracrine-Acting Growth Factors on Fetal Growth

Growth hormone, which classically acts as the major regulator of postnatal growth, has no demonstrable influence on fetal growth. Fetal insulin does regulate fetal growth, although the complete absence of insulin does not abolish fetal growth. In sheep, for example, fetal pancreatectomy in late gestation limits fetal growth rate only by 20–30%, and pancreatic agenesis in humans produces IUGR fetuses who are 30–50% less than normal weight near term. Insulin infusions into the fetus and excessive fetal insulin secretion enhance fetal glucose utilization and produce increased adiposity, but only a 10–15% increase in fetal nonfat growth. Such hyperinsulinemic conditions also limit protein breakdown, which leads to increased protein accretion, although by limiting protein breakdown, as well as by enhancing amino acid synthesis into proteins, insulin actually decreases plasma concentrations of amino acids, thereby limiting protein synthesis at the same time. Therefore, it is not clear how increased fetal insulin enhances, or its deficiency limits, protein accretion. The primary action of fetal insulin may be to promote glucose utilization and, in turn, enhance protein accretion by providing more energy substrate to fuel protein synthesis and to substitute glucose carbon for amino acids to fuel oxidative metabolism. For example, removal of insulin from the fetus increases fetal glucose concentration and the transfer of glucose from mother to fetus via the placenta, which reduces net fetal carbon accretion. Insulin also directly activates proteins in its signal transduction pathway, promoting the incorporation of amino acids into protein synthesis, and by activation of the MAP-kinase pathway; this occurs even when glucose utilization and oxidation rates are limited by reduction of glucose supply.

Interaction of amino acids with insulin also regulates amino acid synthesis into proteins. Recent studies in the fetal sheep have shown that amino acid infusion, independent of insulin, increases the skeletal muscle concentration of mTOR and elF4E, the key regulatory proteins for ribosomal synthesis of amino acids into protein. In contrast, increases in phosphorylated mTOR and 4EBP1 were only demonstrated when insulin concentrations were also elevated. These observations indicate that amino acids can independently upregulate particular signal transduction proteins during late gestation fetal growth, and emphasize, as does the data showing insulin activation of the MAP-kinase pathway, that nutrient–hormone interaction is central to regulation of growth.

Both IGF_1 and IGF_2 regulate fetal growth. Mice lacking the IGF_1 gene have markedly reduced rates of fetal growth in late gestation. IGF_2 knockouts also have delayed fetal growth that is more pronounced in early to mid-gestation. IGF_1 receptor knockout mice are more growth retarded than either IGF_1 or IGF_2 knockouts alone. These IGF_1 receptor knockouts are growth restricted to the same extent as mice in which both IGF_1 and IGF_2 genes are deleted, confirming that receptor activation is the principal growth-regulating step in IGF_1 and IGF_2 action. Infusions of IGF_1 into fetal sheep demonstrate limited insulin-like effects on fetal glucose metabolism, but they do limit fetal protein breakdown, particularly when sustained hypoglycemia is present in the presence of increased proteolysis. IGFs also regulate fetal growth by regulating placental growth. IGF_2 gene knockout mice have small placentas and, in turn, lower IGF_1 and IGF_2 binding proteins. IGF binding proteins modulate effects of IGF_1 and IGF_2 on fetal growth. Circulating IGF_2 receptors limit IGF_2 effects by binding most of it in the circulation. IGFBP-1 and -2 levels are relatively high in fetal plasma, perhaps limiting the effectiveness of IGF_1, while IGFBP-3 is low in the plasma of fetuses with IUGR, perhaps due to simultaneous insulin deficiency.

Interpretation of Growth Curves

Cross-sectional growth curves have been developed from anthropometric measurements in populations of infants born at different gestational ages. Such curves have been used to estimate whether growth of an individual fetus or preterm newborn is within or outside of the normal range of fetal growth, which is defined as between the 10th and 90th percentile, although what the curves actually show is simply how big a given fetus or newborn is relative to others at any given gestational age. Fetuses and newborn infants who are between the 10th and 90th percentiles for weight vs. gestational age are considered appropriate for gestational age (AGA), those who are less than the 10th percentile are considered small for gestational age (SGA), and those who are greater than the 90th percentile are considered large for gestational age (LGA). In general, SGA infants come from small parents (particularly the mother) and LGA infants come from large parents (again, particularly when the mother is big as well as the father).

Standard fetal and preterm neonatal growth curves represent the third trimester in humans. Each curve is based on local populations with variable composition of maternal age, parity, socioeconomic status, race, ethnic background, body size, degree of obesity or thinness, health, pregnancy-related problems, and nutrition, as well as the number of fetuses per mother, the number of infants included in the study, and how and how well measurements of body size and gestational age were made. Estimates of gestational age often are imprecise because of variable maternal postimplantation bleeding and irregular menses, onset and appearance of physical features of maturation in the infant, and interobserver assessments of an infant's developmental stage.

Mathematical analyses of various growth curves have been used to determine growth rates over relatively short gestational periods or at discrete gestational ages. The data used in the Lubchenco growth curves (**Figure 2**), for example, reflect a simple exponential function showing fetal weight increasing at about $15\,g\,kg^{-1}\,day^{-1}$ for average-sized infants; this rate will be lower for smaller infants and greater for the larger infants.

More recent growth curves have been developed from serial ultrasound measurements of fetal growth in normal pregnancies, providing continuous rather than cross-sectional growth patterns. The growth of a preterm infant is better correlated with serially determined fetal growth rates than with cross-sectional neonatal growth curves. Serial ultrasound measurements of fetal growth also more accurately determine how environmental factors can inhibit (for example, maternal undernutrition globally, or hypoglycemia specifically) or enhance (for example, maternal overnutrition globally or hyperglycemia specifically) growth.

Extremes of Growth and Development: Intrauterine Growth Restriction and Macrosomia

Newborn birth weights have been steadily increasing since the 1970s throughout much of the developed world, although in developed countries, this increase has been tempered by the increased number of preterm infants born as multiple births following *in vitro* fertilization procedures. However, the relative proportions of the two extremes of birth weight, very small infants with intrauterine growth restriction (IUGR) and those who are excessively large with macrosomia, remain constant, and within some populations are actually increasing.

Intrauterine Growth Restriction (IUGR)

In developed countries, 3–7% of newborns are classified as IUGR. These infants weigh less than two standard deviations below the mean of a population born at the same gestational age. Most of these infants experienced suboptimal nutrient supply, and consequently a restriction of fetal growth, as a result of some form of placental insufficiency. IUGR imposes increased risks of specific types of fetal and neonatal morbidity and mortality (**Table 5**).

Table 5 Risks of specific types of fetal and neonatal morbidity and mortality in IUGR infants

Problem	*Pathogenesis/pathophysiology*
Intrauterine death	Chronic hypoxia
	Placental insufficiency
	Growth failure
	Malformation
	Infection
	Infarction/abruption
	Pre-eclampsia
Asphyxia	Acute hypoxia/abruption
	Chronic hypoxia
	Placental insufficiency/pre-eclampsia
	Acidosis
	Glycogen depletion
Meconium aspiration	Hypoxia
Hypothermia	Cold stress
	Hypoxia
	Hypoglycemia
	Decreased fat stores
	Decreased subcutaneous insulation
	Increased surface area
	Catecholamine depletion
Persistent pulmonary hypertension	Chronic hypoxia
Hypoglycemia	Decreased hepatic/muscle glycogen
	Decreased alternative energy sources
	Heat loss
	Hypoxia
	Decreased gluconeogenesis
	Decreased counter-regulatory hormones
	Increased insulin sensitivity
Hyperglycemia	Low insulin secretion rate
	Excessive glucose delivery
	Increased catecholamine and glucagon effects
Polycythemia/ hyperviscosity	Chronic hypoxia
	Maternal–fetal transfusion
	Increased erythropoiesis
Gastrointestinal perforation	Focal ischemia
	Hypoperistalsis
Acute renal failure	Hypoxia/ischemia
Immunodeficiency	Malnutrition
	Congenital infection

From Anderson S, Hay WW, Jr. The small-for-gestational-age Infant. In: Avery GB, Fletcher MA, MacDonald MG (Eds), *Neonatology*: Pathophysiology and Management of the Newborn, 5th Edition. Lippincott-Raven, Philadelphia, pp. 411–444, 1999.

Possible adult disorders resulting from intrauterine growth restriction Interest in IUGR has been enhanced recently by retrospective epidemiological, clinical follow-up, and animal studies that indicate long-term consequences in adult life of IUGR offspring, including higher incidences of obesity, insulin resistance, impaired glucose tolerance, enhanced hepatic glucose production, pancreatic insulin secretion deficiency, type 2 diabetes mellitus, hypertriglyceridemia, and cardiovascular disease, particularly hypertension. These conditions, often called syndrome X or the metabolic syndrome, may represent an example of 'programing,' in which an insult, when applied at a critical or sensitive stage in development, produces lasting, even lifelong, effects on the structure or function of the organism. Mechanisms responsible for these later-life morbidities are not yet established. There is some evidence of diminished pancreatic growth and development, which might become manifest in later life as pancreatic insufficiency when the adult starts and then continues eating a diet rich in simple carbohydrates and lipids. Peripheral insulin resistance may develop in the same way, and hypertension in adulthood may be the result of restricted renal and adrenal development. A common theme among these observations is that excessive weight gain starting at any weight percentile is the strongest predictor of syndrome X or metabolic syndrome disorders.

Macrosomia

At the other end of the birth weight spectrum are macrosomic or large-for-gestational age (LGA) infants. These infants were exposed to excess nutrient supply *in utero*, principally carbohydrates and lipids. Macrosomic newborns have increased specific morbidities primarily associated with metabolic complications of maternal diabetes mellitus during pregnancy and associated birth complications and birth injuries as a result of excessive fetal size.

Macrosomia is defined in a newborn as a birth weight more than two standard deviations above the mean percentile for gestational age or a birth weight greater than 4000 g at term. Neonatal macrosomia has a strong ethnic predisposition affecting up to 50% of Latino and Native American pregnant women versus 19% of African-American pregnant women. Macrosomia is characteristic of infants of diabetic mothers (IDMs) who were hyperglycemic during pregnancy. The diabetes can be long standing, but the most common group producing macrosomic infants are women with gestational diabetes mellitus (GDM), which complicates 3–5% of all pregnancies. The risk of macrosomia is not consistent a cross all classes of diabetes; it primarily reflects the degree and duration of maternal hyperglycemia and hypertriglyceridemia and particularly high spikes of these conditions following meals that are more common in gestational diabetes. The hyperglycemia results in fetal hyperglycemia and hyperinsulinemia, while the hypertriglyceridemia contributes to the effect of the excess glucose and insulin to produce excess fat deposition.

Development of type 2 diabetes in later life in macrosomic offspring IDMs, particularly those with macrosomia, have increased risk of developing type 2 diabetes earlier in life. Mechanisms responsible for this sequence of events include insulin resistance and insufficient insulin secretion (β-cell dysfunction) in response to hyperglycemia. Typically, glucose intolerance from obesity and increased insulin resistance progresses to fasting hyperglycemia and the inability of β-cells to compensate by increasing insulin secretion. This form of β-cell failure appears to be reversible over short periods by improved glycemic control, but long-term exposure to hyperglycemia can lead to β-cell exhaustion and specific inhibition of insulin secretion, which are irreversible by glycemic normalization. The insulin resistance also extends to the liver where glucose production increases. This triad of insulin resistance, reduced β-cell insulin secretion, and increased hepatic glucose production results in type 2 diabetes.

GROWTH MONITORING

T J Cole, Institute of Child Health, London, UK

Growth is the single quality that most clearly distinguishes between children and adults—children grow, whereas adults do not. This in turn means that healthy children grow well and ill children often grow poorly. For this reason, the monitoring of growth is a logical and effective procedure for detecting child ill health—not just specific growth disorders but also more general conditions that affect growth indirectly.

A Cochrane Review on growth monitoring defined it as "the regular recording of a child's weight, coupled with some specified remedial actions if the weight is abnormal in some way." So the key elements are one or more measurements of weight, plus a protocol for recording, plotting, and interpreting the measurements, leading in suitable cases to some intervention.

The primary purpose of growth monitoring is to detect and treat illness in the individual child. The reasonable question asked by the Cochrane Review is "Does it work?" The Review found only two randomised clinical trials measuring the impact of growth monitoring, and they differed in their conclusions. One found that infants whose growth was monitored for 30 months were no healthier than age-matched controls, whereas the other showed that mothers trained to use a growth chart were more knowledgeable after 4 months. So there is little research on the subject, and even less evidence to justify its use, which is surprising given the enormous resources devoted each year to growth monitoring throughout the industrialized and developing worlds.

A possible reason for this lack of evidence is that growth monitoring is seen as intrinsically 'a good thing.' Parents are always interested to know how their children are growing, and the benefit to them of measuring the child regularly, although difficult to quantify, is assumed. So there is uncertainty as to exactly what growth monitoring is for and what outcome it might lead to.

Purpose and Outcome

The primary aim of growth monitoring is to improve child health by regular anthropometry (which literally means measurement of man and refers to body measures such as weight, height, and mid-upper arm circumference). However, the measurements are useful only if they are properly

recorded and interpreted and a suitable intervention is introduced when the child's growth is suboptimal.

It is important to target the purpose, measurement, and intervention to the environment in which they are used. In practice, this makes growth monitoring a very different proposition in the developing and industrialized worlds due to differences in the burden of disease, resources, and training.

The disease burden is much greater in the developing world, with diarrhea, malaria, respiratory infection, tuberculosis, and HIV all common. Here, effective growth monitoring can in principle save lives. In contrast, in the industrialized world such conditions are less common and milder, so the focus is more on growth disorders such as growth hormone deficiency or Turner's syndrome, where mortality is not the issue.

This different focus also affects the target age range when children are monitored. Mortality risk in the developing world is greatest during infancy, and it is increased by low birth weight. So poor early growth is a potent risk factor for infant mortality, and infancy is the period when growth monitoring is likely to be of greatest value. In contrast, the main concerns in the industrialized world are growth disorders that usually show themselves after infancy, although infant failure to thrive is also a concern. So in the developing world growth monitoring targets the preschool years, whereas in the industrialized world it covers all childhood up to and including puberty.

Throughout the world mothers are encouraged to take their infants to the clinic for regular anthropometry and immunizations. But in the developing world, where infants are much more likely to grow poorly, it makes economic sense to educate mothers, who have the greatest influence over their infant's environment, about the principles of growth monitoring. This education component is not stressed in the same way in the industrialized world.

Maternal education is thus a secondary aim of growth monitoring in the developing world. If growth monitoring makes mothers more aware of their child's state of health, then it should also have an impact on the child's health.

In addition to detecting disease and raising parental awareness at the individual level, growth monitoring in the sense of information gathering has potential benefits at the population level. It provides information about average child growth that is useful for comparison, policy, and planning. For example, a knowledge of mean height for age and weight for age in children from different regions is useful for identifying areas where the prevalence of malnutrition is highest, which in turn allows resources of emergency aid and support staff to be effectively targeted.

Growth monitoring also supports scientific research on the prevention and treatment of disorders affecting growth. Evidence-based child health relies on well-designed studies to test the impact of interventions on child health outcomes. Growth is a proxy for child health and is a common choice of outcome. So growth monitoring fits naturally into the framework of a randomized clinical trial, in which it is used to measure the impact of the intervention. This is different from the situation considered by the Cochrane Review, in which growth monitoring was the intervention. Strictly, the use of repeated anthropometry as an outcome should not be called growth monitoring because it omits the important final stage in which some intervention depends on it.

The Process of Growth Monitoring

The process of growth monitoring involves three stages: anthropometry, interpretation, and referral.

Anthropometry

In infancy, the most common routine measurement is weight. It is simple to do, the required equipment is reasonably cheap, and it provides a convenient global summary of the infant's size. Birth weight in particular is a useful proxy for fetal growth. An advantage of weight is that it relates closely to the mother's own perception of her child's size.

Infant length is more difficult to measure for several reasons. The optimal equipment is a length board with a sliding footboard, which is expensive and needs regular calibration. Simpler equipment such as a tape measure increases the measurement error dramatically. Most important, proper length measurement requires two trained observers—one to hold the infant's head against the headboard and the other to position the footboard and take the measurement. For these reasons, infant length is often measured either poorly or not at all.

Arm circumference (or mid-upper arm circumference (MUAC)) is a popular alternative to weight in the developing world but less so in the industrialized world. This is because arm circumference measurement can detect malnutrition using a simple cutoff. The equipment (a specially marked inextensible tape) is cheaper and easier to use than weighing scales, and arm circumference is highly correlated with weight.

In the industrialized world, head circumference measured in infancy can detect some rare conditions

such as hydrocephalus, which is indicated by a rapid increase in head circumference at approximately the time of birth.

Once past infancy, priorities change. Height becomes much more important, particularly in the industrialized world, where the emphasis is on detecting primary growth disorders such as growth hormone deficiency or Turner's syndrome. Children can be measured standing at approximately 2 years of age using a freestanding stadiometer with counterbalanced headboard. The child's head is positioned in the Frankfort plane (looking straight ahead with the line between the ear hole and eye horizontal), with the child's shoulders, buttocks, and heels touching the back plate, and the observer brings the headboard down gently and reads the height. Alternatively, a second observer can take the measurement while the first checks the child's position. Measurement technique is crucial for height, particularly when it is measured repeatedly. Height velocity is relatively low after infancy, so the height increment over a period of 6 months, for example, may be only 2 or 3 cm depending on age, which can result in excessive measurement error. A competent observer should be able to achieve a measurement error of less than 0.3 cm.

Weight and height are highly correlated, so their assessments are often similar: On average, a tall child is heavy and a short child is light. Once past infancy, weight can be more informative when expressed as an index of weight adjusted for height. There are many weight-for-height indices, but among the most common in the industrialized world is the body mass index, calculated as weight (measured in kilograms) divided by the square of height (in meters). It has been used in adults for decades (the index was originally proposed by Quetelet in the nineteenth century) but in children only relatively recently, and mainly in the area of child obesity. Note that it requires adjustment for age, in the same way as for weight and height. Other weight-for-height indices, used mainly in the developing world, adjust weight for height ignoring the child's age, which is an advantage when the age is not known. However, this leads to biases at certain ages, notably infancy and puberty, when a child's expected weight depends on their age as well as their height.

With the recent steep increase in the prevalence of child obesity, waist circumference has become useful as a measure of central body fatness. Body mass index is less useful because it does not distinguish between fat mass and muscle mass. A child may become fatter over time without becoming heavier simply by losing muscle mass (through inactivity) and gaining an equal mass of fat, as occurred in US adolescents during the 1980s. It is easier to measure waist circumference than skinfold thickness (e.g., triceps or subscapular skinfold), and the required equipment is also simpler—an inextensible tape as opposed to a skinfold caliper (the appearance of which often frightens parents and young children).

Table 1 The suitability of anthropometry for growth monitoring at different ages[a]

Anthropometry	*Infancy*	*Preschool*	*Childhood and adolescence*

Length/height	*	***	***
Body mass index	*	***	***
Arm circumference	**	*	*
Head circumference	***	*	*
Waist circumference	*	***	***

[a]More asterisks indicate better suitability.

Table 1 summarizes the value of anthropometry at various stages of childhood, as described previously. The process of anthropometry requires attention to detail: suitable equipment that is regularly maintained and calibrated; observers who are trained in correct measurement technique; and regular quality control sessions in which observers are checked, against both themselves and each other, for measurement precision and accuracy. Only in this way can accuracy and precision be maintained.

Plotting and Chart Interpretation

The second stage of growth monitoring involves interpreting the anthropometry. The growing child increases in size over time, so the way to assess the child's growth is by comparison with a set of age-specific norms, usually in the form of a growth chart. This involves plotting the child's measurement on the chart and then interpreting it in the context of any previous measurements. First, growth charts and how they are constructed are discussed.

Growth Chart Construction

Charts to Measure Size

A growth chart summarizes the distribution of the measurement (e.g., weight) as it changes with age in some prespecified reference population (e.g., British children measured in 1990). At its simplest, the chart consists of the median curve, a smooth curve connecting median weight for the population at different ages. Usually, however, there are curves for other distribution centiles as well,

extending typically from the 3rd to the 97th centile, to give an idea of the spread of measurements at each age. A centile corresponds to a given percentage (between 0 and 100) and is a measurement below which that percentage of children in the reference population will be found. For example, in the British 1990 boys weight reference, median (or 50th centile) weight at 1 year is 10.1 kg, whereas the 3rd and 97th centiles are respectively 8.3 and 12.3 kg. Therefore, 50% of British boys aged 1 year weigh less than 10.1 kg, whereas 3% weigh less than 8.3 kg and 97% weigh less (and 3% weigh more) than 12.3 kg.

The lowest centile curve on the chart is often used as a cutoff to detect poor growth. Children with measurements falling below this centile are viewed as 'at risk' and may be referred for more detailed examination. **Figure 1** shows the British weight reference for boys in infancy, which has nine centile curves ranging from the 0.4th at the bottom to the 99.6th centile at the top. The value of these more extreme centiles for screening is explained later.

Using a centile curve as the cutoff on the chart is just one approach to identifying at-risk children. In the developing world, where the concept of centiles can be difficult to explain, a simpler alternative is 'percent of the median.' Here, the cutoff is constructed as a curve that is, for example, 80% of the median weight curve, which is broadly similar in shape to the 3rd centile curve. A child whose weight falls below the cutoff is said to be below 80% weight for age.

Another approach to defining cutoffs involves standard deviation (SD) scores, also called *z* scores. These are linked to centiles through the underlying frequency distribution, in particular the SD of the measurement at each age. With a normal distribution, the median and mean coincide and the SD

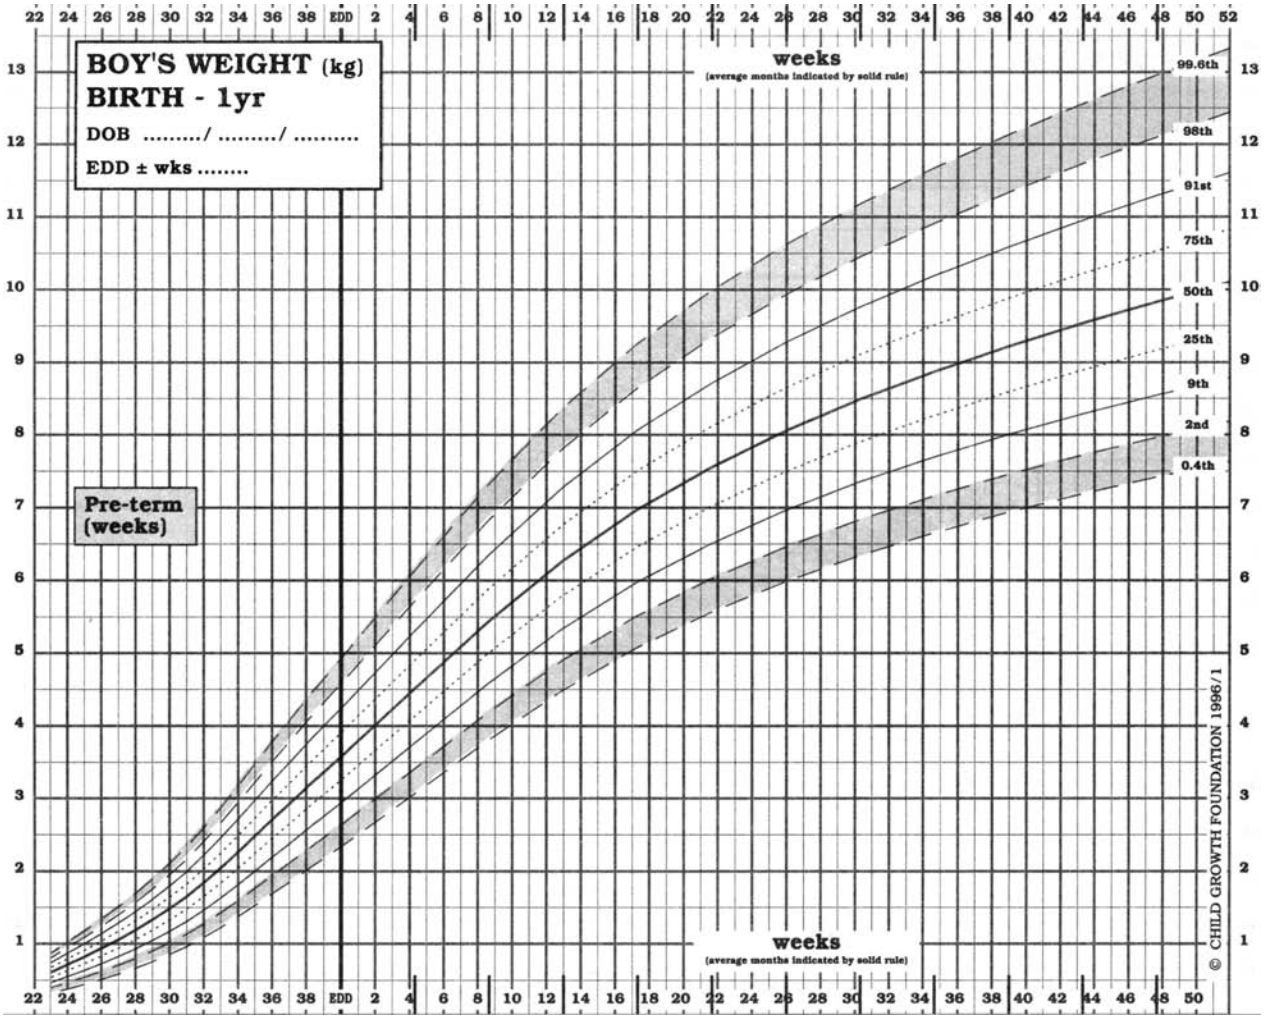

Figure 1 The British 1990 boys infant weight chart, covering 22 weeks of gestation to 12 months. The nine centiles range from the 0.4th to the 99.6th, and infants whose weights fall outside the extreme centiles are referred. (© Child Growth Foundation.)

score is 0. The 2nd centile is approximately 2 SDs below the median at all ages, whereas the 75th centile is 1.3 SDs above the median. Therefore, the 2nd centile corresponds to an SD score of −2 and the 75th centile to +1.3.

Height is normally distributed, but much anthropometry including weight is not—it has a skew distribution. The link between centiles and SD scores can be extended to measurements that are not normally distributed using a technique called the LMS method, which is the basis for many growth reference charts. The telltale sign of a skewness-adjusted chart is that the centile curves are asymmetrically spaced at each age; for example, the gap between the 25th and 50th centile curves is less than the 50th–75th centile gap.

The British growth reference centiles (**Figure 1**) are defined by their corresponding SD scores. The centiles are spaced two-thirds of an SD score apart, so the 0.4th centile corresponds to −2.67 SD scores. Similarly, the WHO chart spaces its centiles 1 SD score apart, from −3 to +3, which allows it to cover the wide range of anthropometry seen internationally.

Charts for use in the developing world tend to be simpler in design, often with only two or three centile curves. They highlight a region on the chart where children's individual growth curves should lie, and mothers are taught that children with curves within this region are healthy children. One common chart is the Road to Health chart (**Figure 2**). The advantage of the chart is that it can also include public health information about the timing of breast feeding, immunizations, etc.

The most difficult part of the measurement process is plotting the data accurately. For use in the developing world, the Direct Reading scale is a clever device that links the weighing scale to the chart so that as the child is weighed a pen records the scale deflection on the chart. This and the Road to Health chart can be obtained via Teaching Aids at Low Cost (TALC).

Another direct-reading chart is the Nabarro height-for-weight wall chart (also available through TALC). The child is first weighed, and then he or she stands against the chart at the point corresponding to his or her weight. The chart consists of

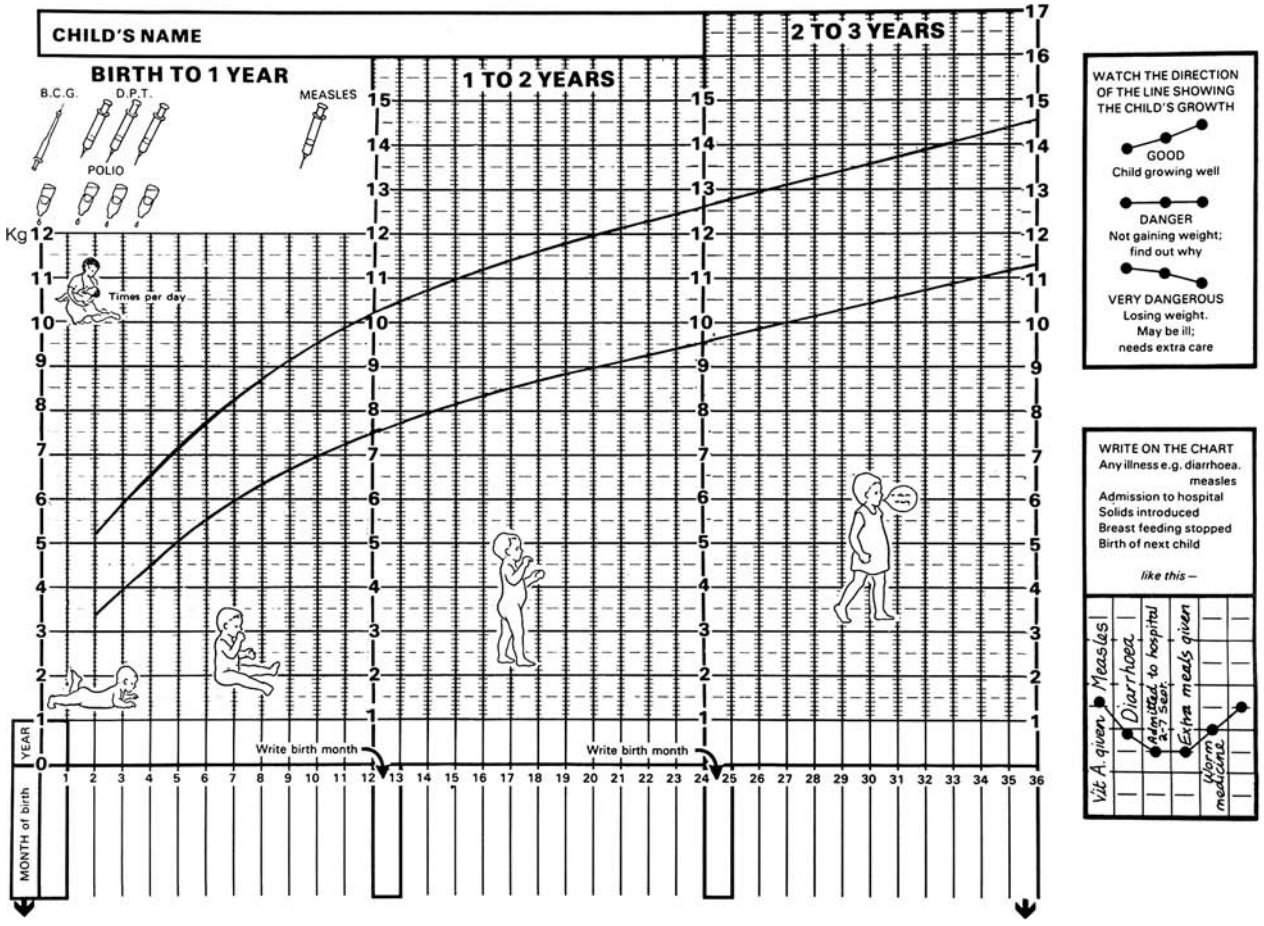

Figure 2 The TALC Road to Health chart. (Reproduced by kind permission of Teaching-Aids at Low Cost.)

vertical bars, and the height of the relevant bar is compared to the child's height. If the child is thin, he or she will be taller than other children of the same weight, and the upper section of the bar is color coded in red to flag excessive thinness, also known as wasting.

Familial Height Adjustment

Child height is strongly correlated with parental height, so many short children have short parents. Short children from tall families are easier to detect if their height is adjusted for midparent height. Tanner published a chart to do perform this adjustment in 1970, but it proved cumbersome to use, and currently the target height method is preferred. This method uses midparent height to estimate the child's likely height centile as an adult and compares it with the child's current centile.

However, the target height approach is also cumbersome and relies on the heights of both parents, one of which may not be available. A familial height chart has been described that compares the child's current height centile with that of his or her mother and/or father and/or sibling(s). The advantages of the chart are that it uses all the available familial height information (a sibling is as close genetically as a parent), it avoids all calculations (apart from reading the centiles off the height chart), and it adjusts for the secular trend in height by using an older height reference for the parents.

Ethnicity

A growth chart reflects the size and growth of its reference population. When the target population is materially different in size, as happens with ethnic minorities in the industrialized world (e.g., Hispanics in the United States or Asians in the United Kingdom), the chart's centiles can be misleading. More than 3% of such children may be found below the 3rd height centile, and the relevant cutoff for referral should take ethnicity into account. One simple way to do this is to estimate an offset, measured in SD score units, to apply to the chart for a given ethnic minority group. For example, Southeast Asian children in the United Kingdom are approximately 0.4 SDs shorter than ethnic Caucasians, corresponding to approximately half a channel width on the chart, the distance between adjacent centiles.

The differences in height between ethnic groups can be explained partly by genetics (i.e., differences in parental height) and partly by differences in the environment. However, the parental height differences reflect the environment of previous generations, so it is not feasible to ascribe the differences purely to genes or the environment—the two are inextricably linked. If the child's height is appropriate for the heights of his or her parents, this should provide reassurance.

Charts to Measure Growth

Growth charts are usually constructed using cross-sectional data—each reference child contributes a single measurement to the data set. This allows children in each age group to be ranked by size to identify the required centiles, which can then be plotted against age. James Tanner coined the term "distance to indicate size attained," meaning the distance the child has travelled on the journey from conceptus to adult.

Growth is the rate of change of size, or velocity in Tanner's notation. To measure growth in an individual child requires at least two measurements separated in time. However, the growth chart is based on cross-sectional data, which provide no information about growth. This is an irony of the conventional growth chart: It is designed to measure size, not growth. It flags poor growth when the child's growth curve rises more slowly than the centile curve, but it does not distinguish between mild and severe faltering. The chart effectively has only three growth categories: normal (i.e., tracking along centiles as recommended by the Road to Health chart), above average growth (i.e., crossing centile curves upwards), and below average growth or crossing centiles downwards. Within the latter two categories, the chart does not grade the rate of centile crossing.

Tanner introduced notation to distinguish between distance or size charts, on the one hand, and velocity or growth charts, on the other hand. Velocity charts display centiles of growth velocity by age, and probably the most useful such chart is for height velocity measured over 1 year. In theory, velocity is better than distance for detecting short-term growth faltering, but in practice it is more difficult to measure because it involves two measurement errors, not one. It is also more complicated to monitor because the process of charting velocity involves taking the two measurements, calculating the velocity in units of cm/year or kg/year, and then plotting it at the mid-age point on the velocity chart.

Other forms of charts have been described that provide more information about growth velocity. Thrive lines are extra lines superimposed on the centile chart to quantify the rate of centile crossing of weight in infancy. Infants with monthly weight measurements who are growing on the 5th velocity centile

track along the thrive lines. If they track in this way for 1 month it is a sign of moderate weight faltering, but if it continues then the faltering is progressively more severe. The thrive lines take into account the child's age and sex and adjust for regression to the mean. **Figure 3** illustrates the thrive lines superimposed on the weight chart of **Figure 1**. An infant measured twice 4 weeks apart whose weight curve tracks along the thrive lines (i.e., crosses centiles downwards) is growing on the 5th velocity centile, indicating moderate weight faltering.

Wright designed a weight monitoring chart in which the centile curves are spaced according to the infant's chance of crossing them in a given period of time. Large infants tend to cross centiles downwards more rapidly than small infants—this is a consequence of regression to the mean. Therefore, the centiles are relatively widely spaced at the top end and become progressively closer together at lower centiles. The chart is designed to simplify the assessment of infants recovering from failure to thrive.

Interpretation

The choice of charts for growth monitoring is bewildering—size charts, growth charts, and parental adjustment, each with many different cutoffs. In the industrialized world, the aim is to detect growth disorders as early as possible, and the key question is "Which form of growth monitoring is most effective at detecting disease?"

A common view is that growth monitoring requires measurements on two or more occasions, whereas growth screening involves a single measurement, and monitoring is therefore better than screening. Indeed, this is a fundamental tenet of growth monitoring as practiced in the developing world. Yet there is no direct evidence either way.

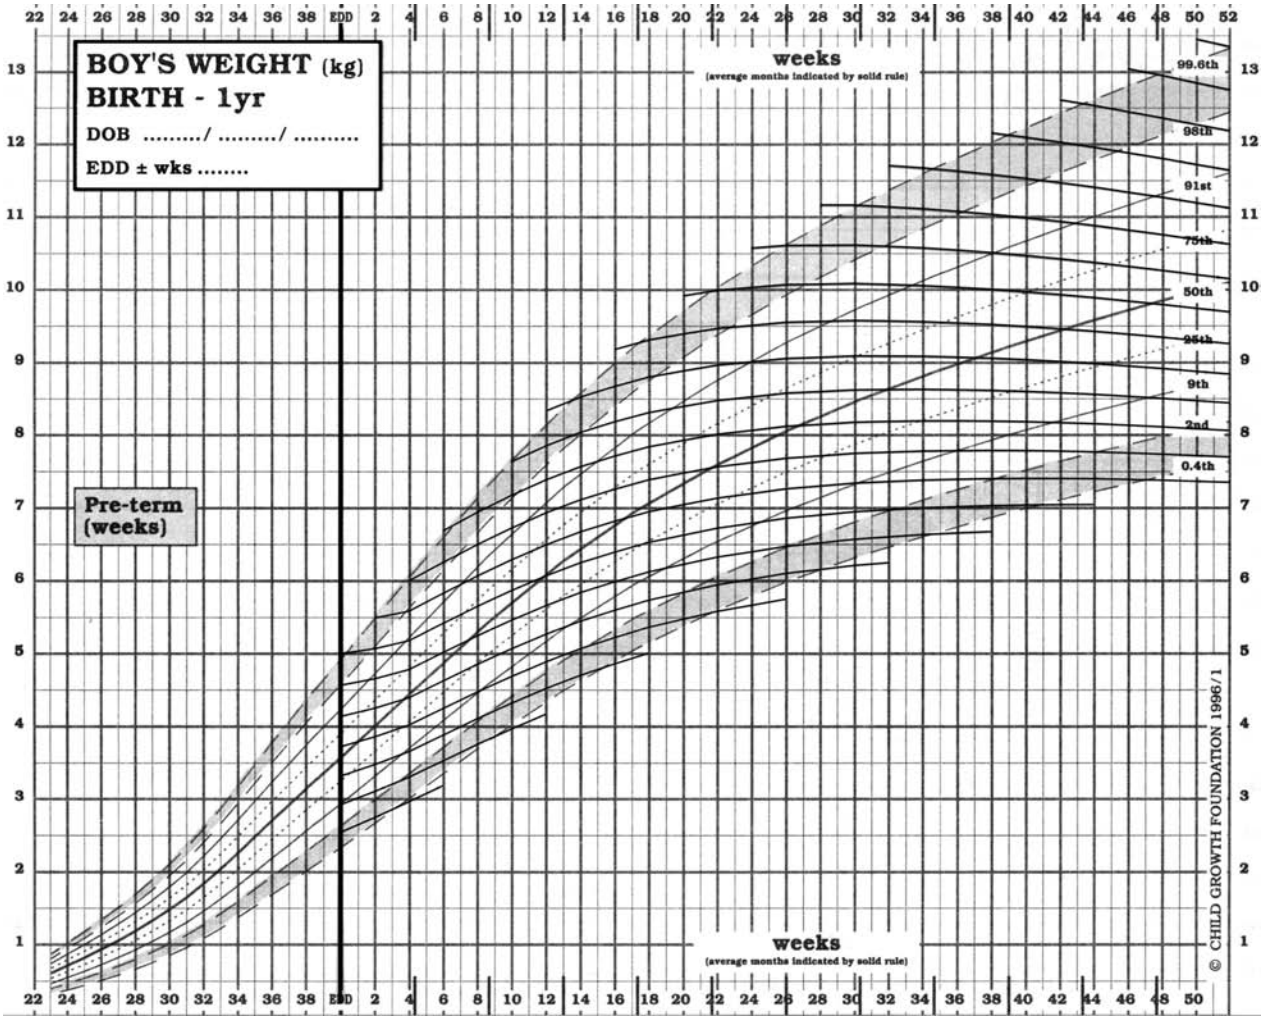

Figure 3 The British 1990 boys infant weight chart with thrive lines superimposed. The thrive lines represent downwards centile crossing corresponding to the 5th velocity centile, i.e., moderate weight faltering. (© Child Growth Foundation.)

A Dutch study by van Buuren and colleagues for the first time addressed this question, treating height monitoring as a diagnostic test with associated sensitivity and specificity. The study aimed to detect Turner's syndrome in girls using a regional growth survey as the corresponding normal population. Three measures of size and growth were used: height SD score, height SD score adjusted for parental height, and height velocity, each with a range of cutoffs. The study found that height alone was not very effective at identifying cases of Turner's syndrome, whereas height adjusted for parental height was very effective. Height velocity was useful for ruling out Turner's syndrome, but it was poor at ruling it in. Overall, the study emphasized the value of height adjusted for parental height and tended to discount the value of repeated measurements.

Similar studies need to be done for other outcomes, but until they are performed, the choice of charts and cutoffs needs to be based on simpler criteria. The British height reference uses the 0.4th centile to screen for short stature (**Figure 1**), which screens in 0.4% of the population and corresponds to a specificity of approximately 99.6%. It is very important for the false-positive rate to be as low as 0.4% to avoid overwhelming growth clinics with referred patients. In the United Kingdom, height velocity is viewed as too noisy, because of the two measurement errors involved, to justify its routine use.

Of course, these conclusions apply to growth monitoring in the industrialized world. They should not be extended uncritically to the developing world, where the purpose of growth monitoring is different—to reduce malnutrition. Here, underweight is judged by the Road to Health chart and is the universal indicator of malnutrition. Weight can fluctuate rapidly due to disease, and encouraging mothers to weigh their infants regularly is a logical way of encouraging the child to grow along the 'road to health.' This philosophy is just one component of UNICEF's GOBI program, which combines growth monitoring, oral rehydration, breast feeding, and immunization.

When height is also available, weight-for-age can be separated into height-for-age and weight-for-height, where low values are known as stunting and wasting. Stunting reflects long-term malnutrition and wasting short-term malnutrition. The implications of the two conditions are different, the latter indicating a need for medical intervention, possibly urgent, and the former is a proxy for more deeply seated socioeconomic problems that are less amenable to intervention. In practice, however, height is rarely measured in infancy and the main focus is on detecting underweight.

Nature of the Intervention

The intervention arising from growth monitoring may be quite specific (e.g., the identification and treatment of a particular growth disorder) or it may be more general (e.g., referral to a growth clinic, a dietician, or a feeding station). If the mother is involved, it may alter her view of her child's health and so modify her child care. At the population level, it may affect the allocation of resources (e.g., between regions for malnutrition relief).

If growth monitoring is evaluated in the spirit of the Cochrane Review, the outcome it leads to needs to be quantifiable and objective. Also, the Cochrane Review evidence, such as it is, suggests that growth monitoring in the developing world is ineffective. However, several potential outcomes are too diffuse to quantify (e.g., increased parental interest and education), and this needs to be recognized. The absence of an evidence base in favor of growth monitoring should not necessarily be interpreted as evidence that it lacks benefit. The benefits may simply be too subtle to detect using conventional trials.

Down's Syndrome

M Collins and A Laverty, Muckamore Abbey Hospital, Antrim, UK

Down's syndrome, named after John Langdon Down, is the most widely recognized chromosomal disorder found in humans and falls into a category of chromosomal disruptions known as trisomies; hence the other term for the condition, trisomy 21. People with Down's syndrome vary widely in their abilities, but the syndrome is the most common genetic cause of learning disability. The syndrome is characterized by abnormalities of both structure and function, some of which may be amenable to nutritional intervention.

More than 90% of Down's syndrome individuals have a total of 47 chromosomes in cells instead of the usual 46. The remaining cases are mainly either translocations, where there is a rearrangement of fragments of chromosomes, or mosaics, in whom there are both normal and trisomic cells (i.e., mosaic trisomy 21). There is a relationship between the frequency of Down's syndrome births and age, with both very young mothers and older mothers having a higher incidence of the syndrome. It has been suggested that nutrition may be implicated in the nondisjunction of the chromosomes. The additional chromosomal material in Down's syndrome usually comes from the mother, but it can come from the father, and one study reported that the maternal age relationship had been found associated with paternal origin of the additional chromosome. This observation may be indicative of hormonal changes in the older mother that reduce the likelihood of spontaneous abortion in an abnormal pregnancy.

The incidence of Down's syndrome is approximately 1 in 600–1000 live births. Prevalence is rising as life expectancy has improved in recent years with advancing medical knowledge and higher standards of care, but concurrently there is a declining incidence of live births in industrialized countries due to prenatal diagnostic screening and abortion.

Physical defects common in Down's syndrome include congenital anomalies of the gastrointestinal tract, which occur in approximately 12% of infants with Down's syndrome. Most of these anomalies require the neonate to be operated on immediately to allow nutrition. Congenital heart disease occurs in approximately 40% of infants with Down's syndrome. Children with congenital heart disease may present with failure to thrive, but after surgical repair of heart defects these children usually improve. Immune dysfunction, increased susceptibility to leukemia, and premature aging with Alzheimer-like changes in the brain are major features of the syndrome.

Thyroid dysfunction is more common in people with Down's syndrome, with the incidence increasing as they get older. Hypothyroidism is most frequently reported, but hyperthyroidism can also occur. Correction of thyroid function is essential to allow normal learning processes to take place and to aid weight control.

There are many biochemical anomalies associated with the syndrome, mainly quantitative rather than qualitative. It is presumed that the overexpression of genes on chromosome 21 contributes to both the structural and the functional pathology. Overdose effects of the genes already mapped to chromosome

Table 1 Nutritional complications of Down's syndrome

Physical	Problems with muscle tone, oral health and dentition, chewing, and swallowing
Metabolic	Anomalies in carbohydrate protein and lipid metabolism
	Increased demands on antioxidant defence system and methylation pathways
	Increased incidence of diabetes, coeliac disease, obesity, and thyroid disorders
Behavioral	Food consumption and exercise choices

21 are thought to alter pathways controlling the production of monocarbons, purines, pyrimidines, tubulins, and myelin.

The nutritional complications associated with Down's syndrome are summarized in **Table 1**.

Nutritional Status

It is debatable how relevant reference data from normal groups are for people with Down's syndrome.

Dietary Assessment

In children with Down's syndrome, conflicting reports have shown energy intake to be less than, similar to, or more than that of age-matched comparison groups, with a small percentage of children exceeding the recommended daily intake by more than 50%. However, because children with this syndrome tend to be shorter than age-matched children, energy intake comparisons need to be calculated per unit of body height.

Lower than recommended intakes of nonstarch polysaccharide coupled with higher than recommended consumption of protein and fats have also been reported. Some, but not all, researchers have reported low intakes of calcium, particularly in preschool and school-age children who refuse or limit milk consumption. Iron intakes have been reported to be low, particularly non-hem iron. Vitamins A and C intakes are limited in those who have a poor intake of fruit and vegetables. Intake of B vitamins has also been reported as low.

Laboratory Assessment

Carbohydrate Metabolism

Fasting blood glucose levels are usually in the normal range, but the glucose tolerance curve has been reported to be flatter and often with a double-humped curve, suggestive of delayed absorption. There is an increased incidence of both type 1 (insulin dependent) and type 2 diabetes in Down's syndrome.

Protein Metabolism

Disturbances in protein metabolism are common in Down's syndrome. An increased level of immunoglobulin A and immunoglobulin G antibodies to food antigens has been reported, and several studies have reported an increased prevalence of coeliac disease. Abnormal levels of fasting plasma and urinary amino acids have been reported.

Lipid Metabolism

One study reported no significant differences between study and control groups, drawn from within the same families, in levels of total cholesterol, low-density lipoprotein, apolipoprotein B, and the apolipoprotein B-to-apolipoprotein A-I ratio. Triacylglycerol levels were significantly increased and serum high-density lipoprotein cholesterol-to-total cholesterol ratio was significantly decreased in Down's syndrome. This suggests increased risk for coronary heart disease. The results of this study and other studies reporting no difference between Down's syndrome and comparison groups with regard to atherosclerosis contrast with early reports that suggested a decreased incidence of coronary artery disease in Down's syndrome. It is not clear whether the differences reflect nutritional variables or population variable changes reflecting the increased survival rate in infancy.

There is evidence of increased lipid peroxidation in Down's syndrome.

Vitamins

Some, but not all, studies have reported biochemical evidence of deficiency of thiamin, nicotinic acid, pyridoxine, cobalamin, folate, ascorbic acid, retinol, β-carotene, and α-tocopherol. Vitamin D metabolites have been reported to be in the normal range in a Spanish study that demonstrated wide seasonal variation linked to intensity of solar radiation.

Minerals

Low iron, calcium, manganese, and zinc concentrations have been reported, and the iron-to-copper ratio has been reported to be decreased. Studies reported that intracellular zinc in blood mononuclear cells was approximately 47% lower than that of normal controls, and it is possible that this may play a role in thyroid dysfunction, immunodeficiency, retarded growth, and faulty DNA repair. Further

research is required to determine if zinc supplements are beneficial and at what level. Supplementation with selenium aimed at increasing levels of the selenium-dependent enzyme glutathione peroxidase is reported to have led to a decrease in initially high blood mononuclear cell levels of copper, but it did not affect iron or zinc.

Vitamin and mineral levels have been held to reflect not just nutrient intake but also abnormal metabolism. Assessments of antioxidants and oxidation by-products are useful indicators of nutritional status in people with Down's syndrome. The overexpression of the superoxide dismutase system, the purine synthesis pathway, and cystathionine β-synthase are thought to create extra demands for antioxidants and for folate, but despite gene dosage effects the many biochemical anomalies that have been reported in people with Down's syndrome show a great deal of individual variation.

Anthropometric Assessment

Growth delay is one of the main characteristics of Down's syndrome, but impaired growth velocity is particularly evident at certain stages of development.

Fetal growth has usually been reported to be relatively normal and the length of the neonate is often within normal limits, allowing for gestation. Some studies have reported prenatal growth delay, and a major Italian study comparing neonatal length, weight, head circumference, and weight/length squared reported all percentiles of growth variables lower in Down's syndrome infants except for weight/length squared percentiles.

At approximately the age of 6 months, when growth starts to become regulated by growth hormone, growth velocity usually begins to show a marked reduction from normal levels. Although for the Down's syndrome child the period between birth and 2 years and the period between 6 years and 10 years of age are times of accelerated growth, the deviation from normal levels remains significant. Slow growth velocity is also a particular feature of adolescence, although there is a pubertal growth spurt. The deviation of adult stature from the means of reference groups is greater than the deviations in early infancy.

The short stature in Down's syndrome seems to be mainly the result of impaired growth of the long bones of the leg, because sitting height measurements show that the growth of the vertebral column is closer to normal.

Why there is growth delay in Down's syndrome is not entirely clear, and several hypotheses have been advanced. Both human growth hormone therapy and zinc sulfate supplementation of the diet have been reported to accelerate growth.

Children with Down's syndrome tend to be not only shorter but also heavier than reference children. Charting the height and weight of a child with Down's syndrome using reference norms from the general population will show the abnormality of the growth pattern. However, it is more useful clinically to compare the height and weight of an individual against syndrome-specific norms because this will identify any deviation from the growth patterns of children with Down's syndrome.

Italian percentile charts have been drawn up for neonates with Down's syndrome based on a large sample of consecutively born infants. Specific growth charts for children with Down's syndrome have been constructed based on anthropometric assessments of US children, Sicilian children (thought to be representative of southern European children), and Dutch children (thought to be representative of northern European children). On average, the Dutch children were taller than the US children, and the US children were taller than the Sicilian children.

Nutritional Requirements

Children and adults with Down's syndrome need the same range of nutrients as the general population. Energy intake standards based on age groups are not appropriate for children with Down's syndrome. Energy intakes in both children and adults need to be tailored to height and weight and to physical activity.

Nutritional Therapy

In the 1970s and 1980s, hopes were raised that megadoses of vitamins and minerals would boost intelligence in children with Down's syndrome, but rigorous studies have shown these doses lead neither to higher intelligence nor to better health. In addition, there is anxiety about possible side effects, particularly from the fat-soluble vitamins.

As more has been learned about the genes on chromosome 21, interest has shifted to targeted nutritional intervention aimed at correcting the metabolic anomalies that are common in Down's syndrome due to genetic overexpression, with the emphasis on nutrients to maintain health and prevent disease. Targeted nutritional supplementation with vitamins, minerals, amino acids, digestive enzymes, and essential fatty acids is still

controversial. Clinicians have reported differences between children treated and not treated in health, growth, and cognitive and speech functions, and extensive double-blind studies are planned.

Dietary Management

Dietary Guidelines

Dietary recommendations are as for the general population until research proves otherwise. There are no specific dietary guidelines for the woman pregnant with a Down's syndrome child or for the pregnant Down's syndrome woman. There are indications that antioxidant and essential fatty acid intake may be particularly important, and folic acid supplements beneficial, but dietary advice is currently the same as for other pregnant women.

The situation is similar for infant feeding. Brain lipids in the human infant are known to change with changing intakes of fatty acids. The needs of a newborn with Down's syndrome for the long-chain polyunsaturated fatty acids docosahexenoic acid and arachidonic acid have not been determined. Since breast milk contains the preformed dietary very long-chain fatty acids that seem to be essential for the development of the brain and the retina, it seems prudent to encourage breast-feeding.

The antioxidant defence system has a particularly important role in Down's syndrome, and parents and caregivers can be advised on providing a diet rich in antioxidants. Dietary intakes need to be considered for the sulfur amino acids (which are needed for glutathione synthesis); fat-soluble vitamins A, C, and E; water-soluble vitamins B_6, B_{12}, and folic acid; and the minerals selenium and zinc. In latitudes where no vitamin D is synthesized in the winter months, it is particularly important to ensure exposure to sunlight during summer months to maintain adequate stores of the vitamin throughout the year because studies indicate an increase in the incidence of osteoporosis in Down's syndrome.

Feeding Behavior

Feeding skills tend to be delayed in the young child with Down's syndrome, but the sequence of the emergence of the skills is the same as that for other children if appropriate learning opportunities are provided.

Infants with Down's syndrome have a smaller oral cavity, which makes it easier for liquids to spill from the sides of the mouth. If a child is hypotonic, the tongue is likely to flatten out when the child sucks instead of forming a groove around the nipple, so the child will have a weak suck, may gag, and milk will leak from the mouth. Feeding will be exhausting, and particularly when the child has a cardiac defect, the child may have difficulty taking in enough milk to meet energy requirements. Tube feeding may be necessary until the child develops better tongue control. As infants with Down's syndrome are often placid, sleepiness may be overlooked and feeding will be easier if the infant is wide awake. Extra support for the infant during feeding, and in particular supporting the infant's chin to help steady the jaw, can help encourage intake. Because of the benefits of breast feeding, it is essential that nursing mothers are given help and advice when their infants have initial difficulties. Breathing during feeding may be helped if the mouth and nose are cleared of mucus with a syringe before feeding.

As with other children, it is important to introduce textured food when the child is developmentally ready, and information should be provided to parents and caregivers regarding both appropriate expectations and helpful feeding techniques as well as dietary advice. In children with Down's syndrome, poor neuromotor control of the tongue may result in the continued use of pureed food. There may be slow initiation of the swallow response, possibly because of hypotonic pharyngeal muscles, and oral sensitivity problems may also make the transition to textured foods difficult. Persistent feeding problems merit multidisciplinary assessment and therapy. Impaired swallow can result in food being aspirated and contribute to respiratory problems. The presence of the tongue protrusion reflex past the age of 12–18 months can result in delayed progression to solid food and can contribute to malocclusion of teeth. Also, dental abnormalities can exacerbate difficulties with chewing and can contribute to poor nutrition because children who have problems chewing may be offered soft, often high-energy food and be given little opportunity to accept meats, fresh fruits, and vegetables, which are lower in energy.

Fresh fruit and vegetables also provide the non-starch polysaccharide that can help prevent the constipation common in Down's syndrome. Prunes, fruit juices, and water between meals also help with constipation. Because the hypotonia in Down's syndrome also contributes to sluggish bowel habits, this is another reason for children and adults to be encouraged to take part in physical activity. If constipation does not respond to dietary management, there should be a medical

assessment to exclude gastrointestinal and thyroid problems.

Dental Problems

Dental anomalies in Down's syndrome include changes in tooth structure, reduced total number of teeth, and delayed or abnormal eruption. Together with the physical abnormalities of the facial appearance and oral cavity, these can all impact on feeding. Dental disease is common in Down's syndrome because teeth are more at risk of wear through bruxism and decay due to fragile enamel. In addition, gum disease (gingivitis) and oral infections due to mouth breathing can lead to teeth becoming loose and falling out. A healthy balanced diet, low in sugar-containing fluids and fizzy drinks (including 'diet' varieties), without frequent snacks and plenty of fruit and vegetables will help preserve teeth.

Obesity

Obesity is not inevitable in Down's syndrome, but it is common. Obesity in children with Down's syndrome has been reported from different cultures and different ethnic backgrounds. From Australian and North American studies, it has been reported that by 2 or 3 years of age more than 30% of children with trisomy 21 are overweight, and by 9 years of age the average child with Down's syndrome is obese; from the age of 10 years, the average weight of Dutch children with Down's syndrome is above the 90th percentile of weight-for-height curves of healthy children. Since the 1960s, obesity has been increasing rapidly in school-age children in Japan, and in 1994 a survey of children at special schools reported that more than 20% of school children with Down's syndrome were obese.

High rates of overweight and obesity have been reported in adults with Down's syndrome, both living in the community and at home, and more commonly in females than males. Overweight and obesity are particularly associated with living in the family home compared to supervised community units or hospitals, but they are not significantly associated with the degree of learning disability.

Because excessive weight gain in childhood often leads to adult obesity, it is important to encourage healthy choices in childhood. Why children with Down's syndrome have a tendency to become fat is not clear, but it is likely that several factors influence the weight gain. Retardation of growth resulting in short stature may be of prime importance. Obesity in people with Down's syndrome has also been linked to poor eating behaviour, excessive energy intake, depressed resting metabolic rate, hypotonia, reduced exercise, and endocrine abnormalities such as hypothyroidism. Abnormal substrate fat oxidation may also be implicated (**Table 2**).

Prepubescent children with Down's syndrome have a decreased resting metabolic rate compared to control children matched for body mass index. Children of approximately the same body composition, whether or not they have Down's syndrome, expend similar levels of energy in physical activity. Since obesity is negatively correlated with motor performance, it is likely to lead to a reduction in sporting and physical recreation activities, and thus obesity has social as well as health implications, in children with Down's syndrome as in other children. However, children and adolescents with Down's syndrome have been shown to have difficulty with sustained physical exercise in both laboratory and recreational situations, and this has been attributed to physiological impairments, notably cardiovascular, as well as to lack of motivation.

Children, adolescents, and adults with Down's syndrome have a deficit in isokinetic strength, and by the age of 14 years adolescents with testosterone levels in the normal range fail to show the pubertal muscle strength increase. Progressive resistance exercise programs can help to build muscle strength, and regular aerobic exercise will improve exercise tolerance. Often, individuals can attain high standards in competitive gymnastics and swimming. The overexpression of collagen genes on chromosome 21 affects both muscle and connective tissue, and it has been claimed that targeted nutritional treatment leads to rapid improvement in both muscle strength and joint stability.

In a cross-sectional study of men and women with Down's syndrome, body mass index (weight in kilograms divided by height in meters squared)

Table 2 Factors predisposing to obesity in Down's syndrome

Factor	*Increased*	*Decreased*
Poor eating behavior	↑	
Calorie intake	↑	
Resting metabolic rate		↓
Muscle tone		↓
Exercise		↓
Thyroid function		↓
Substrate fat oxidation		? ↓

declined with increasing age. Further research is needed to clarify whether individuals lose weight as they age or whether there is a shorter life expectancy for individuals with higher body mass indices.

Aging

The rapid aging that characterizes Down's syndrome is in line with the accumulating evidence that many degenerative diseases are associated with deleterious activated oxygen species reactions. Activated oxygen species can damage genetic material and inactivate membrane-bound enzymes as well as cause lipid peroxidation in cell membranes. Of particular relevance to Down's syndrome is evidence relating to cancer, inflammatory joint disease, diabetes, degenerative vascular disorders, degenerative eye disease, and senile dementia—all reported to have increased prevalence in Down's syndrome.

The gene for copper/zinc superoxide dismutase is on chromosome 21, and copper/zinc superoxide dismutase levels are elevated by 50% in a range of cells of people with Down's syndrome, including erythrocytes, blood platelets, leucocytes, and fibroblasts. The increase has also been reported in fetal cerebral cortical cells. Although copper/zinc superoxide dismutase usually functions as an antioxidant, it seems likely that in Down's syndrome the raised levels lead to oxidative stress. When the increased production of hydrogen peroxide through catalysis of superoxide free radicals is not matched by a sufficient increase in glutathione peroxidase to metabolize the additional hydrogen peroxide to water and oxygen, there is thought to be an increase in highly reactive hydroxyl radicals leading to increased lipid peroxidation.

Fibroblasts derived from people with Down's syndrome show elevated lipid peroxidation, and levels of thiobarbituric reaction products, which indicate the extent of lipid peroxidation, have been reported to be raised in erythrocytes from Down's syndrome subjects compared to controls.

A reported increase in the activity of the hexose monophosphate pathway in Down's syndrome is thought to be a compensatory mechanism to deal with increased hydrogen peroxide, allowing greater production of the reduced form of nicotinamide-adenine-dinucleotide phosphate, thus improving the ability of cells to reduce oxidized glutathione. However, it has been suggested that this shift of glucose utilization from energy production to reducing power may compromise cellular cation pumps.

Among the genes identified on chromosome 21 is that for the β-amyloid precursor protein. Amyloidosis is evident in the brain tissue of both patients with Alzheimer's disease and those with Down's syndrome. Studies are investigating the implications of the anomalies in the expression of the β-amyloid precursor protein and also the effect on cobalamin/folate metabolism of the gene for the enzyme cystathionine β-synthase, also on chromosome 21. The overexpression of both these genes is believed to contribute substantially to the development of dementia of the Alzheimer type. Although all people with Down's syndrome have evidence of brain pathology similar to Alzheimer's disease by their early thirties, not all show Alzheimer-like behavior changes as they age.

It may be that an increase in dietary antioxidants could delay the onset of Alzheimer-type symptoms, but more research is required. However, standard dietary recommendations for healthier lifestyles (i.e., eating more fruit and vegetables and including more oily fish in the diet) may have the added potential benefits of increasing antioxidant intake. Unfortunately, these are often the foods least favored by individuals with Down's syndrome.

Low vitamin E levels have been found to be associated with dementia, not only in the elderly but also in those with Down's syndrome. Vitamin E may have a potential therapeutic role in Alzheimer-like neurological changes by protecting the integrity of the muscarinc receptors. Continuing research into the etiology of the Down's syndrome phenotype is expected to lead to advances in the treatment of both Down's syndrome and Alzheimer's disease.

Care in the Community

Most people with Down's syndrome live in the community; some live with parents or caregivers, but adults often live independently or semi-independently. Many people with Down's syndrome can learn about healthy eating and manage their own diets. A dietitian's role in a community learning disability support team is likely to encompass not only individual assessment but also teaching and educating people with Down's syndrome as well as parents, caregivers, and other professionals.

Prader–Willi Syndrome

A O Scheimann, Johns Hopkins School of Medicine, Baltimore, MD, USA

Introduction

Prader–Willi syndrome (PWS) is a genetic disorder caused by deletion of the paternally derived genes in the proximal arm of chromosome 15. Patients with PWS manifest several common features, including hypotonia, decreased fetal movement, obesity, hyperphagia, short stature, growth hormone deficiency, hypogonadism, strabismus, and small hands and feet. Clinical features of PWS present ongoing medical and nutritional management issues.

Clinical History

Infants with PWS exhibit decreased fetal movement, weak cry, neonatal hypotonia, genital hypoplasia (cryptorchidism and clitoral hypoplasia), and failure to thrive (due to hypotonia and poor feeding). Toddlers with PWS acquire major motor milestones later than controls (walk at 24 months). Hyperphagia becomes evident between 18 months and 7 years of age. The majority of patients with PWS have growth hormone deficiency with short stature manifest during childhood and lack of a pubertal growth spurt. Individuals with PWS have an elevated pain threshold and vomiting threshold, with reports of delayed diagnoses of fractures, appendicitis, and gastroenteritis with significant morbidity. Obesity-related comorbidities, including sleep apnea, diabetes, and cor pulmonale, will shorten life expectancy without aggressive interventions. Behavioral problems, including obsessive–compulsive behavior (skin picking and rectal digging), stubbornness, and food foraging (including garbage and frozen food), are common; 5–10% of adults with PWS have features of psychosis.

Genetics of Prader–Willi Syndrome

Prader–Willi syndrome (PWS) is the first human disorder caused by altered imprinting. The incidence has been estimated between 1 in 8,000 to 1 in 25,000. During the process of imprinting, genes are differentially expressed based upon the parent of origin. Prader–Willi syndrome results from loss of imprinted genetic material localized to the paternal 15q11.2–13 region; loss of maternal genes in the same region results in Angelman's syndrome. The majority of cases are sporadic mutations. Nearly 70% of PWS patients have

deletions of the paternal 15q11.2–13 region; 28% of patients have maternal uniparental disomy. Approximately 1% of patients have mutations within the imprinting center, which has a higher recurrence risk unlike patients with deletions and uniparental disomy.

Fulfillment of diagnostic criteria and genetic testing confirm in individuals suspected with PWS. In 1993, age-stratified diagnostic criteria were published by Holm *et al*. PWS is very likely in children <3 years of age with 5 points (3 from major criteria) or in those >3 years of age with 8 points (4 from major criteria). Major diagnostic criteria for PWS (1 point for each) include infantile central hypotonia, feeding difficulties in infancy, accelerated weight gain in early childhood, hypgonadism, developmental delay and typical facial features (narrow bifrontal diameter, almond palpebral fissures, narrow nasal bridge, down-turned mouth). Current minor diagnostic criteria for PWS (1/2 point each) include decreased fetal movement, sleep apnea, short stature, hypopigmentation, small hands/feet, narrow hands with straight ulnar border, esotropia/myopia, thick saliva, skin picking and speech problems. Other commonly reported features of individuals with PWS include high pain threshold, decreased vomiting, temperature instability, premature adrenarche and osteoporosis.

In those suspected of having Prader–Willi syndrome, genetic testing should be pursued. Genetic testing for PWS includes chromosomal analysis and assessment for methylation patterns in the PWS region on chromosome 15. Flourescent in situ hybridization (FISH) is diagnostic in patients with deletions of the 15 q11.2–13 regions. Analysis for underlying uniparental disomy requires samples from both parents and the index case for DNA methylation patterns.

Nutritional Assessment

Nutritional monitoring in Prader–Willi syndrome requires attention to growth, body composition, and intake. Infants and children should be weighed on calibrated scales in minimal garments with heights obtained via a stadiometer. PWS-specific charts are available through the Prader–Willi Syndrome Association (www.pwsausa.org) to monitor linear growth.

Nutritional Management

Long-term management of patients with PWS presents unique evolving nutritional challenges. During infancy, muscle hypotonia impairs oral feeding and causes inadequate caloric intake and failure to thrive. The combination of altered body composition (with diminished metabolically active lean mass), growth hormone deficiency, and excessive intake results in obesity unless intake is restricted. Without aggressive nutritional interventions, the life expectancy is shortened for individuals with PWS due to obesity comorbidities.

Prior studies have reported metabolic differences among individuals with PWS. Adults with PWS have a low basal metabolic rate (BMR) dependent on the technique of body composition analysis. Despite differences in body composition, energy expenditure during physical activity is similar to that of controls but their overall activity level is less than that of controls. The combination of diminished BMR and activity level necessitates lower caloric intake to avoid significant obesity.

Dietary Interventions

Nutritional support for patients with PWS requires ongoing adaptation to meet age-specific needs. During infancy, hypotonia of the muscles associated with sucking limits the volume of caloric intake during feedings. Through the use of adaptive bottles/nipples, thickening agents (Thick-It and cereal), formula concentration, and short-term nasogastric tubes, infants with PWS can meet caloric requirements without placement of a gastrostomy. The feeding therapy utilized is determined by the adequacy of swallowing skills and nutritional status under the supervision of an oromotor therapist and nutritionist.

During infancy and early childhood, caloric intake should conform to the current guidelines from the Nutrition Committee of the American Academy of Pediatrics. During the first 6 months of life, breast milk or infant formulas are primary nutritional sources, followed by introduction of solids at 5 or 6 months of age. Solid textures are gradually advanced based on oromotor skills (jaw strength and tongue mobility). Due to the high likelihood for development of hyperphagia and obesity, the majority of parents avoid exposure of the PWS child to high-calorie solids, desserts, and juices. Via close nutritional follow-up during the first 2 years, oral intake can be appropriately adjusted to maintain weight for height between the 25th and 80th percentiles. Caloric restriction under the guidance of an experienced nutritionist is employed only if weight gain becomes excessive.

Nutritional strategies beyond the toddler years focus on avoidance of obesity. A number of studies have evaluated the caloric requirements for individuals with PWS. Weight maintenance has been reported with intakes of 8–11 kcal/cm/day (non-PWS children require 11–14 kcal/cm/day); weight loss has been documented with intakes of 7 kcal/cm/day. Proper implementation of caloric restrictions requires

attention to all potential sources of intake, including cafeterias, school buses, classroom activities ('life skills'), vending machines, neighbors, convenience stores, as well as home access (e.g., pantry, garbage cans, refrigerator, and tabletop).

Individuals with PWS and significant obesity-related comorbidities may require more aggressive weight loss interventions. To promote aggressive inpatient weight loss, a protein-sparing modified fast diet with micronutrient supplementation has been used over short time periods. Ongoing monitoring of food access is essential for long-term weight management.

Bariatric surgery causes weight loss through either a diminished capacity for intake or malabsorption. A long-term analysis of 10 non-PWS adolescents with a mean weight of 148 kg demonstrated a mean 5-year weight loss of >30 kg in 90% of patients; only 1 patient regained the weight. Bariatric surgery was initially attempted in PWS in the early 1970s. Gastroplasties were performed with the goal of decreasing PWS-related hyperphagic tendencies. More than half of PWS patients required subsequent revisions of the gastric pouch due to inadequate weight loss. The overall experiences with bariatric surgery in PWS are summarized in **Table 1**. The reported outcomes of bariatric

Table 1 Outcomes of bariatric surgery in Prader–Willi syndrome

Year	*Author*	*Type of surgery*	*No. of patients*	*Media age (years)*	*Median weight (kg)*	*Success rate*	*Complications*
1974	Soper	Gastroplasty	7	15	92.5	43%?	57% required revisions due to inadequate weight (wt) loss
1980	Anderson	91% gastric bypass; 9% gastroplasty	11	13	85		1 (9%) wound infection 54% required revision due to inadequate wt loss 1 dumping/diarrhea 1 death from uncontrolled wt gain
1981	Fonkalsrud	Vagotomy	1	17	120	?	29-kg initial wt loss followed by 20-kg gain
1983	Touquet	Jejunoileal bypass	1	24	181	62 kg (1 year)	Postoperative wound infection DVT/pulmonary embolus 4 or 5 stools/day
1991	Laurent-Jacard	Biliopancreatic diversion	3	27.6	84.5	Significant wt loss 1st year followed by wt gain ($2\frac{1}{2}$–6 years)	Diarrhea Vitamin D, vitamin B_{12}, folate, and iron deficiency
1992	Dousei	Vertical banded gastroplasty	1	21	57.4	Initial improved DM control	Short-term wt loss followed by break of staple line and wt gain
1997	Chelala	Laparoscopic adjustable gastric band	1	?	?		Death 45 days postoperatively from GI bleeding
2000	Grugni	Biliopancreatic diversion	1	24	80	Initial wt loss but wt gain without restriction	Diarrhea, severe osteopenia, anemia, hypoproteinemia
2001	Marinari	Biliopancreatic diversion	15	21	127	56–59% wt loss at 2–3 years; then regain 10–20% of wt lost	2 deaths from unrelated causes; no vitamin levels or bone density data provided

procedures have been less than satisfactory, with short-term weight loss followed by weight gain.

Micronutrients

Adequate vitamin and mineral supplementation is imperative for the patient with PWS. Hypocaloric diets required for patients with PWS preclude acquisition of adequate vitamin and minerals from traditional dietary sources. Commonly used meal plans for individuals with PWS are deficient in calcium, iron, vitamin D, vitamin E, biotin, pantothenic acid, magnesium, zinc, and copper.

Cerebral Palsy

J Krick and P Miller, Kennedy–Krieger Institute, Baltimore, MD, USA

This article focuses on cerebral palsy (CP) and its nutritional implications. The first section defines CP and describes its causes, prevalence, and classification types. Associated deficits related to CP are also explored. The topic of nutritional assessment of children with CP includes discussions on growth, body composition, and energy, protein, fluid, and nutrient needs. Feeding and swallowing problems and the influence of muscle tone on the ability to eat safely are discussed in-depth, as are alternative feeding routes. The interdisciplinary approach is emphasized throughout as the ideal model to provide services to people with CP in order to ensure quality of life in the community.

Definition and Etiology

Cerebral palsy is a term that refers to a number of nonprogressive disorders of movement and posture that result from an injury to the central nervous system during early brain development (**Table 1**).

Table 1 Causes of cerebral palsy

Cause	*% of cases*
Perinatal	44
First trimester	
– Teratogens	
– Genetic syndromes	
– Chromosomal abnormalities	
– Brain malformations	
Second and third trimesters	
– Intrauterine infections	
– Problems in fetal/placental functioning	
Labor and delivery	19
Preeclampsia	
Complications of labor and delivery	
Perinatal	8
Sepsis/central nervous system infection	
Asphyxia	
Prematurity	
Childhood	5
Meningitis	
Traumatic brain injury	
Toxins	
Not obvious	24

Classification

There are several different classifications of CP. The three most predominant types are pyramidal, extrapyramidal, and mixed-type. The type of CP and the degree of involvement play an important part in nutritional assessment and treatment.

Pyramidal (spastic) cerebral palsy Children with spastic CP have increased muscle tone with a clasped-knife quality. In spastic quadriplegia (30% of cases of pyramidal CP), all four extremities are involved. In spastic diplegia (25%), both lower extremities are spastic with minimal upper extremity involvement. Hemiplegia (45%) implies involvement on only one side of the body, with the upper extremity usually more affected than the lower extremity.

Extrapyramidal cerebral palsy Choreoathetosis involves the presence of abrupt, involuntary movements of the upper and lower extremities. This condition can greatly increase energy expenditure and is further discussed in the energy needs section.

Mixed-type cerebral palsy Mixed-type CP includes characteristics of both the pyramidal and the extrapyramidal types. For example, a child may have rigidity in the upper extremities and spasticity in the lower extremities.

Associated Disabilities/Deficits

Associated deficits of CP are important to note since they impact on nutritional status. Cognitive impairments are quite common. Mental retardation occurs in 60% of CP cases, with the remainder at high risk for some type of learning disability. Sensory deficits are prevalent, including those in the visual and auditory modalities. Seizures occur in 20–30% of cases, with the highest proportion in the spastic type. Feeding, behavioral, or emotional problems are also frequently noted.

Nutritional Assessment

The goal for nutritional assessment and intervention is to have healthy, alert, interactive individuals who are able to take advantage of all that the environment has to offer. Each person must be able to participate to his or her capacity in the learning and therapeutic habilitative processes and in social, community, and leisure activities.

Growth

The literature describes children with CP who are shorter and lighter than the reference standard. This may be the result of several factors. Individuals with CP have alterations in muscle tone affecting their limbs and torso, depending on the level of severity and topography. They often exhibit muscle contractures, depending on the type of CP; muscle spasticity may retard bone growth. Limited physical activity may impede growth. Immobilization may be required after orthopedic surgery. Immobilization inhibits bone formation and longitudinal growth and results in suppression of certain growth-stimulating hormones. It has been suggested that dysregulation of growth hormone secretion may be another factor affecting growth.

A growth reference for children with spastic quadriplegia has been developed to facilitate uniformity in clinical appraisal as well as to simplify comparative interpretation of growth data. These growth curves can be seen in **Figures 1–6**. It is important to view the velocity of rate of growth from one measurement to another to aid clinical management. The rate of growth in children with CP is slower so that as they get older, the difference from the standard becomes greater.

Both nutritional and nonnutritional factors influence growth in children with CP. Nonnutritional

influences that have been suggested to impact growth include weight-bearing opportunities and, by extension, interventions using aggressive physical therapy, growth hormones, and electrical stimulation of muscle. In 1995, Stevenson reviewed growth in hemiplegics and noted that there is diminished

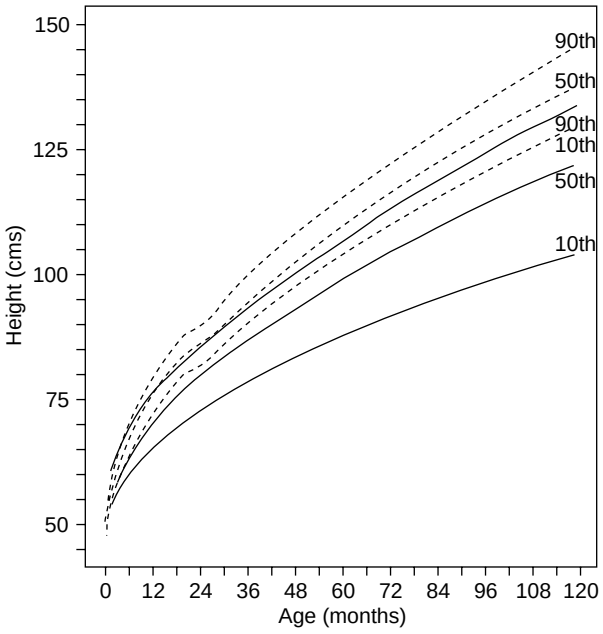

Figure 5 Length for age for boys aged 0 to 120 months. The solid line represents boys with quadriplegic cerebral palsy and the dotted line represents the National Center for Health Statistics standard curve for 10th, 50th and 90th percentiles.

growth, decreased muscle mass, and decreased fat stores on the affected side, and that the magnitude of the differences increases with age and functional severity. Gender, age, cognitive impairment, and ambulatory status have also been noted to contribute to the slow growth seen in this population.

Measurement of length or height for individuals with CP may require techniques and standards using arm span, lower leg length, or segmental measurements because of the difficulties encountered with joint contractures and/or scoliosis. The use of height age, rather than chronological age, is a common technique and is defined as the age at which the child's height crosses the 50th percentile on the National Center for Health Statistics chart.

The use of z scores for length-for-age, weight-for-age, and weight-for-length promotes an accurate evaluation of discrete changes from one measurement date to another. Percentile tables describe ranges, and consequently detection of movement within the range is difficult to describe. The z score denotes standard deviation units from the median and allows the practicing clinician and investigator to pinpoint precisely any given measurement.

For screening purposes, conventional length/height and weight measures can be completed and compared to the Centers for Disease Control and Prevention growth charts. Reference standards for body mass index for children with CP do not exist; therefore, one must use body mass index data in conjunction with body composition data to determine adequacy of growth. Samson-Fang and Stevenson recommend using the TSF as a screening for identifying suboptimal fat stores in children with CP.

When trying to obtain growth measurements, joint contractures, muscle spasms, and poor cooperation will impact accuracy. Upper extremity (arm) length, tibial length, and knee height are often noted in the literature as valid proxies for length in children with CP up to the age of 18 years. (See **Table 2** for estimation of height using segmental measures.)

Researchers from the multicenter North American Growth in Cerebral Palsy Project suggest that a practical method to assess nutritional status in a child with CP is to measure body fat. This can be done in the form of either the triceps skin fold or

Table 2 Estimation of height from segmental measures

Age 0–12 years
$(4.35 \times \text{UAL}) + 21.8$
$(3.26 \times \text{TL}) + 30.8$
$(2.68 \times \text{KH}) + 24.2$
Age 6–18 years
White male $(2.22 \times \text{KH}) + 40.54$
Black male $(2.18 \times \text{KH}) + 39.60$
White female $(2.15 \times \text{KH}) + 43.21$
Black female $(2.02 \times \text{KH}) + 46.59$

UAL, upper arm length; TL, tibia length; KH, knee height.

both the TSF and subscapular skin folds. However, patient cooperation with the measuring techniques, required for accuracy and safety, may be difficult to obtain or maintain. For some individuals with CP, the process may be difficult, and training is needed to learn the technique for body fat measures and segmental measures mentioned previously.

Ideal Body Weight

The estimate of ideal body weight (IBW) is also in part determined by the severity of the CP. The IBW should be aimed at maintaining adequate fat and muscle stores to endure repeated surgeries or a common virus while facilitating daily physical care and management. Weight-for-length is an indicator of nutritional status, which obscures the issue of chronological age and addresses whether the individual is proportionate. IBW can be expressed as this ratio. Those with cerebral palsy should attain and maintain an IBW that takes into account their age, level of physical ability, and their independence. Measurement of arm anthropometry will provide a description of body composition and support clinical judgments related to IBW. For example, children with spastic quadriplegia are the most dependent and the 10th percentile weight-for-length would be designated as the IBW. However, this assignment is done in tandem with assessment and monitoring of body composition, and if either the arm fat or the arm muscle area were less than the 5th percentile, then the IBW would be adjusted upward.

Body Composition

Since the 1970s, researchers reviewing body composition have noted reduced lean body mass in children with CP. Recent work examining adults with CP and their age-matched controls found no difference in lean body mass or percentage of body fat.

Bone Mineral Density

Bone mineral density (BMD) is markedly reduced in nonambulatory children with CP, placing them at risk for nontraumatic fractures. Osteopenia defined as <2 standard deviations below the mean was found in the femur of most nonambulatory children by the age of 10 years. Decreased BMD results from a combination of factors, including immobilization, antiepileptic therapy, and nutritional deficiencies. Serum levels of calcium, phosphate, alkaline phosphatase, and osteocalcin were not found to be reliable indicators of low BMD when studied by Henderson. The same author noted that fracture rate is fourfold higher following spica casting and more than threefold higher following an initial fracture.

Many nonambulatory children require and are given less calories than recommended for their non-CP counterparts; therefore, the clinician is obliged to review the adequacy of the micronutrients, specifically calcium. Most likely, their diets will require supplementation to meet 100% of the DRI standards for age and gender.

Methods to increase BMD include weight-bearing activities, dietary adequacy, and the use of bisphosphonates. In several studies, bisphosphonate use has demonstrated increased bone density by 20–89% with no obvious adverse effects.

Energy Needs

Equations that are frequently used to predict energy requirements were developed using healthy children and adults in usual environmental and physical activity conditions and do not provide an accurate assessment of the needs of those with CP. From a nutrition perspective, wide-ranging studies demonstrate underreporting of energy needs on food records, which at best provide a qualitative measure of intake. Therefore, clinicians have turned to the use of more sophisticated technology, such as doubly labeled water and indirect calorimetry, to assess the energy needs of this population. Additionally, the energy cost of movement, whether it be wheelchair propulsion, crutch ambulation, or the involuntary movements of the individual with athetosis, must be considered. Those with CP may undergo repeated orthopedic surgery that insults nutritional status, resulting in increased nutrient and energy demands. It has also been hypothesized that whole body metabolic rate may be related to differences in skeletal muscle fiber proportions and/or differences in enzymatic activity. People with CP have abnormal variation in the size of muscle fibers and altered distribution of fiber types.

Altered energy needs are common among those with CP and differ widely from the norm. Clinicians use a variety of approaches to estimate energy needs, such as the Dietary Reference Intakes (DRIs) for chronological age, the RDAs for height age, and the World Health Organization equation. When estimating energy needs, information related to muscle tone, activity level, and needs for growth or catchup growth must be added to the estimate for resting energy expenditure (REE).

One equation designed specifically for this population is:

$$\text{REE} \times \text{muscle tone factor} \times \text{activity factor} + \text{growth factor(s)} = \text{kcal per day}$$

The REE can be determined using indirect calorimetry or can be derived from estimating body surface

area standard metabolic rate 24 h. Body surface area (m^2) is calculated from length and weight using the nomogram derived from the formula of DuBois and DuBois, and the standard metabolic rate (kcal/m^2/h) is identified using height age and sex applying Fleisch data. The modifying factors are applied as follows:

- Muscle tone factors: Multiply by 10% for high tone (hypertonicity) and decrease by 10% for low tone (hypotonicity); no adjustment for normal tone.
- Activity factors: Multiply by 15% for bedridden state, 20% for wheelchair, and 30% for ambulation.
- Growth factors: Add 5 kcal (20.92 kJ) per gram of desired growth, expected growth, and catchup.

Energy needs must be viewed on an individual basis assimilating the concepts noted previously. The use of any approach is regarded as a guidepost and requires careful monitoring of body weight. Modifications to the diet should be based on clinical observation and measurement. There is a subset of individuals with CP who require significantly less kilocalories than anticipated (as few as perhaps 15 kcal/kg). Care should be exercised to provide adequate nutrients, protein/kg, and fluid despite the very low calorie needs.

Nutrient and Fluid Needs

Nutrient and protein needs are based on DRIs similar to those of the population without CP. Height age is often used in these determinations.

Fluid needs are based on body size rather than calorie intake. **Table 3** demonstrates how to calculate fluid needs. Constipation is a chronic problem for most children with CP and is related to muscle tone, loss of sensation, limited physical activity, medication side effects, and inadequate dietary fiber and/or fluid intake. Oral motor dysfunction results in diminished intake as well as in food and fluid loss. Modified food and fluid textures result in less free water and fiber in the diet. Discomfort associated with constipation may decrease appetite and increase gastroesophageal reflux. Dietary intervention may therefore be limited and medical management may be necessary.

Table 3 Fluid needs based on body weight[a]

Body weight (kg)	*Fluid need ($cm^3\,kg^{-1}$)*
≤10	100
11–20	+50
≥21	+25

[a]Suggest monitoring urine-specific gravities when available and quantity, color, and odor of urine, and adjust for periods of stress and temperature. Example: 28-kg child
100 ml × 10 kg = 1000 ml
50 ml × 10 kg = 500 ml
25 ml × 8 kg = 200 ml
Total need = 1700 ml

Assessment of Feeding Skills and Safety

Eating skills are acquired in a sequential pattern so that a developmental history will be helpful in evaluating current function and planning treatment options. Factors affecting feeding performance are shown in **Table 4**.

Oral Motor Evaluation

Feeding and swallowing problems are common in the child with CP, depending on the type of muscle tone, the presence of primitive reflexes, movement patterns, and the integrity of the sensory system. Clinical indicators of feeding and swallowing dysfunction are shown in **Table 5**. Problems often include poor intake, inefficient and lengthy mealtimes, abnormal oral motor patterns, inappropriate progression of feeding skills, and/or physiological compromise with feeding. Sensory, cognitive, and language deficits may also complicate the feeding process. An interdisciplinary team evaluation is

Table 4 General factors affecting feeding performance

Neuromotor performance	Constipation
Perceptual deficits	Amount of physical and verbal assistance required
Cognition and communication skills	Physiological support
Vision and hearing	Oral motor skills and swallowing status
Behavior/interaction	Medications
Growth	Dental and gum disease
Dietary adequacy	Multiple orthopedic procedures
GER and other gastrointestinal-related issues	Family/psychosocial stressors

Table 5 Clinical indicators of feeding and swallowing dysfunction

Congestion	Difficulty managing secretions
Noisy 'wet' sounds	History of upper respiratory infections
Multiple swallows to clear bolus	Apnea during feeding
Unexplained fevers, unexplained irritability	Failure to thrive, failure to maintain weight
Coughing/choking/gagging before, during, or after swallow	
Food refusal	

essential for the assessment, development of appropriate goals, and facilitation of a treatment plan that respects the developmental progression. A clinical assessment of the feeding process should include observance of facial muscle tone, oral reflex activity, functional oral motor skills, structural abnormalities, sensory responses, behavior and interaction during feeding, respiratory and phonatory status, and posture and positioning.

Radiographic and ultrasound studies can provide more detailed information about the oral structures and the competency of the oral, pharyngeal, and esophageal phases, including the detection of aspiration. Cervical auscultation can also be helpful in evaluating the pharyngeal phase of swallowing. In addition, these techniques can assist in determining the suitable solid and liquid texture and appropriate head and neck positioning. Hypertonicity leads to abnormal movements of the tongue, lip, and jaw. These abnormal movements can be manifested as tongue retraction, tongue tip elevation, tongue thrust, tonic biting, jaw thrust, jaw instability, lip retraction, and lip/cheek instability. An abnormally strong gag reflex, tactile hypersensitivity in the oral area, and drooling can also complicate feeding. Individuals with CP are also at risk for dental problems due to poor oral hygiene, teeth grinding, hypersensitivity in the oral area, and hyperplasia of the gums from long-term use of phenytoin, a medicine commonly prescribed for seizure management.

Aspiration and Gastroesophageal Reflux

Clinical signs of aspiration may include coughing, choking, gagging, inability to handle oral secretions, wet upper airway sounds with poor vocal quality, apnea, food refusal, frequent upper respiratory infections, and aspiration pneumonia. Aspiration of food may occur without physical evidence if the protective cough or gag is not functioning, sensory deficits exist, and/or the swallowing mechanism is dysfunctional. This results in what is termed silent aspiration. Although aspiration from solid food can be detected, the possibility of aspiration from gastroesophageal reflux (GER) may also need to be considered. The regurgitation of gastric contents from the stomach into the esophagus can lead to irritability during or after feeding, arching, esophagitis, and ultimately food refusal. Other symptoms of GER include respiratory compromise, apnea, and drooling. Treatment for GER includes the use of antacids, H2 blockers, medications to increase gut motility, reduction in feeding rate, positioning, thickening of foods or liquids, or surgical intervention. Small, frequent feedings help to decrease the volume in the stomach at one time.

Fatigue may occur in the child who is not able to sustain the work involved with feeding and may be expressed by an increase in respiratory rate, diaphoresis, or increased work of breathing. The causes may be muscular, respiratory, or cardiac, and they may increase the risk of aspiration or hypoxia. The work required to eat a meal is accomplished at a higher physiological cost to the child, thereby increasing caloric needs.

Muscle Tone and Positioning

It is important to understand the influences of muscle tone and proper positioning on the ability to eat safely and efficiently in this population. Increased or decreased muscle tone contributes to difficulty preserving a patent airway, compromised self-feeding skills, poor rib cage expansion and esophageal motility, and difficulty in maintaining a stable supported base for seating. Fluctuating muscle tone leads to involuntary movements and limited postural stability. Despite the type of muscle tone, optimal positioning is crucial for feeding and swallowing. The proper feeding position includes neutral alignment of head and neck, midline orientation, symmetrical trunk position, 90° pelvic/femoral alignment, and symmetrical arm position with neutral shoulders. An example of proper positioning can be seen in **Figure 7**. Consultations with orthopedists and/or rehabilitation physicians to address current and potential musculoskeletal problems, physical and occupational therapists for functional assessment, orthotists for deformity management, and durable medical equipment specialists to customize standard wheelchair components are valuable.

Underweight and Overweight

Overweight Most children with CP who are overweight or obese have low muscle tone. Their nutritional status impacts sleeping and breathing patterns, mobility, physical care, and peer relationships. It is difficult to attain an ideal body weight because energy needs are significantly reduced and the options for exercise are limited.

Underweight Typically, children with athetosis struggle to maintain weight given their excessive involuntary movements, which significantly increase energy needs. As these children age, the problem becomes more apparent, and many of these children will require enteral supplementation. One evaluation of this population noted that the basal energy requirement was 40% higher than expected.

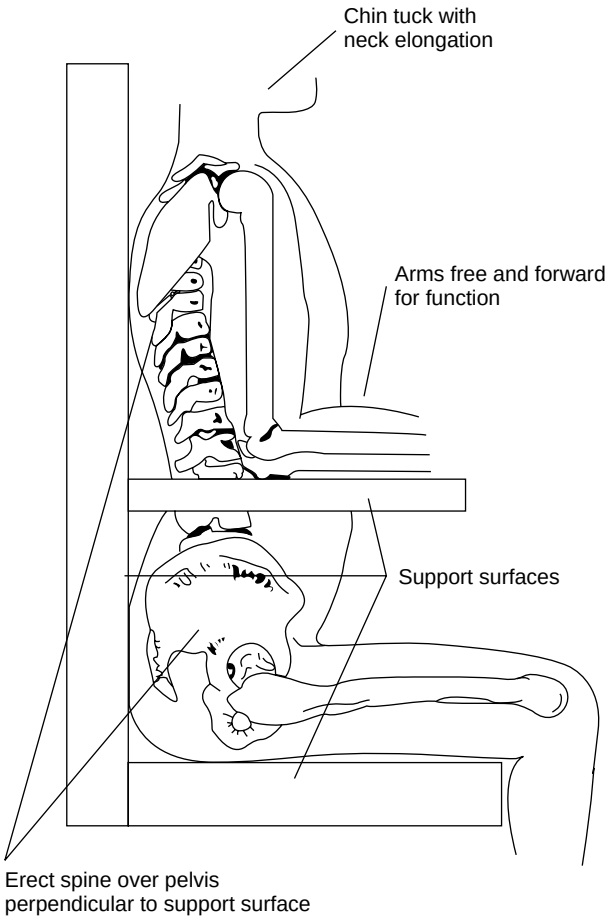

Figure 7 Proper seating position. (Reproduced with permission from: *The Handbook of Assistive Technology*. Singular Publishing Group, Inc.)

Superior Mesenteric Artery Syndrome

Superior mesenteric artery (SMA) syndrome is a condition in which the third portion of the duodenum is intermittently compressed by the overlying SMA, resulting in gastrointestinal obstruction. Symptoms include recurrent vomiting, abdominal distension, weight loss, and postprandial distress. People with CP are at high risk for several of the reported causes of SMA syndrome, including body cast compression, severe weight loss, prolonged supine positioning, and scoliosis surgery. Consequently, it is important to recognize the symptoms and know the appropriate treatments for this syndrome. Most people can be treated nonsurgically with gastric aspiration and nasojejunal or gastrojejunal feedings distal to the obstruction. One study also found that turning to the left from a supine position displaces the SMA from the right to the left side of the aorta in scoliosis cases. Thus, positioning can help alleviate symptoms and special considerations may be indicated in light of the limitations imposed by the CP.

Behaviors at Mealtimes

Parent–child interactions can also influence feedings. Ineffective communication, lack of bonding, the absence of social interaction or poor interactive skills, family dysfunction, and decreased environmental stimuli can exacerbate feeding difficulties or lead to frustration and anxiety with subsequent food refusal or parental withdrawal. Aversion to oral feeds can also be an outcome of medical complications, such as esophagitis and GER, or lack of feeding experience at critical milestones secondary to prolonged tube feedings. Behavioral treatment should only be undertaken after thorough medical, nutritional, and neurodevelopmental assessments are completed.

Feeding Issues

The feeding plan should be safe, promote growth or weight maintenance without excessive energy expenditure in order to obtain the required calories, and meet the needs of the family. It should reflect their resources in time and skill, and it should address their concerns and expectations. The goals for treatment once feeding and swallowing problems are identified are to prevent aspiration and thereby respiratory compromise; provide adequate calories, protein, vitamins, minerals, and fluid; and educate caregivers regarding nutritional requirements.

Oral Motor Considerations

Management strategies for daily mealtime feeding include positioning, modification of the sensory properties of the food, oral motor facilitation techniques, and equipment adaptations. For individuals with increased energy needs, the nutrient density of their meals may need to be maximized. **Table 6** lists

Table 6 Calorie boosters

Instant breakfast	Margarine, butter, oils, gravy
Powdered, evaporated milk	Sugar, honey, syrup
Whole milk cheeses	Cream cheese
Peanut butter	Sour cream
Wheat germ	Concentrate juices
Yogurt, pudding, custards	Breading or cracker meal
Milkshakes, eggnog	Fruit canned in heavy syrup
Supplements such as Polycose, Promod, Microlipid, Pediasure, and Ensure	

commonly used calorie boosters. It is important to acknowledge the inability to change the underlying feeding problem while providing a method of circumventing the problem to allow adequate nutrition and growth. For example, facilitative techniques to minimize excessive jaw movement may entail the feeder providing physical jaw control/support; a change in the food consistency, texture, temperature, or taste to improve the ability to propel a bolus through the oropharynx; the careful selection of adaptive feeding equipment to assist with self-feeding and/or increased intake; and an appropriate seating system. Proper positioning also allows the feeder use of both hands.

Alternative Feeding Routes

Many children with CP are not able to meet some or all of their calorie needs by mouth due to one or more of the following conditions: oral motor dysfunction, excessive energy needs, recurrent infections, illnesses, and orthopedic surgical interventions. Consequently, if the gastrointestinal tract is functioning, supplemental or total tube feedings may be indicated. Early intervention with enteral nutrition may prevent protein–energy malnutrition and its complications. Studies have shown improvements in weight gain (fat mass as opposed to fat-free mass) with supplemental tube feedings, which better enables individuals to endure short-term medical insults.

Enteral nutrition may be delivered by nasogastric, nasojejunal, gastrostomy, gastrostomy–jejunal, and jejunostomy tubes. The degree of GER and risk of aspiration determine where the tube is placed, whereas the length of time needed for tube feedings determines whether a nasoenteral or surgically placed tube is required. The decision regarding continuous, intermittent, or combination tube feeds is dependent on the individual needs of the patient.

Tube feedings should be considered a tool to improve nutritional status rather than failure of the child's ability to eat. Based on the medical diagnosis and developmental stage of the child, the prognosis for return to oral feeding varies, and the length of time to achieve this goal is extremely variable. For some children, the goal of returning to full or partial oral feeding is not realistic. In a study evaluating the health of children with CP, Liptak describes those who were tube fed as having the lowest mental age, requiring the most health care resources, using the most medications, and having the most respiratory problems. These children were characterized as especially frail and required numerous health-related resources and treatments. Oral motor therapy should focus on maintaining existing oral motor skills, encouraging pleasurable oral experiences, and tolerance of oral hygiene practices. Nonnutritive oral stimulation must be performed when tube feedings are employed as the route of nutrition. The benefits are listed in **Table 7**. Improvement in nutritional status can result in positive changes in oral feeding.

Table 7 Benefits of nonnutritive oral stimulation

Maintains oral sensation and tolerance
Facilitates saliva production, swallowing, and other oral motor patterns
Maintains or develops coordination of respiration and swallowing
Facilitates parent–child interactions

Parenteral nutrition should only be used when the gastrointestinal tract is dysfunctional. When initiating feedings in patients with major weight loss or failure to thrive, whether enteral or parenteral nutrition is used, it is important to be aware of the 'refeeding syndrome.' This syndrome refers to phosphorus depletion and alterations in potassium, magnesium, and glucose metabolism, resulting in severe metabolic and physiological complications. It is imperative to increase calorie delivery slowly with close laboratory monitoring.

Medications

Drug–nutrient interactions should be considered for all children receiving long-term medications for seizure disorders, alterations in muscle tone, attentional deficits, gastrointestinal disorders, and/or other chronic conditions. One drug or the combination of multiple drugs may affect nutrition in many ways, such as causing decreased appetite, interference with absorption of specific nutrients, nausea, and vomiting.

Medication treatment options offer challenges to nutrition. For instance, diazepam, often used to decrease spasticity, increases the potential for drooling. This raises concerns of fluid loss/balance as well as loss of the protective effect of saliva on esophageal mucosa. Additionally, attention must be paid to tone reduction in the trunk and oral structures that would compromise safety of feeding skills.

Tone-lowering drugs potentially reduce energy expenditure and, as a result, require increased vigilance to avert excessive weight gain. Anecdotally, as tone is significantly reduced in children for whom intrathecal Baclofen pumps are used, so is the energy requirement. Most of these children seen have been on tube feedings with a constant intake over time.

With the use of the Baclofen pump, weight gain is seen and adjustments in the kilocaloric level may be necessary.

Repeated Orthopedic Surgeries

These are common in children with CP, and each surgery must be preceded by an evaluation of nutritional status and assessment of the child's ability to physically heal and recover quickly from the trauma. Many children who are marginal oral feeders will decompensate, lose weight, and have a difficult time healing because of a cascade of events including pain, poor positioning for safe feeding, worsening constipation, minimal intake, lethargy, and increased medications for pain that may have a sedative effect. They may require supplemental feedings prior to surgery or during the postoperative period.

Coordinated Services

The provision of nutrition services and prevention of further disabling conditions can be done in a variety of health care, school, vocational, home, and community settings. It is the responsibility of the family in concert with the health care team to promote nutrition care planning in these settings. More than 90% of children with CP live to adulthood; however, their life expectancy is less than that of the general population. The chronicity of nutrition problems for individuals with CP is recognized and has in part created a need for care coordination and integrated service planning to provide meaningful and cost-effective services.

HOMOCYSTEINE

J W Miller, UC Davis Medical Center, Sacramento, CA, USA

Introduction

Homocysteine is a sulfur amino acid and an intermediate in the biochemical conversion of methionine to cysteine, a process called trans-sulfuration. Vincent Du Vigneaud and others elucidated the biochemistry of homocysteine over the period from the 1930s to the 1950s. In the early 1960s, the description and characterization of the inborn error of metabolism, homocystinuria, initiated a 40-year (and continuing) period of investigation that has revealed homocysteine as an independent risk factor for vascular disease. The association between elevated blood levels of homocysteine (hyperhomocysteinemia) and vascular disease may be similar in magnitude to the association between cholesterol and vascular disease, thus implicating hyperhomocysteinemia as a significant public health concern. Currently, large-scale intervention trials are being conducted to determine if supplements of the B vitamins folate, vitamin B_{12}, and vitamin B_6, each of which plays an integral role in homocysteine metabolism, reduce the incidence of vascular disease. If successful, B vitamin supplements may prove to be an inexpensive and safe prophylactic to reduce the risk of heart attacks and strokes.

Structure and Forms

The structure of homocysteine is shown in **Table 1** along with the related structures of cysteine and methionine. The most prominent features of homocysteine and cysteine are the free sulfhydryl groups located at the end of the side-chains of both amino acids. These sulfhydryl groups are highly susceptible to oxidation and the formation of disulfide linkages with other sulfhydryl compounds. The primary forms of homocysteine found in the blood (**Table 1**) consist of homocysteine in disulfide linkage with: (1) cysteine residues within the primary sequences of albumin and other plasma proteins (protein-bound); (2) free cysteines or cysteine-containing peptides (mixed disulfides); and (3) other homocysteine molecules (homocystine). Only about 1% of homocysteine in the blood is in the free-reduced form. Methionine, in contrast, does not have a free sulfhydryl group, and thus does not form disulfide compounds.

Biosynthesis and Metabolism

The biosynthesis and metabolism of homocysteine is presented in **Figure 1**. The ultimate source of homocysteine is dietary methionine. Methionine is first activated by addition of an adenosyl group (from ATP) to form *S*-adenosylmethionine (SAM). SAM is an important intermediate known as the universal methyl donor for its role as the methylating agent in a variety of essential reactions, including those involving DNA, RNA, proteins, membrane phospholipids,

Table 1 Structures and forms of homocysteine and related amino acids

Structures of homocysteine and related amino acids		*Forms of homocysteine found in blood*	
	Homocysteine	HCY-S—S-CYS-albumin	Protein-bound
	Cysteine	HCY-S—S-CYS	Mixed disulfide
		HCY-S—S-HCY	Homocystine
	Methionine	HCY-SH	Free reduced

HCY, homocysteine; CYS, cysteine.

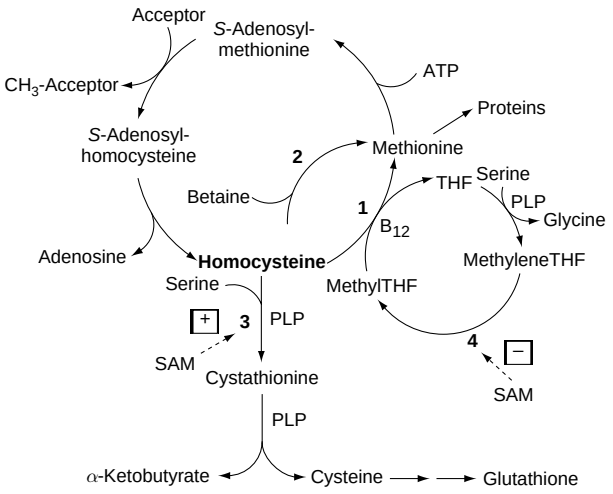

Figure 1 The biosynthesis and metabolism of homocysteine. Reactions that are regulated by *S*-adenosylmethionine (SAM) are indicated by positive and negative signs. Key enzymes: (1) methyltetrahydrofolate-homocysteine methyltransferase or methionine synthase; (2) betaine-homocysteine methyltransferase; (3) cystathionine β-synthase; (4) methylenetetrahydrofolate reductase. Abbreviations: THF, tetrahydrofolate; PLP, pyridoxal-5′-phosphate (vitamin B_6).

neurotransmitters, and the synthesis of creatine. A product of all SAM-dependent methylation reactions is *S*-adenosylhomocysteine (SAH), which in turn is metabolized to form adenosine and homocysteine. Homocysteine is then at a metabolic crossroad: it can be remethylated to form methionine or catabolized through cystathionine synthesis.

In remethylation, homocysteine reacquires a methyl group in a reaction catalyzed by methionine synthase (5-methyltetrahydrofolate-homocysteine methyltransferase) (EC 2.1.1.13) with methyltetrahydrofolate serving as the methyl donor and vitamin B_{12} serving as a cofactor. This reaction occurs in all mammalian cells. Alternatively, homocysteine can be remethylated in a folate- and vitamin B_{12}-independent reaction utilizing betaine as the methyl donor and catalyzed by betaine-homocysteine methyltransferase (EC 2.1.1.5). This reaction occurs primarily in the liver, and to a lesser extent in the kidney and possibly the brain.

Homocysteine catabolism occurs through cystathionine synthesis in a condensation reaction with serine. This reaction is catalyzed by cystathionine β-synthase (EC 4.2.1.22), which requires vitamin B_6 in the form of pyridoxal-5′-phosphate (PLP) as a cofactor. Cystathionine is then cleaved to form α-ketobutyrate and cysteine in a second PLP-dependent reaction catalyzed by cystathionase (EC 4.4.1.1). Further metabolism of cysteine leads to the formation of glutathione or inorganic sulfate.

Regulation of Metabolism

An important aspect of homocysteine metabolism is that it is subject to allosteric control. In addition to serving as the universal methyl donor, SAM also is an activator of cystathionine β-synthase and an inhibitor of methylenetetrahydrofolate reductase (MTHFR) (EC 1.7.99.5), the enzyme responsible for the synthesis of methyltetrahydrofolate (**Figure 1**). These allosteric functions serve to control whether homocysteine is recycled to form methionine or catabolized to form cystathionine. When dietary supply of methionine is high, i.e., after a protein meal, intracellular SAM levels increase. The high concentration of SAM activates cystathionine β-synthase and inhibits MTHFR, thus promoting homocysteine catabolism and limiting homocysteine remethylation. This serves to reduce the recycling of homocysteine when there is an adequate dietary supply of methionine. Conversely, under fasting conditions when there is no dietary influx of methionine, intracellular SAM levels go down. Cystathionine β-synthase is then not activated and the inhibition of MTHFR is relieved, thus promoting homocysteine remethylation over catabolism. Consequently, this maintains intracellular methionine levels during times of limited dietary supply.

An additional level of control of homocysteine metabolism is exerted by oxidative stress. Though the biochemical mechanism remains undefined, oxidative stress tends to divert homocysteine toward cystathionine synthesis away from methionine synthesis. This serves to increase synthesis of glutathione, a product of homocysteine metabolism through the trans-sulfuration pathway and an important intracellular antioxidant.

As discussed below, alterations in homocysteine metabolism also occur after menopause, in diabetes, and in hypothyroidism. These observations suggest that hormones, including estrogen, insulin, thyroxine, and thyroid-stimulating hormone, may directly or indirectly affect homocysteine metabolism. As for oxidative stress, the mechanisms by which these hormones affect homocysteine metabolism are poorly understood.

Hyperhomocysteinemia

Under conditions of maximal metabolic efficiency, plasma levels of homocysteine range from 4 to $10\,\mu mol\,l^{-1}$. Metabolic blocks in homocysteine metabolism lead to accumulation of intracellular homocysteine with subsequent export into the blood. Depending on the magnitude of the metabolic impairment, plasma homocysteine levels can rise to varying degrees, as defined in **Table 2**.

Table 2 Degrees of hyperhomocysteinemia

Total plasma homocysteine	*Designation*
4–10 μmol l^{-1}	Normal
11–25 μmol l^{-1}	Mild to moderate
26–50 μmol l^{-1}	Intermediate
>50 μmol l^{-1}	Severe

Genetic Defects

Severe elevations in plasma homocysteine (concentrations as high as several hundred μmol l^{-1}) are observed in individuals with homozygous genetic defects affecting cystathionine β-synthase, MTHFR, or any of several enzymes responsible for the conversion of vitamin B_{12} to its methionine synthase-associated cofactor form. These autosomal recessive genetic disorders, collectively termed homocystinuria because homocysteine accumulates in the urine as well as the blood, are associated with severe premature vascular disease, including thrombosis and atherosclerosis, mental retardation, dislocation of the eye lens (ectopia lentis), and skeletal malformations. Premature death (often in childhood) usually results from a major thrombotic or embolic event. Notably, one of the genetic defects that afflicts a significant proportion of homocystinuria patients reduces the affinity of cystathionine β-synthase for its vitamin B_6 cofactor, PLP. For these patients, the metabolic defect can be overcome to some extent with high-dose vitamin B_6 supplements, which significantly lower plasma homocysteine levels, reduce morbidity, and increase life expectancy. Interestingly, for other genetic defects involving cystathionine β-synthase that cause homocystinuria independent of the affinity of the enzyme for PLP, high-dose vitamin B_6 supplements nonetheless have a therapeutic effect despite having little or no influence on plasma homocysteine levels.

B Vitamin Deficiencies

Hyperhomocysteinemia is also caused by B vitamin deficiencies. Deficiencies of folate and vitamin B_{12} lead to impaired remethylation of homocysteine causing mild, moderate, or severe elevations in plasma homocysteine, depending on the severity of the deficiency, as well as coexistence of genetic or other factors that interfere with homocysteine metabolism (see below). Because riboflavin is required for the synthesis of flavin adenine dinucleotide (FAD), and because FAD serves as a cofactor for MTHFR, riboflavin deficiency can also affect homocysteine remethylation, and thus contribute to elevations in plasma homocysteine. Vitamin B_6 deficiency leads to impairment of homocysteine catabolism and thus also causes hyperhomocysteinemia. However, the nature of hyperhomocysteinemia caused by vitamin B_6 deficiency differs from that caused by folate and vitamin B_{12} deficiencies: In vitamin B_6 deficiency, fasting blood levels of homocysteine are usually not elevated or only slightly elevated. Only after a protein meal or after consumption of an oral methionine load (see below), does plasma homocysteine become abnormally elevated in vitamin B_6-deficient patients. In contrast, plasma homocysteine levels tend to be elevated regardless of prandial state in patients with folate or vitamin B_{12} deficiency. The basis for these different manifestations is likely due to differential effects of the vitamin deficiencies on intracellular SAM levels and consequent disruption of the allosteric control of homocysteine metabolism.

Recently, there has been growing interest in the concept of nutritional genomics. This refers to genetic variability among individuals and its effect on nutritional requirements. A prime example of this concept is a common polymorphism in MTHFR (677C→T) in which an alanine is replaced by valine at codon 222 in the primary sequence of the enzyme. Individuals with the homozygous variant (677TT) of this gene (10–15% of the general population; lower in blacks, higher in Latinos and in some parts of Europe, e.g., Southern Italy) have an enzyme that is thermolabile, with reduced affinity for its substrate (methylenetetrahydrofolate) and its cofactor (FAD). Consequently, 677TT individuals require a higher intake of folate and riboflavin to maintain optimal enzyme activity than those with the wild-type isoform of the enzyme (677CC). This is reflected by the fact that blood homocysteine levels are higher in people with the 677TT isoform than in those with the 677CC isoform, but only when overall folate and/or riboflavin status is low. When overall folate and riboflavin status is high, no difference in homocysteine levels is observed between the isoforms.

The clinical and public health importance of the MTHFR polymorphism is that women with the 677TT isoform are at increased risk of having a child with a neural tube defect (e.g., spina bifida, *sp*. anencephaly). This risk can be reduced by folic acid supplements, an observation that underlies the decision by the US government to mandate folic acid fortification of grain products as of January, 1998. This program has been highly successful, having reduced the prevalence of folate deficiency from over 20% to about 1%, the prevalence of hyperhomocysteinemia by about 50%, and the incidence of neural tube defects by at least 20%. The success of the folic acid fortification program in the US

spawned similar programs in several countries in the Americas, including Canada, Chile, and Costa Rica. Folic acid fortification has also been initiated in Hungary and Israel, but other European countries, most notably the UK, have been slow to adopt this intervention strategy. This is due to concerns about the feasibility of fortification, a hesitancy to impose manditory fortification on the population, lingering concerns over masking B_{12} deficiency, and the possibility of other unrecognized health consequences associated with excess folic acid intake.

Other polymorphisms in MTHFR and other enzymes involved in homocysteine metabolism (e.g., methionine synthase, methionine synthase reductase (EC 1.16.1.8), cystathionine β-synthase) have been identified and their overall influence on homocysteine metabolism, B vitamin requirements, and disease risk have been and continue to be evaluated.

Other Causes of Hyperhomocysteinemia

Other pathophysiological causes of hyperhomocysteinemia include renal dysfunction and hypothyroidism. The kidney is a major site of homocysteine metabolism and renal disease leads to a significant reduction in the body's overall capacity to metabolize this amino acid. The resulting moderate to severe hyperhomocysteinemia can be attenuated, in part, by high-dose B vitamin supplements, which putatively maximize the residual renal metabolism, as well as the metabolic capacities of the extrarenal organs. Mild elevations in homocysteine occur in patients with hypothyroidism, which resolve to normal with thyroid replacement therapy. This observation implies that thyroxine and/or thyroid-stimulating hormone influence homocysteine metabolism directly, perhaps through up- or downregulation of key homocysteine-metabolizing enzymes. Alternatively, homocysteine may become elevated in hypothyroid patients secondary to mild impairment of renal function that may accompany the disorder.

Patients with diabetes (both insulin dependent and insulin independent) tend to have mild hyperhomocysteinemia. However, this seems to be confined to those patients whose diabetic condition has progressed to involve renal insufficiency. Interestingly, in the absence of renal involvement, homocysteine levels in diabetic patients tend to be lower than normal. Insulin has been shown to inhibit homocysteine catabolism through cystathionine synthesis. Therefore, reduced insulin levels in diabetic patients may actually promote homocysteine catabolism, thus leading to lower plasma levels.

Premenopausal women tend to have lower plasma homocysteine than men of similar age, and homocysteine levels tend to rise in women after the menopause. Hormone replacement therapy reduces homocysteine back to premenopausal levels. Moreover, homocysteine decreases in male to female transsexuals, and increases in female to male transsexuals, primarily related to the estrogen and androgen regimens that such individuals respectively follow. Taken together, these observations strongly suggest an influence of sex hormones on homocysteine metabolism, though the mechanisms are not well understood.

Drugs can also affect homocysteine metabolism and lead to elevations of homocysteine in the blood. Certain anticancer drugs, such as methotrexate, and antiepilepsy medications, such as valproate and carbamazepine, are inhibitors of folate metabolism. The resulting functional folate deficiency leads to hyperhomocysteinemia. The anti-Parkinsonian drug, levodopa or L-dopa, causes elevations in blood homocysteine levels by a different mechanism: a significant proportion of an oral dose of L-dopa is methylated by SAM, leading to increased intracellular synthesis of SAH and homocysteine. The excess synthesis of homocysteine can overwhelm the capacities of the homocysteine metabolic pathways, particularly when B vitamin status is suboptimal, leading to hyperhomocysteinemia.

Homocysteine and Vascular Disease

The current interest in homocysteine is primarily related to its recognized status as an independent risk factor for cardiovascular, cerebrovascular, and peripheral vascular disease. This homocysteine theory of vascular disease comes directly from a seminal observation made by Kilmer McCully. In the early to mid-1960s, it was recognized that a prominent characteristic of patients with homocystinuria caused by defects in cystathionine β-synthase were very high elevations of both homocysteine and methionine in the blood. Therefore, it was not clear whether the vascular complications of this disorder were the consequence of hyperhomocysteinemia or hypermethioninemia. McCully observed that a patient with homocystinuria caused by a defect in a B_{12}-metabolizing enzyme had hyperhomocysteinemia, but not hypermethioninemia. Nonetheless, this patient had similar (though not identical) vascular pathology to that observed in patients with homocystinuria caused by cystathionine β-synthase deficiency. From this McCully concluded that the vascular culprit was homocysteine, and not methionine.

McCully's hypothesis, however, was not immediately embraced. The prevailing theory of atherosclerosis at the time centered on cholesterol, and it proved difficult for McCully to convince his peers and

national funding agencies of the potential importance of this new and competing hypothesis. Contributing to this was a lack of a reproducible animal model of homocysteine-induced vascular disease and a lack of a sensitive method to measure homocysteine in the blood. Consequently, McCully's hypothesis went into temporary obscurity.

In the mid-1970s, David and Bridget Wilcken reinvigorated McCully's hypothesis with their observation that a subset of patients with premature coronary artery disease had reduced ability to metabolize homocysteine. Notably, this association was observed in individuals who did not have any of the severe genetic defects that underly homocystinuria, suggesting that less severe or modest impairment of homocysteine metabolism may contribute to vascular disease risk. Subsequently, the advent of reliable, high-throughput assays for total plasma or serum homocysteine in the 1980s (see below) allowed for large-scale epidemiological assessment of associations between homocysteine and vascular diseases, both cross-sectionally and longitudinally. Through the 1990s, an explosion of population and case–control studies established that hyperhomocysteinemia is, indeed, a risk factor for heart attack, stroke, thrombosis, and peripheral atherosclerotic disease. Moreover, the risk associated with hyperhomocysteinemia is independent of other prominent risk factors, such as hypertension, hypercholesterolemia, hyperlipidemia, smoking, male gender, and others. Further indication of the importance of homocysteine with respect to vascular disease is the estimate that the relative risk of coronary artery disease associated with hyperhomocysteinemia is about equivalent to that associated with hypercholesterolemia. As the evidence mounted, McCully was vindicated and his contribution became widely recognized.

Homocysteine, Cognitive Function, and Dementia

As the relationship between homocysteine and vascular disease became increasingly apparent, researchers also addressed the hypothesis that hyperhomocysteinemia may affect cognitive function and the risk of dementia in older adults. This was based primarily on the recognized association between homocysteine and cerebrovascular disease, but also the observation that homocysteine and its metabolite, homocysteic acid, can induce excitotoxicity in neurons. Throughout the 1990s and into the new century, many cohort studies revealed significant inverse correlations between plasma homocysteine concentration and performance on a variety of cognitive function tests. Moreover, individuals with Alzheimer's disease were found to have higher plasma homocysteine than age- and gender-matched controls, while baseline homocysteine levels predicted the risk of incident dementia.

Homocysteine and Pregnancy Outcomes

Hyperhomocysteinemia has also been suspected as a risk factor for pregnancy complications and birth defects. Elevated plasma homocysteine levels have been associated with placental vasculopathy, pre-eclampsia, and placental infarction, as well as recurrent premature delivery, low birth weight, and spontaneous abortion. Birth defects associated with hyperhomocysteinemia in the mother include neural tube defects, orofacial clefts, clubfoot, and Down's syndrome. The protective effect of folic acid supplementation and fortification against neural tube defects, and perhaps the other abnormal birth outcomes cited, may be related to reduced homocysteine levels.

Mechanisms

In parallel with epidemiological studies, a significant amount of basic research has focused on the mechanism(s) by which homocysteine may induce atherosclerosis and thrombosis. A definitive answer has proven elusive. Potential mechanisms with significant experimental support include, but are not limited to, the following: (1) modification of the endothelial cell surface; (2) modification of plasma proteins by formation of disulfides; (3) activation of platelets; (4) modification of monocyte functions; (5) increased expression or activity of vascular adhesion molecules; and (6) oxidative damage induced by peroxides formed during disulfide bond formation.

A seventh potential mechanism relates to a known quirk of homocysteine synthesis and metabolism. The equilibrium of the interconversion between SAH and homocysteine (catalyzed by SAH hydrolase) actually favors SAH synthesis (**Figure 1**). *In vivo*, this reaction proceeds toward homocysteine synthesis because of product removal, i.e., the efficient metabolism of homocysteine back to methionine or through cystathionine synthesis. However, when there is a block in homocysteine metabolism, as occurs in the genetic defects, B vitamin deficiencies, and other causes delineated above, homocysteine accumulates intracellularly. Consequently, SAH also accumulates within cells. The significance of this phenomenon is that SAH is a feedback inhibitor of all SAM-dependent methylation reactions. Therefore, hyperhomocysteinemia may cause or contribute to vascular disease through SAH-mediated inhibition of methylation.

Another area that is receiving increasing attention is the relationship between homocysteine, nitric

oxide, and endothelial function. One of the roles of nitric oxide is as a vasodilator. Homocysteine has been shown to be an inhibitor of nitric oxide synthesis, and thus can inhibit vasodilatation. This has led to the hypothesis that hyperhomocysteinemia, by inhibiting nitric oxide synthesis, impairs the ability of the vascular endothelium to maintain homeostasis of vascular tone. This in turn may directly or indirectly increase susceptibility to vascular insults, thus promoting atherosclerosis and thrombosis.

The search for the definitive pathogenetic mechanism implicating homocysteine as a cause of vascular disease continues, and it is recognized that several mechanisms may contribute synergistically. However, some have questioned whether homocysteine is a cause of vascular disease, or simply a consequence.

Cause or Effect?

Though there is considerable evidence, both epidemiological and experimental, that homocysteine is a causative factor in vascular disease, there are data that contradict this conclusion. First, though cross-sectional and case–control studies fairly consistently demonstrate that hyperhomocysteinemia is associated with vascular disease, some prospective studies have found no relationship between baseline homocysteine levels and risk of incident vascular events. Second, several studies have found no relationship between the MTHFR 667C→T polymorphism and venous thrombosis, despite the association of this polymorphism with elevated plasma homocysteine levels.

With these observations in mind, a plausible alternative hypothesis has been put forward to explain the association between hyperhomocysteinemia and vascular disease. One of the organs that can be significantly affected by vascular disease is the kidney. Reduced kidney function caused by atherosclerosis may lead to renal insufficiency and reduced capacity to metabolize homocysteine. In this way, hyperhomocysteinemia may actually result from vascular disease. This hypothesis remains to be tested. The possibility of a vicious cycle, i.e., one in which vascular disease causes homocysteine to become elevated in the blood, which in turn induces further vascular damage, must also be considered.

B Vitamin Supplementation

Currently, several large-scale intervention trials are underway to determine if B vitamin supplements (folic acid, B_{12}, B_6), which effectively lower blood homocysteine levels, reduce the incidence of vascular disease (**Table 3**). If proven effective, such supplements would be an inexpensive and relatively innocuous means by which the risk of vascular disease may be reduced. However, it must be recognized that if these trials are successful, they will not serve as definitive proof that homocysteine is a vascular toxin. It may be the case that one or more of the B vitamins influences vascular disease risk through separate mechanisms. For example, several studies have shown that low B_6 status has an association with vascular disease independent of homocysteine. The uncertain relationship between hyperhomocysteinemia, B vitamins, and vascular disease is summarized in **Figure 2**. If homocysteine is not a vascular toxin, it may still serve as a marker of both vascular disease and as an indicator of the efficacy of B vitamin supplementation.

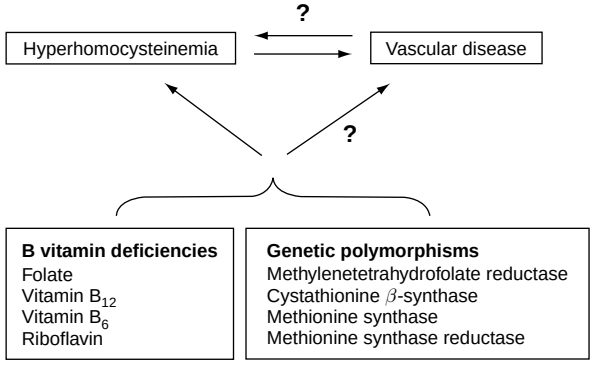

Figure 2 Hyperhomocysteinemia, B vitamins, genetic polymorphisms, and vascular disease. There is still some question whether elevated plasma homocysteine is a cause or consequence of vascular disease and whether there are influences of B vitamins and related polymorphisms on vascular disease risk that are independent of homocysteine.

Measurement of Blood Levels

A variety of assays have been developed to quantify blood homocysteine levels, with those employing high-pressure liquid chromatography perhaps being the most common. These assays have proven to be relatively accurate and precise (coefficients of variation less than 10%), and are relatively simple and quick to perform. The development of such assays in the 1980s was the technological breakthrough that spurred the exponential increase in homocysteine-related research over the last 15–20 years and the establishment of hyperhomocysteinemia as an independent risk factor for vascular disease.

As described above, homocysteine comes in several forms in the blood, including protein-bound, mixed disulfides, homocystine, and free-reduced. Assays for homocysteine usually measure the sum total of all these forms, i.e., total homocysteine. To accomplish this, the first procedure in homocysteine assays is a reduction step to break all disulfide bonds, thus converting all homocysteine to the free-reduced form. The free-reduced form is then quantified by one of various methods.

Blood sample collection and processing are critical factors in the determination of homocysteine concentrations. Typically, blood samples for homocysteine analysis are collected in tubes containing an anticoagulant (e.g., EDTA, heparin). Prompt separation of plasma from the blood cells after centrifugation is required to avoid excess release of intracellular homocysteine into the plasma or removal of homocysteine from the plasma by metabolically active leucocytes after blood draw. Keeping the blood sample cold until centrifugation and separation (ideally within 4 h of blood draw) minimizes this problem. Serum homocysteine concentrations typically exceed plasma concentrations by 20%. This is likely due to the fact that blood collected to isolate serum (i.e., without an anticoagulant) must clot at room temperature for 30–60 min before centrifugation and separation. Therefore, plasma is preferred for measurement of homocysteine. Once separated from the blood cells, the concentration of homocysteine in plasma or serum remains stable for years when stored frozen.

Another important issue in the measurement of homocysteine is the prandial state of the individual. For individuals with adequate B vitamin status, no genetic abnormalities, and no pathophysiological conditions that affect homocysteine metabolism, plasma homocysteine levels after an overnight fast are similar to levels after a meal (even high-protein meals containing methionine). However, for individuals with low vitamin B_6 status or heterozygous genetic defects in cystathionine β-synthase, postprandial homocysteine levels can be significantly higher than fasting levels. Because of the nutritional or genetic block in the conversion of homocysteine to cystathionine, there is decreased capacity to metabolize the influx of homocysteine synthesized from dietary methionine. This, in fact, is the basis for the methionine load test for detection of impaired cystathionine β-synthase activity. In this test, baseline blood is drawn after an overnight fast, and then again 4 h after consumption of a large dose of methionine dissolved in orange juice (100 mg methionine per kilogram body weight). Plasma homocysteine increases to a greater extent in individuals with low vitamin B_6 status or heterozygous genetic defects in cystathionine β-synthase than in individuals without these problems. Importantly, individuals with elevated fasting homocysteine and those with normal fasting levels, but elevated post-methionine load levels, are both at increased risk of vascular disease.

HUNGER

J C G Halford, University of Liverpool, Liverpool, UK
A J Hill and J E Blundell, University of Leeds, Leeds, UK

This article is a revision of the previous edition article by A J Hill and J E Blundell, pp. 1015–1020, © 1999, Elsevier Ltd.

Hunger is a familiar but commonly misunderstood and mistrusted part of our eating behavior. This article will clarify the meaning of the term, describe the common procedures for measuring hunger, the ways in which hunger and satiety are interrelated, and the adaptability of hunger experience in a learning framework. The relationship between hunger and eating behavior will be examined at both a methodological and conceptual level, and putative disorders of hunger will be briefly examined.

Definition

The term hunger is used in more than one sense by both scientists and the lay public. World hunger is a widely used phrase to describe the shortage of food and state of malnutrition experienced by a substantial proportion of the world's population. Its use is emotive and largely descriptive. It is in the study of motivation that the term takes on a more precise and individual definition. In this context, hunger describes the drive or the motivational force that urges us to seek and consume food. It is the expression of a biological need to sustain growth and life. Hunger is therefore a purposeful experience that possesses a clear biological function.

There are two ways in which the term hunger is used within nutritional science. One is its use as a motivational construct in a scientific theory. Here, hunger is inferred from directly observable and measurable events. In this way, inferring increased or high levels of hunger from a long period of food deprivation or an increased willingness to expend effort in order to obtain food, hunger becomes a mediating concept or intervening variable. However, a more familiar use of the word is that collection of conscious feelings or sensations

that are linked to a desire to obtain and eat food. This is the sense in which lay people understand the term hunger and is what researchers attempt to capture by means of rating scales and other measurement devices.

The first serious investigation of the everyday experience of hunger used a questionnaire in which people were asked to note the presence of physical sensations in a number of bodily areas, together with moods, urges to eat, and preoccupation with thoughts of food. It was found that the observation, 'I feel hungry,' is typically based on the perception of bodily feelings, which at times are very strong. Gastric sensations, a hollow feeling or stomach rumbling, are frequent indicators of hunger, although people also report sensations in the mouth, throat, and head. These accompany more diffuse feelings of restlessness and excitability as well as an urge to eat. The consumption of food changes both the pattern of physical sensations and the accompanying emotional feelings, with unpleasant and aversive sensations becoming replaced by more pleasant ones. So, for example, an aching stomach becomes relaxed and the feeling of excitement and irritability is replaced by one of contentment.

Subsequent research has confirmed these general patterns of characteristic premeal sensations and feelings, particularly with regard to the salience of gastric sensations. However, it has also noted a great deal of variability both within and between individuals. In other words, hunger demands neither the consistent presence of single sensations prior to every act of eating nor in every person sitting down to eat. Despite this variability people are able to, and frequently do, make judgments regarding their state of hunger, partly through reference to these sensations.

The Measurement of Hunger

The process of measuring hunger is not as straightforward as it might seem. One reason is the frequently raised mistrust of subjective reports. Critics point to the variability in response between individuals and the absence of any objective 'standard' by which internal experience can be calibrated. However, as argued later, this issue of 'validity' is more complex than this criticism suggests. A second reason is the failure to appreciate the distinction made previously between an individual's assessment of his or her disposition to eat and inferring hunger from the amount of food consumed or from some part of the act of eating (e.g., eating speed). While in many circumstances they will be in accord, the subjective report and inferred construct can as easily diverge.

The two most common methods for quantifying hunger are fixed-point rating scales and visual analog scales (**Figure 1**). Fixed-point scales are quick and simple to use, and the data they provide are easy to analyze. Past examples of these scales show they vary greatly in complexity. In considering the appropriate number of points to be included in this type of scale, the freedom to make a range of possible responses must be balanced against the precision and reliability of the device. Research seems to indicate that scales with an insufficient number of fixed points can be insensitive to subtle changes in subjective experience. In addition, the fixed points are important determinants of the way people use the scales and distribute their ratings.

One way of overcoming some of these failings is to abolish the points completely. Thus, visual analog scales are horizontal lines (often 100 or 150 mm long), unbroken and unmarked except for word anchors at each end. The user of the scale is instructed to mark the line at the point that most accurately reflects the intensity of the subjective feeling at that time. The researcher measures the distance to that mark in millimeters from the negative end (no hunger), thus yielding a score of 0–100 (or 150). This is done either by hand or automatically if presented by computer screen. By doing away with all of the verbal labels except the end definitions, visual analog scales retain the advantages of fixed-point scales, while avoiding many of the problems with uneven response distributions.

An important aspect of these methods concerns the interpretation of differences between the fixed points or intervals on a visual analog scale. So, for example, it should not be assumed that the difference between 20 and 30 mm on a hunger scale is

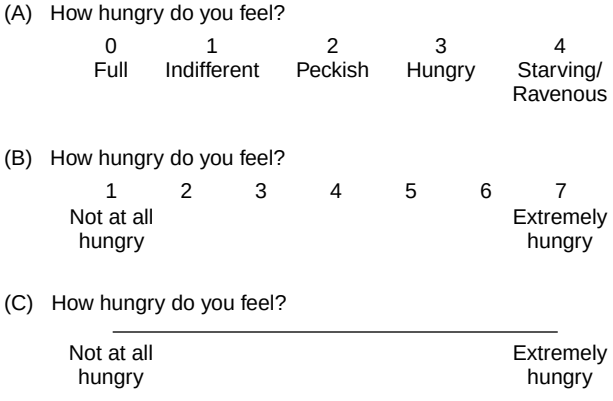

Figure 1 Examples of different types of scales used in the assessment of hunger: (A) fixed-point scale with points defined, (B) fixed-point scale, and (C) visual analog scale.

perceptually the same as the difference between 80 and 90 mm. Nor can a hunger rating of 80 mm be said to represent a feeling of hunger that is twice the intensity of that rated at 40 mm. Related to this is the problem of 'end effects.' This refers to the reluctance of a minority of subjects to make ratings away from the upper or lower end points of the scale, despite clear instructions. Despite these limitations, data from such scales are often analyzed using parametric statistical procedures, such as analysis of variance, and in general this appears to be a satisfactory approach.

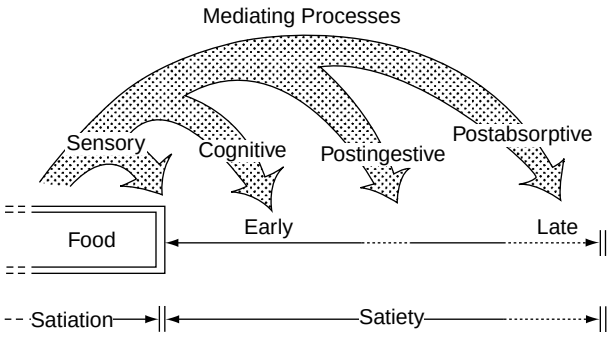

Figure 2 A representation of the satiety cascade showing the different phases of satiety and their associated mechanisms.

Hunger and Satiety

If hunger is that feeling that reminds us to seek food, then eating relieves hunger, albeit until the next snack or meal. The capacity of a food to reduce the experience of hunger is called 'satiating power' or 'satiating efficiency.' This power is the product of the body's handling of the nutritional composition and structure of the food eaten. It follows that some foods will have a greater capacity to maintain suppression over hunger than other foods.

The distinction between hunger and satiety is both conceptual and technical. As hunger diminishes, satiety rises. But it is useful to further separate those events that occur across the course of a meal from those between meals. In this way the process of satiation can be clearly distinguished from the state of satiety. Satiation can be regarded as the process that develops during eating and that eventually brings a period of eating to an end. Accordingly, satiation can be defined in terms of the measured size of an eating episode (such as its energy, weight, or volume). Hunger declines as satiation develops and usually reaches its lowest point at the end of a meal. Satiety is defined as the state of inhibition over further eating that follows at the end of a meal and that arises from the consequences of food ingestion. The intensity of satiety can be measured by the duration of time until eating starts once more, or by the amount consumed at the next meal. The strength of satiety is also measured by the time that hunger is suppressed. And as satiety weakens, hunger is restored.

In examining the mechanisms responsible for suppressing hunger and maintaining its low state, it is clear that they range from those that occur when food is initially sensed to the effects of metabolites on body tissues following the digestion and absorption of food (across the wall of the intestine and into the bloodstream). By definition, satiety is not an instantaneous event but occurs over a considerable time period. The different phases of satiety and their associated mechanisms are shown in **Figure 2**. Sensory effects are generated through the smell, taste, temperature, and texture of food, and it is likely that these factors have effects on eating in the very short term. Cognitive influences represent the beliefs held about the properties of foods, and these factors may also help inhibit hunger in the short term.

The category identified as postingestive processes includes a number of possible actions, such as gastric distension and rate of emptying, the release of hormones such as cholecystokinin, and the stimulation of certain receptors along the gastrointestinal tract. The postabsorptive phase of satiety includes those mechanisms arising from the action of metabolites after absorption into the bloodstream. These include the action of glucose and amino acids, which act directly on the brain after crossing the blood–brain barrier, and which influence the brain indirectly via neural inputs following stimulation of peripheral chemoreceptors. The most important suppression and subsequent control of hunger is brought about by postingestive and postabsorptive mediating processes.

It follows from this framework that foods of varying nutrient composition will have different effects on the mediating processes and will therefore differ in their effects on hunger, satiation, and satiety. There is considerable interest, for example, in whether protein, fat, and carbohydrate differ in their satiating power.

The balance of evidence shows that per unit energy, protein (within normal dietary limits) has the greatest satiating efficiency of all the macronutrients. This is particularly true in short-term studies and is observed in lean and obese subjects alike. Longer term evidence of this effect is currently lacking. However, of great practical and theoretical interest is the comparative effect of carbohydrate and fat since they form the majority of our routine energy intake. Research shows that carbohydrates are efficient hunger relievers. A variety of carbohydrates, including glucose, fructose, sucrose, and maltodextrins, all suppress

later test meal energy intake. This suppression is roughly equivalent to their energy value, although the time course of this effect varies according to the rate at which they are metabolized. In contrast, high-fat foods appear to stimulate energy intake (in contrast to low-fat, high-carbohydrate foods), or at least have a disproportionately weak action on satiety. The mechanisms responsible for this may include the effect of fat-promoting food palatability, the high-energy density of fat, and the absence of inhibitory feedback from body fat stores. Taken together, these findings show why diets high in fat can promote weight gain and lead to obesity.

Hunger: Physiological Determinants

Stomach distension and the detection of macronutrients such as fat or protein within the gut are all powerful satiety cues. They bring a meal to an end and for a time inhibit further consumption. Eventually, hunger again prevails and food intake follows. The flux between hunger and satiety is episodic and underpins the expression of our eating behavior throughout the day. However, it is not just the absence of episodic satiety cues (e.g., stomach distension and intestinal or absorbed nutrients) that influence the expression of hunger. Reduction in blood glucose levels or in levels of the circulating adipose tissue hormone leptin indicates a deficit in available energy and in energy reserves. Fluctuation of these factors indicates the metabolism and storage of the body's energy reserves. These are a tonic class of physiological signals that also influence the expression of appetite. Like episodic satiety signals, these tonic signals normally act on inhibitory mechanisms with the hypothalamus (anorexogenic circuits). Their absence elicits an active feeding response. Other tonic factors that indicate the body's energy status, such as adiponectin, cytokines, and gonadal hormones, also appear to act on energy regulator centres within the brain, particularly the hypothalamus, mainly to suppress hunger.

However, not all physiological signals, episodic or tonic, inhibit hunger. For instance, blood levels of the recently discovered gut hormone ghrelin have been shown to increase prior to a meal. Subsequent intake has been shown to suppress ghrelin release. Further studies have shown that ghrelin infusions increase food intake. Thus, this is a hormone that acts to promote food intake. Interestingly, ghrelin receptors are found in various hypothalamic locations that form part of the orexogenic circuits promoting food intake. These circuits contain many neuropeptides, such as neuropeptide Y, orexins, melanocortin concentrating hormone, and galanin, which all stimulate food intake. The precise nature of the physiological and neurobiological regulation of appetite is discussed elsewhere in this encyclopedia. Finally, it should be noted that the biological mechanisms critical to the expression of hunger are not independent of psychological ones. Indeed, the sensory and cognitive cues that stimulate hunger produce physiological changes that anticipate the ingestion and metabolism of energy and subsequently aid these processes. This brings on the psychological factors critical in the expression of appetite.

Conditioned Hunger

One of the essentials for an omnivore faced with a variety of new and different foods is the capacity to learn. It is not possible for an inborn preference or aversion to guide the choice of every possible food. Therefore, we learn which foods are beneficial (and which are not) by eating them. This learning involves the association between the sensory and the postabsorptive characteristics of foods. In this way the sensory characteristics of foods act as cues and come to predict the impact that foods will later have. Consequently, these cues should suppress hunger according to their relationship with subsequent physiological events.

It is possible to demonstrate experimentally how human beings adapt their eating to a food's energy content. A distinctively flavored food which contains 'extra' hidden energy, presented on several occasions, will result in a change in eating and in preference. When deprived of food, subjects' preference for the taste increases with gained experience. If presented when satiated, preference for the taste decreases. This process is also observable in young children, who eat smaller meals following a taste previously associated with a high-energy snack, and larger meals following a taste previously associated with a low-energy snack.

The idea that we can have conditioned hunger for specific nutrients is far more contentious. The concept of conditioned hunger suggests that the organism, faced with a diet deficient in a single important nutrient, will seek an alternative food source that contains the missing nutrient. However, earlier evidence from animals has largely been reinterpreted from the standpoint of conditioned aversions. Indeed, conditioned aversions are far more potent examples of the impact of learning on eating behavior than any examples of conditioned hunger. A conditioned aversion that will be familiar to many readers is the profound dislike that occurs in response to a food or drink that was eaten prior to vomiting or illness. An example of a conditioned taste aversion was famously described by learning theorist Martin Seligman. Steak with sauce

Béarnaise was Seligman's last meal before a bout of gastric flu. Yet knowing that it was the flu rather than the food that made him sick did not prevent the subsequent aversion to sauce Béarnaise. In fact, surveys show that conditioned taste aversions are commonplace and reported by 40–60% of people.

Conditioned taste aversions are important in the present context not because they represent a special form of one-trial learning that we are biologically pre-prepared to acquire. Rather, they show that the strength of cue–consequence learning in the area of food intake depends on the stability and reliability of the relationship between tastes (sensory cues) and physiological effects (metabolic consequences) of food. When there is distortion, variation, or extreme complexity in the relationship between sensory characteristics and nutritional properties, then the conditioned control of hunger is weakened or lost. In many respects, the variety of foods available to us represents a cacophony of different sensory characteristics and has the added complication of ingredients that preserve the sensory qualities while altering their nutritive value. Learned hunger therefore is a relatively less important factor when the food supply contains many food items with identical tastes but differing metabolic properties.

Hunger and Eating Behavior

If hunger is biologically useful and a subjective experience that indicates a depleted nutritional state, then a close correspondence between hunger and eating would be expected. So hunger should be either a necessary or a sufficient condition for eating to occur. However, this is not invariably the case. Instances of people deliberately refraining from eating in spite of hunger (fasting for moral or political conviction) show hunger not to be a sufficient condition. And examples in research and daily experience, of eating a tempting food when otherwise satiated, show hunger not to be necessary for eating to take place. But while the relationship between hunger and eating is not based on biological inevitability, in many circumstances they are closely linked.

Unfortunately, the lack of a one-to-one correspondence between hunger and eating has been used as another way to question the validity of hunger ratings. But should a high correlation between hunger ratings and subsequent food intake be expected in all circumstances? The previous examples show that in certain circumstances the two can be disengaged. So, for example, eating can occur when hunger is low (such as when highly palatable food is offered unexpectedly) and not at other times when hunger is high (when food is unavailable or other activities have priority). In addition, many experimental analyzes of the correlational relationship between hunger and food intake report the relationship only when subjects are hungry. In other words, the correlation is only examined for a small portion of the available scale. Very few studies have looked at the association between hunger and food intake when hunger has been represented in all its possible degrees.

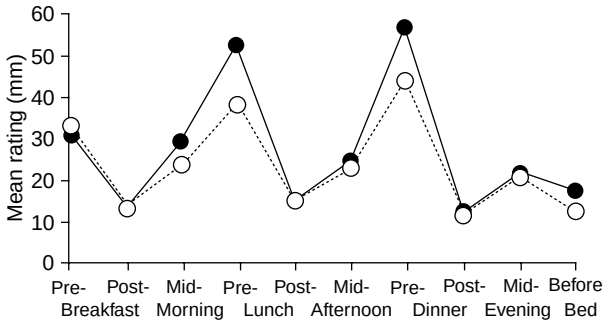

Figure 3 Ratings of hunger made across the day by a group of obese women taking an appetite suppressant drug (dotted lines) or placebo (solid lines).

It is clear that hunger ratings cannot be used simply as a proxy measure for food intake. Equally, there is good evidence that in most circumstances self-report ratings of hunger correlate statistically and meaningfully with eating. This association exists not simply across single meals, but across the entire day as shown in **Figure 3**. The rhythmic oscillation of hunger is tied closely to the overall pattern of food intake in this group of individuals. As such, it presents an elegant and experimentally useful way of examining diurnal variations in the experience of hunger.

In questioning the relationship between hunger and eating, we are also forced to place the action of hunger within a broader context of social and psychological variables that moderate food choice and eating behavior. Eating patterns are maintained by enduring habits, attitudes and opinions about the value and suitability of foods, and an overall liking for them. These factors, derived from the cultural ethos, largely determine the range of foods that will be consumed and sometimes the timing of consumption. The intensity of hunger experienced may also be determined, in part, by the culturally approved appropriateness of this feeling and by the host of preconceptions brought to the dining table. Hunger is therefore only one portion of the range of determinants of eating in any given situation.

Disorders of Hunger

The clinical eating disorders, anorexia nervosa and bulimia nervosa, are commonly believed to

encompass major disturbances of hunger. Yet the role that hunger may play is not entirely clear. Contrary to the literal meaning of the term, 'anorexia' is not experienced as a loss of appetite. Rather, clinicians recognize that anorexics may endure intense periods of hunger during their self-restricted eating. For some, their strength in resisting intense episodes of hunger provides a feeling of self-mastery and control that is absent in other areas of their lives. Research suggests that restricting anorexics (compared with those who binge) have the greatest blunting of hunger response, and that this disturbance in hunger is not a product of other areas of perceptual confusion.

There is evidence that in conditions of total starvation hunger may become temporarily diminished. This circumstance is extremely rare and obviously relatively brief. Once eating is recommenced, hunger returns rapidly and with extreme intensity. The accounts of the male volunteers who submitted to a 6-month period of semistarvation during World War II (the 'Minnesota Experiment') are a testament to the extreme power of hunger. Referred to as semistarvation neurosis, these men's activities were shaped by their need for food. And their hunger experience was extreme. Nearly two-thirds reported feeling hungry all the time and a similar proportion experienced physical discomfort due to hunger. Participants described a marked increase in what was referred to as 'hunger pain.' For some this was mildly discomforting and vaguely localized in the abdomen. For others, it was extremely painful. This account is especially useful in reminding why energy-reduced diets aimed at achieving weight loss are often difficult to maintain and easy to abandon.

Like anorexia, bulimia finds its literal meaning in changed hunger — 'ox hunger.' Again, however, the term is imprecise. Close analysis of the precursors of binge episodes show hunger to be lower than it is prior to a normal meal. In addition, while the urge to eat may be strong during a binge, the large amount of food consumed implies some defect in satiation rather than in hunger. And binging is often a well-practised behavior that develops and changes with time. As with anorexics, it is likely that a stable eating pattern is necessary in order to normalize the experience of hunger, a process that may take a long time to establish.

The question of whether obesity reflects a disorder of hunger is now regarded as largely redundant. Obesity is strictly a disorder of weight, and as such reflects potentially long-term failure in the regulation of energy balance. There is hardly any evidence of heightened levels of hunger contributing to excessive energy input. However, an exception to this is the rare disorder Prader–Willi syndrome. Genetically determined and characterized mainly by intellectual disability, obesity is a well-recognised feature of the syndrome. Emerging research suggests that the excessive levels of food intake are associated with both a delayed reduction in hunger while eating and a more rapid return to premeal states when eating has finished. Clearly, a better understanding of the biological events that accompany such aberrant eating patterns will strengthen understanding of the psychobiological framework that supports hunger.

HYPERACTIVITY

M Wolraich, Vanderbilt University, Nashville, TN, USA

To discuss the issues of hyperactivity and diet, it is first important to understand the issues related to the diagnosis of hyperactivity, or what is now called the 'attention deficit/hyperactivity disorder' (ADHD). Since most of the recommendations for dietary changes have been for children who have been diagnosed with ADHD, this article will first review the historic and current changes in the diagnosis of ADHD and then review the diets that have been recommended for treatment and the evidence as to their efficacy.

Diagnostic Issues

Hyperactivity, or ADHD, is a condition that has been recognized for many years and has been quite extensively researched, but the diagnostic criteria and treatment continue to be controversial. The symptoms of ADHD were first described by a German physician, Heinrich Hoffman, in a children's book written in 1848. The symptoms were represented by two children, Harry, who looks in the air (inattention), and Fidgety Phil (hyperactivity). In 1902, George Still presented a lecture in England about 20 children who were aggressive, defiant, excessively emotional and lacking inhibitory volition, and who were also noted to have impaired attention and overactivity. A more etiological conceptualization of the condition did not occur until after World War I.

Symptoms of hyperactivity and inattention were suspected to be caused by the influenza epidemic that occurred after World War I, when postencephalitic behavior manifestations in children included extreme examples of hyperactivity and inattention. This led to the suggestion that these symptoms were due to organic brain damage. The concept of inattention and hyperactivity being part of a spectrum with less intense manifestations secondary to subtle injuries became known as the syndrome of 'minimal brain damage' in the 1960s. However, the lack of clear evidence for brain damage eventually resulted in a shift to a more descriptive labeling of the disorder. This is reflected in the American Psychiatric Association classification system (DSM) defining the 'hyperkinetic reaction of childhood.' The same disorder was similarly described in the United Kingdom, as reflected in the World Health Organization (WHO) classification. However, the conditions described differed in that the British disorder included more severe symptomatology and required that the symptoms had to be present in all settings.

In 1980, the US characterization of inattention and hyperactivity was changed in several ways. It was conceptually defined by three symptom dimensions: inattention, impulsiveness, and hyperactivity, with inattention playing a more prominent role. In addition, to address the heterogeneity within the disorder, two subtypes ('attention deficit disorder with hyperactivity' and 'attention deficit disorder without hyperactivity') were defined. Again, different from the British criteria, the symptoms were only required to be present in one setting such as school. Retaining the concept that the major contributions to the symptoms were related to innate characteristics in the child rather than to environmental influences, the symptoms were required to have been present before the age of 7 years and to have lasted for at least 6 months. The British system continued to use the term 'hyperkinetic syndrome of childhood' and to include the pervasive nature of the symptoms.

The most recent changes in diagnostic criteria used by the American Psychiatric Association (DSM-IV) and the WHO have moved the definitions closer to agreement. Considering the most recent studies, there is evidence to support two dimensions. In DSM, the first dimension, inattention, is characterized by the 'often' occurrence of at least six of nine of the inattentive behaviors presented in **Table 1**. The second dimension consists of both hyperactivity and impulsiveness and is characterized by the 'often' occurrence of at least six of nine of the hyperactive and/or impulsive behaviors presented in **Table 1**. The WHO definitions are similar but do not attempt to quantify the specific behaviors and do not include impulsiveness in the hyperactivity dimension.

In DSM, the two dimensions define three subtypes: predominantly inattentive type (meeting criteria on the inattentive dimension), predominantly hyperactive/impulsive type (meeting criteria on the hyperactive/impulsive dimension), and combined type (meeting criteria on both dimensions). In addition, there are other general criteria including the onset of symptoms before 7 years of age, the presence of symptoms for at least 6 months, the presence of symptoms in two or more settings (e.g., home, school, or work), and evidence that

Table 1 DSM-IV behaviors for ADHD

Inattention
Careless mistakes
Difficulty sustaining attention
Seems not to listen
Fails to finish tasks
Difficulty organizing
Avoids tasks requiring sustained attention
Loses things
Easily distracted
Forgetful
Hyperactivity
Fidgeting
Unable to stay seated
Moving excessively (restless)
Difficulty engaging in leisure activities quietly
'On the go'
Talking excessively
Impulsiveness
Blurting answers before questions completed
Difficulty awaiting turn
Interrupting/intruding upon others

the symptoms cause significant clinical impairment in social, academic, or occupational functioning. The WHO condition has been renamed 'disturbances of activity and attention.'

Treatments Other Than Diet

In considering dietary interventions, it is important to note that there are two other forms of treatment with proven efficacy. These are stimulant medications and behavior modification. Considerations about dietary interventions have to be considered in the context of these other interventions. The nature of the main beneficial treatments, stimulant medication and behavioral interventions, makes the issue of diagnostic criteria for ADHD extremely important. Both of these treatments are not specific for the disorder so that the determination about which children are treated is very dependent on who is diagnosed.

The stimulant medications consist of methylphenidate (Ritalin), dextroamphetamine (Dexedrine), and pemoline (Cylert). They are particularly popular in the United States because they represent safe, effective, and low-cost treatment. A review of numerous studies has shown that stimulants improve the core behaviors of inattention, impulsiveness, and hyperactivity for the duration of action of the medication, as well as providing temporary improvement of associated features including aggression, social interaction, and academic productivity. The margin of safety is very high, and the side effects on appetite, sleep, and, infrequently, tics or bizarre behavior are all reversible when the medication is stopped. The concern about growth has proved to be insignificant, and although abused by adults, the stimulants are rarely abused by the children who take them because they usually do not find taking the medication pleasurable. While there is no long-term evidence that the use of stimulant medication or behavioral interventions on their own have any long-term benefits, there is evidence of long-term benefits when they are used in combination.

Effective behavioral interventions have generally consisted of direct contingency management programs (e.g., point or token programs or a response cost program) and social skills training. Like stimulant medication, these interventions are not specific to ADHD and have no proven long-term benefit when used in isolation. Other approaches, such as traditional psychotherapy and play therapy, have not been found to be effective with this group of children. Likewise, cognitive behavioral techniques, where a therapist teaches a child to control his or her behavior, have usually not been effective for children with ADHD because of the difficulty these children experience in generalizing the techniques beyond the therapeutic sessions.

Dietary Interventions

The concept that specific dietary components may adversely affect behavior has rested on three hypotheses:

1. Oligoallergenic diet
2. Sugar restriction
3. Feingold diet.

The idea that food might have an adverse effect on behavior was first raised in 1922 by Shannon. This concept was further elaborated in 1947 by Randolph in his description of the 'tension fatigue syndrome,' a behavioral extension of the vomiting reaction to milk proteins, and was also promoted by Speer. Their theory suggested that some children have atypical allergic reactions to various foods, consisting of subtle and behavioral effects. Their treatment entailed placing a child on a restricted diet and then adding foods one at a time to determine which foods caused an adverse reaction. This has been referred to as the oligoallergenic diet by a recent clinical/research group.

A specific focus on sugar as a nutrient adversely affecting behavior first appeared in the 1970s, with a study reported by Langseth and Dowd. Among 271 hyperactive children, these authors found a large number of children who, during glucose

tolerance tests, had patterns of blood glucose levels similar to the pattern seen in adults with functional reactive hypoglycemia. Similar results have also been found in aggressive criminal offenders. A subsequent study showed that the patterns that Langseth and Dowd found can be normal variations in childhood, but the Langseth and Dowd study was followed by two correlational studies that suggested an association between sugar intake and hyperactivity. The hyperactive children who consumed more sugar displayed more hyperactive and aggressive behavior.

The third dietary intervention suggested to improve behavior was proposed by Dr. Benjamin Feingold in 1975. He reported that at least 50% of hyperactive and learning-disabled children improved when placed on diets that were salicylate and additive free. Over time, the three dietary interventions have been combined so that proposed dietary restrictions now tend to incorporate all three in their recommendations. However, it is useful to examine the scientific evidence for each of these three dietary interventions.

Objective Standards

In discussing the evidence for the efficacy of dietary interventions in improving behavior in children, it is first important to review the concepts important to prove efficacy. The major point to emphasize is that it is impossible to prove the null hypothesis. It is virtually impossible to prove definitively that no relationship exists between dietary constituents and behavior or cognitive function. This is because it is impossible to test every possible variation or type of child. Therefore, a realistic approach needs to be similar to that taken by the US Food and Drug Administration (FDA) for the criteria it requires to license a new medication. Basically, pharmaceutical companies are required to demonstrate that a new medication is both efficacious and does not cause significant harm. It is not the role of the FDA to disprove the efficacy of a drug treatment. With dietary interventions, they should not be recommended as a primary intervention for behavioral problems until there is clear evidence of their efficacy.

The main criteria required to evaluate objectively the efficacy of psychotropic medications are presented in **Table 2**. It is useful to use these criteria to evaluate the scientific merit of any studies on interventions affecting behavior. It is also important to examine the pattern of results of multiple studies from different research groups. Ideally, where other efficacious therapies are available (e.g., stimulant medication and behavior modification for children with ADHD), the proposed therapy should be compared with existing therapies. This latter examination, by and large, has not been undertaken with any of the three dietary interventions.

Study Designs

There are two designs that can be employed to study the effects of nutrients on behavior. The most commonly employed design is the challenge study. This first places the children on the diet under study for a period of time and then challenges them with a food containing the offending agent (e.g., sucrose or tartrazine) or a food that does not contain the offending agent but looks and tastes identical to the offending agent, referred to as a placebo. This is the most commonly employed design because it is the easier and less expensive type to complete. The other design develops diets that appear similar, but the diets differ in what they contain (e.g., sugar or artificial sweeteners). In both designs the children, their families, and the researchers need to be blind about which diet or challenge food the children receive at any given time. In most studies, the children are used as their own controls (crossover studies). They are able to receive both diets or challenges in a sequence because the diets are not believed to result in permanent changes lasting once the diet is stopped.

The measures used to assess the effects (dependent measures) are then completed within the few hours after a challenge or repeatedly while the children are on diets. While parents, clinicians, and teachers are utilized as observers (completing behavior rating scales), ideally multiple measures are employed including some that are by independent observers or include objective assessments (e.g., performance on a continuous performance test and measuring activity level). Finally, it is important not to base results on one study. There need to be multiple studies performed by different groups of researchers, and a clear pattern of effects should emerge. When a number of studies have been completed, it is possible to combine them statistically with such techniques as meta-analysis to gain a more definitive picture.

Oligoallergenic Diet

While this is the oldest of the three dietary interventions, few controlled studies meeting the objective criteria outlined previously have been undertaken. Five investigations have studied the effects of placing children on restricted diets. These studies all included restricting the dietary intake of additives and simple sugars. The studies found beneficial effects from placing children on restricted diets compared with a placebo diet, or they found worsening behaviors in children on the restricted diets when they were challenged with offending foods compared with placebo challenges. In all but one of the studies, the only successfully completed dependent measure was behavior rating scales completed by the parents. While these are important measures and are collected in most studies, the raters are not independent of the children's behaviors. One study had multiple measures, but only those of the parents and physician found a significant difference between the offending agent and placebo challenges. More extensive research by additional research groups and additional independent measures are required to document the efficacy of this intervention before a decision can be made about its efficacy. Since the initial diet is extremely restrictive, care must be taken to make sure that the diet is adequately balanced and contains adequate nutrition.

Sugar Restriction

Sugar restriction usually refers to limiting the amount of sucrose in the diet. While most of the studies examined sucrose restriction, some also examined restriction of fructose or glucose. The artificial sweetener employed as a placebo was most frequently aspartame, but several studies used saccharin or both aspartame and saccharin as separate conditions. The type of sweetener used did not seem to affect the results.

Sugar restriction has been studied as a treatment for children since 1982. There have been a total of 23 appropriate objective studies contained within 16 reports employing a wide variety of types of children, including children with ADHD and aggression as well as normal children, and varying in age from preschool children to adolescents. All of the studies with two exceptions were challenge crossover studies in which children were challenged with drinks containing either sugar (sucrose in most studies) or an artificial sweetener (mostly aspartame). The other two studies consisted of giving the children diets that were high in sucrose content or low in sucrose and sweetened with aspartame or saccharin. A meta-analysis of the 23 studies did not find any significant behavioral or cognitive effects from sugar. There were not enough studies to reach a definitive conclusion, and there was insufficient statistical power to detect small effects or to detect effects on a small subset of children. To date, there is not enough evidence to warrant the recommendation to restrict a child's sugar intake for the purpose of improving the child's behavior or cognitive functioning.

Feingold Diet

The Feingold diet restricts foods with dyes, preservatives, and salicylate compounds. Investigations of this diet, which were reviewed in 1986, generally involved children with ADHD. In most of the studies the children were kept on an additive-free diet and then challenged with a food containing an additive or an additive-free food as placebo. Two studies used additive-containing and additive-free diets. A problem in comparing studies was the variation in type and dose of additives used. There were a total of 13 controlled studies. The summation of the findings found little, if any, effect. At best, there was some suggestion that a small percentage of children (1%) were adversely affected by additives. However, a recent study found that 24 of 34 children referred for hyperactivity (no formal diagnosis was established) who responded in an open clinical trial to an additive-free diet responded adversely to challenges with varying doses of tartrazine compared with placebo, whereas all except 2 of 20 in a comparison group did not. The dependent measures were two behavior rating scales completed by the parents. There appeared to be a dose response that would be contrary to a usual allergic response. This is a much higher rate of response than found in any previous study including those using tartrazine. Further study is required to substantiate these results since they run contrary to most of the previous research. Overall, the evidence to date does not confirm the efficacy of the Feingold diet to warrant its promotion as a treatment for most children with behavioral problems. In addition, if the diet is strictly maintained including foods containing salicylate compounds, the diet may be deficient in vitamin C.

Potential Side Effects of Diets

With all the diets, maintaining compliance may be difficult. Children who have behavioral problems are generally less likely to be compliant, and it can require a major effort to maintain the diet, detracting from efforts to control other areas of behavior. Diets are also problematic because they require the children to eat foods different from their peers. In

children who are already singled out as different, this can further reduce their self-esteem. Care has to be taken to weight the benefits of diets with as yet objectively unproved effects against the potential harm and difficulties in administering them.

Conclusions

ADHD is a mental disorder and its diagnosis is based on a child manifesting the symptoms of inattention, hyperactivity, and impulsiveness to the extent that the symptoms impair the child's ability to function. The main beneficial treatments are two nonspecific treatments, stimulant medication and behavioral interventions. While neither alone has any proven long-term benefits, there is evidence that the combination of both treatments does have some long-term benefits.

Dietary interventions have included (1) restriction of allergenic foods starting with a generally restricted diet and adding those foods that do not worsen the child's behavior, (2) restriction of food additives and preservatives referred to as the Feingold diet, and (3) restriction of sugar. These dietary interventions have not been proved to be efficacious and more study is required to determine their effects.

HYPERLIPIDEMIA

Contents

Overview

T R Trinick and E B Duly, Ulster Hospital, Belfast, UK

Normal Lipid Metabolism

Lipids are a heterogeneous group of substances soluble in organic solvents but insoluble in water. They are largely intracellular but circulate in blood as lipoprotein particles. There are four general functions for lipids:

- Structural components of membranes
- Storage forms of metabolic fuel
- Transport forms of metabolic fuel
- Protective functions as an outer coating of the organism

Lipids consist of cholesterol and its derivatives, fatty acids, triacylglycerols, phospholipids, and

apolipoproteins. The lipoprotein particle has a core of neutral lipids (cholesterol esters and triacylglycerol) and a surface coat of polar lipids (unesterified cholesterol and phospholipids) and apolipoproteins. They are classified in terms of density. The following are the main lipoproteins:

- Chylomicrons
- Very low-density lipoprotein (VLDL)
- Immediate-density lipoprotein (IDL)
- Low-density lipoprotein (LDL)
- High-density lipoprotein (HDL)

Synthesis of lipoproteins occurs in the intestine or liver. They are then modified by enzymes and taken up by cell surface receptors in processes largely regulated by the apolipoproteins. A series of receptors, transporters, and enzymes are important in lipoprotein metabolism and function as detailed later. The physicochemical characteristics of the main lipoprotein classes are shown in **Table 1**.

Interest in lipids lies in circulating lipid concentrations and their relationship to atherosclerosis, particularly coronary heart disease, stroke, and peripheral vascular disease.

Cholesterol

Cholesterol is a sterol with the structure shown in **Figure 1**. Daily cholesterol intake is 0.5–1.0 g, half of which is absorbed. On a low-cholesterol diet (<300 mg/day) the body synthesizes approximately 800 mg of cholesterol per day, mainly in the liver and, to a lesser extent, in the intestine.

The rate-limiting step in synthesis is highly sensitive to cellular levels of cholesterol, themselves sensitive to circulating levels of cholesterol. This feedback regulation occurs through changes in the amount and activity of an enzyme called 3-hydroxy-3-methylglutaryl CoA reductase (HMG-CoA reductase), which catalyzes the formation of mevalonate, the rate-limiting step in cholesterol biosynthesis. The rate of synthesis of HMG-CoA reductase mRNA is controlled by the sterol regulatory element binding protein (SREBP). SREBP in its inactive state is attached to the endoplasmic reticulum or nuclear membrane, but when cholesterol levels decline the amino-terminal domain is released from its association with the membrane by proteolytic cleavage; it migrates to the nucleus and binds to the sterol regulatory element (SRE) on the 5′ side of the reductase gene to enhance transcription. As cholesterol levels increase, the proteolytic release of SREBP is blocked, SREBP in the nucleus is rapidly degraded, and cholesterol synthesis is switched off.

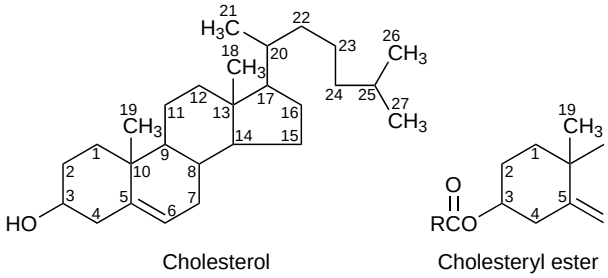

Figure 1 Structure of cholesterol and cholesteryl ester.

Cholesterol is found in the body largely as free cholesterol in membranes, but in the plasma it is two-thirds esterified, mainly as cholesterol linoleate and cholesterol oleate. Free cholesterol in plasma exchanges freely with cholesterol in membranes. The major route of cholesterol excretion is through the bile, directly as cholesterol or after conversion to bile salts, some of which are reabsorbed from the terminal ileum in the enterohepatic circulation.

Triacylglycerol

Triacylglycerols are glycerol molecules esterified with three fatty acid molecules (**Figure 2**). Diacylglycerols and monoacylglycerols have two and one fatty acid molecules, respectively. Triacylglycerols constitute the main energy storage form in mammals and are the main storage form of fatty acids.

Table 1 Physicochemical characteristics of the major lipoprotein classes

Lipoprotein	*Density (g/ml)*	*Molecular weight ($Da \times 10^6$)*	*Diameter (nm)*	*Triacylglycerol (% lipid)*	*Cholesterol (% lipid)*	*Phospholipid (% lipid)*	*Source*
Chylomicrons	0.95	>400	75–1200	80–95	2–7	3–9	Intestine
VLDL	0.95–1.006	10–80	30–80	55–80	5–15	10–20	Liver
IDL	1.006–1.019	5–10	25–35	20–50	20–40	15–25	Catabolism of VLDL
LDL	1.019–1.063	2.3	18–25	5–15	40–50	20–25	Catabolism of IDL
HDL	1.063–1.21	1.7–3.6	5–12	5–10	15–25	20–30	Liver, intestine

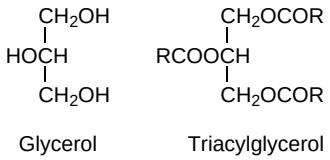

Figure 2 Structure of glycerol and triacylglycerol. 'R' denotes the position of a fatty acid within the triacylglycerol.

Fatty Acids

Fatty acids can be present as triacylglycerol, as part of lipoprotein particles, and as free fatty acids (bound to albumin). Common fatty acids and their sources are listed in **Table 2**.

Fatty acids are straight-chain compounds of differing lengths connecting a hydrocarbon group to a hydroxyl group. With only single bonds in the straight chain, the fatty acid is saturated; with one or more additional double bonds, the fatty acid is unsaturated. Fatty acids with only one double bond are said to be monounsaturated (e.g., oleic acid, C18:1), whereas fatty acids with two or more double bonds are said to be polyunsaturated (e.g., arachidonic acid, C20:4). The presence of a double bond allows there to be two isomers, depending on whether the hydrogen atoms attached to the carbon atoms on either side of the double bond lie on the same side (*cis*) or opposing sides (*trans*). *Cis* isomers are the only naturally occurring isomers and form kinks in the fatty acid chain. *Trans* isomers occur as part of food processing and maintain the straight direction of fatty acid chains. The common saturated fatty acids are palmitic (C16:0) and stearic (C18:0) acids.

Table 2 Fatty acids and their sources

Fatty acid	*Structure*	*Source*	*Melting point (°C)*
Saturated			
Lauric	C12:0	Coconut oil, palm kernel oil	44
Palmitic	C16:0	Palm oil, milk, butter, cocoa, butter, beef, pork, lamb	63
Stearic	C18:0		69
Behanic	C22:0	Some seed oils, especially peanut	80
Lignoceric	C24:0		84
Unsaturated			
Oleic	C18:1	Olive oil, most commonly occurring fatty acid	11
Linoleic	C18:2	Corn oil, soya bean oil, sunflower oil and sunflower seed oil	−5
Linolenic	C18:3	Linseed oil	−11
Arachidonic	C20:4	Fish oils	−50
Eicosapentenoic	C20:5	Cod, salmon, pilchard, mussel, oyster	−54
Docosahexenoic	C22:6		

From Durrington PN (2004) *Hyperlipidaemia: Diagnosis and Management*. London: Hodder Arnold.

Diets rich in omega-3 polyunsaturated fatty acids (n-3 PUFAs), such as α-linoleic acid, eicosapentanaenoic acid, and decosahexaenoic acid, are associated with less coronary heart disease, and conjugated linoleic acids have beneficial effects against atherosclerosis. n-3 PUFAs function mainly by changing membrane lipid composition, cellular metabolism, signal transduction, and regulation of gene expression. It is postulated that receptors exist for fatty acids or their metabolites that are able to regulate gene expression and affect metabolic or signalling pathways associated with coronary heart disease. Three nuclear receptors are thought to be fatty acid receptors that respond to dietary and endogenous ligands: peroxisome proliferator activated receptors, retinoid X receptors, and liver X receptors.

Phospholipids

The common phospholipids in plasma are derived from glycerol and consist of triacylglycerol containing phosphate and a nitrogenous base (glycerophospholipids). The phosphate group is usually attached at position 3 of the glycerol molecule, and the nitrogenous base is usually an amino acid or an alcohol. The phosphatidyl cholines (lecithins) are the most common phospholipid and are found in plasma and in cell membranes. Lecithin–cholesterol acyl transferase (LCAT) catalyzes the transfer of a fatty acyl group at position 2 on glycerol to cholesterol to produce cholesteryl ester and leaves monoacyl glycerophosphate (lysolecithin). Another class of phospholipids, the cephalins, includes phosphatidyl ethanolamine, phosphatidyl serine, and phosphatidyl inositol.

Phospholipids are able to bridge nonpolar lipids and water and act to allow lipids to mix with water in an emulsion. The nonpolar hydrocarbon end of the phospholipid is attracted to lipid, whereas the polar phosphate group is attracted to water. In a lipid droplet, the inner oily centre is surrounded by phospholipid, which has its outer phosphate group attracted to the surrounding water environment, to form a micelle.

Apolipoproteins A, B, C, and E

The lipoprotein particle (VLDL, LDL, and HDL) is composed of lipid and protein molecules. Among the protein molecules are a group of proteins found at the surface of the lipoprotein particle called apolipoproteins. Their function is integral to the metabolism of lipoproteins. They interact with phospholipids to solubilize cholesterol esters and triacylglycerol, regulate the reaction of enzymes (LCAT, lipoprotein lipase, and hepatic lipase) with lipid, and bind with cell surface receptors to determine the metabolism of lipoproteins.

Apolipoprotein A This is the main protein of HDL and has two forms, apoA-I and apoA-II. ApoA-I is the main protein component in HDL, and the production and catabolism of apoA-I determine the plasma concentration of HDL cholesterol. It acts as an activator of LCAT, which is responsible for esterification of free cholesterol in plasma, and allows the binding of HDL to many cell surfaces. ApoA-II is a structural component of HDL.

Apolipoprotein A-I Milano ApoA-I Milano is a specific form of apoA-I seen in some Italian families, which appears to protect against the development of atherosclerosis.

Apolipoprotein B ApoB-100 is the main protein component of LDL and is synthesized in the liver. It is also found in chylomicrons and VLDL. ApoB-48 is synthesized from the intestine and is the amino-terminal half of apoB-100 synthesized from the same gene. ApoB-100 is the receptor ligand for the LDL receptor.

Apolipoprotein C ApoC is composed of three separate apolipoproteins. ApoC-I is mainly found in VLDL but also in chylomicrons and HDL. ApoC-II is present in a circulating reservoir of HDL, transferring to chylomicrons and VLDL, where it acts as an activator of lipoprotein lipase, allowing the lipolysis of triacylglycerols from circulating triacylglycerol-rich lipoproteins. ApoC-III is the most abundant form of apoC and may act as a modulator of lipoprotein lipase.

Apolipoprotein E ApoE is a glycoprotein with several isoforms designated as apoE-2, -E-3, and -E-4. ApoE-3 is the most common isoform. It is present in VLDL, IDL, and HDL (mainly HDL_2). ApoE facilitates chylomicron remnant metabolism through the chylomicron remnant and VLDL receptors of the liver. ApoE-3 and -E-4 bind avidly with hepatic receptors, whereas apoE-2 is poorly bound. Patients with only apoE-2 isoform clear chylomicron remnants and IDL slowly, and apoE-2 is associated with dysbetalipoproteinemia (type III hyperlipoproteinemia). ApoE also facilitates metabolism through the LDL receptor (particularly the apoE-4 isoform). A large number of tissues express mRNA for apoE, including the brain, although the reason for this is unclear.

Apolipoprotein (a) Apo(a) joined together with one LDL particle, which contains apoB, constitutes a lipoprotein called Lp(a). Interest in Lp(a) arose because apo(a) shows close sequence homology with plasminogen, suggesting that a high level of Lp(a) would impair thrombolysis. Lp(a) is an independent risk factor for developing vascular disease, with levels above a cutoff value of 300 mg/l placing individuals at risk, especially if combined with other risk factors.

Lipoproteins

The main function of the lipoproteins is to transport lipids from one organ to another. Their main characteristics are shown in **Table 1**.

Chylomicrons These are the largest lipoproteins, consisting mainly of triacylglycerol with apoB-48 and apoA, -C, and -E. Triacylglycerol is hydrolyzed with endothelial-bound lipoprotein lipase, changing the chylomicron into a chylomicron remnant rich in cholesteryl ester. These remnants are removed from the circulation by interaction with the remnant receptors mainly present on hepatocytes. Peak chylomicronemia occurs 3–6 h after a meal, with a half-life of less than 1 h, and is cleared from the circulation after a 12-h fast.

Very low-density lipoproteins These triacylglycerol-rich lipoproteins are secreted mainly by the liver, with apoB-100 and apoE on their surface, whereas some VLDLs are synthesized by the gut. They are transformed into mature VLDLs by accumulating cholesterol ester, apoC, and apoE from HDLs. They then either interact with lipoprotein lipase to convert into IDLs, which can be taken up by the liver, or convert to LDLs by interacting with hepatic triglyceride lipase.

VLDL particles vary in size. Small VLDL is converted into LDL, via IDL, to a greater extent than large VLDL, which is converted to a form of IDL that appears to be removed from the plasma before conversion to LDL.

Intermediate-density lipoproteins IDLs are intermediate particles formed from the conversion of VLDL to LDL. Also known as VLDL remnants, some are removed directly from plasma, whereas some convert into LDL.

Low-density lipoproteins LDL is the major cholesterol-carrying particle in the plasma. The core is cholesterol ester and has one apolipoprotein, apoB-100, per LDL particle. There are different sizes of LDL. Approximately one-third of the intravascular pool is catabolized per day and three-fourths of the circulating LDL is cleared through the liver, mainly through the LDL receptor. Small, dense LDL is more common in some dyslipidemias and may be more easily oxidized than larger LDL. Normal LDL does not cause foam cell formation, but lipid peroxidation of LDL makes the LDL a ligand for certain receptors (the scavenger receptor and perhaps a specific receptor for oxidized LDL) and results in the formation of cholesterol-laden foam cells. In addition, oxidized LDL in the cell wall stimulates the production of cytokines and growth factors, resulting in monocyte recruitment and the proliferation of smooth muscle cells. This mechanism underlies one model of atherogenesis.

High-density lipoproteins Nascent HDL is secreted by the liver and gut. It acquires unesterified cholesterol in the circulation, catalysed by LCAT to cholesteryl ester. HDL can pass cholesteryl ester to VLDL in exchange for triacylglycerol, facilitated by cholesterol ester transfer protein (CETP), or HDL can be taken up by the liver directly. The idea that HDL protects against coronary heart disease (CHD) comes from epidemiological studies. A 0.026 mmol/l increase in plasma HDL cholesterol decreases CHD risk by 2% in men and 3% in women.

Enzymes and Transfer Proteins

Acylcoenzyme A Cholesterol acyltransferase (ACAT; EC 2.3.1.26) ACAT-1 and ACAT-2 are membrane-bound proteins responsible for cholesterol ester formation, metabolizing excess cholesterol within cells to cholesterol ester, which is allosterically activated by cholesterol.

Adenosine-binding cassette transporter In peripheral tissues, adenosine-binding cassette transporter (ABCA-1) protein facilitates transfer of intracellular cholesterol out of cells to lipid-poor apoA-1 or pre-β HDL particles. When it is deficient or inactive, cholesterol accumulates in peripheral tissues as in Tangier disease or familial HDL deficiency.

Cholesterol Ester transfer protein CETP mediates the exchange of cholesteryl ester from HDL with triacylglycerol from VLDL or chylomicrons.

Fatty acid binding protein Fatty acid binding proteins (FABPs) play a role in the solubilization of long-chain fatty acids (LCFAs) and their CoA-esters to various intracellular organelles. FABPs serve as intracellular receptors of LCFAs and are involved in ligand-dependent transactivation of peroxisome proliferator-activated receptors (PPARs) in trafficking LCFAs to the nucleus.

Hepatic lipase (EC 3.1.1.3) Hepatic lipase (HL) is an endothelial-bound enzyme that removes triacylglycerol from lipoproteins in the metabolism of chylomicrons, VLDL, and HDL. HL hydrolyzes HDL triacylglycerol and phospholipids to form HDL_3 from HDL_2, contributing to the process of HDL regeneration in the reverse cholesterol transfer process.

Lecithin-cholesterol acyltransferase (EC 2.3.1.43) LCAT mediates the esterification of cholesterol by transferring a fatty acid from lecithin to cholesterol to form cholesteryl ester.

Lipoprotein lipase (EC 3.1.1.34) Lipoprotein lipase and hepatic lipase are endothelial-bound enzymes that remove triacylglycerol from lipoproteins. Lipoprotein lipase is activated by apoC-II and is involved in catabolism of chylomicrons and VLDL. Endothelial lipase, lipoprotein lipase, and hepatic lipase belong to the same gene family.

Microsomal triglyceride transfer protein Microsomal triglyceride transfer protein is present in enterocytes and hepatocytes, and it is responsible for adding neutral lipid to apoB to protect it from ubiquitinylation and degradation.

Phospholipid transfer protein Phospholipid transfer protein transfers phospholipids from other lipoproteins to HDL, contributing to the functionality of HDL.

Sterol regulatory element binding protein SREBP is a protein that binds with part of the LDL receptor promoter to increase cholesterol synthesis.

Receptors

A large number of lipoprotein receptors have been identified. Some of the more important receptors are discussed here. Lipoprotein uptake at the cell

membrane may be non-receptor-mediated, perhaps by pinocytosis, where 'binding' is of low affinity but is not saturable.

LDL receptor The LDL receptor (LDLR) is a transmembrane glycoprotein present on most cell surfaces, encoded on chromosome 19. Free cholesterol, building up in the cell through the receptor, reduces both cell synthesis of cholesterol and cell uptake of more LDL cholesterol.

LDL receptor-related protein The LDL receptor-related protein (LRP) is a multifunctional receptor (binding VLDL/chylomicron remnants and other nonlipid ligands such as bacterial toxins) present in nearly all tissues. It has a high affinity for apoE and a low affinity for apoB-100.

VLDL receptor This receptor binds VLDL, β-VLDL, and IDL. It recognizes apoE and is located mainly in adipose tissue and muscle.

Scavenger receptors These receptors are found on macrophages and hepatic endothelium. They bind and degrade chemically modified LDL, such as oxidized or acetylated LDL. They are not downregulated by intracellular cholesterol accumulation. Hepatocellular uptake of HDL and/or its cholesteryl ester content is facilitated by a scavenger receptor and a HDL receptor.

Other remnant receptors The lipolysis-stimulated receptor found on fibroblasts recognizes surface apoE and takes up VLDL, chylomicrons, and LDL. Two membrane-binding proteins (MBP 200 and MBP 235) have been described on macrophages and appear to bind VLDL. Remnants from both chylomicrons and VLDL (after hydrolysis of more than 70% of their triacylglycerol content) appear to be removed by both the LDL and the LRP receptors.

Peroxisome proliferator-activated receptors PPARs are a family of intranuclear receptors, including PPARα and PPARδ, that regulate a variety of genes involved in lipid metabolism, thrombosis, and inflammation.

Exogenous (Dietary) Lipid Pathways

Ingestion of food containing fat (triacylglycerol) and cholesterol results in absorption into the enterocyte of fatty acids, monoacylglycerols, free cholesterol, and lysolecithin. In the enterocyte, reesterification of fatty acids into triacylglycerol and cholesterol into cholesteryl ester occurs to form chylomicrons, to which is added a surface layer of apoB-48, -A-I, -A-II, and -A-IV, phospholipid, and free cholesterol. This allows secretion of the chylomicron into the intestinal lymphatics. ApoB-48 is required for secretion of the chylomicron. ApoB-48 is a truncated form of apoB-100, synthesized in the liver but missing the LDL receptor-binding domain of apoB-100. The action of the apoB-editing enzyme in enterocytes changes a nucleotide base in apoB mRNA to a stop codon. There is one apoB-48 per intestinal triglyceride-rich particle.

Chylomicrons in the circulation take up apoC from HDL (releasing it back to HDL later) and acquire apoE. ApoC-II allows the chylomicron to activate lipoprotein lipase on capillary endothelial cells of muscle and fat. This allows hydrolysis of triacylglycerol, releasing glycerol and fatty acids to be taken up by local tissue. Surface phospholipids, free cholesterol, and apoC transfer to HDL as the particle shrinks. This small chylomicron is called a chylomicron remnant and is catabolized through the LDL receptor and other remnant receptors on the liver. This transport of dietary lipid from the intestinal to the peripheral tissues is shown in **Figure 3**.

Endogenous Lipid Pathways

The liver is the main source of endogenous lipid (**Figure 4**). In particular, the liver secretes the triacylglycerol-rich lipoprotein VLDL. Triacylglycerol, which is formed from fatty acids either newly synthesised or taken up from plasma, together with free cholesterol, synthesised from acetate or delivered to the liver in chylomicron remnants, join with apoB and phospholipids to form VLDL. ApoC and apoE are added in the circulation. Triacylglycerol is progressively removed from VLDL in the same way as occurs with chylomicrons. Free cholesterol transfers to HDL and is esterified with LCAT and transferred back to VLDL, using a protein called cholesteryl ester transfer protein (CETP), in exchange for triacylglycerol transfer from VLDL to HDL. In this way, VLDL becomes smaller and transforms to become IDL, although some small VLDLs may be removed directly. IDL is further changed through interaction with hepatic lipase to LDL. In this way, most VLDL is transformed to LDL.

Reverse Cholesterol Transport

Lipids are transported to the peripheries from the gut and the liver. They return to the liver via HDL in a process known as reverse cholesterol transport (**Figure 5**). HDL particles arise in the liver and gut from a coalescence of apoA-I and phospholipid to

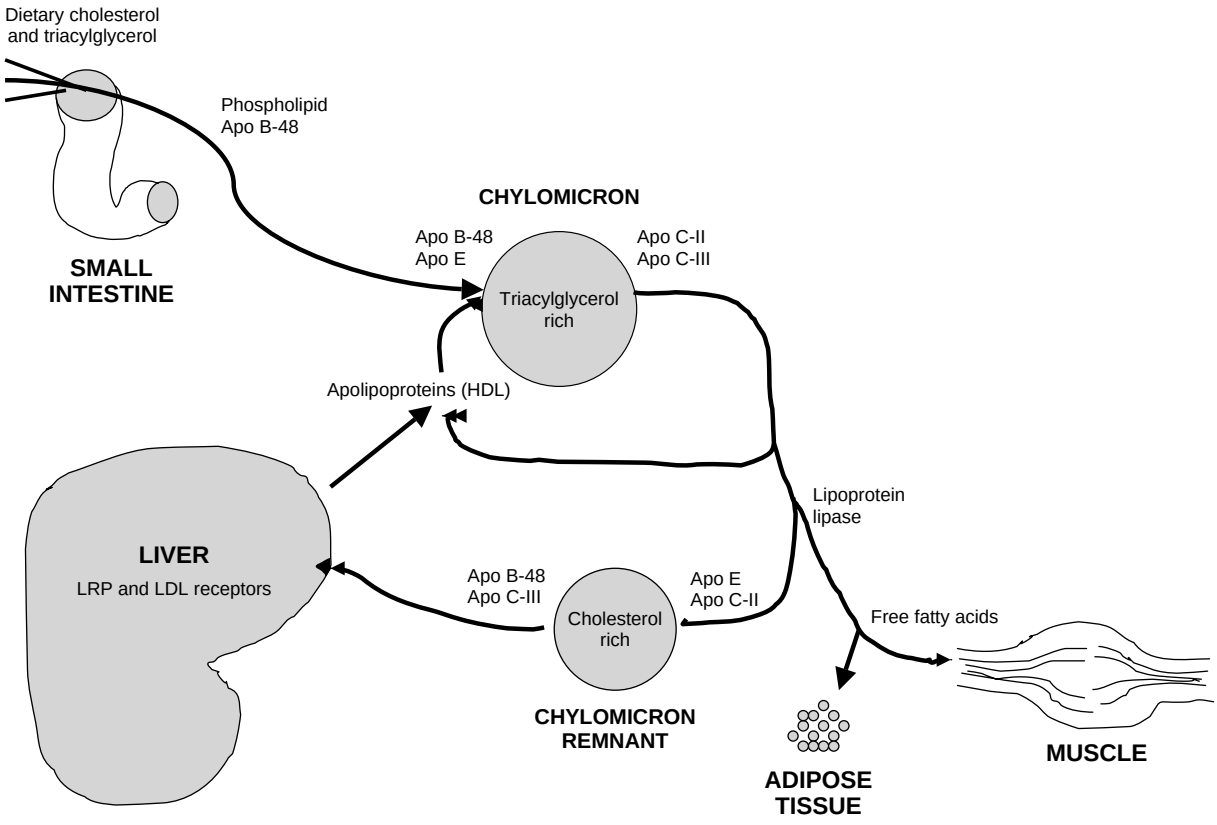

Figure 3 Exogenous (dietary) lipid pathway. This shows the transport of dietary lipid from intestine to peripheral tissues and liver. Movement of apolipoprotein between high-density lipoprotein (HDL) and chylomicrons is shown. LRP, low-density lipoprotein (LDL) receptor-related protein.

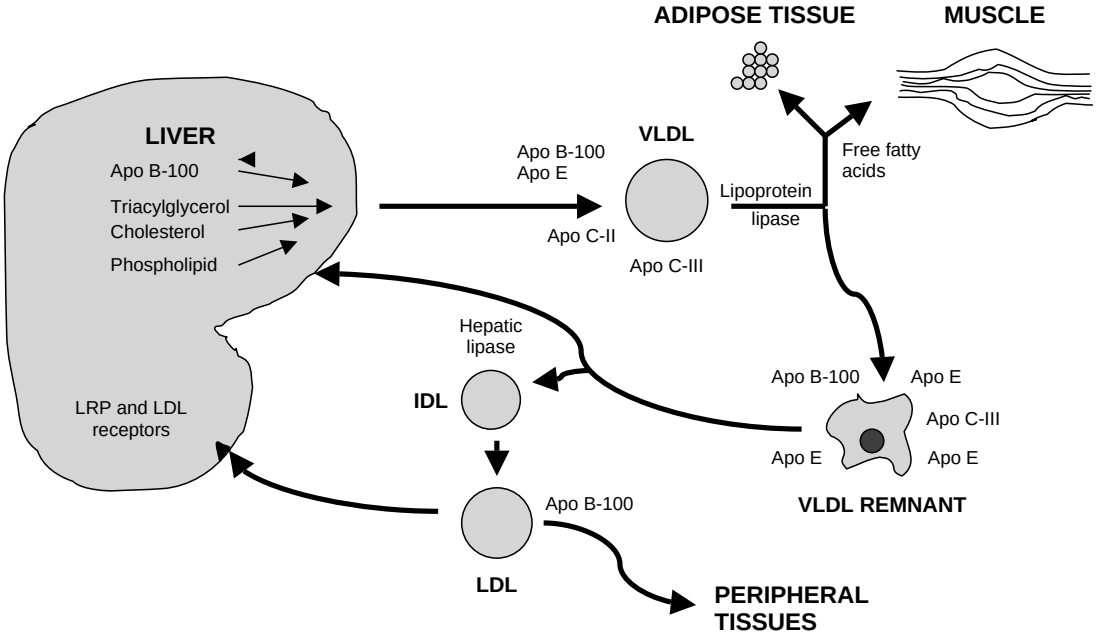

Figure 4 Endogenous lipid pathway. This shows the formation of very low-density lipoprotein (VLDL) lipid particles ($VLDL_1$ and $VLDL_2$) in the liver with the interconversion, through the action of lipoprotein lipase, to VLDL remnant and through immediate-density lipoprotein (IDL) to LDL. Lipids are taken up from LDL both peripherally and in the liver. LRP, low-density lipoprotein receptor-related protein.

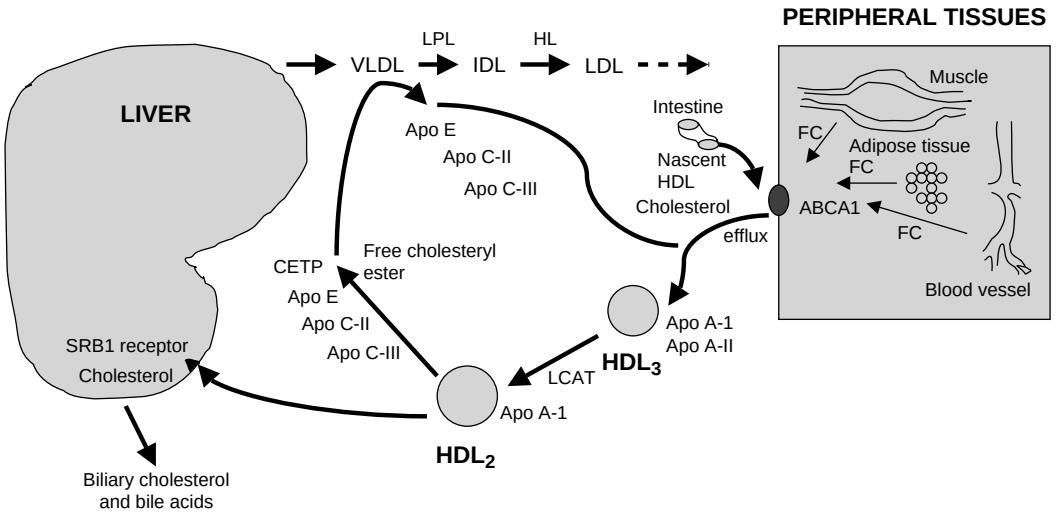

Figure 5 Reverse cholesterol transport. Nascent high-density lipoprotein (HDL_3) picks up free cholesterol from the peripheries to become HDL_2, by a lecithin–cholesterol acyl transferase (LCAT)-mediated conversion. Cholesterol is then transported to the liver with uptake by the SRBI receptor. A second method of transport to the liver involves CETP-mediated esterification of HDL and conversion into immediate-density lipoprotein (IDL) and low-density lipoprotein (LDL), which is then taken up by the LDL receptor. This transfer of lipid between HDL_2 and VLDL/IDL maintains a cycle within HDL, and IDL/LDL deliver cholesterol from the peripheries to the liver. HDL may also deliver cholesterol directly to the liver. FC, free cholesterol.

form cholesterol-deficient bilayered discs in the form of HDL_3. Circulating HDL particles, particularly a subset of HDL_3 called pre-β HDL or lipid-poor apoA-I, come into contact with cells, and ABCA-1 acts to move free cholesterol from the cell surface and out of the cells. This cholesterol is converted by LCAT to cholesteryl ester and moves into the core of the HDL, forming mature cholesterol-rich HDL. After accumulating cholesterol, the HDL starts to accept other apolipoproteins and becomes HDL_2. In turn, HDL_2 appears to pass cholesteryl ester to triglyceride-rich lipoproteins such as chylomicrons, chylomicron remnants, and VLDL under the influence of CETP. The cholesterol then finds its way back to the liver in the form of chylomicron remnants, IDL, and LDL. Some of the HDL_2 particles may lose cholesterol directly to the liver and some may be taken up directly by the liver.

Consequences of Hyperlipidemia

Clear evidence exists that as serum cholesterol rises, the risk of CHD rises, and as serum cholesterol falls, the risk of developing CHD falls. The epidemiological evidence comes from within-country studies, between-country studies, and migration studies. Support comes from animal studies and there is evidence of the beneficial effects of reducing serum cholesterol in both primary and secondary prevention of ischemic heart disease.

The within-country studies include the Multiple Risk Factor Trial Intervention (MRFIT) study, which followed 360 000 middle-aged men screened and followed up for CHD mortality. MRFIT showed a strong positive correlation between cholesterol levels at initial screening and later death from CHD. The Framingham Heart Study, started in 1949, is another prospective survey that followed a large cohort of Americans and examined lipid levels and risk of CHD, particularly the relationships between lipoprotein fractions and CHD. It showed a strong association between elevated LDL cholesterol and increased incidence of CHD and an inverse association between HDL cholesterol and CHD risk. Framingham has drawn attention to the value of the ratio of total cholesterol to HDL cholesterol, where a ratio of 3 or less suggests the disease is static and a ratio of 4 or higher suggests the disease is progressive. Framingham also drew attention to the incremental effect of additional risk factors in the development of CHD, such as hypertension, hyperglycemia, and smoking. Combinations of risk factors occur in the metabolic syndrome, in which insulin resistance appears to be the common denominator.

The best known between-country study is the Seven Countries Study by Ancel Keys linking diet, hypercholesterolemia, and CHD. He showed that a plot of each country's median total cholesterol against deaths from CHD was highly correlated. The variations in serum cholesterol were highly

correlated with the ratio of saturated to unsaturated fats in the diet.

Studies of migration and CHD include the Ni-Hon-San Study, in which cholesterol levels and CHD rates were compared in Japanese living in Japan, Honolulu, and San Francisco. There was a rise in both cholesterol levels and CHD rates across these groups, suggesting that as Japanese adopted a Western lifestyle their cholesterol increased and their risk of CHD increased.

Evidence that treatment of hyperlipidemia influences CHD is substantial. The methods of treating hyperlipidemia have varied from diet to drugs, surgery, meditation, and multiple risk factor reduction. The conclusion is that treatment of hyperlipidemia improves CHD morbidity and mortality. The Lipid Research Clinics Coronary Primary Prevention Trial, started in the 1970s, examined 4000 men without evidence of CHD but with hypercholesterolemia, randomized to receive cholestyramine or placebo. After 7 years, despite a relatively minor difference in cholesterol levels, there was a 20% decrease in CHD in the drug-treated group.

In the Oslo study, high-risk Norwegian men were given antismoking and dietary advice, resulting in a significant reduction in the incidence of CHD. The effect of partial ileal bypass surgery has been studied in patients who had experienced a myocardial infarction and were hypercholesterolemic (POSCH study). This surgical procedure improved blood lipids and reduced morbidity caused by CHD. In the Scandinavian Simvastatin Survival Study (4S study), patients with CHD and hypercholesterolemia were randomized to receive the HMG-CoA reductase inhibitor simvastatin or placebo. After a 4-year follow-up period, both morbidity and mortality were significantly reduced in the treatment group. This secondary prevention study was followed by a primary prevention study using pravastatin in men with hypercholesterolemia. This study (WOSCOPS study) randomized men without evidence of CHD to treatment with the HMG-CoA reductase inhibitor pravastatin or to placebo and followed them for 4.9 years. Treatment with the drug significantly reduced the incidence of myocardial infarction and death from cardiovascular causes. In the Air Force/Texas Coronary Atherosclerosis Prevention Study, a primary prevention study, subjects with low levels of LDL cholesterol and HDL cholesterol showed a reduced risk of CHD with statins. The Helsinki Heart Study and the Veterans Affairs-HDL Intervention Study used fibrate drugs in patients with low LDL cholesterol and showed impressive increases in HDL cholesterol and reductions in CHD risk. A 1% increase in HDL was equivalent to a 3% decrease in CHD risk.

Studies such as the Cholesterol Lowering Atherosclerosis Study, in which patients were allocated to drug therapy or placebo, used coronary angiography to follow the effect of drugs on disease. A small reduction in cholesterol results in a disproportionately larger reduction in cardiovascular events.

These studies show that it is possible to arrest progress of the disease and, in some cases, bring about regression of atherosclerosis. The extent to which this happens seems to depend on the underlying disease and the degree of cholesterol lowering.

Atherosclerosis has a complex and multifactorial etiology characterized by inflammation. Clinical markers of inflammation include C-reactive protein, modified LDL, homocysteine, lipoprotein (a), and fibrinogen, which are emerging risk factors and may give prognostic information for patient management. Folate may be beneficial by reducing plasma homocysteine, enhancing endothelial nitric oxide, and showing antiinflammatory properties. Other antiinflammatory agents, such as IL-10, may be of benefit.

Classification of Hyperlipidemia

There are a number of classification systems available. In 1967, Fredrickson, Levy, and Lees introduced the first classification as a method of reporting that lipoproteins were raised. The World Health Organization adopted this classification (**Table 3**).

In 1987, the European Atherosclerosis Society recommended a five-group classification of primary hyperlipidemia (**Table 4**), and the National Cholesterol Education Program Adult Treatment Panel III published guidelines in 2002 for normal and elevated lipid levels (**Table 5**).

Clinically, the most important step is to determine if the lipid abnormality is primary or secondary to another condition. **Table 6** shows the lipid changes seen in some common conditions. In practice, it is often easiest to classify lipid abnormalities into three

Table 3 Fredrickson/WHO classification of hyperlipoproteinemia

Type	*Lipids increased*	*Lipoprotein increased*
I	Triacylglycerol	Chylomicrons
II-a	Cholesterol	LDL
II-b	Cholesterol and triacylglycerol	LDL and VLDL
III	Cholesterol and triacylglycerol	Chylomicron remnants and IDL
IV	Triacylglycerol	VLDL
V	Cholesterol and triacylglycerol	Chylomicrons and VLDL

Table 4 European Atherosclerosis Society classification of hyperlipoproteinemia

Group	*Total cholesterol (mmol/l)*	*Triacylglycerols (mmol/l)*
Normal	<5.2	<2.3
A (mild hypercholesterolemia)	5.2–6.5	and <2.3
B (moderate hypercholesterolemia)	6.5–7.8	and <2.3
C (isolated hypertriglyceridemia)	<5.2	and 2.3–5.6
D (combined hyperlipidemia)	5.2–7.8	and 2.3–5.6
E (severe hypercholesterolemia and/or hypertriglyceridemia)	>7.8	and/or >5.6

Table 5 Adult Treatment Panel III levels for blood lipids

Classification	*Total cholesterol (mmol/l)*	*LDL cholesterol (mmol/l)*	*Triacylglycerols (mmol/l)*
Normal	<5.2	<2.59	<1.7
Above optimal	—	2.6–3.3	—
Borderline high	5.2–6.2	3.4–4.1	1.8–2.2
High	>6.2	4.2–4.8	2.3–5.6
Very high	—	>4.9	>5.6

Table 6 Lipid changes in some common conditions

Condition	*Total cholesterol*	*HDL cholesterol*	*Triacylglycerol*
Diabetes mellitus	Normal or ↑	↓	↑
Hypothyroidism	↑	↑	Can be ↑
Chronic renal failure	Normal or ↑	↓	↑
Nephrotic syndrome	↑	Often ↓	Often ↑
Cholestasis[a]	↑	↓	Can be ↑

[a]An abnormal lipoprotein called LpX is present.

categories: raised total cholesterol, raised triacylglycerol, mixed hyperlipidemia.

It is becoming clear that certain lipoprotein patterns are particularly atherogenic. Elevated IDL with increased small, dense LDL particles and low HDL is one such pattern. Classifications based on these patterns may emerge.

Causes of Hypercholesterolemia

Serum cholesterol at birth does not exceed 2.5 mmol/l and is rarely above 4.0 mmol/l in children. The values for adults are given in **Table 5**. A raised cholesterol level, with little or no elevation of triacylglycerol, is usually a result of raised LDL level. Occasionally, a raised HDL level is responsible for high cholesterol, as seen in the familial condition of primary hyper-α-lipoproteinemia. Secondary causes given in **Table 6** include hypothyroidism, nephrotic syndrome, some cases of diabetes mellitus, and cholestasis. Primary causes include polygenic familial hypercholesterolemia, in which several gene abnormalities together with environmental effects serve to raise serum cholesterol. Several genetic loci contribute to increased plasma LDL levels, but there are five specific monogenic disorders that increase LDL: familial hypercholesterolemia (LDL receptor gene), familial ligand-defective apoB-100 (apoB gene), autosomal recessive hypercholesterolemia (ARH gene), sitosterolen (*ABCG5* or *ABCG8* genes), and cholesterol 7α-hydroxylase deficiency (*CYP7A1* gene).

Much less common, but more clearly defined, are the two autosomal conditions of familial combined hyperlipidemia (FCH) and monogenic familial hypercholesterolemia (FH). In FCH, there appears to be an increase in apoB production and thus an increase in serum LDL. Serum VLDL levels are raised in one-third of these subjects with an associated triacylglycerol increase, one-third show increases in LDL, and one-third show increases in LDL and VLDL. Monogenic FH is caused by a defect in the LDL receptor (LDLR). The consequent reduced LDL uptake by cells, particularly in the liver, results in raised LDL and cholesterol levels. There are 683 mutations in the LDLR gene. Of these, 58.9% are missense mutations, 21.1% are minor rearrangements, 13.5% are major rearrangements, and 6.6% are splice site mutations. The majority of mutations are found in two functional domains of the LDLR, the ligand binding domain (42%) and the epidermal growth factor precursor-like domain (47%).

Predominant hypertriglyceridemia may result from raised VLDL or chylomicron levels. Secondary causes include excess alcohol ingestion, obesity and excess carbohydrate intake, diabetes mellitus, renal failure, and pancreatitis. Primary hypertriglyceridemia can be a result of familial combined hypertriglyceridemia, familial endogenous hypertriglyceridemia, or hyperchylomicronemia.

Familial endogenous hypertriglyceridemia results from increased hepatic triacylglycerol production with increased VLDL production. It is associated with obesity, glucose intolerance, and hyperuricemia. Hyperchylomicronemia is a result of inherited or acquired impairment of lipoprotein lipase activity.

Reduced insulin levels in diabetes mellitus impair the activity of lipoprotein lipase, and hyperchylomicronemia can occur. Inherited deficiency of the lipase enzyme

is rarely seen, as is deficiency of the apolipoprotein (apoC-II) required to activate the enzyme.

Mixed hyperlipidemia is often a secondary condition. Primary causes include familial combined hyperlipidemia and type III hyperlipidemia (dys-β-lipoproteinemia or broad β disease). Type III hyperlipidemia is associated with the apoE 2/2 phenotype, resulting in impaired recognition of apoE by hepatic receptors and an accumulation of IDL.

Dyslipoproteinemia is a central feature of the metabolic syndrome, which is associated with accelerated atherosclerosis. Visceral obesity, dyslipidemia, insulin resistance, hypertension, and a proinflammatory and prothrombotic state are the main characteristics of this condition. It has been defined by the World Health Organization and the National Cholesterol Education Programme. The worldwide increase in levels of obesity in the developed world may presage an increase in CHD.

Dietary Effects

Principles of Treatment

Treatment of hyperlipidemia is part of the management of CHD risk. This encompasses lifestyle changes, such as stopping smoking, increasing exercise, and modifying diet, as well as management of hypertension. Diet is the cornerstone of treating hyperlipidemia, best delivered by qualified dieticians, involving the whole family.

The main aims of diet are to correct excess calorie intake and to reduce the cholesterol and saturated fat content. Patients with hyperlipidemia can expect to see benefits from diet after 6 weeks and are reviewed every 4 months.

Diet can reduce total cholesterol 8–12%, with 60–80% of this change attributed to reductions in saturated fatty acid intake. The remaining change comes from reduced dietary cholesterol and changes in the intake of fiber and monounsaturated and polyunsaturated fatty acids. Dietary modification may not be successful in some primary hyperlipidemias. The Diet and Reinfarction Trial and the Mediterranean Diet Study in postmyocardial infarction survivors showed that dietary modification, not necessarily accompanied by plasma cholesterol lowering, can improve short-term prognosis.

Fat Most of the saturated fats in the diet come from just four fatty acids: lauric acid (C12:0), myristic acid (C14:0), palmitic acid (C16:0), and stearic acid (C18:0). The first three fatty acids reduce LDL receptor activity, raising LDL and total cholesterol by approximately 0.25 mmol/l per 10 g of saturated fat ingested. Watts and coworkers showed that total dietary fat (mainly saturated) increases hepatic VLDL-apoB secretion, so decreasing total fat intake should decrease hepatic apoB secretion.

Monounsaturates are being recommended more often. The most common is oleic acid (C18:1), found in the Mediterranean diet as olive oil. Animal fats are rich in monounsaturates but are also rich in saturated fats. The *trans* isomers of monounsaturates may raise total and LDL cholesterol and are best avoided.

In both type I and type V hyperlipidemia, the dietary management is to reduce fat intake to 20–40 g/day. Medium-chain triacylglycerols are used and fish oils can be tried, but the mainstay of therapy is reduced fat intake. Dietary β-sitosterol can block cholesterol absorption to a limited extent but is not used therapeutically.

Carbohydrate and calories Obesity is a common cause of hypertriglyceridemia due to raised VLDL levels in the obese subject. This may be because of an increase in insulin resistance resulting from obesity with concomitant hyperinsulinemia and elevation in hepatic VLDL synthesis. Some hypertriglyceridemic patients experience a further increase in triacylglycerol levels with an increase in carbohydrate intake, known as carbohydrate induction. This situation is accompanied by an increase in serum insulin levels. With weight reduction, the hypertryglyceridemia reduces and HDL cholesterol increases after 24 months.

Mild alcohol ingestion increases HDL cholesterol. Excess alcohol ingestion can precipitate hypertriglyceridemia of a type IV phenotype due to increased hepatic synthesis and secretion that, in subjects who cannot clear triacylglycerols efficiently, can progress to a type V phenotype. Serum LDL levels are usually low in alcoholics, although in some individuals they can be elevated.

Protein Changes in dietary protein intake have minimal effects on lipid levels. Vegetarians have lower serum lipids than nonvegetarians, but it is not clear how much of this is the result of a change from animal to vegetable protein.

Fiber Soluble fiber such as oat bran and guar lower cholesterol levels, perhaps by reducing bile acid absorption.

Recommendations

The National Food Survey 1999 showed that the total amount of fat in the British diet decreased

from 93 g/day in the1980s to 75 g/day in 1998 and so fat now contributes approximately 40% of calories, of which 15–20% comes from saturated fat. Cholesterol intake in the diet is approximately 500 mg/day. The American Heart Association (AHA) has recommended a two-step approach to dietary change, outlined in **Table 7**, and European recommendations for the diet of the population are shown in **Table 8**. The central approach of dietary therapy is to reduce cholesterol-raising fatty foods, reduce cholesterol intake, and achieve a desirable body weight. The AHA step 1 diet can reduce total cholesterol by 0.5–1.0 mmol/l and the step 2 diet can provide a further 0.2–0.4 mmol/l reduction. Saturated fat in the diet is best replaced by increasing complex carbohydrates, with modest increases in monounsaturated and ω-6 polyunsaturated fatty acids. Increased fish oil intake giving additional ω-3 fatty acids will reduce triacylglycerol levels (but increase LDL cholesterol in certain patients).

Although a low-fat, high-carbohydrate, energy-deficient diet may be used for weight reduction in obese subjects, increasing evidence suggests that increased carbohydrate may not be desirable. Recently, a low-carbohydrate, high-protein, high-fat diet (the Atkins diet) has become popular. Although current studies are promising, the long-term effects of this diet are unknown and it is not currently recommended. Fresh fruit, vegetables, and fiber are encouraged.

Table 7 American Heart Association dietary recommendations

Nutrient	*Recommendations (% of total calories)*	
	AHA step 1	*AHA step 2*
Total fat	<30	<30
Fatty acids		
Saturated fat	<10	<7
Polyunsaturated fatty acid	<10	<10
Monounsaturated fatty acids	10–15	10–15

Nutritional Management

A H Lichtenstein, Tufts University, Boston, MA, USA

Introduction

There is a wide range of dietary approaches purported to decrease the risk of developing cardiovascular disease (CVD). Some were first identified early in the twentieth century while others have been recognized more recently. None are without controversy as to their absolute and relative efficacy. Some of this controversy is more likely attributable to biological variation among individuals (e.g., genetics, gender), interaction among putative dietary factors (e.g., per cent of energy as fat relative to carbohydrate), and differences in environmental factors (e.g., body weight, level of physical activity) than actual differences in whether they are effective modalities or not. This chapter will present current trends in dietary approaches to the prevention and management of CVD.

Surrogate Markers of CVD Risk

It is difficult, if not impossible, to directly assess the effect of any dietary intervention on CVD risk because the natural course of the disease frequently is as long or longer than the productive research life span of the scientists designing and implementing the studies. Hence, most dietary interventions aimed at reducing CVD risk are evaluated on the basis of surrogate markers of disease. However, as with dietary variables thought to be efficacious in decreasing CVD risk, the number of surrogate markers purported to be predictive of CVD has likewise multiplied in the past two decades. The relative importance of each has yet to be sorted out.

Traditionally, total cholesterol, high-density lipoprotein (HDL) cholesterol, and triacylglycerol (triglyceride) levels were measured directly. Low-density lipoprotein (LDL) levels were calculated using the 'Friedewald formula' (LDL cholesterol = total cholesterol − HDL cholesterol − (triglyceride/5)). Reliable automated direct assays for LDL cholesterol are now available and obviate the need for this calculation. Also potentially important in estimating changes in CVD risk as a function of dietary intervention are changes in the levels of lipoprotein (a) (Lp(a)), homocysteine, C-reactive protein (and other markers of inflammation), LDL particle size, hematologic factors, apolipoprotein genotypes, insulin and glucose levels, HDL subspecies, and remnant-like particles. No doubt in the near future the relative importance of each will be clarified and others will emerge.

Dietary Lipid: Approaches to the Prevention and Management of CVD

Level of Dietary Fat

Dietary fat serves as a major energy source for humans. One gram of fat contributes 9 cal, a little more than twice that contributed by protein or carbohydrate ($4\,\mathrm{cal\,g^{-1}}$) and somewhat more than that contributed by alcohol ($7\,\mathrm{cal\,g^{-1}}$). When considering the importance of the level of dietary fat with respect to CVD prevention and management there are two major factors to consider; the impact on plasma lipoprotein profiles and body weight. The potential relationship with body weight is important because of secondary effects on plasma lipids, blood pressure, dyslipidemia, and type 2 diabetes, all potential risk factors for CVD.

With respect to the effect of the level of dietary fat on plasma lipoprotein profiles, the focus is usually on triglyceride and HDL cholesterol levels or total

cholesterol to HDL cholesterol ratios. Evidence indicates that when body weight is maintained at a constant level, decreasing the total fat content of the diet, expressed as a per cent of total energy, and replacing it with carbohydrate results in an increase in triglyceride levels, decrease in HDL cholesterol levels, and a less favorable (higher) total cholesterol/HDL cholesterol ratio. Low HDL cholesterol levels are an independent risk factor for CVD. Low fat diets are of particular concern in diabetic or overweight individuals who tend to have low HDL cholesterol levels.

With respect to the effect of the level of dietary fat on body weight two reviews of the long-term data published on the relationship between per cent of energy from fat and body weight have concluded that even a relatively large downward shift in dietary fat intake (approximately 10% of energy) resulted in only modest weight loss of 1.0 kg over a 12-month period in normal weight subjects and 3 kg in overweight or obese subjects. Some evidence suggests that dietary fiber content may be a mitigating factor. That is, substituting fruits, vegetables, and whole grains for fat instead of fat-free cookies, cakes, and snack foods may be more efficacious in promoting weight loss within the context of low-fat diets. The area of dietary fat and obesity is clearly complex. However, it is important to note that in those long-term studies where patients achieved a drastic reduction in dietary fat intake, in no case was weight gain reported.

Type of Fat

Studies done in the mid-1960s demonstrated that changes in the dietary fatty acid profiles altered plasma total cholesterol levels in most individuals. As analytical techniques became more sophisticated, data on lipid, lipoprotein, and apolipoprotein levels routinely became available. Although many studies have confirmed these early observations, inconsistencies among the more recent results are not rare. These inconsistencies, when they do occur, are attributable to differences among the experimental diets, such as the magnitude or type of dietary perturbation, length of study period, habituation to nutrient intakes prior to the start of the study period, and the background diet on which the dietary variable was superimposed, as well as differences among experimental subjects, such as in age, sex, genetics, efficiency of cholesterol absorption, and initial blood lipid concentrations.

Saturated Fatty Acids

Early evidence demonstrated that the consumption of foods relatively high in saturated fatty acids (SFAs) increased plasma total cholesterol levels and that not all SFAs had identical effects. Subsequent work confirmed the hypercholesterolemic effect of SFAs, demonstrated that SFA intake results in an increase in both LDL and HDL cholesterol levels, and reaffirmed that not all SFAs have the same effect. Short-chain fatty acids (6:0 to 10:0) and stearic acid (18:0) produce little or no change in blood cholesterol levels, whereas SFAs with intermediate chain lengths (lauric (12:0) to palmitic (16:0) acids) appear to be the most potent in increasing blood cholesterol levels (**Table 1**). It has been postulated that stearic acid (18:0) is not absorbed or is rapidly converted to oleic acid (18:1), and for this reason has a relatively neutral effect on blood cholesterol levels. The underlying mechanism by which fatty

Table 1 Dietary fatty acids

Code	*Common name*	*Formula*
Saturated		
12:0	Lauric acid	$CH_3(CH_2)_{10}COOH$

acids with 10 or fewer carbon atoms have different effects from those with 12–16 carbons is unknown.

When SFAs displace carbohydrate in the diet, total cholesterol levels increase (**Figure 1**). SFAs tend to be solid at room temperature. Notable exceptions are the tropical oils (palm, palm kernel, and coconut), which are liquid at room temperature because they have high levels of short-chain SFAs. Efforts to reduce dietary SFA intakes should include use of lean meat, the trimming of excess fat and skin from poultry, limiting portion size, and the substituting of non-fat and low-fat dairy products for their full-fat counterparts. The judicious use of ingredient listings and nutrient labels on processed foods will also help achieve the goal of reducing the SFA intakes.

Unsaturated Fatty Acids

Unsaturated fatty acids are fatty acids that contain one or more double bonds in the acyl chain. As the name implies, monounsaturated fatty acids (MUFAs) have one double bond and polyunsaturated fatty acids (PUFAs) have two or more double bonds. The majority of double bonds in fatty acids occurring in food are in the *cis* configuration, that is, the hydrogen atoms attached to the carbons forming the double bond are on the same side of the acyl chain. Alternatively, some double bonds occur in the *trans* configuration, that is, the hydrogen atoms attached to the carbons forming the double bond are on the opposite side of the acyl chain. This part of the discussion of unsaturated fatty acids will be restricted to those containing *cis* double bonds.

Relative to SFAs, MUFAs and PUFAs lower both LDL and HDL cholesterol levels. The absolute magnitude of the change is greater for LDL cholesterol than HDL cholesterol. Most of the data suggest that MUFAs have a slightly smaller effect than PUFAs in lowering both LDL and HDL cholesterol levels so that the change in the total cholesterol/HDL

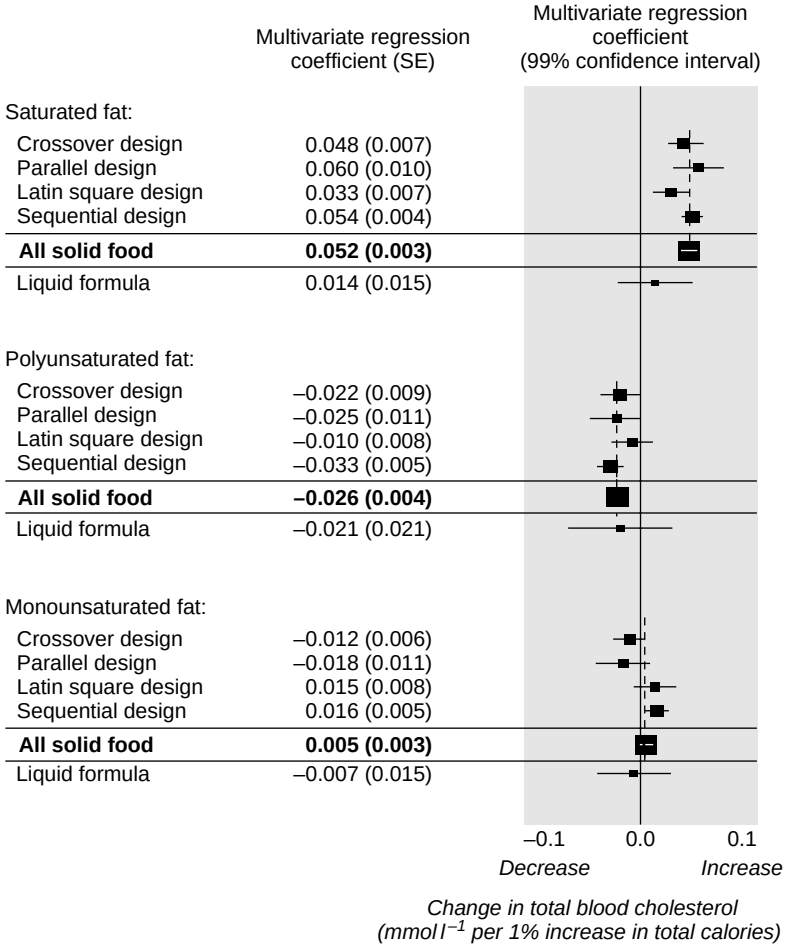

Figure 1 Change in total cholesterol when each fatty acid class displaces carbohydrate from the diet. (Reproduced from Clarke R, Frost C, Collins R, Appleby P, and Peto R (1997) Dietary lipids and blood cholesterol: quantitative meta-analysis of metabolic ward studies. *British Medical Journal* **314**: 112–117.)

cholesterol ratio (decrease) is similar. Because of the changes in plasma lipids and lipoproteins caused when unsaturated fat displaces SFAs from the diet, such a shift should be encouraged in the prevention and management of CVD.

MUFAs The major MUFA in the diet is oleic acid (18:1) (**Table 1**). Vegetable oils high in MUFAs include canola (rapeseed) and olive oils. Fat from meats are also relatively high in MUFAs but unlike vegetable oils, they also contain relatively high levels of SFA, hence would not be recommended as good sources of MUFAs. When MUFAs displace carbohydrate in the diet, there is little effect on total cholesterol levels (**Figure 1**). When MUFAs displace SFA in the diet, total cholesterol levels tend to decrease.

PUFAs There is a wider range of PUFAs than MUFAs in the diet. Dietary PUFAs vary on the basis of chain length, degree of saturation (number of double bonds), and position of the double bond(s) (positional isomers). Two positional isomers of interest with respect to diet and CVD risk are n-6 and n-3 (**Table 1**). The distinction is made on the basis of the location of the first double bond counting from the methyl end of the fatty acyl chain (as opposed to the carboxyl end). If the first double bond is six carbons from the methyl end, the fatty acid is classified as an n-6 fatty acid. If the first double bond is three carbons from the methyl end the fatty acid is classified as an n-3 fatty acid. When PUFAs displace carbohydrate in the diet, total cholesterol levels decrease (**Figure 1**). Vegetable oils high in PUFA include soy bean, corn, sunflower, and safflower oils. The major n-6 PUFA in the diet is linoleic acid (18:2n-6); other n-6 PUFAs, such as γ-linolenic acid (18:3 n-6) and arachidonic acid (20:4n-6), occur in smaller amounts but are important biologically.

n-3 fatty acids Quantitatively, the major n-3 PUFA in the diet is α-linolenic acid (18:3n-3). Major dietary sources include soy bean and canola oils. Two other n-3 PUFAs are eicosapentenoic acid (EPA, 20:5n-3) and docosahexenoic acid (DHA, 22:6n-3) and are sometimes referred to as very long-chain n-3 fatty acids (**Table 1**). The major source of these fatty acids is marine oils found in fish. Dietary intakes of very long-chain n-3 fatty acids are associated with decreased risk of heart disease and stroke (**Figure 2**). Interventions studies have substantiated these findings. The beneficial effects of EPA and DHA are attributed to decreased ventricular fibrillation resulting in decreased sudden death, and decreased triglyceride levels, platelet aggregation, and blood pressure.

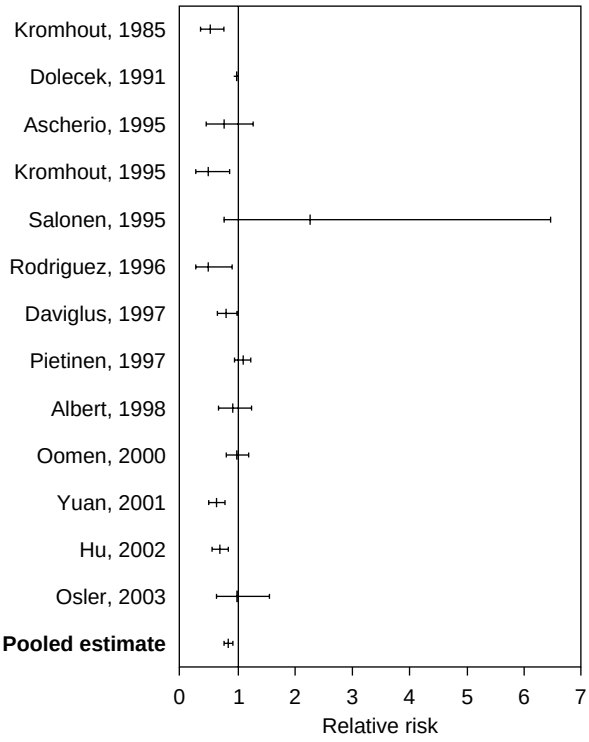

Figure 2 Mean relative risk of coronary heart disease for those consuming any amount of fish versus those reporting none. (Reproduced from Whelton SP, He J, Whelton PK, and Muntner P (2004) Meta-analysis of observational studies on fish intake and coronary heart disease. *American Journal of Cardiology* **93**: 1119–1123.)

Trans-Fatty Acids

Trans-fatty acids, by definition, contain at least one double bond in the *trans* configuration (**Figure 3**). Dietary *trans*-fatty acids occur naturally in meat and dairy products as a result of anaerobic bacterial fermentation in ruminant animals. *Trans*-fatty acids are also introduced into the diet as a result of the consumption of hydrogenated vegetable or fish oils. Hydrogenation results in a number of changes in the fatty acyl chain: the conversion of *cis* to *trans* double bonds, the saturation of double bonds, and the migration of double bonds along the acyl chain, resulting in multiple positional isomers. Oils are primarily hydrogenated to increase viscosity (change a liquid oil into a semiliquid or solid) and extend shelf life (decrease susceptibility to oxidation). The major source of dietary *trans*-fatty acids worldwide is from hydrogenated fat, primarily in products made from this, such as commercially fried foods and baked goods.

Since the early 1990s attention has been focused on the effects of *trans*-fatty acids on specific lipoprotein fractions. The findings of this work have suggested that, similar to saturated fatty acids,

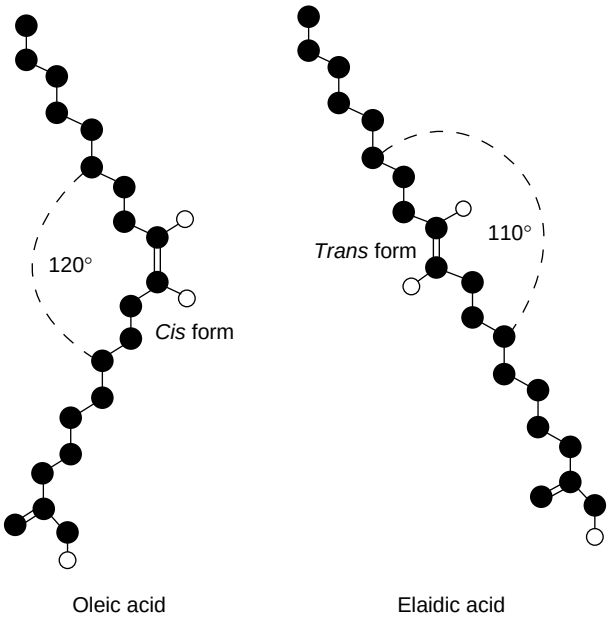

Figure 3 Geometric isomers of 18:1n-9 (oleic and elaidic acids).

trans-fatty acids result in increased LDL cholesterol levels. In contrast to saturated fatty acids, they do not raise HDL cholesterol levels. The changes result in a less favorable LDL cholesterol:HDL cholesterol ratio, with respect to CVD risk (**Figure 4**). A trend towards increased triglyceride levels is frequently reported. Some research has also suggested that *trans*-fatty acids may increase Lp(a) levels. Levels of Lp(a) tend to be positively correlated with risk of developing CVD. However, at this time it appears that the magnitude of increase in Lp(a) levels reported is not within the physiological range that would be predicted to increase CVD risk.

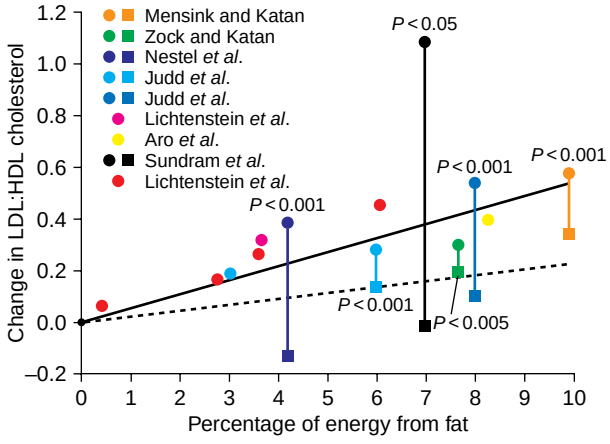

Figure 4 Change in LDL:HDL cholesterol ratio in response to *trans*-fatty acids (solid line) and saturated fatty acids (dashed line). (Reproduced from Ascherio A, Katan MB, Zock PL, Stampfer MJ, and Willett WC (1999) *Trans* fatty acids and coronary heart disease. *New England Journal of Medicine* **340**: 1994–1998.)

Recent estimates from 14 Western European countries report *trans*-fatty acid intakes ranging from 0.8% (Greece) to 1.9% (Iceland) of energy in women and 0.5% (Greece and Italy) to 2.1% (Iceland) of energy in men. Data collected in the US and Canada suggest average *trans*-fatty acid intakes ranging from 1% to 2.5% of energy. By way of contrast, estimates of saturated fat intake range from 10% to 19% per cent of energy.

Dietary Cholesterol

The observation that dietary cholesterol increased blood cholesterol levels and was associated with the development of arteriosclerosis was originally made early in the 20th century in rabbits. In humans, a positive correlation has been repeatedly observed between dietary cholesterol and both blood cholesterol levels and CVD risk, although relative to SFA, the effect is modest. Whether the increase in plasma cholesterol levels induced by dietary cholesterol is linear or curvilinear, or whether there is a break point or threshold/ceiling relationship beyond which individuals are no longer responsive, remains to be determined. With few exceptions, dietary cholesterol is present in foods of animal origin. Therefore, restricting saturated fat intake is likely to result in a decrease in dietary cholesterol.

Other Dietary Approaches for the Prevention and Management of CVD

Very Low-Fat/High-Carbohydrate Diet and High-Protein/Low-Carbohydrate Diet

When considering diets very low in fat and high in carbohydrates ('very low-fat' diets), it is important to separate the effects of the composition of the diet from confounding factors associated with intentional weight loss. For the purposes of this discussion, a very low-fat diet will be defined as less than 15% of energy as fat. Consumption of a very low-fat diet without a decrease in energy intake frequently decreases blood total, LDL, and HDL cholesterol levels and increases the total cholesterol:HDL cholesterol ratio (less favorable) and triglyceride levels. A mitigating factor may be the type of carbohydrate providing the bulk of the dietary energy: complex (whole grains, fruits, and vegetables) or simple (fat-free cookies and ice cream). The reason for this later observation has yet to be investigated. Notwithstanding these considerations, for this reason moderate fat intakes, ranging from <30% to 25 to 35% of energy

as fat, are currently recommended to optimize lipoprotein profiles with respect to decreasing CVD risk.

Current interest in the area of weight loss is centered on high-protein/low-carbohydrate (high protein) diets. Recently, high-protein diets were shown to result in significantly more weight loss than standard reduced energy diets and were accompanied by more favorable blood lipid profiles (lower triglyceride, higher HDL cholesterol levels). However, by 1 year the advantage in terms of weight loss attributed to the high-protein diet did not persist (**Table 2**). The major concern with high-protein diets is that in the absence of steady weight loss the higher intakes of saturated fat and cholesterol can ultimately have an adverse effect on LDL cholesterol levels. Ongoing work will most likely resolve some of these issues.

Fiber

Dietary soluble fiber, primarily β-glucan, has been reported to have a modest independent effect on decreasing blood total and LDL cholesterol levels. A meta-analysis concluded that 3 g of soluble fiber (equivalent of three servings of oatmeal) reduced both total and LDL cholesterol levels approximately $0.13\,\mathrm{mmol\,l^{-1}}$ (**Figure 5**). Most evidence suggests that soluble fiber exerts its hypocholesterolemic effect by binding bile acids and cholesterol in the intestine, resulting in an increased fecal loss and altered colonic metabolism of bile acids. The fermentation of fiber polysaccharides in the colon yields short-chain fatty acids. Some evidence suggests that these compounds may have hypocholesterolemic effects via alterations in hepatic metabolism. At this time there is no evidence to suggest that insoluble fiber has an effect on blood lipid levels.

Soy Protein

The potential relationship between soy protein and the risk of developing CVD has a long history dating back to the 1940s. Despite this relatively protracted lead-time attempts at more precisely defining this relationship have been slow in coming and somewhat inconsistent. Renewed interest developed in the relationship between soy protein and blood lipid levels after a meta-analysis was published in the mid-1990s suggesting that soy protein resulted in significant reductions in total and LDL cholesterol levels, with the most pronounced effect in hypercholesterolemic individuals. Changes in HDL cholesterol levels were not significant. Whether the effect on total and LDL cholesterol levels was attributable to the soy protein *per se* or other soybean derived factor(s), the most likely being the constitutive isoflavones, had yet to be determined. Since then a number of well-controlled studies have re-examined the effect of soy protein and/or isoflavones on blood lipid levels in humans. The results of more recent studies are variable. Declines in LDL cholesterol levels attributable to the substitution of 25–50 g of soy protein for animal protein range from null to small (3–6%) in normocholesterolemic and hypercholesterolemic individuals. Changes in HDL cholesterol levels were highly variable, ranging from -15% to $+7\%$. Soy-derived isoflavones do not appear to have an independent effect on blood lipid levels. On the basis of the most recent data it can be concluded that, although helpful when used to displace products containing animal (saturated) fat from the diet, despite the current claims, individuals should be cautioned against an overreliance on the casual use of soy protein containing foods or the use of isolated isoflavones to control serum lipid levels.

Plant Sterols

Sterols compare for a group of compounds that are essential constituents of cell membranes in animals and plants. Cholesterol is the major sterol of mammalian cells. Phytosterols, such as beta-sitosterol, campesterol, and stigmasterol, are the major sterols of plant cells. In humans, plant sterols are not synthesized, are poorly absorbed, and appear to interfere with cholesterol absorption. It is this later property that has been exploited in the use of these compounds as blood cholesterol-lowering agents. Maximal LDL cholesterol lowering attributable to plant sterols occurs at a dose of about $2\,\mathrm{g\,day^{-1}}$ (**Figure 6**). Although a relatively wide range of responses has been reported, the majority of work suggests an expected LDL cholesterol lowering of about 10% in hypercholesterolemic subjects. Plant sterol-enriched margarines and other foods are currently available in some countries. Few side effects of plant sterols have been reported with the exception of decreased levels of circulating carotenoids; the long-term effect of this is unclear at this time but should continue to be monitored carefully.

Antioxidant Nutrients

Considerable interest had been generated in the potential benefit of dietary supplementation with vitamin E and other antioxidant nutrients in reducing CVD risk. Support for this hypothesis came from two sources. First from the epidemiological observations suggesting that vitamin E supplement use was associated with decreased risk of CVD.

Table 2 Summary mean outcomes

Second from the *in vitro* work demonstrating that vitamin E in LDL was correlated with decreased susceptibility of the lipoprotein particle to oxidation and that in cell culture oxidized LDL resulted in foam cell formation. A number of recent intervention studies have failed to demonstrate a benefit of vitamin E or other antioxidant vitamins. At this time the data do not support a recommendation to use antioxidant vitamins for the prevention or management of CVD.

Conclusions

The relationship between diet and blood lipid levels has clearly been established. Current data support dietary recommendations to decrease CVD risk that include restrictions in saturated and *trans*-fatty acids, and cholesterol and to include a source of long-chain n-3 fatty acids. Other dietary approaches to prevent and manage CVD include consuming fiber-rich diets such as that founds in fruits, vegetables, and whole grains. Attainment or maintenance of optimal body weight should be emphasized. All individuals should be encouraged to engage in physical activity daily. These recommendations are the culmination of nearly a century of work. They have evolved slowly. No doubt this evolution, frequently accompanied by debate, will continue into the future. It is important for nutrition scientists to implement current recommendations aimed at optimizing blood lipid levels and favorably affecting newer surrogate markers of CVD risk, and to reassess these recommendations as new findings emerge.

Blood pressure (BP) is determined by cardiac output (CO) and total peripheral resistance (TPR):

$$BP = CO \times TPR$$

These variables are controlled in turn by the activity of the autonomic nervous system, regulated by a variety of nuclei in the brain. There is a complex interaction between plasma volume, blood pressure, and a variety of humoral and neural mechanisms that determine blood pressure.

Blood pressure is not, however, a static value. It varies markedly in response to a variety of stimuli. Change of posture activates a variety of controls which keep the pressure relatively constant. Physical and mental activity may be associated with alterations in blood pressure, and there is a marked fall in blood pressure during sleep. Thus, there is no such value as a normal blood pressure based on a single measurement, as blood pressure needs to be related to the circumstances under which it is measured. Likewise, there is no single blood pressure level that means a person is hypertensive. The present convention is that a blood pressure greater than 140 mmHg systolic or 90 mmHg diastolic on clinic recording makes a person hypertensive. Recently the JNC VII report has stated that patients with a blood pressure >120/80 are prehypertensive. However, blood pressure has a marked circadian variation (**Figure 1**), and an individual could have a blood pressure of

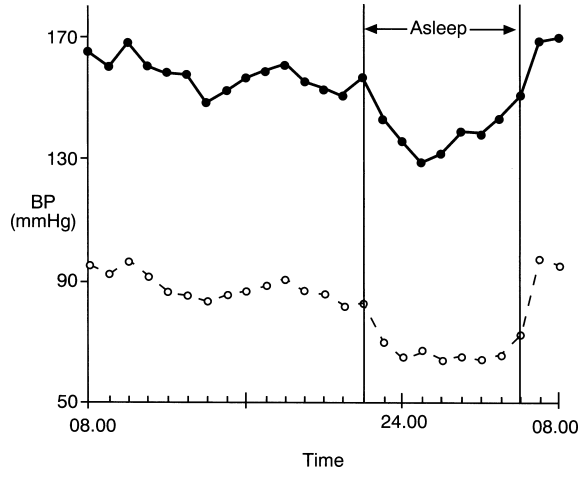

Figure 1 Hourly ambulatory blood pressure (BP) measurements in a 58-year-old man with borderline hypertension. Solid circles, systolic pressure; open circles, diastolic pressure.

150/90 mmHg at 09:00 h and be classified as hypertensive, while at 14:00 h it might be 137/85 mmHg and would be classified as normotensive. Thus in a normal person blood pressure may vary markedly during a day associated with reactive events, but in some people the baseline blood pressure eventually rises to a level that is defined as 'hypertension.' In this person with hypertension there will be fluctuations in blood pressure associated with the same controls as in normal people, but the fluctuations may be exaggerated, leading to high blood pressure levels.

At different times of the day blood pressure is regulated by different systems. Thus, during the day the cardiovascular sympathetics activated by the baroreceptors are important controls of blood pressure. When asleep the cardiovascular sympathetics turn off and blood pressure then appears to be maintained more by the renin angiotensin system. The variability in the activity of systems controlling blood pressure means that in hypertensive patients the response to drugs that act on these systems may have a circadian variation.

The etiology of essential hypertension is unknown; however, the condition is believed to result from an interaction of environmental and genetic factors. Environmental factors are undoubtedly of major importance, because in certain communities hypertension is virtually nonexistent; however, when such a community alters its life style, hypertension becomes common and may exist in 30% of the population. Not all people develop hypertension, and the ones who do are determined by their genetic composition (**Figure 2**). Investigations are under way to attempt to determine which individuals are more likely to develop hypertension and its complications, so that life style and environmental alterations can be initiated to prevent the disease occurring in such people. Certain specific genetic abnormalities have been identified and these cases are then removed from the classification of essential hypertension. It is of interest that the disorders that have been found in general alter sodium handling by the body. These have been either abnormalities in channels or transporters in the nephron that alter sodium excretion, or alternatively defects in circulating hormones that regulate the activity of the renal transporters. Hypertension is not seen in hunter-gatherer communities where sodium intake is low and potassium intake is high, and thus the genetic abnormality is not expressed phenotypically even though the genotype is probably present.

In established hypertension the defect is an increased peripheral resistance rather than an increased cardiac output. However, in people with minor blood pressure elevations and prehypertensive people cardiac output is increased, and it has been postulated that increased cardiac output in response to the retention of sodium

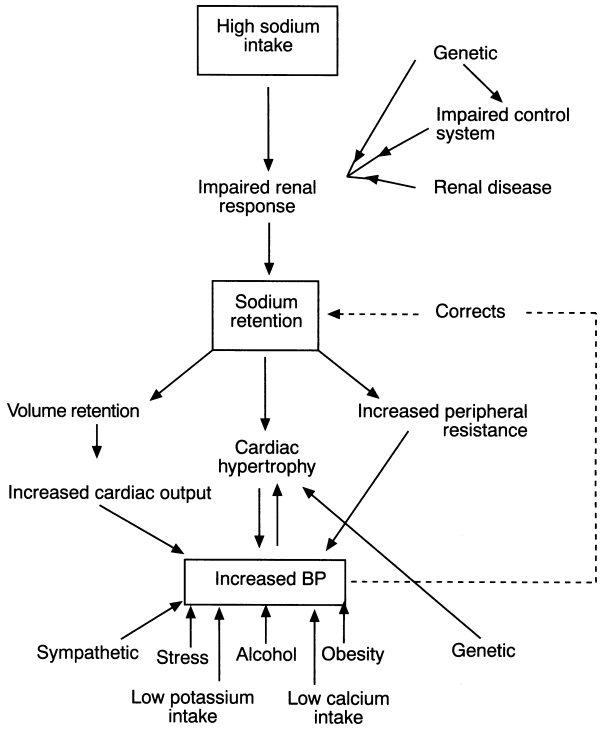

Figure 2 The interrelationships between sodium intake, renal function, hormonal control systems, and genetic inheritance in the etiology of hypertension and cardiac hypertrophy. BP, blood pressure.

is the initial hemodynamic change that leads to hypertension (**Figure 2**). However, experimentally hypertension can be produced without a stage of increased cardiac output, and increased peripheral resistance can result without an antecedent high cardiac output. It is likely that there is heterogeneity in the way people respond. The concept of an increased cardiac output leading to hypertension has been extensively developed by Guyton in a variety of computer and experimental models. However, in carefully conducted studies in which blood volume was measured in hypertensive patients, blood volume was decreased rather than increased, making this theory probably not applicable to all people. The relationship with sodium is also complicated. In young hypertensive subjects there is a better inverse correlation with total body potassium rather than a direct correlation with total body sodium content. In older people the correlation with body sodium content becomes more pronounced. The lack of a direct correlation between body sodium and hypertension in the young casts doubt on the absoluteness of the link between sodium and hypertension, and clearly potassium has an important effect modulating the response.

It has been suggested that the prime defect leading to increased peripheral resistance is the presence of a circulating factor that inhibits $(Na^+\text{-}K^+)$-ATPase

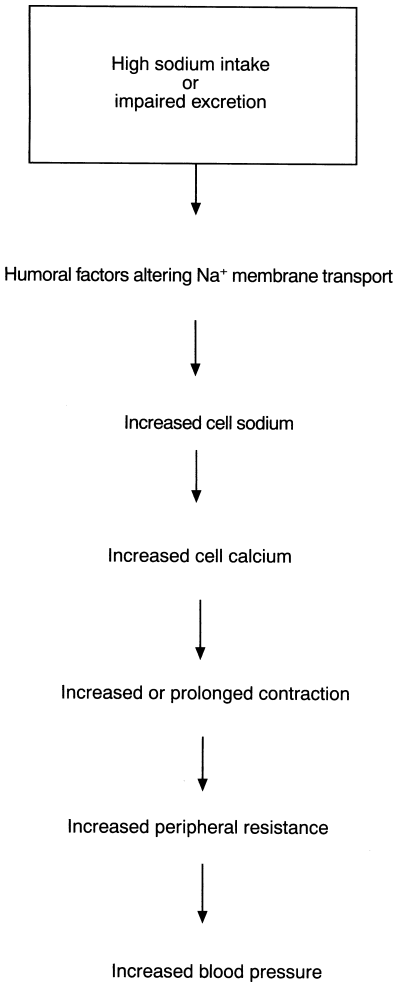

Figure 3 Mechanistic approach indicating how at the cellular level a high sodium intake may initiate the series of events leading to increased peripheral resistance and a high blood pressure.

activity, thereby increasing the sodium content of cells (**Figure 3**). This increased sodium content decreases the rate at which calcium can be removed from the cell by the Na^+-Ca^{2+} countertransport. In skeletal and cardiac muscle cells the contractile response is triggered by a small influx of Ca^{2+} that releases Ca^{2+} from the endoplasmic reticulum. The response is terminated by reuptake of Ca^{2+} into the endoplasmic reticulum and thus the Na^+-Ca^{2+} countertransport is not of critical importance, though in all cells the basal level and total content of calcium may be increased. In smooth muscle cells, including the arteriolar (resistance vessels) cells, contraction is initiated by entry of calcium across the cell membrane. If there is a defect in calcium removal by the Na^+-Ca^{2+} countertransport contraction will be prolonged, and if the basal level of cellular calcium is higher contraction may be more intense. Thus, peripheral resistance rises and hypertension results. All the physiological factors to support the above have been identified. However, despite intensive research it is unclear if a true circulating physiological factor capable of inhibiting (Na^+-K^+)-ATPase has been identified. Claims have been made for an ouabain-like factor in plasma and the hypothalamus, but there is skepticism whether this is the important physiological variable. In hypertensive patients cell sodium levels are elevated. This elevation need not necessarily be due to inhibition of (Na^+-K^+)-ATPase but could result from an increased entry of sodium into the cell down its electrochemical gradient by a variety of channels or transporters. There is evidence that abnormalities of these exist and are more prevalent in hypertensive people. There is also evidence that the rate of entry of Na^+ can be increased by a high sodium intake and that a circulating but unidentified factor may be increased. The signal for release of such a factor is unclear and does not appear to be plasma sodium concentration and probably not total plasma volume. It may be modulated by the kidney and related to 'turnover' of sodium.

The body can control plasma sodium concentration (by antidiuretic hormone) and plasma volume and total body sodium within well-defined limits, despite large variations (20–400 mmol) in daily sodium chloride intake. This control involves a variety of humoral factors (**Table 1**). Renin-angiotensin, aldosterone, atrial natriuretic peptide, sympathetic activity, and other variables are all altered by changes in sodium chloride and/or potassium intake. The capacity of these systems to respond maintains blood pressure in the 'normal' range. It is only when this capacity is exceeded that blood pressure becomes elevated. The increase in blood pressure will also correct the body sodium because the kidney has a sensitive 'pressure natriuresis response'. Thus, in most people as blood pressure rises sodium is excreted; this self-correction ensures that blood pressure does not rise to excessive levels. It has been suggested that in addition to high sodium intake and abnormalities of sodium handling by cells there must be a defect in the pressure natriuresis response. This could be due to

Table 1 Factors altering sodium balance

Variable	*Site of action*
Increases Na^+ retention	
Angiotensin II	Proximal tubule
	Increases aldosterone
Aldosterone	Distal nephron
Sympathetic	Proximal tubule
	Hemodynamics
Increases Na^+ excretion	
Atrial peptide	Proximal tubule

Elevated blood pressure	Hemodynamics

excessive amounts of circulating hormones (aldosterone) or defective control systems in the kidney. The pressure natriuresis response may also be defective owing to reduction in nephron number following developmental problems or disease, or associated with the aging process. An association has been found between the weight of children at birth and subsequent development of hypertension and cardiovascular disease. The low birthweight could be due to defective nutritional intake of the mother or to diseases that affect fetal and placental growth. It has been suggested that the total nephron number is reduced, and that this alters sodium handling and causes hypertension.

Much research has focused on the importance of dietary sodium chloride, but there needs to be an associated genetic defect which may be a subtle defect in the systems controlling sodium excretion. Thus, the defect may be an inability of the renin–angiotensin–aldosterone system to suppress adequately or appropriately for that level of sodium intake. There is evidence from twin studies that the suppressibility of renin secretion is genetically determined and thus in some people there are inappropriate levels of angiotensin II for their level of sodium intake, resulting in hypertension. There are changes in secretion or response of renin, aldosterone, adrenaline, sympathetic activity, atrial peptide, and nitric oxide with increase in sodium intake. In most cases these responses are appropriate and prevent the unfettered rise in blood pressure. However, the ability to respond may be exceeded and blood pressure then rises.

Hemodynamics

As discussed above, it is unlikely that all people go through an increased cardiac output stage. Well-established hypertensive patients have high peripheral resistance and a normal cardiac output, but there are exceptions. The hypertension process itself causes significant alterations in hemodynamics affecting both the heart and the blood vessels, and reversal of these effects may be as important as reducing blood pressure (**Figure 4**).

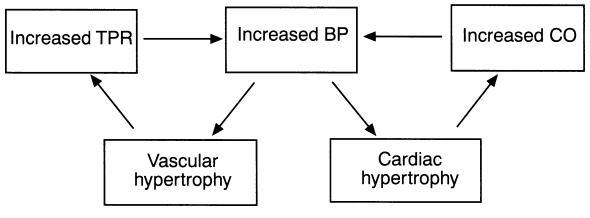

Figure 4 Interaction between the various parameters that control blood pressure, showing how they set up a positive feedback leading to worsening blood pressure. BP, blood pressure; CO, cardiac output; TPR, total peripheral resistance.

Early in the hypertensive process there is an increase in the thickness of the arteriolar muscle wall. This is probably a compensatory process which returns the wall tension to normal. Contrary to expectations, compliance of larger arteries is normal or increased in young hypertensive patients. However, the thickening of the resistance vessels, depending on the way it takes place, has certain consequences, and for a similar degree of muscle contraction there is a greater increase in vascular tone and thus peripheral resistance rises more, leading to a higher blood pressure, greater wall tension, and a further increase in vessel thickness. This is a positive feedback response and a vicious cycle may result (**Figure 4**). In the early hypertensive process the systolic and diastolic blood pressures rise more or less in parallel. However, in the older hypertensive patient the pulse pressure widens, due probably to increased stiffness of the arteries. This increased stiffness, which is associated with a loss of elastin and an increase in collagen, has important effects on the heart.

The endothelium of blood vessels is a major regulator of vascular tone and an important mechanism is the production of nitric oxide. If nitric oxide is removed, peripheral resistance rises and hypertension results. However, it is unlikely that defects in nitric oxide production are the cause of high blood pressure. In fact in early hypertension the nitric oxide production may be increased as a compensatory event modulating the rise in pressure, and this may explain why dynamic compliance is normal (**Figure 5**). However, when hypertension is established and there is vessel disease the nitric oxide response and endothelial control become impaired. This is probably an important factor leading to stiffness of the arteries and atherosclerosis.

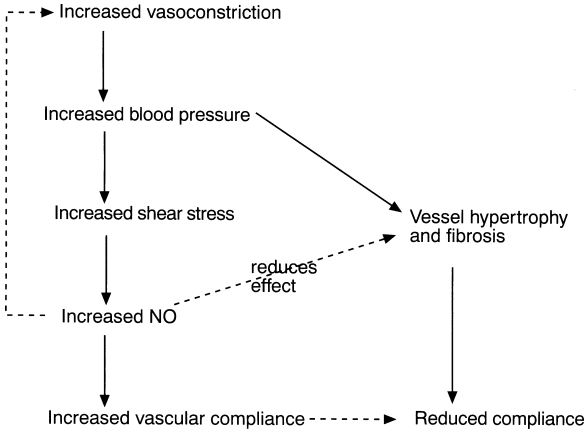

Figure 5 An outline indicating how the initial response of the endothelium is to prevent the rise of blood pressure by releasing nitric oxide (NO). This increases vessel compliance, reducing the adverse effects. If this system's capacity is exceeded the arterial damage process is accelerated. The dotted lines represent negative feedback attempting to restore the status quo.

Table 2 Factors determining extent of reflection and site where the reflected wave meets the flow wave

Poor arterial compliance	Increased pulse wave velocity Reflected wave closer to heart
Arterial branch points	Reflective site
Peripheral resistance	Increased reflection

The stiffness of blood vessels in older hypertensive patients has a number of important consequences. The pulse wave velocity is increased and thus reflected waves arrive back at the heart while the ventricle is still contracting, thereby augmenting the central systolic pressure (**Table 2**). In normotensive people the place at which the reflected wave and the oncoming flow meet is near the brachial artery, and thus central systolic pressure is lower than brachial artery systolic pressure (**Figure 6**). This increased central systolic blood pressure means that the heart contracts against a greater load and thus performs more work, leading to hypertrophy greater than might be predicted from the brachial artery pressure. The extent of the augmentation due to the pressure wave depends upon the degree of reflection, which is controlled in part by the peripheral resistance. The site at which augmentation is highest depends on the pulse wave velocity. The deterioration in the elastic properties of the large blood vessels with loss of elastin and more collagen leads to increased pulse pressure, increased augmentation of central systolic pressure and a decrease in the peripheral diastolic pressure, all of which are common in the elderly hypertensive patient.

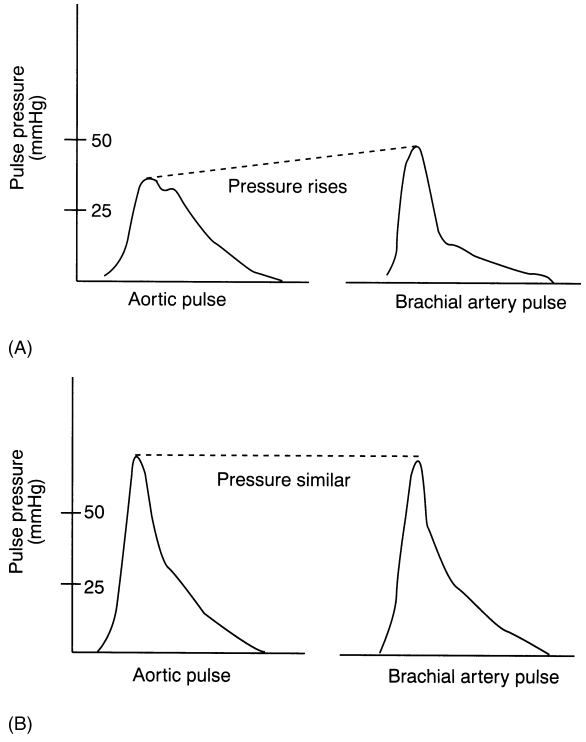

Figure 6 The central aortic and brachial artery pulse wave forms in normotensive (A) and hypertensive (B) subjects. In (B) the heart pumps blood out against a higher pressure leading to cardiac hypertrophy. See O'Rourke (1995) for discussion of how central aortic pressure is higher than brachial artery pressure due to reflected waves.

The Heart

In hypertensive patients the left ventricle is frequently enlarged and this is associated with an increased risk of cardiovascular death. When assessed by electrocardiography left ventricular hypertrophy (LVH) is relatively uncommon, but if assessed by echocardiography LVH is present in up to 50% of mild hypertensive patients and in adolescents not classified as hypertensive, but in the upper 10 percentile of blood pressure there is a 10–15% prevalence of LVH (**Table 3**). The cause of the LVH is not certain (**Table 4**). There is a better correlation with 24 h blood pressure than with clinic values, but the r value is about 0.14 indicating considerable variability. It is possible that acute elevations of blood pressure sustained for 1–2 h may have a potent effect by increasing wall stress and activating the processes that lead to myocyte hypertrophy. This may be of particular importance if it occurs at a time when plasma levels of potential growth factors such as angiotensin II and growth hormone are elevated. These hormones are elevated during sleep and thus blood pressure elevation at that time may be particularly detrimental. This is supported by observations that people who do not have the usual night-time (sleep) fall in blood pressure are more likely to have cardiac and renal complications. There is a significant genetic influence on cardiac hypertrophy and it has been proposed that cardiac enlargement may be antecedent to and the cause of hypertension. High blood pressure can undoubtedly cause cardiac enlargement, but independent of blood pressure elevation angiotensin II and salt can probably enlarge the heart.

The strongest predictor in some studies of cardiac size was the salt intake. In animals a high salt intake

Table 3 Prevalence of left ventricular hypertrophy

Subjects	*Prevalence (%)*
Normotensive	1–2
Adolescent, upper 10%	10–15

Genotype	

can cause cardiac hypertrophy and a low salt intake allows resolution. The increased size of the heart is a response that decreases the wall stress of the ventricle and is a compensatory phenomenon. The cardiac hypertrophy with hypertension is concentric in nature, with sarcomeres laid down in the myocytes in parallel (**Figure 7**). The increased thickness of the myocytes together with associated fibrosis of the interstitium means that the oxygen diffusion pathway is increased and this may lead to precipitation of arrhythmias and sudden death. In cardiac hypertrophy associated with exercise the sarcomeres are laid down in series, and with this 'eccentric' hypertrophy there is no increased mortality.

In addition to cardiac hypertrophy in hypertensive patients there is significant impairment of diastolic relaxation. This may result from poor oxygen delivery to the mitochondria and thus a retarded reuptake of calcium into cell organelles. Thus, there is a dynamic aspect to diastolic dysfunction which may be reversible. However, in addition the laying down of fibrous tissue in the heart contributes to stiffness and poor diastolic filling. The poor diastolic function may occur prior to any increase in cardiac size. The poor diastolic filling due to reduction in left ventricular compliance may explain the subnormal stroke volume seen in hypertensive patients during exercise. In these circumstances the increased pulse rate means that there is insufficient time for a stiff left ventricle to fill adequately.

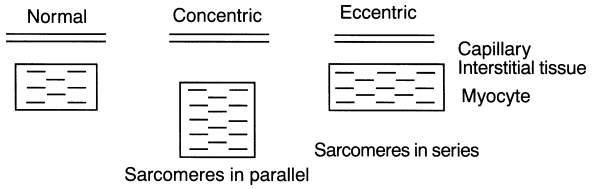

Figure 7 The diffusion distance in normal and eccentric hypertrophy is not increased. In concentric hypertrophy there is often associated fibrosis; this leads to a longer extracellular diffusion distance as well as a longer intercellular pathway. Thus, oxygen delivery to mitochondria is poor, the reuptake of calcium (an energy-dependent process) is sluggish, and 'functional' relaxation is slow, leading to impaired diastolic filling.

Early in the development of hypertension in spontaneously hypertensive rats and in humans total peripheral resistance is elevated. In rats changes in the resistance vessels are seen early. In borderline and mild hypertension in humans there may be little increase in total peripheral resistance at rest, but the total peripheral resistance does not fall to normal levels during conditions when maximal vasodilatation would be expected (e.g., exercise, heating, autonomic blockade). This probably indicates that structural changes occur early in the disease and the failure to dilate adequately may in part explain the excess rise in blood pressure seen in hypertensive patients during exercise.

Increased peripheral resistance is not evenly distributed across all regional vascular beds and the resistance in the kidney frequently appears to be increased, resulting in a reduction of about 10% in renal blood flow. In contrast, in prehypertensive people an increase has been reported in renal blood flow. Whether this has any pathogenic significance is not known. However, the reduced blood flow could result from activation of the tubuloglomerular feedback response due to altered sodium reabsorption in the proximal tubule.

The coronary flow in hypertensive patients is of importance. These people already may have an increased oxygen demand. The flow at rest is usually normal but even in patients with no evidence of coronary artery disease the flow reserve is impaired. In normal people the coronary artery rapidly dilates to meet the increased oxygen demand but in hypertensive patients this dilation is sluggish and does not reach the same maximal flow. The reason is complex and is possibly a combination of structural change and an impaired endothelial response.

The Sympathetic Nervous System

Many investigators have postulated that hypertension may result from impaired central control and this is mediated via the sympathetic nervous system. The increased cardiac output and heart rate seen in many people with early or incipient essential hypertension could be explained by excess sympathetic activity. However, it has been difficult to demonstrate that there is increased sympathetic activity because many of the techniques are relatively crude. It has been reported that plasma noradrenaline levels correlate with cardiac index and peripheral resistance in mildly hypertensive patients. It is difficult to know if increased sympathetic activity is primary, but in adolescents who later develop hypertension there is an increased blood pressure rise associated with mental or physical stress, which

supports the concept of a dysregulatory neurogenic component. Sympathetic activity may also be altered by changes in sodium or potassium intake, and thus the 'prime' cause of hypertension remains to be elucidated.

Renal Function

There are undoubtedly subtle abnormalities in renal function in most hypertensive people. It is unclear if this is a cause or effect of hypertension. In spontaneous hypertensive rats (SHR) early in life the proximal tubule cells are very responsive to angiotensin II and this could cause sodium retention and initiate the development of the hypertensive process. However, in mature rats the responsiveness to angiotensin II of the proximal tubule is lost.

In hypertensive patients there is a reduced renal blood and plasma flow associated with an increased filtration fraction and hence a normal glomerular filtration rate. These changes would result in an increased fractional absorption of sodium by the proximal tubule and potential difficulty in excreting sodium by a pressure natriuresis. The pressure natriuresis curve is shifted with less sodium being excreted for a given pressure at rest, but exaggerated when pressure is acutely increased. It is not clear what is cause or effect, but it is tempting to assume that resetting of the pressure natriuresis response takes place, because if it operated normally the increased pressure should cause salt loss and correct the hypertensive process.

In some but not all people blood pressure falls with sodium restriction. Patients with salt-sensitive hypertension tend not to have a nocturnal fall in blood pressure; they have a greater prevalence of cardiac hypertrophy, microalbuminuria, and a worse prognosis.

Conclusions

Hypertension is not a disease but a sign of some underlying disturbance in the usual control systems for blood pressure. It is thus difficult to have a single description of the physiology of essential hypertension as it will depend upon the cause. There are, however, certain features common to many people. In people with certain (at present unknown) abnormalities in their genotype, exposure to a high-sodium, low-potassium diet together with other alterations in their life style leads to an elevation in blood pressure. In some people there is an initial stage of high cardiac output, but when hypertension is established peripheral resistance is elevated and is the explanation for the high blood pressure. The genetic abnormalities may relate to impairment of the control systems for excreting sodium chloride or a deficit in the ability of the kidney to excrete sodium. There are associated abnormalities in the sympathetic nervous system and the central regulation of blood pressure. When blood pressure is elevated a series of compensatory events are activated, particularly cardiac and vascular hypertrophy, which are initially appropriate responses but lead to the creation of a positive feedback loop which eventually becomes a vicious cycle leading to malignant hypertension.

Essential hypertension in some ways is a misnomer. It is caused by alterations in nutrition and life style in people with a susceptible genotype. The challenge is to identify such people and remove the appropriate environmental factor.

Dietary Factors

L J Appel, Johns Hopkins University, Baltimore, MD, USA

Worldwide, elevated blood pressure is an extraordinarily common and important risk factor for cardiovascular and kidney diseases. As blood pressure rises, so does the risk of these diseases (**Figure 1**). The relationship is strong, consistent, continuous, independent, and etiologically relevant. Accordingly, the adverse consequences of elevated blood pressure are not just restricted to individuals with hypertension (a systolic blood pressure $\geq$140 mmHg or a diastolic blood pressure $\geq$90 mmHg). Those with prehypertension, namely, a systolic blood pressure of 120–139 mmHg or diastolic blood pressure of 80–89 mmHg, have a high probability of developing hypertension and carry an excess risk of cardiovascular disease compared to those with a normal blood pressure (systolic blood pressure $<$120 mmHg and diastolic blood pressure $<$90 mmHg). In fact, almost one-third of blood pressure-related deaths from coronary heart disease occur in individuals with blood pressure in the nonhypertensive range.

In Western countries and most economically developing countries, systolic blood pressure rises with age. As a consequence, the lifetime risk of developing hypertension is extremely high, approximately 90% among US adults older than age 50 years. However, the rise in blood pressure with age is not inevitable. There are numerous isolated populations in which the rise in blood pressure is blunted or even flat. These populations are typically characterized by extremely low intakes of salt, relatively high intakes of potassium, and a lean body habitus.

Lifestyle modification, which includes dietary changes and increased physical activity, has important roles in both nonhypertensive and hypertensive individuals. In nonhypertensive individuals, including those with prehypertension, lifestyle modifications have the potential to prevent hypertension, reduce blood pressure, and thereby lower the risk of blood pressure-related cardiovascular disease. Even an apparently small reduction in blood pressure, if applied to an entire population, could have an enormous beneficial impact. It has been estimated that a 3 mmHg reduction in systolic blood pressure could lead to an 8% reduction in stroke mortality and a 5% reduction in mortality from coronary heart disease (**Figure 2**). In hypertensive individuals, lifestyle modifications can serve as initial

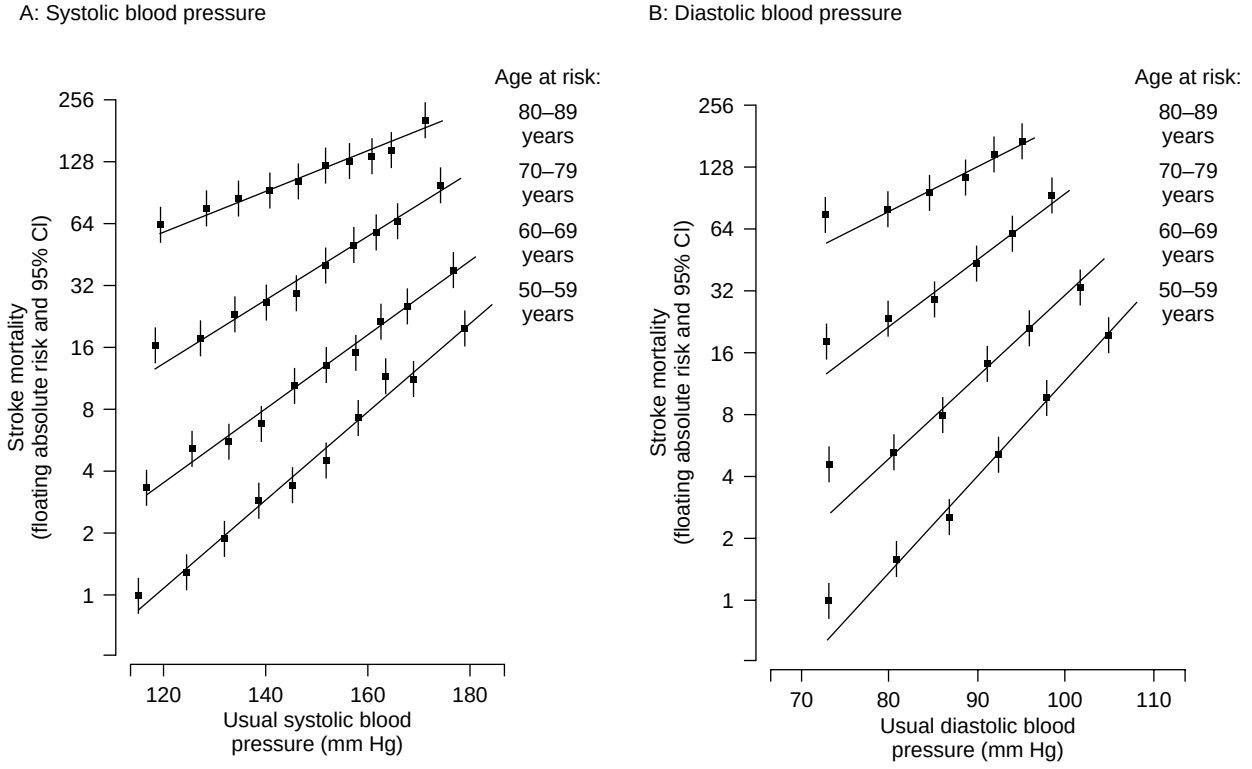

Figure 1 Stroke mortality rate by decade of age versus systolic blood pressure (A) and diastolic blood pressure (B): meta-analysis of 61 prospective studies with 2.7 million person-years. treatment before the start of drug therapy and as an adjunct to medication in people already on antihypertensive drug therapy. In hypertensive individuals with medication-controlled blood pressure, lifestyle therapies can facilitate drug step-down and potentially drug withdrawal in individuals who sustain lifestyle changes.

Dietary Factors That Lower Blood Pressure

Weight Loss

On average, as weight increases, so does blood pressure. The importance of this relationship is reinforced by the high and increasing prevalence of overweight and obesity throughout the world. With rare exception, clinical trials have documented that weight loss lowers blood pressure. Importantly, reductions in blood pressure occur before and without attainment of a desirable body weight. In one meta-analysis that aggregated results across 25 trials, mean systolic and diastolic blood pressure reductions from an average weight loss of 5.1 kg were 4.4 and 3.6 mmHg, respectively. Greater weight loss leads to greater blood pressure reduction.

Additional trials have documented that modest weight loss can prevent hypertension by approximately 20% among overweight, prehypertensive individuals and can facilitate medication step-down and drug withdrawal. Lifestyle intervention trials have uniformly achieved short-term weight loss, primary through a reduction in total caloric intake. In some instances, substantial weight loss has also been sustained over 3 or more years.

In aggregate, available evidence strongly supports weight reduction, ideally attainment of a body mass index less than 25 kg/m^2, as an effective approach to prevent and treat hypertension. Weight reduction can also prevent diabetes and control lipids. Hence, the beneficial effects of weight reduction in preventing cardiovascular–renal disease should be substantial. Finally, in view of the well-recognized challenges of maintaining weight loss, efforts to prevent weight gain among those with a normal body weight are critical.

Reduced Salt Intake

On average, as dietary salt (sodium chloride) intake rises, so does blood pressure.[1] To date, more than 50 randomized trials have tested the effects of salt on blood pressure, including several dose–response trials. Approximately 10 meta-analyses have aggregated data across these trials. In a recent meta-analysis that focused on moderate reductions in salt intake, a reduced sodium intake of 1.8 g/day (77 mmol/day) led to average systolic/diastolic blood pressure reductions of 5.2/3.7 mmHg in hypertensives and 1.3/1.1 mmHg in nonhypertensives.

One of the most important dose–response trials is the DASH-Sodium trial, which tested the effects of three different salt intakes separately in two distinct diets—the DASH (Dietary Approaches to Stop Hypertension) diet and a control diet more typical of what Americans eat. As displayed in **Figure 3**, the rise in blood pressure with higher salt intake was evident in both diets. Of note, the blood pressure response to salt intake was nonlinear. Specifically, decreasing salt intake caused a greater lowering of blood pressure when the starting sodium intake was less than 2.3 g/day (100 mmol/day) than when it was above this level.

The blood pressure response to changes in salt intake is heterogeneous. Despite the use of the terms 'salt sensitive' and 'salt resistant' to classify individuals in research studies, the change in blood pressure in response to a change in salt intake is not binary. Instead, the change in blood pressure from a reduced salt intake has a continuous distribution, with individuals having greater or lesser degrees of blood pressure reduction. Genetic factors influence the response to salt reduction. Concomitant diet also modifies the effects of salt on blood pressure. The rise in blood pressure for a given increase in salt intake is blunted in the setting of either the DASH diet or a high potassium intake (**Figure 3**). In general, the effects of salt on blood pressure tend to be greater in blacks, middle-aged and older people, and individuals with hypertension, diabetics, or chronic kidney disease. Although it is possible to identify groups that tend to be salt sensitive, it is impossible, given currently available diagnostic tools, to identify individuals who are salt sensitive.

[1]In view of the format of published data and of dietary recommendations, data are presented as g/day (mmol/day) of sodium rather than g/day of salt.

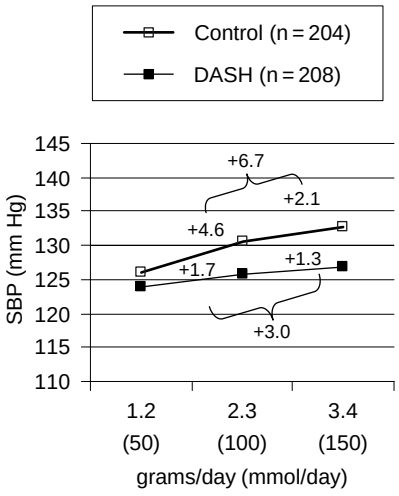

Figure 3 Mean systolic blood pressure (SBP) change in the DASH-Sodium trial from salt reduction in two diets and from the DASH diet at three salt levels. (Adapted with permission from Sacks FM, Svetkey LP, Vollmer WM *et al.* (2001) A clinical trial of the effects on blood pressure of reduced dietary sodium and the DASH dietary pattern (The DASH-Sodium Trial). *New England Journal of Medicine* **344**: 3–10.)

In addition to lowering blood pressure, clinical trials have documented that a reduced salt intake can prevent hypertension by approximately 20% (with or without concomitant weight loss) and can lower blood pressure in the setting of antihypertensive medication. Evidence from observational studies suggests that a reduced salt intake can blunt the age-related rise in systolic blood pressure (**Figure 4**) and can potentially prevent atherosclerotic cardiovascular events and heart failure. A reduced salt intake may also reduce the risk of left ventricular hypertrophy, osteoporosis, and gastric cancer.

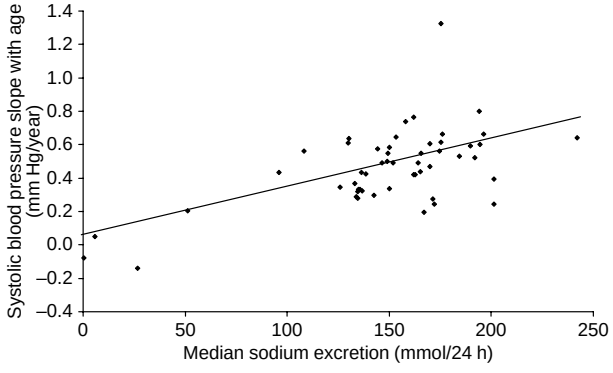

Figure 4 Slope of systolic blood pressure increase with age plotted by median sodium excretion in 52 communities worldwide: results from INTERSALT. (Adapted with permission from Rose G, Stamler J, Stamler R *et al.* (1988) INTERSALT: An international study of electrolyte excretion and blood pressure. Results for 24 hour urinary sodium and potassium excretion. *British Medical Journal* **297**: 319–328.)

Still, the effects of salt on health have been debated. Some have argued that the increases in plasma renin activity and perhaps insulin resistance that occur as a result of a reduced salt intake mitigate the beneficial effects of salt reduction on blood pressure. However, in contrast to blood pressure, the clinical relevance of increased plasma renin activity is uncertain, especially because antihypertensive medications that raise plasma renin levels actually lower cardiovascular disease risk. It has also been argued that a reduced salt intake has little or no effect on blood pressure in many individuals and that other aspects of diet (e.g., increased potassium intake or adoption of a mineral-rich diet) mitigate the harmful effects of salt on blood pressure. Although one cannot guarantee that all individuals will achieve a lower blood pressure from salt reduction, the fraction of individuals who will benefit is substantial.

In view of the progressive dose–response relationship between salt intake and blood pressure, it is difficult to set specific levels for dietary recommendations. Recently, an Institute of Medicine committee set 1.5 g/day (65 mmol/day) of sodium as an adequate intake level and 2.3 g/day (100 mmol/day) as an upper limit. Western-type diets that provide 1.5 g/day (65 mmol/day) have been shown to provide adequate levels of other nutrients. This level of salt intake also allows for excess sweat salt loss among unacclimatized individuals who become physically active or who become exposed to high temperatures. Numerous policymaking organizations have recommended an upper limit of 2.3 g/day (100 mmol/day) for sodium intake.

In most Western counties, average intake of sodium is high, greatly exceeding 2.3 g/day (100 mmol/day). In the United States, the median intake of sodium from foods, not including salt added at the table, varies by age and, according to a recent survey, ranges from 3.1 to 4.7 g/day (135 to 204 mmol/day) in adult men and 2.3 to 3.1 g/day (100 to 135 mmol/day) in adult women. Worldwide, there is greater variation in sodium intake, ranging from an estimated mean intake of 0.02 g/day (1.0 mmol/day) in Yanomamo Indians to more than 10.3 g/day (450 mmol/day) in northern Japanese.

In aggregate, available data strongly support current populationwide recommendations to lower salt intake. To reduce salt intake, consumers should choose foods low in salt and limit the amount of salt added to food. However, even motivated individuals find it difficult to reduce salt intake because more than 75% of consumed salt comes from processed foods (**Figure 5**). Hence, any meaningful strategy to reduce salt intake must involve the efforts of food manufacturers, who should reduce the amount of salt added during food processing.

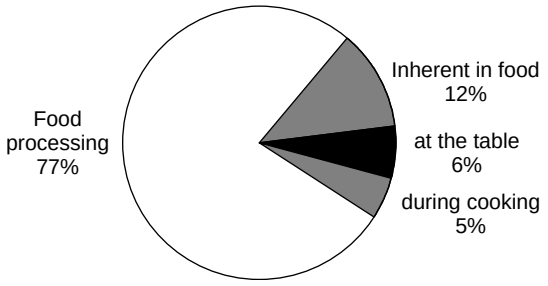

Figure 5 Sources of dietary sodium. (Data from Mattes RD and Donnelly D (1991) Relative contributions of dietary sodium sources *Journal of the American College of Nutrition* **10**: 383–393.)

Increased Potassium intake

High levels of potassium intake are associated with reduced blood pressure. Observational data have been reasonably consistent in documenting this inverse relationship, whereas data from individual trials have been less consistent. However, three meta-analyses of these trials have each documented a significant inverse relationship between potassium intake and blood pressure in nonhypertensive and hypertensive individuals. In one meta-analysis, average net systolic/diastolic blood pressure reductions from increased potassium intake were 4.4/2.4 mmHg. Available studies have documented greater blood pressure reductions from potassium in African Americans compared to non-African Americans. A high potassium intake has been shown to blunt the rise in blood pressure in response to increased salt intake. Potassium has greater blood pressure lowering in the context of a higher salt intake and lesser blood pressure reduction in the setting of a lower salt intake. Conversely, the blood pressure reduction from a reduced salt intake is greatest when potassium intake is low. These data are consistent with subadditive effects of reduced salt intake and increased potassium intake on blood pressure.

Most trials that tested the effects of potassium on blood pressure used pill supplements, typically potassium chloride. However, in foods, the conjugate anions associated with potassium are mainly citrate and other bicarbonate precursors. The latter is important because other potential benefits of foods rich in potassium (i.e., reduced risk of kidney stones and reduced bone turnover) likely result from effects of the conjugate anion. Because a high dietary intake of potassium can be achieved through diet rather than pills and because potassium derived from foods also comes with a variety of other nutrients, the preferred strategy to increase potassium intake is to consume foods, such as fruits and vegetables, rather than supplements.

On the basis of available data, an Institute of Medicine committee set an Adequate Intake for potassium of 4.7 g/day (120 mmol/day) for adults. This level of dietary intake should maintain lower blood pressure levels, reduce the adverse effects of salt on blood pressure, reduce the risk of kidney stones, and possibly decrease bone loss. Currently, dietary intake of potassium is considerably lower than this level. In recent surveys, the median intake of potassium by adults in the United States was approximately 2.9–3.2 g/day (74–82 mmol/day) for men and 2.1–2.3 g/day (54–59 mmol/day) for women. Because African Americans have a relatively low intake of potassium and a high prevalence of elevated blood pressure and salt sensitivity, this subgroup of the population would especially benefit from an increased potassium intake.

In the generally healthy population with normal kidney function, a potassium intake from foods higher than 4.7 g/day (120 mmol/day) poses no potential for increased risk because excess potassium is readily excreted in the urine. However, in individuals whose urinary potassium excretion is impaired, a potassium intake of less than 4.7 g/day (120 mmol/day) is appropriate because of adverse cardiac effects (arrhythmias) from hyperkalemia. Common drugs that impair potassium excretion are angiotensin converting enzyme inhibitors, angiotensin receptor blockers, and potassium-sparing diuretics. Medical conditions associated with impaired potassium excretion include diabetes, chronic renal insufficiency, end stage renal disease, severe heart failure, and adrenal insufficiency. Elderly individuals are at increased risk of hyperkalemia because they often have one or more of these conditions or take one or more of the medications that impair potassium excretion.

Moderation of Alcohol Intake

The relationship between alcohol intake and blood pressure is direct and progressive, particularly at an alcohol intake above approximately two drinks per day (~1 oz. or ~28 g of ethanol per day). A meta-analysis of 15 trials reported that decreased consumption of alcohol (median reduction in self-reported alcohol consumption of 76%) lowered systolic and diastolic blood pressure by 3.3 and 2.0 mmHg, respectively. In nonhypertensives and hypertensives, blood pressure reductions were similar. In aggregate, evidence supports moderation of alcohol intake (among those who drink) as an effective approach to lower blood pressure. It is recommended that alcohol consumption be limited to no more than 1 oz. (30 ml) of ethanol (e.g., 24 oz. (720 ml) beer, 10 oz. (300 ml) wine, or 2 oz. (60 ml) 100-proof whiskey) per day in most men and to no

more than 0.5 oz. (15 ml) ethanol per day in women and lighter weight people.

Whole Dietary Patterns

Vegetarian diets Vegetarian diets have been associated with low blood pressure. In observational studies, vegetarians also experience a markedly lower, age-related rise in blood pressure. Aspects of a vegetarian lifestyle that might affect blood pressure include nondietary factors (e.g., physical activity), established dietary risk factors (e.g., salt, potassium, weight, and alcohol), and other aspects of a vegetarian diet (e.g., high fiber and no meat). To a very limited extent, observational studies have controlled for the well-established determinants of blood pressure. Hence, it is unclear whether blood pressure reductions result from established dietary risk factors that affect blood pressure or from other aspects of a vegetarian diet.

The DASH diet The DASH trial tested whether modification of whole dietary patterns might affect blood pressure. In this trial, participants were randomized to eat one of three diets: (i) a control diet, (ii) a diet rich in 'fruits and vegetables' but otherwise similar to control, or (iii) the DASH diet. The DASH diet emphasizes fruits, vegetables, and low-fat dairy products; includes whole grains, poultry, fish, and nuts; and is reduced in fats, red meat, sweets, and sugar-containing beverages. Accordingly, it is rich in potassium, magnesium, calcium, and fiber and reduced in total fat, saturated fat, and cholesterol; it is also slightly increased in protein.

Among all participants, the DASH diet significantly lowered mean systolic blood pressure by 5.5 mmHg and mean diastolic blood pressure by 3.0 mmHg. The fruits and vegetables diet also reduced blood pressure but to a lesser extent—approximately half of the effect of the DASH diet. The effect was relatively rapid; the full effect was apparent after 2 weeks (**Figure 6**). In subgroup analyses, the DASH diet significantly lowered blood pressure in all major subgroups (men, women, African Americans, non-African Americans, hypertensives, and nonhypertensives). However, the effects of the DASH diet were especially prominent in African Americans, who experienced net systolic/diastolic blood pressure reductions of 6.9/3.7 mmHg, and hypertensive individuals, who experienced net blood pressure reductions of 11.6/5.3 mmHg.

Results from the DASH trial have important clinical and public health implications. The effect of the DASH diet in hypertensive individuals was similar in magnitude to that of drug monotherapy. From a public health perspective, the DASH diet could potentially shift the population distribution of blood pressure downward, thereby reducing the risk of blood pressure-related cardiovascular disease (**Figure 2**).

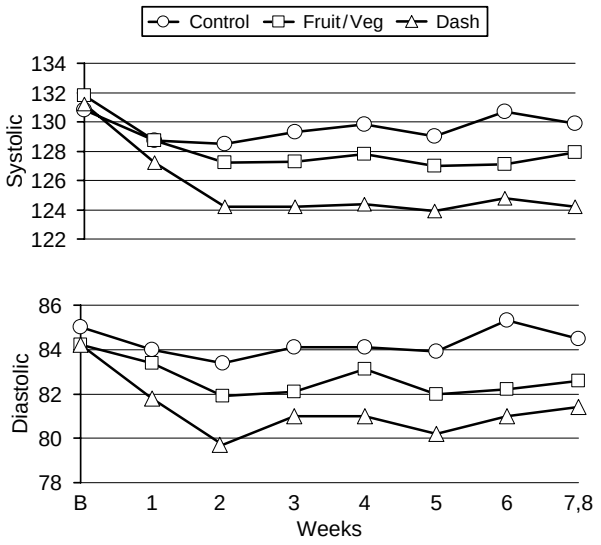

Figure 6 Blood pressure by week during the DASH feeding study in three diets (control diet, fruits and vegetables diet, and DASH diet). (Adapted with permission from Appel LJ, Moore TJ, Obarzanek E *et al.* (1997) The effect of dietary patterns on blood pressure: Results from the Dietary Approaches to Stop Hypertension (DASH) clinical trial. *New England Journal of Medicine* **336**: 1117–1124.)

Fish Oil Supplementation

High-dose, omega-3 polyunsaturated fatty acid (commonly termed 'fish oil') supplements can lower blood pressure in hypertensive individuals. In a meta-analysis of trials, average systolic and diastolic blood pressure reductions in hypertensive individuals were 5.5 and 3.5 mmHg, respectively. The effect of fish oil appears to be dose dependent, with blood pressure reductions only occurring at relatively high doses, namely 3 g/day or more. In nonhypertensive individuals, blood pressure reductions were nonsignificant and small. Side effects, including belching and a fishy taste, are common. In view of the side effect profile and the high dose required to lower blood pressure, fish oil supplements are not routinely recommended.

Dietary Factors with Limited or Uncertain Effect on Blood Pressure

Fiber

Evidence from observational studies and several clinical trials suggests that increased fiber intake may reduce blood pressure. A meta-analysis

documented that supplemental fiber (average increase of 14 g/day) was associated with net systolic/diastolic reductions of 1.6/2.0 mmHg, respectively. Still, high-quality epidemiologic studies and clinical trials are needed before one can recommend increased fiber intake as a means to lower blood pressure.

Calcium and Magnesium

Evidence that increased calcium intake might lower blood pressure comes from a variety of sources, including animal studies, observational studies, clinical trials, and meta-analyses. Meta-analyses of trials documented modest reductions in systolic and diastolic blood pressure of 0.89–1.44 and 0.18–0.84 mmHg, respectively, with calcium supplementation (400–2000 mg/day). There is also evidence that calcium intake may affect the blood pressure response to salt. Overall, data are insufficient to recommend supplemental calcium alone as a means to lower blood pressure.

The body of evidence implicating magnesium as a major determinant of blood pressure is inconsistent. In observational studies, often cross-sectional in design, a common finding is an inverse association of dietary magnesium with blood pressure. However, in pooled analyses of clinical trials, there is no clear effect of magnesium intake on blood pressure. Hence, data are insufficient to recommend increased magnesium intake alone as a means to lower blood pressure.

Fats (Other Than Fish Oil) and Cholesterol

Numerous studies, including both observational studies and clinical trials, have examined the effects of fat intake on blood pressure. Overall, there is no apparent effect of saturated fat and n-6 polyunsaturated fat intake on blood pressure. Although a few trials suggest that an increased intake of monounsaturated fat may lower blood pressure, evidence is insufficient to make recommendations. Likewise, few studies have examined the effect of dietary cholesterol intake on blood pressure. Hence, although modification of dietary fat and cholesterol intake can be recommended as a means to prevent and treat hyperlipidemia and dyslipidemia, evidence is insufficient to recommend these changes alone as a means to lower blood pressure.

Protein Intake

A large and generally consistent body of evidence from observational studies has documented that higher protein intake, particularly protein from plant-based sources, is associated with lower blood pressure. In contrast to the large volume of evidence from observational studies, comparatively few trials have examined the effects of protein intake on blood pressure. Recent trials have tested the effects of soy-based interventions on blood pressure. In several but not all of these trials, soy supplementation reduced blood pressure. Although it is reasonable to speculate that an increased intake of protein from plant sources can lower blood pressure, this hypothesis has not been adequately tested in a clinical trial of sufficient size and rigor.

Vitamin C

Laboratory studies, depletion–repletion studies, and epidemiological studies suggest that increased vitamin C intake or status is associated with lower blood pressure. However, few trials have addressed this issue, and results of these trials have been inconsistent. Overall, it remains unclear whether an increased intake of vitamin C lowers blood pressure.

Gene–Diet Interactions

A rapidly increasing body of evidence indicates that genetic factors affect blood pressure levels and the blood pressure response to dietary changes. Most of the evidence relates to genetic factors that influence the blood pressure response to salt. Several genotypes that influence blood pressure have been identified. Most of these genotypes influence the renin–angiotensin–aldosterone axis or renal salt handling.

Special Populations

Children

Elevated blood pressure begins well before adulthood, during the first two decades of life and perhaps earlier during gestation. Numerous observational studies have documented that blood pressure tracks with age from childhood into the adult years. Hence, efforts to reduce blood pressure and to prevent the age-related rise in blood pressure in childhood are prudent.

Direct empiric evidence from rigorous, well-controlled trials in children and adolescents is sparse. There is some direct evidence from studies conducted in children that the dietary determinants of blood pressure in children and adults are similar. In this setting, the effect of diet on blood pressure in children and adolescents is, in large part, extrapolated from studies of adults. Such extrapolations are reasonable because elevated blood pressure is a chronic condition resulting from the insidious

rise in blood pressure throughout childhood and adulthood.

Pregnant Women

Hypertension during pregnancy is a constellation of diverse clinical conditions, some of which can be extremely serious. Of substantial concern are preeclampsia and eclampsia. Both are multisystem disorders that are manifest by the onset of hypertension and proteinuria during the second half of pregnancy. Convulsions occur in the setting of eclampsia but not preeclampsia. The cause of these disorders is unknown. Several dietary interventions, including salt restriction, fish oil supplementation, and calcium supplementation, have been tested as a means to prevent preeclampsia, but none is considered effective. Although a meta-analysis of small trials suggested that calcium supplementation has some benefit in high-risk women, a large trial of calcium supplementation documented no benefit, either overall or in high-risk subgroups.

Older People

Because of the age-related rise in systolic blood pressure and because of the high prevalence of blood pressure-related cardiovascular disease in middle-aged and older people, dietary strategies should be especially beneficial as adults age. It is well documented that older people can make and sustain dietary changes, specifically weight loss and dietary salt reduction. Furthermore, salt sensitivity increases as individuals age. Lastly, because of the high attributable risk associated with elevated blood pressure in older people, the beneficial effects of dietary changes on blood pressure should translate into substantial reductions in cardiovascular risk in this age group.

Populations Defined by Race/Ethnicity or Geography

Worldwide, there is substantial variation in blood pressure among populations. In certain primitive societies, such as the Yanomamo Indians in Brazil, blood pressure does not rise with age, and hypertension is absent. In rural Africa and southern China, the prevalence of hypertension is less than 20%. Among urbanized populations, the prevalence of hypertension is high, especially among African Americans, a population in which the prevalence of hypertension approaches 40%. Other groups, such as Australian Aborigines, Eastern Europeans, and Russians, also have a high prevalence of hypertension.

Understanding the causes of geographic variation is difficult. However, migration studies provide strong evidence that modifiable environmental factors (e.g., diet and physical activity) rather than genetic factors or geographic factors account for this variation. Furthermore, as noted previously, trials have documented that compared to non-African Americans, African Americans achieve greater blood pressure reduction from several nonpharmacologic therapies, specifically a reduced salt intake, increased potassium intake, and the DASH diet. The potential benefits of these dietary therapies is amplified because US survey data indicate that African Americans consume less potassium than non-African Americans. On average, salt intake is high and similar in African Americans and non-African Americans. Hence, changes in diet should provide a means to reduce racial and perhaps geographic disparities in blood pressure.

Conclusion

In view of the continuing epidemic of blood pressure-related cardiovascular disease, efforts to reduce blood pressure in both nonhypertensive and hypertensive individuals are warranted. Such efforts will require individuals to change behavior and society to make substantial environmental changes. The current challenge to health care providers, researchers, government officials, and the general public is to develop and implement effective clinical and public health strategies that lead to sustained dietary changes among individuals and more broadly among populations.

Nutritional Management

C M Champagne, Pennington Biomedical Research Center, Baton Rouge, LA, USA

Hypertension or high blood pressure affects more than 25% of adult Americans (50 million) and Canadians, and the rate of hypertension is reportedly as much as 60% higher in some European countries. African Americans typically have higher rates of hypertension compared to whites. Hypertension is also more common among older people, occurring in two-thirds of those older than 65 years of age—a population that is often untreated. The lifetime risk of developing hypertension for middle-aged and elderly individuals is 90%.

Recently, new guidelines suggest that the previous values of 120 mmHg/80 mmHg should not be considered normal. The revised categories are shown in **Table 1**. The recommendations for management of hypertension include lifestyle modification for all categories (even normal), with drugs not routinely promoted until the patient presents with at least stage 1 hypertension or other compelling indications.

The most definitive trials directed toward the nutritional management of hypertension are the DASH (Dietary Approaches to Stop Hypertension) and DASH-Sodium trials. DASH focused on establishing dietary patterns that would lower blood pressure while keeping sodium content constant. DASH-Sodium was designed to test the effects of varying levels of sodium in conjunction with the DASH diet in order to determine whether lowering sodium intake would have additional beneficial effects. Both trials were metabolic feeding trials, and each enrolled more than 400 participants at four sites in the United States. As a follow-up to the DASH and DASH-Sodium trials, essentially the same group of investigators conducted the PREMIER trial to test whether individuals could lower blood pressure by implementing established guidelines for treating hypertension and included the DASH diet in addition to the established recommendations. PREMIER used a lifestyle counseling approach and randomized more than 800 subjects to one of three treatment arms: advice only, established recommendations, and established recommendations plus DASH.

Table 1 Classification of blood pressure for adults 18 years of age or older

Category	*Systolic blood pressure (mmHg)*	*Diastolic blood pressure (mmHg)*
Normal or desirable	<120	<80
Prehypertensive	120–139	80–89
Stage 1 hypertension	140–159	90–99
Stage 2 hypertension	≥160	≥100

U.S. Dept of Health and Human Services, National Institutes of Health, National Heart, Lung and Blood Institute. The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. NIH Publication No. 04-5230, August 2004.

Recommended Lifestyle Modifications

Traditionally, the following lifestyle modifications have been recommended for the treatment of hypertension:

Lose weight, if one is overweight.
Reduce intake of salt, sodium, and foods containing them as much as possible.
Increase physical activity.
Limit intake of alcohol.
Stop smoking.
Control stress.

The established recommendations for lifestyle modification used in one arm of the PREMIER clinical trial were weight loss, increasing physical activity, reducing sodium intake, limiting alcohol consumption, and reducing total and saturated fat intake to that of an American Heart Association step 1 diet with 30% of energy from total and 10% from saturated fat. A second arm in PREMIER included essentially the same lifestyle modifications but a lower fat diet comparable to an American Heart Association step 2 diet with 25% of energy from total and 7% from saturated fat and also adherence to the DASH diet (emphasizing consumption of fruits, vegetables, and low-fat dairy products).

Nutritional Considerations

Reduction of Sodium Intake

Sodium reduction typically results in lower blood pressure in industrialized societies. Current guidelines in the United States suggest reducing the daily intake of sodium to approximately 100 mmol, or approximately 2.4 g of sodium or less per day.

The DASH-Sodium trial demonstrated that reduction of sodium intake from 100 to 50 mmol per day (approximately 1.5 g) significantly reduced blood pressure in individuals following either the common US diet or the DASH diet. In addition, TOHP2 (phase 2 of the Trials of Hypertension Prevention) and TONE (Trials of Nonpharmacologic Interventions in the Elderly) documented that reducing sodium can either prevent hypertension or facilitate hypertension control. It should also be noted that salt sensitivity increases with age, so those who demonstrate this sensitivity should maintain a reduced salt diet.

Consumers should either eliminate or limit salt added to foods in cooking and at the table as a means of reducing sodium intake. Nutrition facts labels require sodium content to be listed so that consumers can be more prudent about their diets. The amount of sodium in processed food, such as convenience foods (e.g., boxed products one would prepare at home), soups, and processed meats (e.g., sausage, ham, and other meat products), is often alarming. If there is not a nutrition label on a processed food product, one should assume sodium content is high. Canned products generally contain more sodium than fresh or frozen items, unless a product is specifically labeled as 'no salt added.' The consumption of fresh, unprocessed foods should be promoted.

Moderation of Alcohol Intake

The relationship between high consumption of alcohol (typically three or more drinks per day) and elevated blood pressure has been shown in numerous epidemiologic studies. A drink is defined as 12 oz. of beer, 5 oz. of wine, or 1.5 oz. of distilled spirits. Most evidence indicates that alcohol should be limited to two drinks per day for men and one drink per day for women. Ideally, daily alcohol consumption should be avoided. Whenever possible, alcohol, if consumed, should be done so with meals.

Consumption of a DASH Diet (Increasing Potassium, Magnesium, Calcium, and Fiber Intakes by Increasing Intakes of Fruits, Vegetables, and Low-Fat Dairy Foods)

The contribution of minerals, particularly potassium, magnesium, and calcium, and fiber was identified by contributions from fruits, vegetables, low-fat dairy products, whole grains, and nuts in the DASH eating plan. The DASH diet effectively used these components through an ideal dietary pattern to lower blood pressure.

Increased intakes of potassium have been associated with lower blood pressure. A meta-analysis of several trials suggested that 60–120 mmol per day of supplemental potassium reduces systolic and diastolic blood pressure by 4.4 and 2.5 mmHg, respectively, in hypertensive individuals. In normotensive individuals, systolic and diastolic blood pressure was reduced by 1.8 and 1.0 mmHg, respectively. Dietary intake of potassium can be easily achieved through consumption of various foods.

The DASH diet, while promoting dietary patterns, was developed very carefully with particular attention paid to the use of specific foods within categories that contribute more to the intakes of desired nutrients. As an example, consider the rank-ordered listing of potassium content of fruits and fruit juices presented in **Tables 2** and **3**. Dried fruits typically have the highest potassium content, followed by raw fruits and frozen fruits. Canned fruit products generally do not contain as high potassium content as other forms. There is less potassium contained in fruit juices and generally the

fresh forms of the juices have incrementally more than the processed forms. Fruits and juices in general contain some magnesium, another mineral of interest to the DASH investigators. Most fruits contain 2–30 mg of magnesium per 100 grams, but dried fruits contain much more (30–90 mg) and the amounts vary greatly. Fruit juices contain less than 20 mg of magnesium per 100 grams, with most containing less than 10 mg. Fiber content of fruit ranges from approximately 7 to 14 g of fiber for dried fruits on a per 100 gram basis and between 1 and 5 g for other fruits per 100 grams. Generally, fruit juices contribute less than 1 g of dietary fiber per 100 grams, but high-pulp varieties of juices provide slightly more dietary fiber.

Table 4 contains a rank-ordered listing of vegetables (including beans) by content of potassium. Magnesium content is also shown. The data are presented for vegetables and beans in the raw form generally. It is important to remember that many fresh forms are concentrated in terms of weight when cooked, especially spinach and other greens, and it is thus possible to obtain a higher mineral content from cooked vegetables (especially in the case of potassium). The magnesium content differs less from the fresh to the cooked state for most vegetables and beans. Most vegetables contain approximately 1–3 g of dietary fiber per

100 grams; beans and legumes offer approximately 5 g of dietary fiber, and some dried vegetables offer more than double this amount.

Nuts were also an important part of the DASH diet, contributing potassium, magnesium, fiber, and protein. They contain fat, mostly monounsaturated, and thereby contribute energy to the diet. **Table 5**

Table 5 Potassium, magnesium, and fiber content of nuts and seeds per 100 grams, ranked by potassium content

Description	*K (mg)*	*Mg (mg)*	*Fiber (g)*
Nuts			
Pistachio nuts, dry roasted	1042	120	10.3
Pistachio nuts, raw	1025	121	10.3
Ginkgo nuts, dried	998	53	9.3
Chestnuts, European, dried, unpeeled	986	74	11.7

includes the potassium, magnesium, and fiber content of some common nuts and seeds. Although this is presented based on a rank-ordered content of potassium, it is easy to see that some nuts and seeds are a significant source of magnesium and dietary fiber and their consumption was therefore encouraged in the DASH diet.

Low-fat dairy products were also an important part of the DASH diets. These were used primarily to increase the calcium content of the diets from a low content of approximately 450 mg on the control and fruit and vegetable diets to approximately 1250 mg on the DASH diet at the 2000 kcal (8368 kJ) level. Calcium has frequently been reported to have an inverse relationship with blood pressure, but studies utilizing supplemental calcium have been inconsistent. With supplements, effects on blood pressure reduction have been negligible. Nonetheless, the blood pressure lowering effect of the DASH diet has been suggested to be in part related to the calcium content of the diet. It should be noted that the DASH diet also was lower in fat and higher in protein, and therefore it is not easily attributable to one factor alone but rather a combination of several factors, as depicted in **Figure 1**.

The final point regarding composition of the DASH diet is that it included specific food choices. The diet contained whole grains, poultry, and fish (in addition to the fruits, vegetables, low-fat dairy, and nuts previously mentioned). Although it was reduced in total and saturated fat, it was also reduced in meats, sweets, and sugar-containing beverages. Food was consumed as an overall pattern in which it is quite possible that the interaction between food items is as important as the specific foods in reducing blood pressure. Thus, the DASH diet contained dietary patterns promoted by the National Institutes of Health, National Heart, Lung, and Blood Institute. The dietary patterns of DASH are presented at three energy levels in **Table 6**.

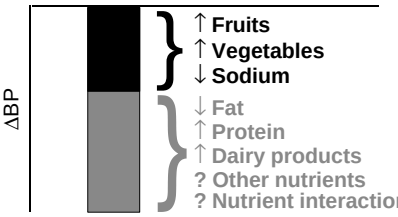

Figure 1 Assessing the effects of the DASH-Sodium diet on blood pressure. The figure depicts the fact that there is some certainty associated with the increases in fruits and vegetables and reduction in sodium. The gray areas represent the other components of the diet and the possible contribution of each, alone or in combination with other factors.

Table 6 Food group servings for the DASH diet at three energy levels

Food group	*Daily servings (except as noted)*		
	1600 kcal or 6694 kJ	*2000 kcal or 8368 kJ*	*3100 kcal or 12970 kJ*
Grains and grain products	6	7–8	12–13
Vegetables	3–4	4–5	6
Fruits	4	4–5	6
Low-fat or fat-free dairy foods	2–3	2–3	3–4
Meats, poultry, fish	1–2	2 or less	2–3
Nuts, seeds, dry beans	3 per week	4–5 per week	1
Fats and oils	2	2–3	4
Sweets	0	5 per week	2

Dietary Protein Consumption

Results of meta-analyses from several investigators indicate an inverse association between dietary protein and blood pressure levels. However, data have not been conclusive. The DASH diet contained approximately 18% of energy from protein compared to 15% of energy from protein in the other diets tested. Because of the addition of low-fat dairy foods and the reduced emphasis on high-fat meats, it can be assumed that this elevation in protein was brought about by foods that contributed protein from perceived beneficial sources. This is an area of dietary intake that requires more research.

Fish Oil Supplementation

Studies suggest that an intake of fish oil at a level of approximately 4 g per day reduces systolic blood pressure by approximately 1.7–2.1 mmHg and diastolic blood pressure by 1.5–1.6 mmHg. These effects tend to be larger in individuals older than 45 years of age and in populations with blood pressure readings greater than 140/90 mmHg. Generally, there have been differences associated with fish oil capsules compared to naturally occurring sources of EPA and DHA from fatty fish, again indicating dietary pattern rather than consumption of individual items may be crucial. The DASH diet had a relatively high fish content (compared to animal meats) and this may be yet one more factor contributing to the lowering of blood pressure in individuals on the DASH diet.

The American Heart Association recommends eating two servings of fish per week and emphasizes that the choice should be a fatty fish (such as salmon, herring, or mackerel). Not all fish have the same content of omega-3 fatty acids. **Table 7** provides a listing of amounts of combined EPA/DHA in fish and other seafood sources and the amount of consumption (in ounces of product) necessary to provide a 4-g intake. Descriptors include common raw and canned products, but the intakes given are rough estimates due to potential variability in oil content within species, season, and diet. Cooking methods and other preparation techniques may affect the final concentrations in raw fish.

Other Fatty Acid Effects

Monounsaturated fatty acids, particularly olive oil, may help lower blood pressure. Olive oil has typically been associated with the popularized Mediterranean diet, which has been promoted as a treatment for cardiovascular disease. Other oils (e.g., canola and peanut oil) have a high monounsaturated fat content. Nuts, which are part of the DASH diet, contain significant amounts of monounsaturated fats and fit well in the Mediterranean diet.

Caffeine

Although a link between caffeine consumption (particularly coffee) and hypertension may exist, effects of coffee drinking on blood pressure appear to be dependent on the time of consumption and subsequent determination of blood pressure values. Generally, a role for caffeine intake and development of hypertension is not believed to be significant.

Weight Reduction

Obesity and overweight are considered independent risk factors for cardiovascular disease and are closely associated with hypertension. This linkage was demonstrated in the 1960s by the Framingham Heart Study investigators in the United States. Obesity in the industrialized world has been increasing at epidemic proportions. The relationship between increasing body weight and increasing blood pressure has been termed obesity hypertension, and treatment requires consideration of physiologic changes related to this disorder. Although efforts have been under way in the United States to reduce overweight and obesity, it is estimated that the age-adjusted prevalence of overweight and obesity (body mass index (BMI) $\geq$25.0) among adults aged 20 or older is 64%; for those considered obese (BMI $\geq$30.0) it is 30%. During a 25-year period in the United States, this reflects approximately a 36% increase in the combined levels of overweight and obesity and essentially a doubling of obesity rates.

Table 7 Eicosapentaenoic (EPA, 20:5 n-3) and docosahexaenoic (DHA, 22:6 n-3) acid in fish/seafood (per 100 grams) and the amount of consumption (in ounces) required to provide ~4 g of EPA + DHA per day (ranked in order of content)

Fish/seafood	*EPA (g)*	*DHA (g)*	*EPA + DHA (g)*	*Oz. to provide ~4 g EPA + DHA*

From U.S. Department of Agriculture, Agricultural Research Service (2003) *USDA National Nutrient Database for Standard Reference*, Release 16. Available at www.nal.usda.gov/fnic/foodcomp.

The increase in obesity is seen in all ethnic, gender, and age groups. This problem is not confined to the average American; the US military reported that more than 50% of military personnel were overweight and more than 6% were obese in the late 1990s, despite high physical activity levels due to the rigors of basic training and regular field exercises. For the military, this reflects a trend that mirrors what is happening in the general population.

Globally, more than 1 billion adults are classified as overweight and approximately 300 million as clinically obese, ranging from less than 5% in China, Japan, and some African nations to more than 75% in urban Samoa. Alarmingly, this epidemic has spread to children, with 17.6 million children younger than 5 years of age estimated to be overweight worldwide. Data from the United States indicate that 15% of children and adolescents 6–19 years of age are overweight, a figure at least three times higher than that reported in the period from 1960 to 1970. Overweight children are at risk of becoming overweight adults but, more important, are likely to experience chronic health problems (including hypertension) associated typically with only adult obesity.

The World Health Organization has recommended an integrated, multifaceted, population approach be implemented to bring about effective weight management for those at risk of overweight and obesity. The key elements for developing such an environmental support include the following:

- Availability and access to a variety of low-fat, high-fiber foods
- Opportunities for physical activities

- Promotion of healthy behavior to encourage, motivate, and enable individuals to lose weight by
  - Eating more fruits, vegetables, nuts, and whole grains
  - Engaging in moderate physical activity for at least 30 minutes a day
  - Reducing the amounts of fat and sugar in the diet
  - Changing from a diet containing saturated animal fats to one emphasizing unsaturated vegetable oils
- Proper training of clinical personnel to ensure effective support for those trying to lose weight or avoid further weight gain

Obviously, it is essential to maintain a healthy body weight and thus necessary to keep a focus on energy intake in an effort to prevent overweight. Regarding hypertension, weight reduction appears to be the most promising answer in terms of potential impact on lowering blood pressure. Losing as few as 4.5 kg, or 10 pounds, of body weight can reduce blood pressure. Adopting healthy eating patterns yields additional benefits.

Strategies for Implementing Nutritional Changes to Control Blood Pressure

Self-Monitoring

A strategy undeniably praised for weight control is self-monitoring of one's food intake. Although a difficult undertaking for most individuals, the success of this technique is impressive, as evidenced by the successful long-term weight loss maintainers in the National Weight Control Registry.

The self-monitoring technique has been used to help people comply with other lifestyle recommendations (e.g., to increase physical activity by recording physical activity minutes). In the PREMIER clinical trial, participants in the 'established plus DASH' arm were required to monitor intake of energy, sodium, total fat, and saturated fat and servings of fruit, vegetables, and dairy to determine their compliance with the intervention. Those participants in the 'established' arm only recorded energy, sodium, and total fat intake. Most people find these recordings difficult but readily admit that they are successful in documenting dietary compliance if taken seriously.

Although a time-consuming and difficult task, successful diet compliers continue this behavior change strategy over the long term. Those who discontinue this technique often revert back to their old habits and relapse.

Working with a Dietetics Professional

Dietitians in North America and abroad typically have to meet national standards set by professional organizations such as the American Dietetic Association and the Canadian Dietetic Association. As such, these individuals are called 'registered dietitian' or other titles used only by those who have met these standards. Although one does not necessarily need to work with a professional, for some it is often easier to implement change when they can clear up confusing and often conflicting information by working with a dietitian who can provide credible nutrition information. Dietitians are taught to interpret the science into meaningful terms for the consumer. In addition, a well-trained professional will be equipped with a knowledge of motivational and behavior strategies to help effect change.

There are many important aspects of behavior change that are taught to the hypertensive client. Making lifestyle changes gradually so that one adjusts to one change before making another change is important. One should strive for short-term, attainable goals. Getting off track is not uncommon, but identifying what triggered the sidetrack and getting back on track are equally important. One should understand that slips are inevitable; it takes time to get used to the changes. In essence, lifestyle change is a long-term process, but it is worthwhile for good health.

Conclusions

Ultimately, blood pressure control will mandate lifestyle changes, even if hypertensive medications are prescribed. Most important, body weight has to be a key focus and the goal should be to work toward an ideal body weight and avoid gaining weight during the aging process. In addition to diet, physical activity factors into this scenario, and one should strive to be more physically active and less sedentary as one grows older. Diet, as described previously, plays a key role in blood pressure control. Increasing fruits, vegetables, and dairy products in the diet and reducing sodium should be the first objective. This will increase potassium, magnesium, and calcium by natural sources as much as possible. Increasing whole grains, nuts, and legumes will also improve mineral and fiber content of the diet. One should focus less on red meat; instead, one should choose fatty fish to increase consumption of omega-3 fatty acids. If one drinks alcohol, one should do so in moderation. These simple, but often difficult to accomplish, strategies will help to lower blood pressure and improve risk against cardiovascular disease.

HYPOGLYCEMIA

V Marks, University of Surrey, Guildford, UK

Introduction

Hypoglycemia is defined as a blood glucose concentration of 2.2 mmol l^{-1} (plasma glucose concentration of 2.5 mmol l^{-1}) or less. Its definition is necessarily arbitrary and owes its importance to the fact that hypoglycemia (literally low blood glucose) of this severity produces brain dysfunction by depriving its neurons of glucose.

Hypoglycemia is not a disease but a manifestation of it. It has, however, come to have a totally different meaning amongst certain sections of the

population that has very little to do with blood glucose concentration but a lot to do with their feelings of well being, discomfort, and attitudes to life but, above all, with the role of diet in the achievement and maintenance of good health. And whilst no discussion of the dietary treatment of hypoglycemia can be meaningful without reference to this concept – referred to, for want of a better term, as nonhypoglycemia, – hypoglycemia will, throughout this article, be used only to describe a measured low blood glucose concentration.

Brain Function and Hypoglycemia

The brain malfunction to which hypoglycemia gives rise will be referred to as neuroglycopenia.

The brain is often thought of as being incapable of using metabolites other than glucose as a source of energy. This is untrue. It has been known for more than 30 years to be able, under certain circumstances including prolonged fasting, to utilize the 'ketone bodies,' β-hydroxybutyrate and aceto-acetate. Under these circumstances the need for glucose and its supply through gluconeogenesis is drastically reduced. The survival value of this ability is immense as it permits fat stores rather than structural muscle and other tissue proteins to be utilized for maintenance of vital processes under these stressful conditions. Only when fat stores have become completely exhausted and plasma ketone levels fallen to below normal fasting levels does the brain's demand for glucose rise above the ability of gluconeogenesis to provide it. Only at this point does hypoglycemia intervene and portend death from starvation or inanition (see later).

The Blood Glucose Concentration

Failure to appreciate the differences between arterial and venous blood glucose is a major cause of the confusion that has surrounded the recognition and diagnosis of hypoglycemia and been responsible for nonhypoglycaemia becoming a common diagnosis amongst those whom Singer and coworkers refer to as, the folk sector.

In the fasting subject the concentration of glucose in arterial and venous blood is virtually identical but may differ by as much as $2.5\,\mathrm{mmol\,l^{-1}}$ following ingestion of a carbohydrate-rich meal. Because it is arterial blood glucose that determines glucose supply to the brain, regulates the secretion of insulin and other hormones, and is itself homeostatically controlled, it is necessary to define hypoglycemia in terms of glucose in arterial (or more realistically free flowing capillary) than in venous blood.

Mechanism of Hypoglycemia Glucose Pool in Fasting Subjects

Glucose is confined within the body to the extracellular fluid where it is referred to as the glucose pool: detailed discussion of its regulation is outside the scope of this article except to stress that it reflects the concentration of glucose in the blood. This remains remarkably constant despite huge changes in the rates of delivery and utilization of glucose, by meals and exercise (and fasting), respectively, and is described as glucose homeostasis (**Figure 1**). The main but far from sole regulator is insulin.

Insulin Release in Response to Eating and Fasting

Evidence for a 'cephalic phase' of insulin secretion in humans is scanty and conflicting. Most observers have found a minimal, if any, response to the prospect of eating, or the reality of drinking, a noncalorigenic sweet drink except in some obese individuals.

After a carbohydrate-containing meal, glucose derived from food enters the portal vein. From here it is conveyed to the liver where much of it is extracted and converted to glycogen. What remains unabsorbed passes into the systemic circulation, producing small and variable rises in arterial, capillary, and, initially, venous blood glucose concentrations. The modest rise in arterial blood glucose concentration perfusing the pancreas, augmented by nervous stimuli and insulinotrophic hormones, collectively called incretins, released from the gut in response to meals containing carbohydrate and/or fats, leads to the secretion of insulin in greater amounts than is occasioned by the rise in blood glucose concentration alone.

In the postprandial period, as the blood glucose concentration fall towards its homeostatically controlled level, insulin secretion declines to a level that is just sufficient to suppress unbridled lipolysis. Absence of this constitutive insulin secretion in patients with type 1 diabetes is the cause of diabetic ketoacidosis.

The Role of the Liver in Glucose Homeostasis

The liver, under the influence of insulin reaching it in high concentration in the portal vein after ingestion of a meal, switches from being a net exporter to net importer of glucose from the glucose pool. Any insulin not extracted and degraded by the liver passes through the heart and lungs to reach peripheral tissues, notably muscle, adipose tissue, and skin, where, providing the concentration of insulin in blood is sufficiently high, it promotes glucose uptake.

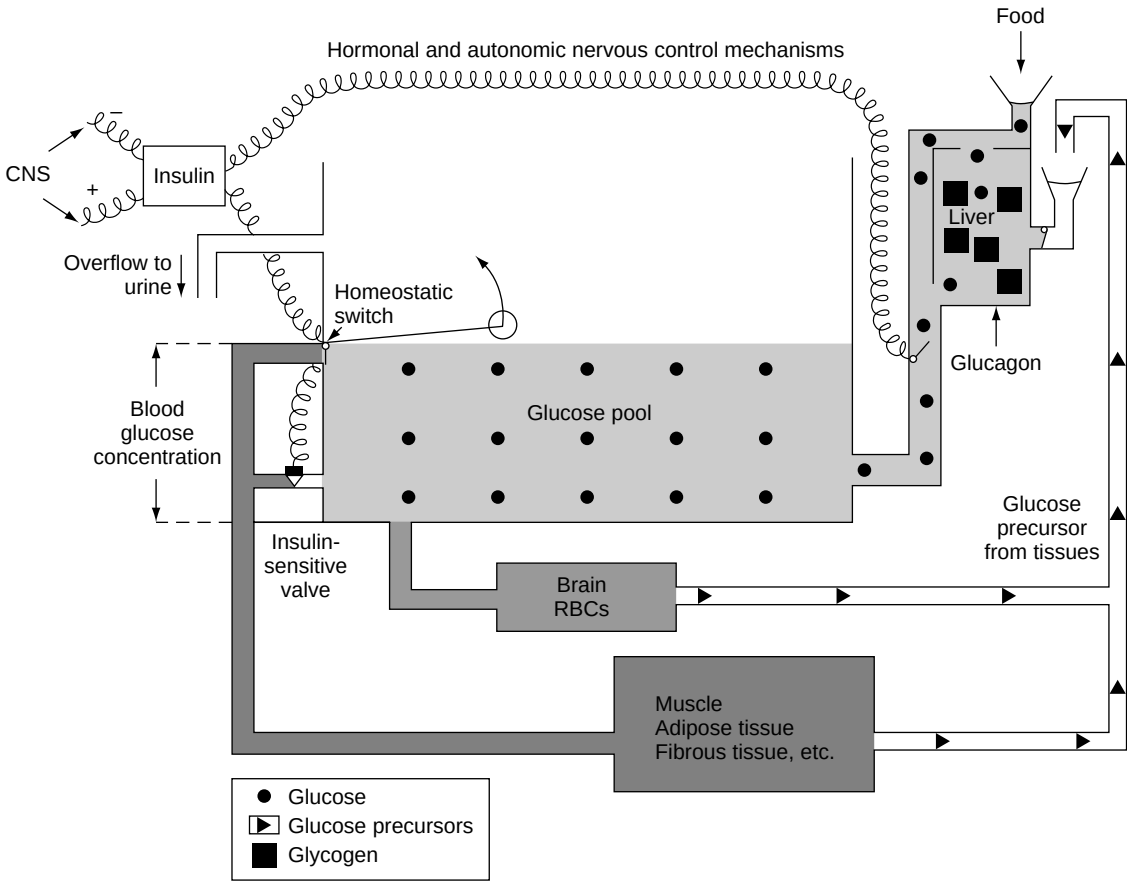

Figure 1 Schematic representation of homeostatic control of blood glucose level and mechanism of hypoglycemia. Hypoglycemia results whenever inflow of glucose from the gut and/or liver fails to meet the outflow of glucose from the glucose pool, which consists of glucose dissolved in the extracellular water only. Imbalance arises from: (1) excessive outflow into the tissues due to insulin (or very rarely IGF-II) overproduction or activity; or (2) in the fasting state, an inability of the liver to liberate or produce glucose at a rate sufficient to meet the non-insulin-dependent, and obligatory, requirements of the brain and red blood cells for glucose.

Except in disease, the glucose pool, amounting to just 5–15 g, rarely expands by more than 100% even after ingestion of a meal providing up to 300 g of carbohydrate as starch or glucose. Nor does it shrink to less than 4 g even after many days of fasting.

Entry of glucose into the glucose pool is limited by the rate at which it can be absorbed from the intestine. This is normally in the region of 25–50 g h^{-1}. In people with normal glucose tolerance, venous blood glucose levels generally return to overnight fasting values within 2 h of eating a meal regardless of how much carbohydrate it contains. Arterial blood glucose levels take somewhat longer to return to preingestion levels but they too are always within the normal fasting range by 3 h, even though the evidence provided by measurement of the gut hormones Glucose-Dependent Insulinotrophic Peptide (GIP), the main incretin, indicate that absorption of large meals continues for much longer. Absorption of a 200-g liquid glucose meal by normal healthy subjects, for example, is still incomplete after 5 h even though both their venous and arterial blood glucose levels have long since returned to normal.

The outflow of glucose into the tissues, on the other hand, depends upon many factors; the two most important are the plasma insulin concentration and the blood concentration itself. Under maximum insulin stimulation – and at 'normal' blood glucose levels – glucose can disappear from the glucose pool at a rate of up to 40–50 g h^{-1} but these conditions are rarely encountered except experimentally or in cases of gross insulin overdose.

Onset of insulin action is almost instantaneous and persists for as long as insulin remains bound to insulin receptors. This is generally slightly longer than insulin levels in the blood themselves remain elevated. In other words glucose continues to enter insulin-dependent cells for up to 30 min after plasma insulin levels have returned to 'fasting' levels. During this time the glucose pool may shrink sufficiently to produce hypoglycemia unless replenished by glucose continuing to enter from the intestine (or

experimentally/therapeutically by intravenous infusion) or from the liver, once it has switched from the glycogenic to glycogenolytic mode.

Small, and always temporary, imbalances between the rate at which insulin action declines and glucose enters the glucose pool can occur in healthy subjects after ingestion of a large dose of glucose in solution on an empty stomach, but is rare following the ingestion of an ordinary mixed meal.

A slight delay in stimulating insulin release in response to a meal is the earliest and most characteristic abnormality observed in patients with non-insulin-dependent diabetes mellitus (NIDDM) who may secrete more insulin in total than people of comparable age, though not of body mass index. They are, however, generally insulin resistant, which explains why, despite the larger amounts of insulin secreted in response to meals in the early stages of their illness, they do not suffer from meal-induced hypoglycemia.

Hypoglycemic Syndromes

Brain Malfunction from Hypoglycemia

The brain ordinarily requires a regular and plentiful supply of glucose, which gets to it from the blood by active transport utilizing the glucose transporter protein GLUT 1. Reduction of supply to below critical limits causes the brain to malfunction and this manifests itself subjectively as symptoms and objectively as neurological deficit. The blood glucose level at which impairment occurs varies. Symptoms are unusual at blood glucose levels above $3.0\,\text{mmol}\,\text{l}^{-1}$ except in diabetic and elderly subjects in whom they may occur at higher levels. Objective evidence of cerebral impairment can however often be discerned by an investigator at blood glucose levels around $3.5–4\,\text{mmol}\,\text{l}^{-1}$.

Causes of neuroglycopenia other than hypoglycemia, i.e., normoglycemic neuroglycopenia, are currently thought to be rare but include congenital or acquired reduction in GLUT 1. The possibility that such defects are more common than currently supposed and are responsible for some cases of 'nonhypoglycemia' cannot be dismissed at the present time, and would help explain why, under research conditions, some people diagnosed with this condition appear to develop symptoms at higher blood glucose levels than control subjects.

Neuroglycopenic Syndromes

Four more or less distinct neuroglycopenic syndromes (one of which is so rare that it will not be considered further here) can be recognized. They are not mutually exclusive, nor do they depend upon the ultimate cause of the hypoglycemia.

Acute Neuroglycopenia

This syndrome comprises a collection of vague symptoms such as feelings of alternating hot and cold, feeling unwell, anxiety, panic, inner trembling, unnatural feelings, blurring of vision, and palpitations, any or all of which may be accompanied by objective signs of facial flushing, sweating, tachycardia, and unsteadiness of gait. There is no particular order in which these features occur, nor are they constant. Nevertheless, patients on insulin therapy for diabetes, in whom they are common, rely upon them to warn of more severe neuroglycopenic impairment culminating in loss of consciousness. These patients can be taught to abort progression of symptoms by eating carbohydrate.

Many of the features of acute neuroglycopenia resemble those produced by adrenaline and consequently are often referred to as adrenergic.

Subacute Neuroglycopenia

This syndrome is more insidious and may go completely unrecognized unless or until the patient loses consciousness. Often, however, there is loss of spontaneous activity, impairment of cognitive function and the onset of somnolence that is more discernible to the bystander than to the patient and which, when it occurs *de novo* in an insulin-treated diabetic, is often referred to as 'hypoglycemia unawareness.'

Acute can proceed to subacute neuroglycopenia and both can progress to stupor or coma unless relieved by food or injection of glucagon. Even when this is not done, however, full recovery, under the influence of endogenous counter-regulatory mechanisms, is almost invariable and is the reason why treatment with insulin is so safe despite the potential dangers of hypoglycemia.

Chronic Neuroglycopenia

The third syndrome is exceedingly rare. It occurs only when the blood glucose concentration remains low, either due to the presence of an insulin-secreting tumor of the pancreas or overzealous treatment of diabetes with insulin for weeks or months on end. It is characterized by mental dysfunction resembling clinical depression, schizophrenia, or dementia, the symptoms of which are not relieved by restoring the blood glucose level to normal. Partial recovery may, however, take place over the

ensuing months or years if the cause of the hypoglycemia is remedied.

This condition might be confused with 'nonhypoglycaemia' were it not for the fact that the blood glucose concentration is invariably low ($<3.0\,\text{mmol}\,l^{-1}$) while the patient is fasting, does not rise normally in response to food, and evidence of underlying disease can always be found.

Diagnosis

Causes of Hypoglycemia

There is something in the region of 100 causes of hypoglycemia but all, apart from exogenous (or iatrogenic) insulin overdose, are uncommon. Some of the most important causes of recurrent hypoglycemia are listed and briefly described in **Table 1**. Simultaneous occurrence of symptoms, a measured low blood glucose concentration, and relief from intravenous glucose are a sine qua non for diagnosis. Differentiation is seldom simple and always rests heavily upon the results of laboratory data of which measurements of plasma insulin and C-peptide are the most important.

Endocrinological and other anatomico-pathological causes of hypoglycemia will not be considered further. Nor will iatrogenic or toxic causes, of which alcohol-induced fasting hypoglycemia is easily the most common. Instead, attention will be given to those conditions (including 'nonhypoglycaemia') that have a mainly or exclusively dietary etiology and which respond partially or completely to dietary measures.

Spontaneous Reactive Hypoglycemia

Within a year of the discovery of insulin, and the symptoms to which hypoglycemia can give rise, Seale Harris, an American physician, had proposed that spontaneous overproduction of endogenous insulin might produce a similar condition. Confirmation of this hypothesis soon followed. The seminal work of Whipple on the diagnosis of insulinoma and of Conn on diet-induced postprandial reactive hypoglycemia, both in 1936, distinguished between fast-induced (fasting) hypoglycemia and that which occurred only in response to feeding. The latter, reactive or postprandial hypoglycemia, could be reproduced by oral administration of large doses of glucose in solution and this became the standard criterion for its diagnosis – the 5-h glucose tolerance test.

Glucose Load Test

The observation that in a substantial percentage of normal healthy people glucose taken in solution on an empty stomach produces a rebound fall in venous blood glucose levels to below fasting levels was made soon after blood glucose measurements became possible and before the discovery of insulin. It attracted little attention at the time being considered to have only curiosity value and little pathological significance.

The situation changed dramatically during the early 1950s and, subsequently, particularly in the US, with the appearance of books written for lay consumption attributing a vast array of common symptoms to hypoglycemia, whether the blood glucose concentration was low at the time or not. Belief in the importance and prevalence of 'hypoglycemia' grew amongst fashionable medical practitioners and the general public alike to such an extent that, by the early 1970s, alarm bells began to ring amongst consumer action groups and the scientific medical community.

With the passage of time the original, well-defined syndrome of postprandial reactive hypoglycemia had become so distorted, and the criteria for its diagnosis so blurred, that anyone with vague symptoms could be, and often was, described as suffering from 'hypoglycemia,' without anyone bothering to measure their blood glucose concentration.

Not until a consensus 'Statement on 'Post Prandial' or 'Reactive' Hypoglycemia' was issued by the Third International Symposium on Hypoglycemia and generally recognized by medical practitioners throughout the world did scientific criteria for the diagnosis of reactive hypoglycemia gain universal acceptance and its purported incidence declined dramatically.

Definition

It is now accepted that some people exhibit, in the course of their everyday life, symptoms similar to those caused by acute neuroglycopenia and may, if accompanied by a capillary or arterialized venous blood glucose concentration of $2.8–2.5\,\text{mmol}\,l^{-1}$ or less, justify description as being of postprandial reactive hypoglycemic origin. Reactive hypoglycemia may itself be a consequence of any one of a large number of well-recognized but generally uncommon conditions that can also produce fast-induced hypoglycemia, and it is only after they have been excluded by appropriate laboratory investigations that a diagnosis of functional or dietary reactive hypoglycemia is justified.

Specifically, the prolonged oral glucose load (tolerance) test is now deemed inappropriate for the diagnosis of postprandial or reactive hypoglycemia since the incidence of false-positive results with this test is so high as to make it meaningless, especially if, as is so often the case, venous rather than arterial blood is sampled.

Table 1 The main causes of non-iatrogenic hypoglycemia

Description	*Mechanism*	*Diagnostic criteria*	*Dietary considerations*
Fasting hypoglycemia			
Insulin-secreting tumor (insulinoma) and nesidioblastosis	Abnormal B cells with failure to suppress insulin secretion in response to hypoglycemia	Inappropriate high plasma insulin ($>30\,pmol\,l^{-1}$) and C-peptide ($>100\,pmol\,l^{-1}$) concentrations in presence of hypoglycemia (BG $<2.2\,mmol\,l^{-1}$); Suppressed β-hydroxybutyrate levels ($<500\,\mu mol\,l^{-1}$)	High-carbohydrate intake orally or intravenously until curative surgical ablation or effective hyperglycemic therapy with diazoxide plus chlorothiazide can be instituted
Non-Islet cell tumor hypoglycemia (NICTH)	Abnormal tumor cells secreting big IGF-II	Low plasma insulin & C-peptide levels; low plasma IGF-I, normal or raised IGF-II levels; abnormal IGF-I:IGF-II ratio. Suppressed β-hydroxybutyrate levels ($<500\,\mu mol\,l^{-1}$)	High-carbohydrate intake orally or intravenously until curative surgical ablation of effective hyperglycemic therapy with growth hormone &/or prednisone can be instituted
Endocrine disease, e.g., Hypopituitarism, Addison's disease	Reduced availability of diabetogenic or hypoglycemia counterregulatory hormones	Clinical features of primary disease with subnormal levels of appropriate counter-regulatory hormones, e.g., cortisol, growth hormone. Appropriately raised β-hyroxybutyrate levels ($>500\,\mu mol\,l^{-1}$) during hypoglycemia	High-carbohydrate intake orally or intravenously until effective hormone replacement therapy has been established
Glycogen storage disease	Inability to release glucose from liver during fasting	Usually present in childhood; low blood glucose, high β-hydroxybutyrate levels, low insulin and C-peptide; high lactate; impaired or absent glucose response to glucagon	Avoid fasting: a constant intake of slowly absorbed carbohydrate may be required day and night in infants
Disorders of mitochondrial β-oxidation	Defective utilization of fat as fuel in tissues: compensatory increase in glucose utilization	Occurs in infancy; low glucose, low insulin & C-peptide, high FFA, normal lactate, low β-hydroxybutyrate, increased urinary organic acids. Hypocarnitinemia in some cases	Avoid fasting; frequent high-carbohydrate, low-fat feeding
Fasting alcohol-induced hypoglycemia	Alcohol impaired hepatic gluconeogenesis	Low blood glucose, raised blood alcohol, lactate and usually β-hydroxybutyrate: low plasma insulin and C-peptide	Avoid drinking alcohol whilst fasting or whilst on a low-energy diet
Idiopathic ketotic hypoglycemia of childhood	Varied: but always due to exhaustion of hepatic glycogen stores faster than cerebral adaptation to ketosis can occur	Low blood glucose; high plasma fatty acids and β-hydroxybutyrate; low insulin and C-peptide	High-carbohydrate feeding; avoidance of prolonged abstinence from food particularly during intercurrent illness, especially infections
Stimulative hypoglycemia			
Inborn errors of metabolism, e.g., hereditary fructose intolerance, galactosemia	Impaired release of glucose from liver in response to hepatotoxicity of food constituent	Hypoglycemia evoked by ingestion of foods containing appropriate noxious stimulus: galactose in galactosemia; fructose in hereditary fructose intolerance and fructose 1-6 bisphosphatase deficiency	Avoid foods containing provocative sugars, e.g., fructose, galactose as appropriate
Autoimmune insulin syndrome	Delayed release of insulin from antibody binding after all of meal has been absorbed	Profound hypoglycemia from 3 to 12 hs after last eating; total plasma insulin high; C-peptide high, normal or low proinsulin normal or high. Antibodies to insulin present. Common in Japan, infrequent elsewhere	Frequent small mixed meals, low in rapidly absorbed carbohydrate; rich in dietary fiber

Continued

Table 1 Continued

Description	*Mechanism*	*Diagnostic criteria*	*Dietary considerations*
Postgastrectomy and rapid gastric empying	Accelerated deposition of nutrients in duodenum and increased release of insulinotrophic hormones, e.g., GIP, GLP-1	Normal blood glucose during fasting; hypoglycemia only follows 1–3 hs after eating. History of gastrectomy or objective evidence of rapid gastric emptying. Exaggerated insulinemic response to food	Frequent small mixed meals rich in dietary fiber. May benefit from treatment with acabose or miglitol (α-glucosidase inhibitors)
Idiopathic reactive or functional hypoglycemia	Unknown: probably heterogeneous including increased insulin sensitivity, lowered cerebral threshold to neuroglycopenia	Hypoglycemia 3–5 hs after eating. Normal blood glucose during fasting: low capillary (arterial) blood glucose during spontaneous symptomatic neuroglycopenic episodes ($<3\,\text{mmol}\,l^{-1}$). All other objective tests of glucose homeostasis normal (including GIP and GLP-1 responses to food). Exclude noninsulinoma pancreatogenic hypoglycemia by intra-arterial calcium test	Frequent small mixed meals low in absorbed carbohydrates; rich in soluble dietary fiber. May benefit from treatment with acabose or miglitol (α-glucosidase inhibitors)

The Postprandial Syndrome

Typically, the patient is a normal-weight woman of 20–50 years whose main complaint is of vague feelings of distress occurring predominantly mid morning, about 11.00 a.m.–12.00 noon, but occasionally mid afternoon or evening and never before breakfast. In between attacks, characterized by feeling of faintness, anxiety, nervousness, irritability, inner trembling, rapid heart beat, headache, and sweatiness, either alone or in combination, they may be completely well. More often they describe themselves as suffering from increased tiredness, lacking in zest for life, and apathetic much, or all, of the time: symptoms often associated with depression or chronic alcohol abuse.

Patients seldom notice any fixed relationship to food unless, as so often happens nowadays, they have diagnosed themselves, on the basis of articles they may have read, as suffering from 'hypoglycemia.' Almost without exception they reject the possibility that their symptoms might have a contributory, or even large, psychogenic element.

Symptoms wax and wane during middle life but often remit completely for years or may never recur. They are not progressive and never cause severe neurological dysfunction such as coma, psychosis, or dementia. Hypoglycemia cannot be demonstrated during spontaneous symptomatic episodes in most people with the postprandial syndrome and some other explanation should be sought for them.

Differential Diagnosis

Studies using finger-prick blood sampling during spontaneous symptomatic episodes have shown that only a very small proportion of sufferers from the postprandial syndrome have hypoglycemia at the relevant time. Of those who do, a substantial proportion have an identifiable cause for it. The commonest is partial gastrectomy and rapid gastric emptying from any cause, in the West, and the autoimmune insulin syndrome in the Far East, i.e., Japan. Other more rare causes include insulinoma, the newly described condition of noninsulinoma pancreatogenic hypoglycemia, and abnormalities of GLP-1 secretion.

In some people reactive hypoglycemia occurs only in response to a specific dietary indiscretion: for example, ingestion of large amounts of gin (alcohol) and tonic (sugar and quinine) on an empty stomach. A hard core of subjects remains for whom no satisfactory pathogenic mechanism can be identified. Only in them is it justified to describe them as suffering from (idiopathic or functional) reactive hypoglycemia (**Figure 2**).

Dietary Management

Treatment of Attacks

Because of their short duration and modest severity, acute spontaneous neuroglycopenic episodes require no specific treatment beyond ingestion of a rapidly assimilable form of carbohydrate (e.g., a lump of sugar), exactly as for iatrogenic hypoglycemia.

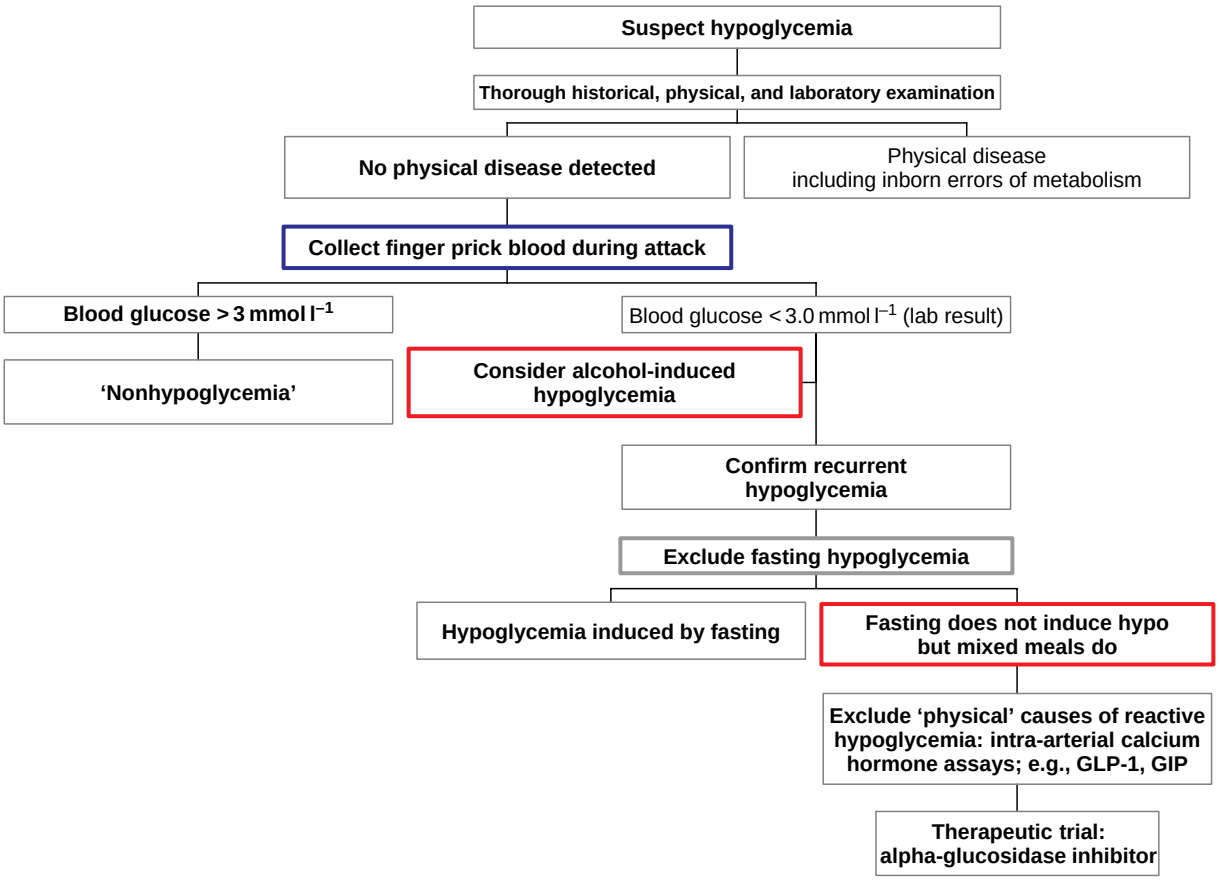

Figure 2 Investigation of reactive hypoglycemia. Steps in the diagnosis of reactive hypoglycemia of unknown etiology.

There is no evidence that this ever produces rebound hypoglycemia and should it do so the grounds for making a diagnosis of essential reactive hypoglycemia should be reviewed.

Prevention

Dietary prevention of reactive hypoglycemia, whether of the 'idiopathic', alimentary variety, or secondary to some other disease, is based on the premise that it is caused by imbalance between the timing and amount of insulin secreted in response to the ingestion of a meal and disposal of the glucose derived from it. Evidence for this supposition is small and disputed but provides the best explanation for the apparent breakdown in glucose homeostasis in patients with idiopathic reactive hypoglycemia.

Frequent small meals containing only modest amounts of sugars (glucose and sucrose) and refined starches but rich in poorly absorbed complex carbohydrates and containing dietary fiber have replaced the diets rich in proteins (and fats) previously advocated, but evidence of their unique efficacy is lacking. Avoidance of drinks rich in sucrose or glucose, especially with alcohol, may be helpful in subjects who are highly susceptible to this combination. There is no evidence that confectionery eaten in moderation is uniquely detrimental, though excessive use should be discouraged on general health grounds.

The long-term outcome of such dietary advice in patients in whom strict criteria for diagnosis were adopted are not available and most published studies on the subject have drawn attention to the need for supplementary pharmacological methods in order to achieve a satisfactory therapeutic outcome.

Pharmaceutical agents that have been used include guar, acarbose, and miglitol, all of which slow glucose absorption and decrease the insulinemic response to food, while others including phenytoin and propranolol do not. Paradoxically, diazoxide, which inhibits insulin secretion by direct action, has not been found effective except in patients with proven endogenous hyperinsulinism.

Nonhypoglycemia

No account of dietetic treatment of hypoglycemia would be complete without a brief description of 'nonhypoglycemia', which has been described as a

controversial illness and epidemic in the US. Clinically, the illness is indistinguishable from (idiopathic) reactive hypoglycemia, except that the blood glucose level is never pathologically low during symptomatic episodes. Moreover, although transient 'turns' are often a major feature of the illness, only rarely, if ever, does the patient consider their health, between turns, as normal.

The attribution of these patients' illness to hypoglycemia had its origins in the early 1950s with the appearance, in the US, of a book by Drs Abrahams and Pezet entitled 'Body, Mind and Sugar.' Other American practitioners, notably John Tintera, founder of the Hypoglycemia Foundation Inc., Stephen Gyland, Harry Saltzer and, others, including the medical writer Carlton Fredericks, publicized the concept. This led to 'hypoglycemia' being held, by a large section of the public, responsible for such diverse diseases as coronary artery disease, allergy, asthma, rheumatic fever, susceptibility to viral infections, epilepsy, gastric ulcer, alcoholism, suicide, and even homicide, as well as for a whole galaxy of symptoms in their own right. 'Hypoglycemia' was treated as though it were a disease entity and asserted by its advocates to be 'one of the most common illnesses in the United States' and that because of it 'thousands of Americans have forgotten, or perhaps never known, what it is like to feel completely healthy.' Diagnosis of 'nonhypoglycemia' generally depends upon the results of the 6-h oral glucose tolerance test, using venous blood, although some have dispensed even with this discredited formality in favor of just purely clinical criteria.

The appearance in the *New England Journal of Medicine* of an article entitled "Nonhypoglycemia is an epidemic condition" first drew international attention to the illness in 1974. It had previously been almost unknown outside the US and Australia, though known to a few fashionable medical practitioners in Britain.

Many patients with 'nonhypoglycemia' undoubtedly derive some benefit, probably through a powerful placebo effect, from severely restrictive dietary regimes. Although differing in details most of the diets emphasize the purported specifically detrimental effects of sugar (sucrose), salt, alcohol, and caffeine.

While the cause of illness in people with 'nonhypoglycemia' remains unknown, and is unlikely to be the same in all cases, in a tiny proportion it is due to caffeine intoxication, which can be confirmed by a dietary history and, above all, by measurement of plasma caffeine levels. Such patients do benefit specifically from reducing their intake of caffeinated beverages, though not necessarily from avoiding them completely. Ironically, and probably significantly, caffeine restores hypoglycemia awareness to diabetic patients on insulin who have become insensitive to it. The possibility exists, therefore, that a combination of reasonable or normal caffeine intake occurring in combination with the normal rebound in arterial blood glucose to just below fasting levels that sometimes occurs 3–5 h after a meal in someone with an unusually low threshold for neuroglycopenia, might precipitate symptoms. This explanation must, however, be considered no more than speculative.

On the other hand such diverse illnesses as hyperventilation, panic attacks, unadmitted alcohol or drug abuse, and genuine food intolerances are all established as capable of producing the 'nonhypoglyacemia' syndrome and should always be considered in the differential diagnosis.

Exercise-Induced Hypoglycemia

Previously only associated with marathon running, hypoglycemia is now recognized to be comparatively common in inadequately trained individuals undertaking strenuous exercise. Consumption of rapidly absorbed carbohydrate prior to taking exercise may encourage its appearance whilst consumption of slowly absorbed, low glycemic index foods may prevent it as does appropriate training.

Hepatic and Renal Failure

Considering the importance of the liver and kidney in the maintenance of blood glucose levels hypoglycemia is remarkably rare in both liver and kidney disease. In liver disease hypoglycemia is virtually confined to patients with acute toxic hepatic necrosis, whether due to overwhelming viral infection or specific hepatotoxins such as poisonous mushrooms, unripe akee fruit, and paracetamol in excess. Its appearance always portends an extremely poor prognosis. The association of hypoglycemia with primary cancer of the liver is comparatively common and due to overexpression and secretion of aberrant, or big IGF-II, and is not, as was once supposed, due to nonspecific destruction of hepatic tissue. Hypoglycemia is very rarely due to hepatic secondaries except from IGF-II secreting tumors.

Kidney failure is one of the commoner causes of hypoglycemia in nondiabetic hospital inpatients and does not carry as grave a prognostic significance as in patients with liver disease. It generally responds to appropriate dietary and other supportive treatments for end-stage kidney disease.

Inborn Errors of Metabolism

Hypoglycemia is a manifestation of many inborn errors of metabolism (see **Table 1**) especially in children but also occasionally in adults. It is particularly important in some varieties of liver glycogen storage diseases, especially types I and III, and in disorders of fatty acid metabolism in which it is often the presenting symptom.

Type I liver glycogen storage disease is due to a defect in glucose-6-phosphatase activity and produces a severe form of fasting hypoglycemia. Fortunately, this responds to dietary therapy in the form of continuous feeding with slowly absorbed starch solution through a nasal or gastrostomy tube, especially during the night when the body normally has to resort to glycogenolysis to maintain the supply of glucose to the brain. Hypoglycemia in untreated type I patients produces hypoinsulinemia and high to very high plasma ketone levels. Children with abnormalities of fatty acid metabolism, on the other hand, are characterized by hypoglycemia, hypoinsulinemia, and hypoketonemia. As with children with liver glycogen disease, treatment is to ensure that they are constantly supplied with carbohydrates and are never fasting for more than a very short period.

Starvation

Although average fasting blood glucose levels are lower in victims of famine than in well-fed populations, overt hypoglycemia is rare. Even in patients suffering from kwashiorkor, hypoglycemia is uncommon and is usually associated with infection, hypothermia, and coma. Patients with anorexia nervosa develop hypoglycemia only as an agonal phenomenon and its appearance generally portends imminent death. The characteristic clinical biochemistry findings are of low or undetectably low plasma insulin, proinsulin, C-peptide, and IGF-1 levels, grossly depressed plasma nonesterified fatty acids (NEFA) and β-hydroxybutyrate, and elevated growth hormone and cortisol levels. Relief of hypoglycemia by re-feeding is the only measure carrying any chance of preventing death, but it is rarely successful.

Hypoglycemia in the Elderly Sick

The high incidence of hypoglycemia in sick elderly patients has become apparent from the use of routine blood glucose measurements. The cause is seldom attributable to any of the well-recognized causes of hypoglycemia found in younger fitter people. It is probably due to chronic malnutrition that is so common in the elderly sick, compounded by coincident disease but which is not of itself sufficiently severe to produce hypoglycemia.

Conclusions

Symptoms due to documented spontaneous hypoglycemia are an unusual consequence of many different rare diseases and are sometimes the primary reason for a patient seeking medical help. In a minority of patients no pathological cause can be found to account for the hypoglycemia and no specific curative or palliative therapy can be instituted. Amongst these are a group of patients who only experience neuroglycopenic symptoms 2–5 h after eating a meal. They may benefit from eating small, frequent, slowly absorbed carbohydrate-rich meals. Usually, however, they also need addition of an α-glucosidase inhibitor to their diet.

Patients with self-diagnosed hypoglycemia in whom blood glucose levels are never pathologically low in everyday life and do not have any other known cause for their symptoms may also derive some benefit from a high-fiber, high complex carbohydrate diet, but how much of this is due to a placebo rather than specific dietary effect is still unknown.

IMMUNITY

Contents

Physiological Aspects

A T Borchers, C L Keen and M E Gershwin,
University of California at Davis, Davis, CA, USA

Immunity can be defined as the ability of an organism to resist or eliminate potentially harmful foreign organisms and materials or abnormal cells. Any substance capable of eliciting an immune response is called an antigen (antibody generator). Immune responses can be classified as innate or adaptive. Innate immune responses are also called nonspecific because they can be elicited by a wide range of foreign substances and are the same regardless of the exact nature of the substance and whether it had been encountered before. The major mechanisms of innate immunity include phagocytosis, inflammation, complement activation, and induction of cell death. Neutrophils and macrophages are the main cell types responsible for phagocytosis, and the chemical messengers that they and some other cell types produce play an important role in the initiation of an inflammatory response. The induction of apoptosis (programmed cell death) as part of the innate immune response is accomplished by natural killer (NK) cells.

In contrast to innate immune responses, adaptive immune responses are highly specific for a particular antigen and become stronger and more rapid over time. B cells and T cells represent the two types of lymphocytes responsible for adaptive immune responses. The main function of B cells is to produce antibodies, which neutralize pathogens or stimulate their elimination by other cell types through opsonization or complement activation. There are two major classes of T cells, namely helper T cells and cytotoxic T cells. One subclass of helper T cells provides help to macrophages in killing pathogenic microorganisms they have engulfed. The other subclass of helper T cells is vital for the induction of antibody production by B cells. Cytotoxic T cells directly eliminate infected cells by inducing them to undergo apoptosis. T cells also play a central role in self-tolerance (i.e., the ability not to respond to self antigens).

Initial exposure to pathogens (i.e., disease-producing microorganisms such as viruses and bacteria) most commonly occurs at the interfaces of host tissues and the external environment. Such tissues include the outer cells of the skin and, since the vertebrate body is essentially a 'tube within a tube,' the layers of cells and mucous lining the digestive, reproductive, and respiratory tracts. These cell layers and their secretions constitute nonimmunological physical and chemical barriers that provide a first line of defense against invasion by pathogenic microorganisms. Their barrier function is often reinforced by a variety of bacteria that generally do not harm the host but, on the contrary, provide additional protection from pathogens via competition, production of toxic substances, and stimulation of the immune system.

The main function of the immune system is to provide protection from invading pathogens, primarily viruses and bacteria but also fungi and parasites. For this purpose, the ability to discriminate between self or harmless non-self and potentially harmful non-self is absolutely crucial. Also important is the capability to recognize whether pathogens are extracellular (outside of the host's cells), such as fungi, certain bacteria, and some parasites, or intracellular, such as other bacteria and parasites and all viruses. Other activities of the immune system include the removal of worn-out cells, the identification and destruction of mutant or otherwise abnormal cells and also such inappropriate responses as allergies and autoimmune diseases, and graft rejection after organ transplantation.

Immune Cells and Organs

Immune cells are leukocytes (white blood cells) and, together with red blood cells, are ultimately derived from the same precursor or progenitor cells in the bone marrow. As illustrated in **Figure 1**, these stem cells give rise to either lymphoid or myeloid progenitors that subsequently differentiate into the different immune cells. A few other types of immune cells, including NK cells and mast cells, also arise from these pluripotent stem cells, but the pathways of their development are not fully known.

The differentiation of lymphocytes takes place in the central (also called primary) lymphoid organs—that is, bone marrow in the case of B cells and thymus in the case of T cells. After puberty, the thymus gradually atrophies and the production of new T cells decreases. After their maturation in the primary lymphoid organs, both types of lymphocytes migrate from these tissues through the bloodstream into the peripheral, or secondary, lymphoid tissues. These include the lymph nodes, spleen, and lymphoid tissues associated with mucosa, and they constitute the main sites at which the reaction of B and T lymphocytes with foreign antigens takes place. Lymph then carries circulating lymphocytes from the peripheral lymphoid tissues to the thoracic duct, where they reenter the bloodstream. The functions of the various immune cells are summarized in **Table 1**.

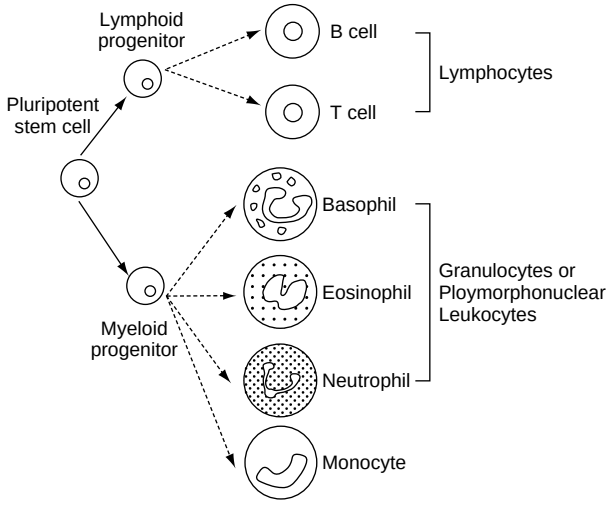

Figure 1 Immune cells give rise to either lymphoid or myeloid progenitors, which subsequently differentiate into the different immune cells.

Table 1 Functions of myeloid and lymphoid immune cells

Cell progenitor	*Cell type*	*Function*
Myeloid		
	Basophil	Unknown
	Eosinophil	Killing of antibody-coated parasites
	Neutrophil	Phagocytosis and activation of bactericidal mechanisms
	Macrophage[a]	Phagocytosis
	Mast cell	Release of histamine and other vasoactive and inflammatory mediators
Lymphoid		
	B cell	Antibody production
	T cell	
	Cytotoxic	Killing of virus-infected cells
	Helper (Th1 and Th2)	Activation of other cells such as B cells and macrophages
	Natural Killer cells	Killing of virus-infected cells and cancer cells

[a]This cell type circulates as monocytes in the bloodstream and matures into macrophages when taking up residence in a tissue.

Innate (Nonspecific) versus Adaptive (Specific) Immunity

Immune responses can be divided into two broad categories: innate and adaptive. Innate immune responses are also called nonspecific since they do not discriminate between most foreign substances. They are also not enhanced by previous exposure to a pathogen. In contrast, adaptive (also called acquired) immunity is highly specific to a particular pathogen and becomes more rapid and stronger with subsequent exposure to an antigen. Upon the initial encounter with an antigen, the adaptive immune response takes 4 or 5 days to become fully effective. During this period, the innate immune response plays a critical role in limiting and controlling infections. In addition, it is crucial in stimulating and directing the subsequent adaptive immune responses.

Innate or Nonspecific Immunity

Phagocytosis Pathogens can cause infection only after they have breached the nonimmunological

barriers of skin or mucosal surfaces. Generally, the first immune cells they come in contact with are macrophages. Among the many chemicals macrophages start to produce are chemokines, small proteins involved in the recruitment and activation of immune cells. The first cells to be recruited to the site of infection are neutrophils. Macrophages along with neutrophils are the major cell types involved in phagocytosis (i.e., the ingestion of foreign materials, including entire microorganisms). Phagocytosis is triggered via receptors on the surface of macrophages and neutrophils that recognize common cell wall components of bacteria. Killing of the ingested bacteria occurs via several different mechanisms involving the production of reactive oxygen and nitrogen species as well as the release of a variety of preformed antimicrobial substances.

Inflammation In addition to stimulating phagocytosis, the encounter of macrophages and neutrophils with bacteria frequently initiates an inflammatory response. The characteristics of inflammation are pain, redness, swelling, and heat. These symptoms are the consequence of the activities of cytokines and chemokines along with a variety of other vasoactive and inflammatory mediators, such as histamine, prostaglandins, and leukotrienes. They act mostly on local blood vessels, where their combined effect is to enhance blood flow, induce vasodilation, and increase the permeability of blood vessels. These changes allow leakage of fluids and plasma proteins, such as immunoglobulins, complement, and acute phase proteins, into the affected tissue. Cytokines also induce the expression of molecules that make it possible for immune cells to adhere to, and eventually pass between, the cells lining the blood vessels. Together, these alterations result in the infiltration of the site of inflammation by immune cells.

The major inflammatory cytokines are tumor necrosis factor-α (TNF-α), interleukin-1 (IL-1, IL-6, and IL-12, all of which are produced mostly by macrophages. Among these, TNF-α, IL-1, and IL-6 are central to mediating the acute phase response, which is characterized by elevation of the body temperature (fever) and a marked shift in the types of proteins secreted by the liver into the bloodstream. Whereas the synthesis of some liver proteins, called acute phase proteins, is dramatically increased, that of others is decreased. Among the acute phase proteins, C-reactive protein, mannose-binding protein, and serum amyloid P component undergo the most striking increase in synthesis, whereas only moderate increases are observed in a number of other acute phase proteins. It appears that the diverse activities of these proteins are ultimately beneficial to the host since they not only enhance the inflammatory response and other immune cell activities, thereby boosting host resistance, but also promote tissue repair.

Natural killer cells All viruses are intracellular pathogens since they lack the ability to replicate on their own and need to penetrate cells of the host in order to take over their replication machinery. The killing of such infected cells before the virus has had a chance to reproduce can be accomplished by a variety of cell types but is one of the major functions of NK cells. NK cells are large granular lymphocytes with a morphology and lineage that are distinct from those of B and T lymphocytes. They are known to be able to distinguish between normal cells and virally infected or tumorous cells, but the exact mechanisms by which they do so remain to be fully established. The granules of NK cells contain perforin, a protein that can polymerize and form transmembrane pores in the infected cell, possibly providing an entry route for a variety of enzymes also stored in the granules. As a result, the infected cell initiates an active suicide program called programmed cell death or apoptosis.

Interferons Interferon-α and interferon-β are proteins produced by many cells types in response to viral infection. They reduce the spread of viruses to uninfected cells by inhibiting protein synthesis and DNA replication in virus-infected cells and activating NK cells. In addition, they increase the expression of certain molecules and enhance certain cellular processes that are of great importance in activating components of the adaptive immune system involved in eliminating virally infected cells.

Complement The complement system consists of a group of proteins synthesized by the liver and released into the bloodstream in inactive form. It is part of the nonspecific immune response but can also be triggered by antigen–antibody complexes (i.e., it forms part of the humoral response in adaptive immunity). The latter pathway of activation is called the classical pathway and constitutes one of the three different pathways of complement activation. All three pathways involve a series of cleavage reactions converting inactive proteins into their active forms and ultimately converge at the formation of C3 convertase, an enzyme that cleaves complement component C3 into the large fragment C3b, on the one hand, and a group of smaller peptides consisting of C3a, C4a, and C5a, on the other hand. These smaller peptides mediate certain inflammatory processes and participate in the recruitment of

phagocytes. C3b binds to the surface of pathogens and, in the presence of simultaneous coating with antibodies, stimulates phagocytes to engulf and ultimately destroy the microorganism. In addition, further cleavage of C3b yields a group of terminal complement components that form a membrane attack complex able to damage the cell membrane and causing the lysis of certain pathogens.

Adaptive or Acquired Immunity

The cells of the innate immune system are vital as a first line of defense, but they are not always able to completely neutralize or eliminate infectious organisms. The adaptive immune system is thought to have evolved later in evolutionary history and now provides not only more specificity and versatility but also has added immunological memory as a further level of protection against reinfection with the same pathogen.

Adaptive immune responses can be classified as either antibody- or cell-mediated. Antibody-mediated, or humoral, responses are accomplished by plasma cells derived from B cells; cellular immune responses are mediated by activated T lymphocytes. Although they use vastly different effector mechanisms, the activation and subsequent differentiation of B and T lymphocytes nonetheless have many features in common.

In adaptive immunity, antigen alone is generally insufficient to activate naive antigen-specific lymphocytes. Naive T cells require a costimulatory signal from antigen presenting cells; naive B cells usually require accessory signals from an activated helper T cell, but in some cases the signal can be provided directly by microbial constituents. T cell help for B cells has to come from activated helper T cells that respond to the same antigen as the B cell, although the epitope—the specific part of the antigen that is recognized—is generally not identical. Upon recognition of its specific antigen in the context of the appropriate costimulatory signals, the previously small lymphocyte enlarges and undergoes a variety of changes in preparation for vastly increased RNA and protein synthesis. The activated cell is called a lymphoblast. This lymphoblast then begins to divide, duplicating every 6–12 h, thereby giving rise to ~1000 daughter cells, each exhibiting specificity that is identical to that of the parent. Thus, this group of cells constitutes a clone, defined as a population of identical cells that derive from the same ancestral line. Note that most antigens stimulate many different lymphocyte clones, making the resulting response polyclonal. The process of clonal expansion is followed by differentiation into either effector cells or memory cells.

Memory cells, unlike effector cells, do not participate in the initial immune response but can become activated cells when they encounter the same antigen at a later time point, in some cases years or even decades later. This, along with other changes in memory cells compared to virgin (or naïve) cells, accounts for the fact that the primary immune response is characterized by a lag phase of several days (the period during which lymphocytes undergo clonal expansion and differentiation) and is relatively weak, whereas a second exposure to the same antigen results in a much more rapid and stronger response.

B cells The primary function of B cells is the production of antibodies, or immunoglobulins. There are five major classes (isotypes) of antibodies: IgA, IgD, IgE, IgG, and IgM, with IgA and IgG having two and four subclasses, respectively. Resting B cells express IgM and IgD on their cell surface as antigen receptors. Their function is to capture antigen so that it can then be processed and displayed to helper T cells specific for peptide fragments of the same antigen. In response to binding antigen and receiving the necessary accessory signal from helper T cells in the form of cell–cell interactions along with secreted molecules, B cells start to produce a secreted version of IgM. Under the influence of certain cytokines produced predominantly by activated helper T cells, B cells undergo isotype switching, also called class switching, meaning that they start to produce other types of immunoglobulins. The types and combinations of immunoglobulin isotypes depend on the nature and relative amounts of these cytokines. In B cell activation and initiation of antibody production, a subclass of helper T cells called Th2 plays the major role; the Th1 subclass of helper T cells, however, participates in isotype switching via the production of interferon-γ, a cytokine that induces switching to specific subclasses of IgG, namely IgG2a and IgG3.

Antibody structure and diversity It is estimated that even in the absence of antigen stimulation, the human body contains B cells capable of producing approximately 10^{15} different antibody molecules. This enormous diversity is generated through a variety of mechanisms.

The basic structure of an antibody is a Y shape (**Figure 2**) consisting of two heavy chains and two light chains, with each arm containing a specific antigen binding site formed by parts of the respective heavy and light chain. The light and the heavy chain each have a constant region and a variable region. Within the variable region three small

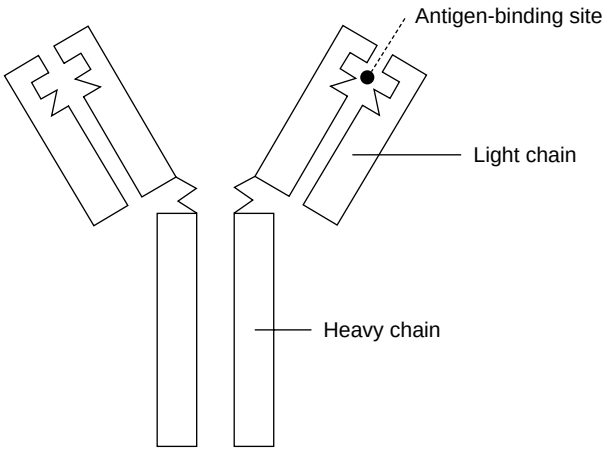

Figure 2 Basic structure of immunoglobulins.

hypervariable regions containing 5–10 amino acids form the antigen binding site. A different pool of gene segments encodes the constant and variable regions and, in addition, there is another pool for joining (J) segments for both heavy and light chains and a pool for diversity (D) segments in the case of heavy chains. The exact number of gene segments in these pools is not known, but the mouse genome is estimated to contain approximately 300 variable (V) segments for one of the two possible light chains, and these can be joined to any of 4 different J segments, yielding at least 1200 different V regions. In addition, there are approximately 500 V segments in the heavy-chain pool of the mouse, which can be combined with 4 J segments and at least 12 D segments to encode 24 000 different heavy-chain V regions. Thus, a total of at least 2.5×10^7 different antigen binding sites can be generated by combinatorial diversification, as the combining of V, J, and D segments is called.

The joining process further increases this diversity via two mechanisms. One operates in heavy- and light-chain segments and is the loss of 1 or more nucleotides from the ends of recombining gene segments. Heavy-chain gene segments can additionally be modified through the random insertion of up to 20 nucleotides. Although it is not uncommon for this junctional diversification to result in the production of nonfunctional genes, it nonetheless increases the number of different B cells in the mouse to an estimated 5×10^8.

After the assembly of functional antibody genes is completed, an additional mechanism for increasing diversity takes place when a B cell is stimulated by antigen. This process is called somatic hypermutation since it involves the insertion of point mutations at a rate that is approximately 1 million times greater than the spontaneous mutation rate in other genes. A few of these point mutations confer increased affinity for the antigen to the antigen receptors, ultimately resulting in the production of antibodies with progressively increasing affinity during the course of an immune response.

The function of antibodies The coating of pathogens and toxins with antibodies helps protect the host from infection in three main ways: neutralization, opsonization, and complement activation. Neutralization refers to the ability of antibodies to inhibit the adherence of pathogens to cells they might invade and destroy. Opsonization is defined as the coating of pathogens with antibodies in order to increase their susceptibility to ingestion by phagocytes. As discussed previously, antibodies complexed with antigen can also trigger the classical pathway of complement, thereby either enhancing opsonization or directly killing some bacteria through the formation of membrane attack complexes. Not all of the secreted antibody isotypes participate in all of these functions, and the extent to which they do so also differs. Certain additional functions are restricted to specific isotypes. For example, only some IgG subclasses can bind to certain viral proteins displayed on virally infected cells and, through interaction with specific receptors, signal NK cells to destroy these cells. Another example is IgE, which is the only isotype capable of sensitizing mast cells, resulting in a local inflammatory response mediated by the release of histamine and other inflammatory mediators. Allergic reactions are the consequence of such a response directed against innocuous antigens.

T cells Whereas B cells recognize and bind directly to extracellular antigens, generally native protein structures, T cells recognize partially degraded protein antigens—that is, peptide fragments that result from intracellular processing and are then carried to the cell surface for display there. The generation of peptide fragments is called antigen processing and the display is called antigen presentation.

Intracellular pathogens can be located in two different compartments of a cell, the cytosol or the vesicular compartment, which is separated from the cytosol by membranes. Depending on the cellular location of the microorganism, one of two different classes of T cells is activated, either cytotoxic T cells or helper T cells. Cells infected with cytosolic pathogens, such as viruses and some bacteria, are eliminated by cytotoxic T cells via mechanisms closely resembling those described for NK cells. Cells containing foreign material or microorganisms in their vesicular compartment stimulate helper T cells.

These do not kill cells but enhance the activity of the very cells stimulating them (i.e., macrophages and B cells). Although macrophages can phagocytose and kill many infectious agents without T cell help, there are certain situations in which such help is indispensable. For example, the mycobacteria responsible for tuberculosis and leprosy have developed mechanisms to survive the process of phagocytosis and can replicate inside vesicular structures. However, they can be eliminated when the macrophage is activated by a helper T cell. T lymphocytes providing help for macrophages belong to a subclass of helper T cells characterized mainly by the types of cytokines it produces and designated as Th1. Another subclass, Th2, activates B cells to make antibody.

Cytotoxic and helper T cells have the same kind of antigen receptors, designated as T cell receptors. This indicates that the ability of the different classes of T cells to distinguish between peptide fragments coming from the cytosolic or the vesicular compartment must involve other molecules. The most important of these are major histocompatibility complex (MHC) molecules.

The MHC is a cluster of genes encoding not only two different classes of MHC molecules but also a variety of other proteins that participate in immune responses. 'Histo' means tissue, and the name 'major histocompatibility complex' reflects the fact that the proteins encoded by this group of genes were first identified as the target of the immune reaction that can result in graft rejection after organ transplantation. In humans, MHC molecules are called human leukocyte-associated antigen (HLA) molecules. In addition to being polygenic (having several genes encoding proteins with the same function), the MHC genes are strikingly polymorphic, meaning that there are multiple alleles, or copies, of each gene.

T cells recognize antigen only when presented as peptide fragments by a MHC molecule. Furthermore, a T cell recognizing a peptide fragment bound by a MHC molecule encoded by a particular allele will not recognize the same peptide bound to another type of MHC molecule, an effect called MHC restriction. Together with the polymorphism of the MHC genes, this limits the ability of a pathogen to put entire populations or even species at risk since the individuals within the population will vary in their susceptibility to the pathogen.

There are two classes (I and II) of MHC molecules that are structurally similar, though distinct, but differ functionally. Class I MHC molecules present foreign peptides to cytotoxic T cells; class II MHC molecules present foreign peptides to helper T cells. Since viruses can infect any cell containing a nucleus, virtually all nucleated cells express MHC class I molecules, although the levels at which they do so can differ considerably. In contrast, the main function of helper T cells is to activate other cells of the immune system. Thus, MHC class II molecules are constitutively expressed on B lymphocytes, macrophages, and other antigen presenting cells, but they are inducible on many other cell types via certain cytokines.

Since MHC molecules insert themselves into the cell membrane once they have picked up processed antigen fragments inside the cell and the T cell receptor is also a cell surface molecule, T lymphocytes must make direct contact with their target cells. This cell–cell interaction is enhanced by so-called coreceptors, designated CD4 on helper T cells and CD8 on cytotoxic T cells. CD4 proteins recognize an invariable part of the class II MHC molecule, whereas CD8 proteins bind to a nonvariable region of the class I MHC molecule, and both play a vital role in ensuring that a T cell recognizes only those target cells bearing the correct type of MHC molecule.

As in the case of B cells, antigen alone is insufficient to activate T cells. For helper T cells, the accessory signal is provided either by a secreted signal such as IL-1 or by a specific plasma membrane molecule on the surface of an antigen presenting cell. The major cell type presenting antigen to T cells is the dendritic cell found in lymphoid organs, but macrophages and, under certain conditions, B cells can also act as antigen presenting cells. Antigen presenting cells with strong costimulatory activity also provide the secondary signal for cytotoxic T cells, but in some cases the presence of CD4 T cells seems to be required as well.

Tolerance

Many immune responses can be destructive to host tissue; hence, it is vital that they be restricted to pathogens and not be raised against innocuous substances. The devastating consequences of autoimmune diseases, which result from immune responses that are inappropriate in that they are directed against self, illustrate the crucial need for self-tolerance. It is now known that the immune system has the inherent capability of responding not only to foreign but also to self antigens. During development, it 'learns' not to respond to self antigens. The two major mechanisms for establishing self-tolerance are clonal deletion, the killing of self-reactive lymphocytes, and clonal anergy, the functional inactivation of self-reactive lymphocytes involving antigen stimulation in the absence of

accessory signals. These processes are focused mainly on T lymphocytes since most B cells require helper T cells to respond to antigen so that the elimination of self-reactive helper T cells also ensures the inactivation of self-reactive B cells.

Interactions between Nutrition and Immunity

There are considerable interactions between nutrition and immunity; that is, not only does nutrition affect immune functions but also immune responses have profound effects on metabolism and nutritional status. Essentially every aspect of immunity can be affected by undernutrition, and there is growing evidence that overnutrition also has detrimental effects on immune responses. Protein–energy malnutrition during childhood leads to stunted development of many of the immune organs. In subjects of all ages suffering from protein–energy malnutrition, almost all immune functions are considerably impaired, resulting in increased severity and prolonged duration of most infectious diseases. However, protein–energy malnutrition rarely occurs in the absence of inadequate intake of other essential nutrients, and deficiencies in virtually every vitamin and essential mineral or trace element are associated with reductions in one or more functions of innate and adaptive immunity. The amount of fat and types of fatty acids in the diet are also known to influence certain immune functions, such as phagocytosis, the ability of cells to move to the site of inflammation, and the production of proinflammatory cytokines and other inflammatory mediators. In addition, evidence is beginning to accumulate that many other dietary constituents (e.g., carotenoids, flavonoids, other plant-derived chemicals, and probiotics (beneficial bacteria)) can also modulate a variety of immune responses, but their effects in humans remain largely unexplored.

Infection, in turn, is associated with profound effects on nutritional status resulting from decreased nutrient intake due to loss of appetite, decreased nutrient absorption as a result of intestinal damage and malabsorption, and nutrient losses arising from diarrhea and increased urinary excretion. Moreover, the inflammatory processes following infection can cause oxidative damage to host cells, and the prevention of such damage increases the demand for antioxidant defenses, including the vitamins C and E and a variety of enzymes that depend on trace metals for their function. In addition to its effects on nutritional status, the acute phase response is accompanied by marked changes in a variety of metabolic processes, with priority being shifted to the synthesis of all the different proteins involved in protecting the host from the invading pathogen. Another protective mechanism involves the redistribution of iron away from the bloodstream into the cells that participate in the phagocytosis and killing of invading pathogens. The removal of iron from the blood is accomplished by lactoferrin, an iron-binding protein that is produced in greatly increased amounts during the inflammatory response. By sequestering iron from pathogens that require this trace element for growth, lactoferrin can prevent such organisms from multiplying. Note that supplementation of iron-deficient subjects may reduce the resistance to malaria and may increase the short-term risk of certain infections. In general, however, correction of nutritional deficiencies via supplementation results in the partial or even full restoration of the compromised immune functions.

Effects of Iron and Zinc

C Doherty, MRC Keneba, The Gambia

Introduction

Iron and zinc have achieved prominence among the micronutrients due to the wealth of research detailing their fundamental importance to a multitude of basic cellular physiological mechanisms. The complexity of the immune system ensures that both divalent cations are necessary for normal function. The effects of deficiency and supplementation on the immune functioning of both deficient and replete individuals have

provided valuable clues to the specific immune processes in which they are involved. However, single nutrient deficiencies rarely occur alone and the effects of coexisting macro- and micronutrient deficiencies have contributed to the continuing debate on individual nutrient importance. Individuals and populations respond differently to supplementation. The basis of this variability is poorly understood but key to the improved targeting of supplementation. Specific mechanisms to explain the immune effects of zinc supplementation of deficient individuals have been particularly difficult to characterize as zinc is involved in so many cellular processes.

These nutrients are also important for prokaryotes and their acquisition by invading microbes is an important step in the development of a potential pathogen. The host action of micronutrient withdrawal is recognized as a mechanism of immune defense. In the era of genomic medicine the characterization of the molecular determinants of acquisition, storage, flux, and excretion of iron have increased our understanding and illustrated the complexity of iron homeostasis. In this article the evidence for the immune importance of both iron and zinc from *in vitro* experimentation and *in vivo* studies of human deficiency and supplementation is considered. The objective of supplementation, dose, route, preexisting level of deficiency, immunocompetence, coexistent deficiencies, genetic determinants, and the presence of infection should all be considered in the decision of who to supplement and when.

Iron and Zinc Homeostasis

Iron is the most abundant element on Earth. Despite this it is the most common micronutrient deficiency on Earth with up to 50% of all children under 5 years and pregnant women in developing countries affected. The ability of iron to both bind oxygen and to donate and accept electrons ensures that it has a central role in cellular energy metabolism. The utility of this redox potential is, however, counterbalanced by the propensity of iron to generate free radicals and damage cell membranes through lipid peroxidation. Genomic investment and redundancy in mechanisms to control iron availability at the cellular level illustrates both its importance and potential for toxicity.

Iron homeostasis depends on the regulation of iron absorption from the intestine as there are no pathways for iron excretion. On average, 1–2 mg enters the adult human body on a daily basis and a variable amount leaves via sloughing of skin and mucosal cells. Diets rich in heme iron and vitamin C promote iron absorption. Meat and nonanimal foods such as legumes and green leafy vegetables combine readily available heme iron with promoters of absorption and utilization of non-heme iron. Phytate-containing foods, e.g., cereals, inhibit absorption. Non-heme iron is reduced and solubilized to the ferrous form in the proton rich environment of the proximal duodenum and actively transported across the enterocyte. The transport of ferrous iron through the enterocyte represents the primary site of iron homeostasis – it can be stored as ferritin, lost through sloughing of intestinal cells, or exported systemically.

Transferrin binds and solubilizes ferric iron exported from the enterocyte with high affinity and transports it to cells. Uptake and internalization of iron-transferrin by endocytosis is followed by its dissociation at lower intracellular pH and storage of iron in cytoplasmic ferritin molecules. Iron absorption, however, does not fulfil the majority of daily hemopoietic requirement. Senescent red blood cells are phagocytosed by reticuloendothelial macrophages, which recycle the iron from heme – they load the ferric iron back onto transferrin for reuse and this recycling of heme iron accounts for 80% of hemopoietic requirement.

Hemoglobin and intracellular ferritin, in the liver, bone marrow and spleen, account for over 99% of total body iron. Iron is more readily available than zinc and we have developed strategies to manage large fluxes of iron. Conditions characterized by hemolysis demonstrate the complex adaptive mechanisms that protect cells from episodes of flux.

Zinc is the twenty-fifth most abundant element comprising less than 0.01% of the earth's crust. Its single oxidant state enables it to hydolyze bonds involving carboxyl and amino groups and its ability to form stable complexes with sulfur and nitrogen atoms is utilized in stabilizing proteins. It has structural and regulatory roles in numerous enzymes, signaling pathways, and gene transcription systems essential for growth, reproduction, and metabolism. Up to 2 g of zinc is present in an adult man but most (95%) is locked away in pools from which it cannot rejoin the circulation and influence plasma levels, e.g., muscle and bone. Small plasma and liver pools are accessible and labile and act as the only reserve available in dietary deficiency. Zinc homeostasis is thus dependent on dietary intake and the average man has an intake of 10 mg day^{-1}. Meat is a good source of zinc but plant sources (e.g., lentils and cereals) are often compromised by the presence of phytate, which inhibits absorption.

Plasma zinc is 99% bound to albumin and other low molecular weight proteins. Plasma zinc makes

up only a small percentage of body zinc. The control of zinc flux at the cellular level is much less well characterized than that of iron.

Metallothionens are a group of intracellular monomeric polypeptides that bind zinc and serve as homeostatic modulators of zinc availability. Relatively little is known of how zinc enters immune cells and how it influences function. Recently, a family of zinc transport genes (ZnT 1–4) has been cloned. ZnT 1 is associated with zinc efflux and expression of this gene is regulated by zinc intake. Further work is needed to clarify the role of this family in zinc transport and its possible regulatory influences, e.g., zinc status and inflammation. Zinc deficiency is difficult to identify both clinically and biochemically and only in the last decade has the widespread nature of this deficiency been recognized particularly in children in developing countries.

Deficiency

Iron and especially zinc deficiency are difficult to diagnose and differing diagnostic criteria contribute to the confusion surrounding deficiency and immune dysfunction. Plasma levels of either micronutrient are not adequate to define status, however they commonly have been used for such. Deficiency of iron can be quantified at individual and community levels using a combination of indices, e.g., hemoglobin/mean cell volume combined with an index of storage iron, ferritin plus an index of iron supply to tissues, or serum transferrin receptor concentration. Plasma zinc level decreases with inflammation and currently the best method of assessment for deficiency is response to supplementation. Alternatively, plasma zinc levels can be interpreted with caution in conjunction with a marker of the acute phase response. In developing countries iron and zinc deficiency are widespread and often occur together. Meat is the most important dietary source for both micronutrients; however, in many countries with predominately vegetarian diets phytate-containing cereals inhibit absorption of both.

Deficiency and Immunity

Proliferation of cells requires iron, as the DNA synthetic enzyme ribonucleotide reductase is iron dependent. Impaired T cell proliferation and impaired delayed type hypersensitivity have been consistently reported in iron deficiency. Phagocytosis is accompanied by the generation of toxic oxygen intermediates to kill ingested bacteria and both neutrophils and macrophages require iron for this process – nitroblue tetrazolium reduction and hydrogen peroxide production are reduced in neutrophils and macrophages if made iron deficient. In contrast, excessive iron results in decreased phagocytosis by neutrophils possibly due to increased free radical production and consequent lipid peroxidation damage of the phagosome membrane. Iron overload and saturation of transferrin also inhibits lymphocyte proliferation. When assessing the effect of iron on the immune system macrophages deserve special attention, as they are responsible for recycling heme iron back to the bone marrow. Iron thus fluxes through macrophages en route to fulfil hemopoietic need and is also utilized to kill intramacrophagal microbes. Macrophage activation and intracellular killing are dependent on the generation of toxic oxidant molecules such as the hydroxyl radical; however, these same free radicals can damage host cell membranes through lipid peroxidation. The control of intracellular iron in macrophages is thus important to hemopoiesis, microbial killing, and cell membrane stability within the macrophage itself. Iron overloading of macrophages impairs normal function and may increase risk of disease. Iron overloading of the macrophage causes oxidant damage to the phagocyte and an impaired ability to kill intracellular pathogens via IFNγ-mediated pathways. Iron has a direct inhibitory effect on the actions of IFN-γ, e.g., formation of tumor necrosis factor apha (TNF-α), expression of major histocompatibility factor (MHC) class II antigens, formation of neopterin, and nitric oxide synthesis.

Studies of immune function in iron-deficient human populations are frequently confounded by coexisting nutritional deficiencies, prevailing socioeconomic conditions, and differing diagnostic criteria, which make them difficult to interpret and compare. Increased morbidity from infectious disease has been reported in iron-deficient populations; however, it is not clear whether this is due to iron deficiency alone or at what level of deficiency the immune system is functionally compromised. In studies of children in predominately malarious areas a definite increase in mortality has only been demonstrated in anemic patients with less than $50\,g\,l^{-1}$ hemoglobin, whereas in those children with milder anemia the evidence for increased risk of mortality is inconclusive.

Zinc promotes mRNA stability, regulates gene expression, and influences DNA replication ensuring an essential role in cell division and activation. These processes are central to the immune response and zinc deficiency affects immune function at many levels both in the innate and specific arms. Zinc deficiency rarely occurs alone and has no pathognomonic clinical features. Cell-mediated immunity is profoundly affected in zinc deficiency. Lymphopenia

is common, as are defects in specific T and B lymphocyte function. Lymphoid atrophy, decreased delayed cutaneous hypersensitivity responses, reduction in numbers of CD4 helper cells, B cell dysfunction, impairment of phagocytosis, and deficient thymic hormone activity have all been described. Secretion and function of cytokines and the potentiation of apoptosis are affected by zinc deficiency. Gastrointestinal barrier function, polymorphonuclear and natural killer cell function, and complement activity are also affected. Zinc may also prevent free radical-induced injury through its antioxidant and cell membrane stabilizing properties. Mild zinc deficiency resulted in an imbalance between TH1 and TH2 functions in male volunteers – reduced serum thymulin activity, reduced CD4/CD8 lymphocyte ratio, and reduced interleukin-2 (IL-2) production but production of IL-4, IL-5, IL-6, and IL-10 was unaffected. Influencing TH1/TH2 balance is a potentially important pathway by which zinc deficiency affects cell-mediated immunity.

Supplementation

Studies of the effect of iron supplementation or food fortification on morbidity from infection have been inconsistent in showing evidence of benefit. Morbidity is difficult to measure accurately and populations differ in relative deficiency, dietary supply of iron, and prevalent infectious agents. Individuals will also differ in their response to supplementation and the causes of population and individual variation are not well defined. Whilst some populations have shown a decline in infectious disease morbidity some observational evidence that iron supplementation leads to increased morbidity and mortality from infection has been reported. Supplemental oral iron given to septic kwashiorkor children was associated with increased risk of death. Prophylactic iron dextran given intramuscularly to Polynesian newborns in New Zealand caused increased neonatal sepsis that declined on stopping supplementation. In a controlled trial of prophylactic iron given intramuscularly to 2-month-old infants in Papua New Guinea supplementation was associated with a significant increase in hospital admissions for pneumonia.

Malaria is associated with hemolysis and fluxing of iron through the reticuloendothelial macrophages back to the bone marrow. Malaria-associated anemia is therefore not necessarily associated with iron deficiency (though it commonly can coexist) but with iron delocalization in macrophages. The effect of supplemental iron on iron delocalization is unclear. An increase in the prevalence of malaria parasites in thick blood films, splenomegaly, and malaria-associated hospital admissions were reported in the Papua New Guinea study. Other trials of oral iron supplementation in children in areas where malaria is endemic have reported mixed findings but concerns persist as to possible increased morbidity from malaria due to iron supplementation. Current guidelines favor the continued use of iron supplementation in malarious regions as benefit to the host is felt to outweigh possible benefits to the parasite. Avoidance of parenteral administration and usage of lower supplementation doses has been advocated.

The study of conditions of chronic iron overload, e.g., hemochromatosis, chronic renal failure or hereditary hemolytic anemia requiring repeated blood transfusions, has provided further insights into how disturbed iron homeostasis affects immunity and infectious disease morbidity. Impaired phagocytic function inversely correlates with ferritin concentration and impaired natural killer cell function from iron overloaded thalassemic patients correlated with their degree of iron overload. Iron-overloaded patients are more susceptible to infections and the excess free iron encourages bacterial growth and pathogenicity. *Yersinia* infection has been reported in patients with hemochromatosis and those treated for acute iron toxicity with desferrioxamine. This bacterium can only acquire free iron and is therefore more likely to be invasive in its presence.

Zinc supplementation has been clearly demonstrated to improve immune function. Marasmic children given zinc supplementation demonstrate enlarged thymic shadows, increased conversion of delayed hypersensitivity skin reactions, enhanced lymphoproliferative response to PHA, and increased salivary IgA concentrations. Supplementation of malnourished children was associated with significantly larger delayed type hypersensitivity skin reactions and significantly decreased incidence of fever, cough, and upper respiratory tract infections. Zinc-supplemented infants also demonstrated significantly better serum IgA and significantly reduced incidence of pyoderma and anergy. Zinc supplementation decreased the percentage of children under 3 years who remained anergic to skin tests of delayed hypersensitivity associated with a significant rise in CD3, CD4, and the CD4/CD8 ratio.

The last decade has provided a wealth of studies detailing benefit from zinc supplementation in populations of under 5s in developing countries despite the difficulties in diagnosing zinc deficiency and understanding zinc homeostasis. By implication widespread deficiency exists. The evidence for immune benefit of zinc supplementation is much stronger than that for iron. There is now clear

evidence that malnourished children and children with chronic diarrhea benefit from therapeutic zinc supplementation and that prophylactic zinc supplementation reduces diarrheal disease morbidity. Studies continue on the use of zinc to prevent and treat acute respiratory tract infection but any benefit to malaria morbidity or mortality has not been clearly established. There is good evidence for zinc deficiency in certain population subgroups, e.g., stunted/wasted children and children with chronic diarrhea. Population-based supplementation rather than targeting specific patient groups has also demonstrated benefit but recognition of appropriate populations to supplement is problematic. Populations with high rates of stunting may well have a high likelihood of zinc deficiency and thus be considered as potential candidates for supplementation. Knowledge of local dietary supply of zinc and results of local intervention studies should guide targeting to zinc-deficient populations.

Population-based supplementation approaches assume the safety of supplementation of individuals within populations who are not deficient. In general zinc supplementation is safe; however, individual variability in response exists and supplementation of replete individuals is not beneficial. There may be subgroups within the population for which supplementation may be detrimental. Zinc supplementation during sepsis has caused clinical problems particularly in the presence of a compromised immune system. Marasmic infants have demonstrated reduced phagocytic and fungicidal monocytic activity and a significantly increased number and duration of episodes of impetigo. High-dose zinc supplementation ($6\,mg\,kg^{-1}\,day^{-1}$) given early in rehabilitation to severely malnourished children led to increased sepsis and mortality compared to low-dose supplementation ($1.5\,mg\,kg^{-1}\,day^{-1}$). *In vitro* evidence points to free zinc ion concentration as a determinant of effects on monocytes and lymphocytes. Excess zinc induces the release of IL-1β and IL-6 and TNF-α from monocytes and inhibits IL-1-dependent T cell stimulation. Granulocyte phagocytosis is also impaired by zinc in a concentration-dependent manner. Supplemental zinc in rats decreased mobilization of polymorphonuclear cells and macrophages into the peritoneal cavity and phagocytic function. In adult men administration of 150 mg of elemental zinc twice a week for 6 weeks was associated with a reduction in lymphocyte stimulation response to phytohemagglutinin as well as chemotaxis and phagocytosis of bacteria by polymorphonuclear leukocytes. *In vitro* evidence points to a concentration-dependent effect of zinc on immune function.

Inflammation and Micronutrient Flux

The acute inflammatory reaction is a coordinated and complex series of physiological and immune adaptations designed to optimize protection to an invading pathogen. Immune cells are activated and cytokines released (e.g., IL-1 and TNF) to increase endothelial permeability and chemotaxis and activate complement. Effector immune cells are thus brought to a site of tissue injury and activated. Cytokines mediate the dramatic changes in the micronutrient milieu that accompanies inflammation. Plasma levels of both iron and zinc fall as both micronutrients are withdrawn from readily available pools and diverted to the reticuloendothelial system so as to both optimize immune response and deny access to invading pathogens. Decreased iron absorption, decreased iron release from reticuloendothelial macrophages, and increased transferrin catabolism contribute to iron withdrawal. Macrophagal sequestration of iron is mediated by inflammatory cytokines. Cellular iron homeostasis is a post-transcriptional event and expression of the transferrin receptor limits acquisition of iron. Iron-response proteins (IRP) 1 and 2 bind to iron-responsive elements (IRE) in transferrin receptor and ferritin mRNA and thus regulate expression of these genes and uptake, utilization, and storage of intracellular iron. Inflammatory cytokines modulate intracellular iron status by regulating the IRP/IRE network. Proinflammatory cytokines released during inflammation, e.g., TNF-α and IL-1, increases ferritin transcription and induce a diversion of metabolically available iron into the storage compartment in macrophages thus limiting iron availability for erythropoiesis. This diversion of iron underlies the anemia of inflammation/chronic disease.

Zinc is also diverted to the reticuloendothelial system during inflammation and lower plasma zinc concentrations are associated with both optimal phagocytic function and decreased microbial virulence. Calprotectin is an acute phase zinc-binding protein produced by polymorphonuclear leucocytes that sequesters zinc from invading pathogens. IL-1 released in inflammation increases the expression of metallothionen 1 and 2 in the liver, bone marrow, and thymus, which accompanies the increased uptake of zinc in these organs.

Iron and zinc are essential for microbial survival as cofactors for both superoxide dismutase and catalase redox enzyme systems. These enzymes neutralize the reactive oxygen intermediates integral to phagosomal killing. Both iron and zinc are also cofactors for bacterial enzymes required for DNA

Table 1 Immune effects of iron and zinc deficiency.

Iron	*Zinc*
Effect of deficiency	**Effect of deficiency**
Impaired lymphocyte proliferation	Lymphopenia
Impaired delayed type hypersensitivity	Impaired T & B lymphocyte function
Impaired phagocytic function	Impaired phagocytic function
	Impaired gastrointestinal barrier function
	Impaired natural killer cell function
	Impaired complement function
	Impaired TH1/TH2 balance
Effect of overload	**Effect of overload**
Impaired lymphocyte proliferation	Impaired lymphocyte stimulation
Impaired phagocytic function	Impaired phagocytic function
Impaired natural killer cell function	

synthesis. Intracellular pathogens, e.g., tuberculosis, must acquire iron and polymorphic variants of host NRAMP1 (natural resistance-associated macrophage protein), which influence intramacrophagal flux of iron, can determine susceptibility to intracellular pathogens. The host macrophage uses iron to generate free radicals to kill *Mycobacterium tuberculosis* – the competition for essential micronutrients between the host and the invading microbe continues within immune cells. The control of iron flux during malaria may be important in determining the severity of malaria, the severity of postmalarial anemia, and the propensity to bacterial coinfection and may underlie the protective effect of hemoglobin, haptoglobin, and red cell enzyme variants. Oxidant stress accompanying the hemolysis of malaria is driven by free hemoglobin and is detrimental to both invading parasite and red blood cell membrane. The intraerythrocytic parasite degrades hemoglobin within its food vacuole and controls the resultant generation of free radicals by polymerizing free hemoglobin to hemozoin. Antimalarials, e.g., chloroquine, prevent this process and the parasite succumbs to its own waste. Hemoglobin, haptoglobin, or red cell enzyme variants that offer a more pro-oxidant environment can offer protection from severe malaria by ensuring earlier immune destruction of parasitized red cells. Strategies to manipulate hemolysis, oxidant stress, and iron flux during malarial episodes are key to the intraerythrocytic battle between host and parasite.

Correction of micronutrient deficiencies associated with defined functional consequences is a worthy goal. Iron and zinc deficiency are commonplace, particularly in children in developing countries, and have a significant effect on public health. Supplementation trials of zinc have been associated with significantly reduced infectious disease morbidity and mortality and there is good rationale for using targeted zinc supplementation to reduce infectious disease morbidity. Iron supplementation would not be advocated solely on the basis of its effect on infectious disease morbidity but this effect should be considered in supplementation programs. A recent meta-analysis showed

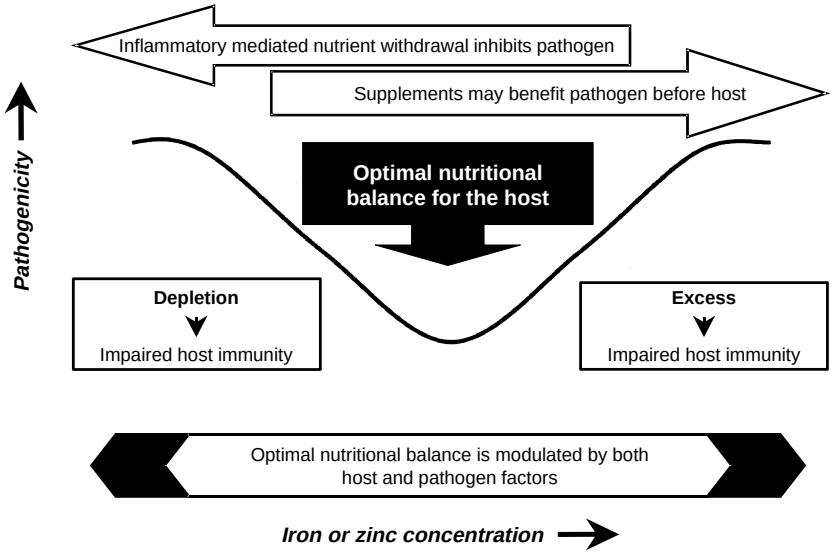

Figure 1 Micronutrient flux and the immune response to infection. (Adapted from Doherty CD, Weaver LT, and Prentice AM (2002) Micronutrient supplementation and infection: a double edged sword? *Journal of Pediatric Gastroenterology and Nutrition* **34**: 346–352.)

no harmful effect of iron supplementation on overall infectious disease incidence. However, if micronutrient withdrawal is a deliberate immune defense strategy and the control of micronutrient flux is worthy of such genomic investment then interference with blanket micronutrient supplementation will likely have adverse effects for subgroups within those populations. Understanding host variability in response to supplementation, the effect of supplementation during infection and nutrient–gene interactions in both host and potential pathogen is key to identifying these subgroups and improving micronutrient targeting.

The objective of supplementation, dose, route, pre-existing level of deficiency, immunocompetence, coexistent deficiencies, genetic determinants, and the presence of infection should all be considered in the decision of who to supplement and when.

INBORN ERRORS OF METABOLISM

Contents

Classification and Biochemical Aspects

D L Marsden, Children's Hospital Boston, Boston, MA, USA

Introduction

Garrod identified the first inborn error of metabolism in 1902 when he described the symptoms that had been observed in patients with alkaptonuria as being due to an inherited enzyme deficiency. Since that time over 400 disorders have been described that are due to an enzyme deficiency in the catabolic pathways of proteins, fatty acids, and carbohydrates. The resulting accumulation of toxic intermediates and, in some cases, the depletion of a necessary end product cause a variety of metabolic derangements, often with significant neurological sequelae. The severity and the age of onset of symptoms usually, although not always, depend on the amount of residual enzyme activity.

The vast majority of these disorders are inherited in an autosomal recessive fashion. While the individual inborn errors of metabolism are rare, based on recent results of expanded newborn screening programs (in which over 30 disorders can be detected), the overall incidence is approximately 1 in 5000 live births

worldwide. The incidence of disorders may vary across populations because of the 'founder effect', where a specific mutation arises and is maintained in subsequent generations, and may be higher where there is a higher incidence of consanguinity.

With a few exceptions, infants are normal at birth because the placenta efficiently eliminates the toxic metabolites.

Newborn Screening

Mass population screening of newborns was introduced in the 1960s, initially for phenylketonuria (PKU), after the development of the bacterial inhibition assay (BIA) for phenylalanine by Robert Guthrie. This simple method, popularly referred to as the Guthrie test, is still the mainstay of screening for PKU in much of the world. Essentially, it entails the addition of a solution of *B. subtilis* to an agar well, to which is added a standardized punched sample from the newborn screening filter paper, from which the blood is then eluted. High levels of phenylalanine inhibit growth of the bacteria, and the laboratory technician can easily visually identify this 'no-growth' zone as abnormal. Quantification is necessary, using a follow-up method such as high-performance liquid chromatography. BIA has been adapted to screen for elevated levels of leucine (for maple syrup urine disease; MSUD) and for methionine (for homocystinuria).

The most significant advance in newborn screening since its inception has been the adaptation of tandem mass spectrometry (MS/MS). With this technology, multiple compounds can be identified (both amino-acids and acylcarnitine species) from the same dried blood filter-paper sample after a simple preparation. Over 30 different inborn errors of metabolism can now be identified. The major drawbacks, however, are the relative expense of the equipment and the lack of long-term outcome data on infants detected and treated presymptomatically. Further modification of MS/MS will enable future screening for many more disorders, for example steroid profiling for congenital adrenal hyperplasia and the identification of lysosomal storage disorders.

Disorders of Protein Metabolism

Amino-Acid Disorders

Amino-acidopathies are due to an enzyme deficiency early in the catabolic pathway of one or more amino-acids that results in the accumulation of the amino-acid(s); they are detected by amino-acid analysis of serum or plasma. Symptoms may be due to the chronic accumulation of toxic amino-acid(s) or due to acute metabolic decompensation, for which aggressive intervention is necessary to prevent death or severe morbidity. Treatment is dietary restriction of the toxic amino-acid by limiting the intake of whole protein and supplementing with special modular amino-acid formulas to provide the appropriate nutrients for normal growth and development. All disorders are inherited in an autosomal recessive fashion.

The classic example is PKU. In PKU, a deficiency of the phenylalanine hydroxylase (PAH) enzyme (**Figure 1**) results in a high level of phenylalanine, which, if not treated with dietary restriction of phenylalanine in the early newborn period, causes severe irreversible mental retardation. The diagnosis is confirmed by a phenylalanine level of more than $1200\,\mu mol\,L^{-1}$ in an infant on unrestricted protein intake. The incidence of PKU is approximately 1 in 20 000 in Caucasians. Although PKU is pan-ethnic, the incidence varies in certain populations. The level of phenylalanine can vary between individual patients because of variations in the amount of residual enzyme activity, which, in turn, depends on the specific mutations. There are currently over 400 known mutations. Most patients are compound heterozygotes (i.e., have one copy each of two different mutations). Prior to the introduction of newborn screening, PKU was the commonest cause of inherited mental retardation. Early recognition of presymptomatic infants allows for the institution of a phenylalanine-restricted diet, with the

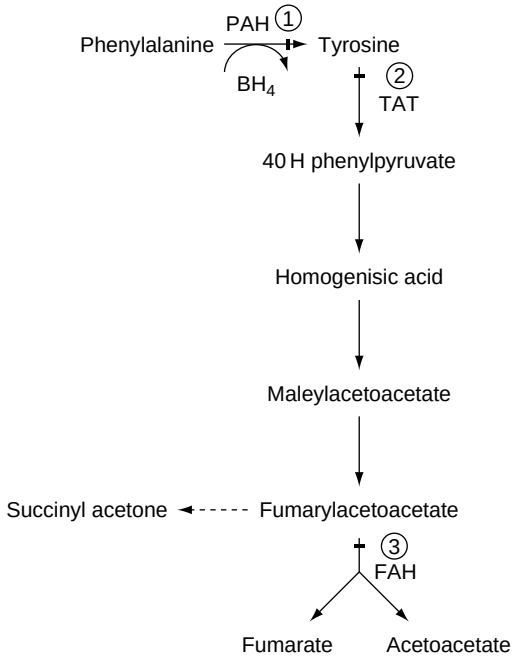

Figure 1 Catabolic pathway of phenylalanine. PAH, phenylalanine hydroxylase; TAT, tyrosine aminotransferase; FAH, fumarylacetoacetase; 1, PKU; 2, tyrosinaemia type II; 3, tyrosinaemia type I.

best outcomes achieved when recommended phenylalanine levels are attained by 2 weeks of age.

Untreated patients develop progressive severe mental retardation, often with seizures and Parkinson-disease-like neurological symptoms. The primary pathogenesis is due to the toxic effect of phenylalanine on the central nervous system; secondary symptoms may be due to a deficiency of tyrosine, which is an important precursor for the synthesis of some neurotransmitters. These symptoms include anxiety and depression.

Benign or mild hyperphenylalaninemia is due to allelic variants of PAH that result in greater residual enzyme activity. On an unrestricted diet, levels are typically in the range 120–360 $\mu mol\,L^{-1}$, and no dietary treatment is necessary.

Moderate elevation of phenylalanine is also present in patients with defects of tetrahydrobiopterin (BH_4), the cofactor for PAH. BH_4 is also the cofactor for other enzymes, tryptophan hydroxylase and tyrosine hydroxylase. These amino-acids are important precursors of the neurotransmitters 5-hydroxytryptophan and dopamine. A deficiency causes a neurological syndrome characterized by hypotonia, seizures, and movement disorder (dystonia).

MSUD has an incidence of approximately 1 in 185 000 births. It is due to a deficiency of the branched chain ketoacid dehydrogenase enzyme and the resulting accumulation of the branched chain amino-acids (BCAAs) leucine, isoleucine, and valine, which are detected by plasma amino-acid analysis. Elevation of alloisoleucine (a derivative of isoleucine) is pathognomonic. In classic MSUD, symptoms typically occur in the first week of life and, if untreated, rapidly progress to cerebral oedema, coma, and death. Toxicity is due primarily to high levels of leucine. The characteristic maple syrup (or burnt sugar) odour is due to the presence of sotolone, a metabolite of isoleucine or alloisoleucine. It is detectable only when the BCAAs are significantly elevated; the ester is concentrated in the urine and the earwax of affected patients.

Variant forms of MSUD also occur. Intermediate MSUD typically presents in infancy with developmental delay; seizures may occur. Moderate levels of the BCAAs (including alloisoleucine) are present. Intermittent MSUD is associated with intermittent symptoms during acute infections or periods of prolonged fasting. Typical symptoms include ataxia, vomiting, and seizures. Acute severe decompensation may occur, similar to the classic form of MSUD. The BCAAs are elevated only during the episode of acute symptoms. Other disorders are listed in **Table 1**.

Urea cycle defects are due to enzyme deficiencies associated with the elimination of waste nitrogen produced by the normal catabolism of protein. There are six enzymatic steps involved in this process (**Figure 2**): a deficiency in any of the first five enzymes causes accumulation of nitrogen, in the form of ammonia (NH_3), and increased levels of the amino-acids glutamine and glycine.

Symptoms typically occur in the newborn period, except in the case of arginase deficiency, but milder late-onset variants have been well described. Symptoms include lethargy, poor feeding, vomiting, tachypnea, and progressive encephalopathy. Routine biochemical testing shows respiratory alkalosis and hyperammonemia. The liver transaminases are usually elevated. Hypoglycemia is not typical.

Plasma amino-acid and urine organic acid analyses are necessary to make a presumptive diagnosis.

Table 1 Disorders of amino-acid metabolism

Disorder (Deficient enzyme)	*Elevated analyte*	*Clinical features*	*Treatment*
Tyrosinemia type I (fumarylacetoacetase)	Tyrosine SA	Cirrhosis Liver failure Failure to thrive Renal tubular acidosis Rickets Hepatocellular Carcinoma (late)	NTBC (inhibits SA production) Tyrosine restriction
Tyrosinemia type II (tyrosine aminotransferase)	Tyrosine (↑↑)	Keratoconjunctivitis Palmar keratosis Mental retardation	Tyrosine restriction
Homocystinuria (cystathionine β synthase)	Methionine Total homocysteine Free homocystine+ Mixed disulfides	Mental retardation Thromboembolism Lens dislocation Osteoporosis	Vitamin B_6 (50% respond) Methionine restriction
Nonketotic hyperglycinemia (glycine cleavage enzyme deficiency)	Glycine (↑↑) (plasma and CSF)	Seizures Developmental delay	Sodium benzoate (decreases glycine)

CSF, cerebrospinal Fluid; SA, Succinylacetone; NTBC, 2-(2-nitro-4-trifluoro-methylbenzoyl)-1,3-cyclohexanedione.

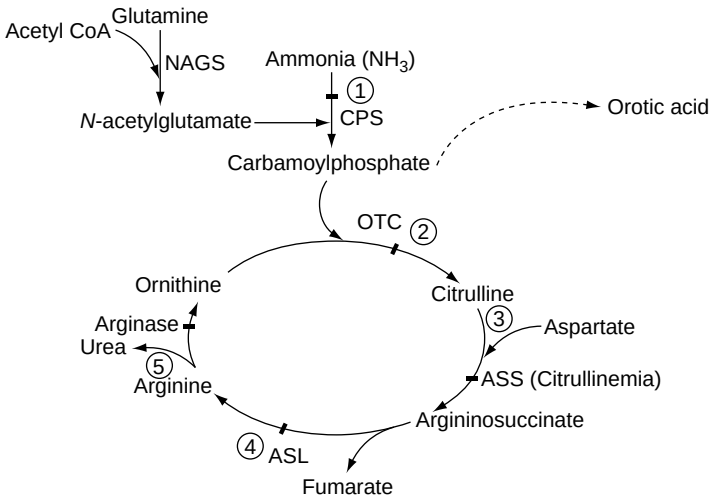

Figure 2 The urea cycle. NAGS, *N*-acetylglutamine synthetase; CPS, carbamoylphosphate synthetase; OTC, ornithine transcarbamoylase; ASS, argininosuccinate synthetase; ASL, argininosuccinate lyase; 1, CPS deficiency; 2, OTC deficiency; 3 citrullinemia; 4, argininosuccinic aciduria; 5, arginase deficiency.

In argininosuccinate synthetase (ASS) deficiency citrulline is elevated, in argininosuccinate lyase (ASL) deficiency argininosuccinic acid and citrulline are elevated, and in arginase deficiency, arginine is elevated. In ornithine transcarbamoylase (OTC) deficiency, on the other hand, citrulline is very low or absent. In each of these disorders, orotic acid is also present (found on urine organic acid analysis); it is produced via the pyrimidine cycle from the excessive carbamoylphosphate that accumulates owing to each enzyme defect. In carbamoylphosphate synthetase (CPS) deficiency, however, the amino-acid and orotic acid levels are normal, so the diagnosis is essentially one of exclusion in a patient who presents with the typical symptoms and severe hyperammonemia in which no other cause is determined. Confirmation of the diagnosis requires a liver biopsy for enzyme analysis of CPS and OTC. Skin fibroblasts can be assayed for ASS and ASL deficiencies, and red blood cells can be assayed for arginase deficiency; mutation analysis may be possible in some cases.

OTC deficiency is the most common urea-cycle defect. It is inherited in an X-linked fashion (all other disorders are autosomal recessive); symptomatic females can present with variable symptoms ranging from acute hyperammonemia to recurrent episodes of nausea, vomiting, and headache. The severity of the symptoms in female patients depends on the degree of lyonization (the normal random inactivation of one of the X chromosomes) and the resultant residual enzyme activity. Some women may remain asymptomatic, and a diagnosis is made only after the birth of a symptomatic son.

Patients with ASL deficiency also have progressive cirrhosis of the liver, possibly owing to the direct toxic effect of the argininosuccinic acid. In arginase deficiency, hyperammonemia is rare (most of the urea has already been eliminated), but arginine itself is toxic to the central nervous system, causing progressive spastic quadriplegia and developmental delay; seizures are common.

The toxicity of these disorders is primarily due to the accumulation of ammonia (NH_3) and glutamine, which is increased because of the transfer of excess ammonium ions (transamination). Acute severe hyperammonemia in the newborn period is catastrophic and often fatal. Survivors have variable neurological deficits.

Acute treatment of hyperammonemia due to a urea cycle defect involves the elimination of dietary protein, elimination of ammonia (by hemodialysis or peritoneal dialysis), administration of a high concentration of dextrose to reverse catabolism, arginine (except in arginase deficiency) to regenerate the cycle, and the nitrogen scavenging drugs sodium benzoate (which conjugates with glycine to form hippurate) and sodium phenylacetate (which conjugates with glutamine to form sodium phenylacetylglutamine). Early reintroduction of limited dietary protein is necessary to provide a substrate for anabolism and prevent further catabolism. This should consist of whole protein and a special formula to provide enough essential amino-acids to ensure normal weight gain, without producing excessive amounts of nitrogen for ammonia production. Chronic treatment involves similar dietary protein restriction, arginine, and an oral

Table 2 Organic acidemias

Disorder (Deficient enzyme)	*Elevated analyte(s)*	*Clinical features*	*Treatment*
Methylmalonic acidemia (methylmalonyl CoA Mutase)	Methylmalonic acid	Metabolic acidosis Hyperammonemia Failure to thrive Vomiting	Protein restriction Carnitine
Isovaleric acidemia (isovaleryl CoA dehydrogenase)	Isovalerylglycine	Metabolic acidosis Vomiting	Protein restriction Glycine
Glutaric aciduria type I (glutaryl CoA dehydrogenase)	3-Hydroxyglutaric acid Glutaric acid	Metabolic acidosis Vomiting Macrocephaly Developmental delay	Protein restriction Carnitine
3-Methylcrotonyl glycinuria (3-methylcrotonyl CoA carboxylase)	3-Hydroxyisovaleric acid 3-Methylcrotonylglycine	Metabolic acidosis Hypoglycemia Hyperammonemia Seizures (Some patients asymptomatic)	Protein restriction Carnitine
Mitochondrial acetoacetyl CoA thiolase deficiency	2-Methyl-3-hydroxybutyrate acid 2-Methylacetoacetic acid Tiglylglycine	Metabolic acidosis Vomiting	Protein restriction Carnitine

form of nitrogen-scavenging medication (sodium phenylbutyrate). For arginase deficiency, dietary protein restriction and formula is usually adequate.

Organic acidemias (**Table 2**) are due to enzyme deficiencies further along the catabolic pathway, usually of several amino-acids, resulting in the accumulation of the toxic products of intermediary metabolism (organic acids). In some cases, there is a functional defect of the enzyme owing to a deficiency of the enzyme cofactor, rather than of the enzyme itself. Examples of this are biotinidase deficiency and defects of cobalamin (vitamin B_{12}) metabolism.

The accumulation of large amounts of organic acids causes severe metabolic acidosis and ketosis. Hyperammonemia is often present, owing to secondary inhibition of the urea cycle. Hypoglycemia may be variably present, owing to secondary inhibition of fatty-acid oxidation. Symptoms are often present in the newborn period; recurrent episodes of metabolic decompensation can occur because of excessive protein intake or because of catabolism (and therefore an increased load of amino-acids endogenously released from muscle) associated with acute infections or prolonged periods of fasting. Morbidity and mortality is due to acute acidosis and the associated neurologic sequelae.

The diagnosis is made by finding high levels of the characteristic organic acids in the urine. Newer analytic methods, such as MS/MS, can detect even small elevations of characteristic plasma acylcarnitine and urine acylglycine conjugates of the intermediary metabolites. Confirmation is by enzyme analysis, usually in skin fibroblasts; DNA mutation analysis is available for many disorders.

Propionic acidaemia is a typical organic acidaemia. It is due to an isolated defect of the enzyme propionyl CoA carboxylase in the catabolic pathways of the amino-acids isoleucine, valine, methionine, and threonine as well as cholesterol and odd chain fatty acids (**Figure 3**). The resulting accumulation of the intermediary metabolites 3-hydroxypropionic acid, methylcitric acid, propionylglycine, and tiglylglycine can cause severe metabolic acidosis, ketosis, coma, and death. Other associated symptoms can include hyperammonemia, hypoglycemia, and pancytopenia, owing to bone marrow suppression by the accumulated toxic organic acids.

Symptoms can occur within days of birth in the classic disease or later in infancy or childhood in the milder variant forms. The later-onset form may be associated with persistent vomiting, failure-to-thrive,

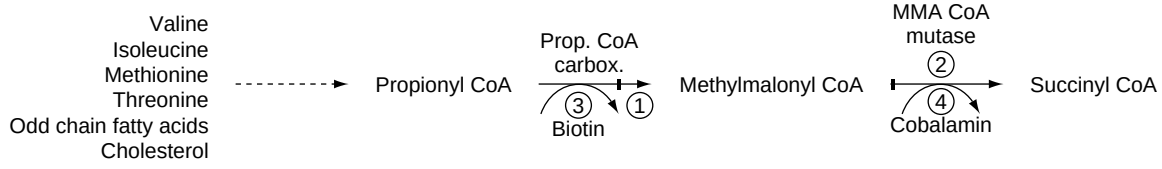

Figure 3 The catabolic pathways of isoleucine, valine, methionine, threonine, cholesterol, and odd chain fatty acids. 1, propionic aciduria; 2, methylmalonic aciduria; 3, multiple carboxylase deficiency; 4, cobalamin disorders.

and developmental delay, but often does not involve severe episodes of metabolic acidosis. Dystonia may occur owing to infarction of the basal ganglia.

Cofactor Deficiencies

Biotin is an essential cofactor for the four carboxylase enzymes propionyl CoA carboxylase, methylcrotonyl CoA carboxylase, pyruvate CoA carboxylase, and acetyl CoA carboxylase. It is endogenously derived from lysine and also present in its protein-bound form in small amounts in many foods. Holocarboxylase synthetase (HCS), which forms the inactive parent apoenzyme, is also biotin dependent. Enzyme activation requires free biotin, which is released by the action of biotinidase; this enzyme also plays an essential role in the recycling of biotin for further use. A deficiency of biotinidase, therefore, results in depletion of biotin and a functional defect of the carboxylases. Symptoms include hypotonia, lethargy, vomiting, and ataxia. Recurrent metabolic acidosis may occur. Alopecia and a generalized erythematous rash are common. The symptoms are more severe in HCS deficiency. The characteristic pattern of organic acids is present in both disorders. The diagnosis is made by measuring biotinidase activity in plasma or carboxylase-enzyme activity in leucocytes or fibroblasts. Treatment with pharmacologic doses of biotin is effective.

Multiple defects of cobalamin (vitamin B_{12}) metabolism can occur, involving the transport of vitamin B_{12} into the cell (defects of the transporter proteins transcobalamin I and II) or subsequent intracellular utilization of the different biologically active forms. These disorders are classified into complementation groups, depending on whether the defect is in adenosylcobalamin (Cbl A and B), methylcobalamin (Cbl G and E), or both (Cbl C and D).

Adenosylcobalamin is the cofactor for methylmalonyl CoA mutase; a defect results in a milder form of methylmalonic acidaemia than that found with a defect of the enzyme itself. Methylcobalamin is the cofactor for methionine synthase; a defect results in low methionine and homocystinuria (distinct from classic homocystinuria due to a defect of cystathionine β synthase). A defect of both adenosylcobalamin and methylcobalamin causes both methylmalonic acidaemia and homocystinuria.

Symptoms vary with the complementation group, but can include metabolic acidosis, hypotonia, developmental delay, macular degeneration, and megaloblastic anemia. Treatment with hydroxocobalamin corrects some of the biochemical derangements, especially in Cbl A and B. Treatment is less successful in the other groups.

A syndrome similar to Cbl C has been described in the breast feeding infants of strict vegetarian (vegan) mothers and in mothers with pernicious anemia, who are vitamin B_{12} deficient.

Disorders of Fatty-Acid Oxidation

Disorders of fatty-acid oxidation have been recognized only since the early 1980s, but as a group they represent the most common inborn errors of metabolism. Fat provides a significant source of energy in the form of glucose and ketone bodies during times of metabolic stress (such as febrile illness) or during prolonged fasting. Free fatty acids, released from the adipose tissue, are transported into the mitochondria via the carnitine shuttle system, where they undergo β-oxidation (**Figure 4**), the progressive cleavage from an 18-carbon very long-chain fatty acid to the two-carbon aceto-acetyl CoA, the substrate for glucose (via the TCA (Tricarboxylic acid) cycle) and ketones. A deficiency of any of the enzymes in this pathway can cause symptoms of hypoketotic hypoglycemia and hepatic encephalopathy, with hyperammonemia (due to secondary inhibition of the urea cycle) and sudden death. Many cases of what would previously have been diagnosed as Reye syndrome are now known to be due to defects of fatty-acid oxidation. Symptoms can occur at any time, from the newborn period to adulthood.

Carnitine has a dual role: in addition to its critical role in the transport of free fatty acids into mitochondria, it conjugates with the fatty acyl CoA intermediates that accumulate proximal to an enzyme block, forming acylcarnitine species that can be excreted by the kidneys. They can also be measured in plasma for diagnostic purposes and in the newborn-screening dried blood spot. Increased use of carnitine owing to an enzyme defect causes a secondary depletion, further impairing fatty-acid oxidation.

Long-chain fatty-acid (carnitine palmityl transferase (CPT) oxidation defects I and II, very long-chain acyl CoA dehydrogenase (VLCAD), TFP (Trifunctional protein), and long-chain 3-hydroxy acyl CoA dehydrogenase (LCHAD)) may present in the newborn period or later in infancy with severe hypoketotic hypoglycemia, cardiomyopathy, and hepatic encephalopathy, due to deposition of fat in the heart and liver. Rhabdomyolysis (lysis of muscle cells) is common. Pigmentary degeneration of the retina may be present in LCHAD and is thought to be due to impaired endogenous production of docosahexanoic acid (DHA), which is necessary for normal retinal function. Milder variant forms of CPT II and VLCAD may present in adolescence or adulthood with muscle cramping and rhabdomyolysis, which may be severe enough to cause

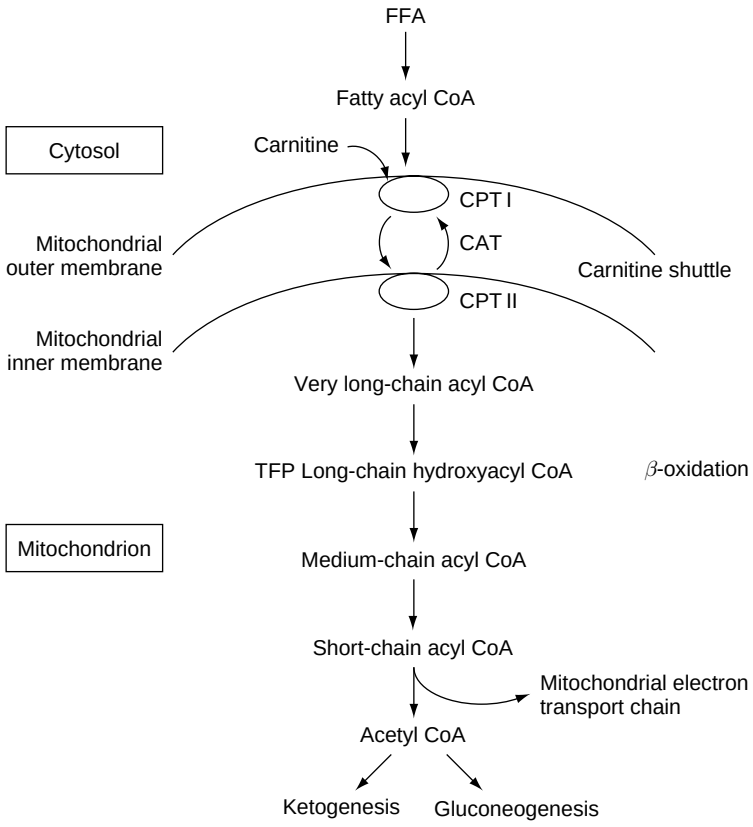

Figure 4 Fatty-acid oxidation. FFA, free fatty acids; CPT I, carnitine palmitoyltransferase type I; CPT II, carnitine palmitoyltransferase type II; CAT, carnitine acylcarnitine translocase; TFP, trifunctional protein.

acute renal failure owing to the deposition of the muscle pigment myoglobin in the renal tubules.

Treatment of these disorders, which can reverse the cardiac and liver disease, includes frequent feeding and avoidance of fasting, together with limitation of dietary fat and supplementation with medium-chain triglycerides (MCT), which bypass the metabolic block. There is no clear consensus on the amount of MCT needed; the general recommendation is to provide 20–40% of total calories from fat, with about half of these calories coming from MCT. Special formulas can provide the MCT requirements, but some are deficient in some essential fatty acids, such as linoleic and linolenic acids and DHA. Addition of oil, such as canola oil, provides most of the essential fatty acids. DHA is not currently commercially available, but fish oil may provide an alternative source. Uncooked cornstarch can provide an alternative source of complex carbohydrate (especially for overnight fasting) after the age of about 9 months. Normal pancreatic amylase activity is necessary and may not be adequate prior to this age.

Treatment of the medium-chain and short-chain defects is simpler, involving avoidance of fasting and early intervention during acute illness to prevent hypoglycemia. Carnitine supplementation is frequently used to prevent secondary depletion. The dietary-fat recommendation is approximately 30% of total calories, or a 'heart healthy' diet.

Disorders of Carbohydrate Metabolism

Galacatosemia

Galactose is derived primarily from dietary lactose, which is the major disaccharide in dairy products, human breast milk, and many fruits and vegetables. There is also a small contribution from endogenous production. There are three known enzyme deficiencies in the pathway that oxidizes galactose to glucose (**Figure 5**); all are autosomal recessive genetic disorders.

Classic galactosemia is due to the almost complete absence of galactose-1-phosphate uridyltransferase (GALT) activity. Symptoms generally occur in the first few weeks of life, with poor weight gain, lethargy, hypotonia, liver disease (hyperbilirubinemia, coagulopathy, and hepatomegaly), and renal tubular acidosis. Hypoglycemia can occur. *Escherichia coli* sepsis may also be a complication: elevated

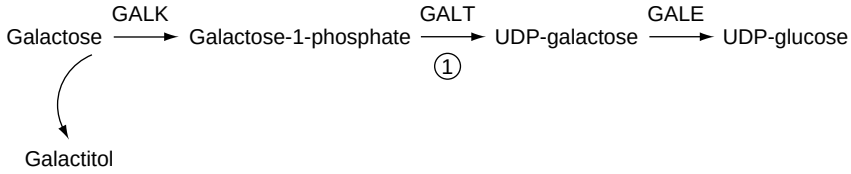

Figure 5 Galactose oxidation. GALK, galactokinase; GALT, galactose-1-phosphate uridyl transferase; GALE, uridine diphosphate galactose 4-epimerase; 1, galactosemia; UDP, uridine diphosphate.

galactose is thought to impair leucocyte bactericidal activity, allowing the bacteria to invade the red blood cells more easily with subsequent dissemination. Mental retardation is a long-term complication.

The underlying pathogenesis of galactosemia is not fully understood; despite compliance with a lactose-restricted diet, speech delay is almost universal, some patients have learning disorders, and female patients have ovarian failure.

Treatment is by restriction of lactose in the diet, primarily by eliminating dairy products and other foods known to be high in galactose.

Variant forms of galactosemia occur owing to mutations in the GALT gene that result in greater residual enzyme activity. The commonest variant is the Duarte variant, in which there is usually one copy of a classic galactosemia mutation (e.g., Q188R) and one copy of the variant N314D. This combination results in approximately 25% residual enzyme activity. There is varying opinion as to whether or not dietary treatment is necessary: some clinicians consider that the residual enzyme activity is sufficient to prevent the pathologic sequelae, others elect to treat the patient with lactose restriction for the first year of life. There are no long-term outcome data to support either approach.

Galactokinase deficiency causes an excessive accumulation of galactitol, which is oxidized from galactose by an alternative pathway. High levels of galactitol cause cataract formation, which is the only symptom of this disorder. Lactose restriction is necessary.

Epimerase deficiency is very rare. There are two isoforms of the enzyme, one isolated to red blood cells and one in the liver. The most common disorder is due to an isolated deficiency of the red-blood-cell isoform, which will be detected incidentally by newborn screening programs that measure total galactose. There are no clinical symptoms and no treatment is necessary. A defect of both isoforms will cause symptoms similar to those of classic galactosemia and should be treated similarly.

Glycogen Storage Disorders

Glycogen is a complex carbohydrate stored primarily in the liver and muscle. Liver glycogen provides glucose to maintain blood-sugar levels between normal feeding; defects of the liver enzymes for glycogen degradation lead to hypoglycemia and/or liver disease because of excessive accumulation of glycogen. Muscle glycogen is an important substrate for energy production for normal muscle function, so disorders are usually indicated by cramping with exercise.

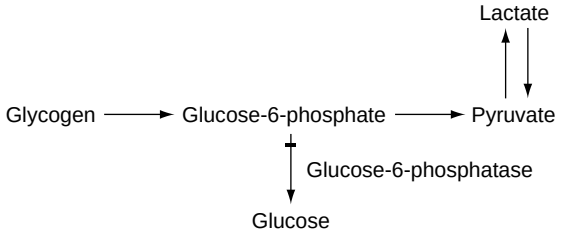

Figure 6 Glycogen storage disease type I.

Glycogen storage disease (GSD) type I (GSD I) (**Figure 6**), the most common disorder, is due to a deficiency of glucose-1-phosphatase in the liver, kidney, and intestinal mucosa. Symptoms typically occur in infancy when the frequency of feeding decreases. Profound hypoglycemia can occur; progressive hepatomegaly and liver dysfunction are due to storage of glycogen. Other metabolic derangements include lactic acidaemia, which is due to increased pyruvate production; increased fatty-acid synthesis causes hypertriglyceridemia and hypercholesterolemia (causing xanthomas); hyperuricemia (causing gout and renal calculi) is due to decreased renal excretion (lactate is preferentially excreted) and increased uric-acid production owing to phosphate depletion. Other long-term complications include progressive renal disease (proteinuria) and hepatocellular carcinoma. Treatment involves frequent meals and continuous nocturnal feeding (in infants); supplemental uncooked cornstarch provides exogenous glucose.

Other GSDs are summarized in **Table 3**.

Disorders of Fructose Metabolism

There are three disorders of fructose metabolism, all inherited in an autosomal recessive fashion. Fructose is widely distributed in the diet as the primary sugar in fruits, vegetables, and honey. It is also derived from sucrose and sorbitol, which are found in large variety of products, including infant formulas and intravenous fluids. The toxic effect of fructose is due to inhibition

Table 3 Glycogen storage disorders

Disorder	*Deficient enzyme*	*Primary affected tissue*	*Symptoms*	*Treatment*
GSD O	Glycogen synthase	Liver	Hypoglycemia	Uncooked cornstarch, frequent feeds
GSD I	Glucose-6-phosphatase	Liver, muscle	Hypoglycemia, hepatomegaly, growth retardation, proteinuria, lactic acidemia, hyperlipidemia, hyperuricemia (gout), hepatocellular carcinoma	Uncooked cornstarch, frequent feeds
GSD II (Pompe disease)	Acid maltase (α glucosidase)	Lysosomes of muscle (skeletal and cardiac)	Cardiomyopathy, skeletal myopathy, cardiorespiratory failure	Enzyme replacement (in clinical trial)
GSD III	Debranching enzyme (amylo-1, 6-glucosidase)	Liver, muscle	Hypoglycemia (mild), hepatomegaly, myopathy, hyperlipidemia	Uncooked cornstarch, frequent feeds
GSD IV (amylopectinosis)	Branching enzyme	Liver	Hepatomegaly, cirrhosis, liver failure, myopathy	Liver transplant, Uncooked cornstarch
GSD V (McArdle disease)	Myophosphorylase	Muscle	Muscle cramping (with exercise)	Oral glucose, high-protein diet
GSD VI (Hers disease)	Liver phosphorylase	Liver	Hepatomegaly, hypoglycemia, myopathy	Frequent feeds
GSD VII (Tarui disease)	Phosphofructokinase	Muscle	Fatigue exercise intolerance, cramping	Avoidance of strenuous exercise
GSD IX	Phosphorylase kinase	Liver, muscle	Hepatomegaly, growth retardation	Frequent feeds

GSD, glycogen storage disorder.

of gluconeogenesis by high levels of fructose-1-phosphate and subsequent depletion of inorganic phosphate and, thus, adenosine triphosphate.

Essential fructosuria is a benign disorder due to a defect of the enzyme fructokinase. Patients have increased urinary excretion of fructose, which is usually an incidental finding on routine testing for reducing substances.

Hereditary fructose intolerance is due to a deficiency in aldolase B, which splits fructose-1-phosphate into glyceraldehyde and dihydroxyacetone. Symptoms occur only after exposure to fructose, usually from dietary ingestion although they are more severe after intravenous infusion. The symptoms include gastrointestinal discomfort, vomiting, and hypoglycemia. Chronic exposure causes failure-to-thrive, liver disease, and renal tubular acidosis. Affected patients are often misdiagnosed as having behavioral problems or an eating disorder. Treatment involves elimination of fructose from the diet.

Fructose-1,6-bisphosphatase deficiency is a defect of gluconeogenesis and not dependent on exposure to fructose. Symptoms, including recurrent episodes of vomiting, lactic acidosis, tachypnea, seizures, and apnea, occur when dietary glucose and glycogen stores are depleted, for example during periods of fasting or febrile illness. Approximately 50% of patients are symptomatic in the newborn period. Treatment involves the prevention of fasting and supplementation with uncooked cornstarch to provide a source of complex carbohydrate. Acute episodes respond to intravenous infusions of dextrose.

Abbreviations

ASL	Argininosuccinate lyase
ASS	Argininosuccinate synthetase
BCAA	Branched chain amino-acids
BH_4	Tetrahydrobiopterin
BIA	Bacterial inhibition assay
CPS	Carbamoyl synthetase
CPT	Carnitine palmityl transferase
GALT	Galactose-1-phosphate uridyl transferase
GSD	Glycogen storage disorder
HCS	Holocarboxylase synthetase
LCHAD	Long-chain 3-hydroxy acyl CoA dehydrogenase
MCAD	Medium-chain acyl CoA dehydrogenase
MS/MS	Tandem mass spectrometry
MSUD	Maple syrup urine disease
OTC	Ornithine transcarbamylase

PAH	Phenylalanine hydroxylase
PKU	Phenylketonuria
SCAD	Short-chain acyl CoA dehydrogenase
VLCAD	Very long-chain acyl CoA dehydrogenase

Nutritional Management of Phenylketonuria

D L Marsden, F J Rohr and K C Costas, Children's Hospital Boston, Boston, MA, USA

Introduction

Phenylketonuria (PKU) is a disorder of amino acid metabolism caused by a deficiency in the enzyme phenylalanine hydroxylase, which converts the essential amino acid phenylalanine to tyrosine. High levels of phenylalanine are toxic to the central nervous system, resulting in severe irreversible mental retardation. Details of the biochemistry are discussed elsewhere in this encyclopedia.

PKU is often considered a paradigm for the nutritional therapy for metabolic disorders. It was the first inborn error of metabolism identified by newborn screening, thus allowing for early dietary treatment. Early treatment was successful in preventing the mental retardation associated with untreated PKU. Since the advent of successful dietary treatment of PKU four decades ago, the field has expanded greatly, but the principle of treating phenylketonuria remains the same – to control the intake of the amino acid that is not metabolized normally. This principle applies to all amino acidopathies, but PKU is used here as an example.

Dietary treatment is started as soon as the diagnosis is confirmed in a newborn. Outcomes are best when the diet is implemented and the phenylalanine levels are within the recommended guidelines by 2 weeks of age. Diet is now recommended to be life-long. Adult and adolescent patients who have resumed an unrestricted diet, while intellectually normal, have been shown to have an increased incidence of neuropsychiatric illness, such as increased anxiety and depression. Others report poor concentration, headaches, and sleep disturbance.

The pathophysiology of PKU is not well understood, although recent focus has been on the role of amino acids in the brain. Phenylalanine competes with other large neutral amino acids for transport across the blood–brain barrier, and it is theorized that high levels of brain phenylalanine and low levels of other amino acids, specifically tyrosine and tryptophan, may impede neurotransmitter synthesis in the brain and be responsible for the symptoms associated with untreated PKU. While the ideal brain level of phenylalanine has not been established, treatment guidelines have been established for blood levels at various ages, although these guidelines differ slightly in different countries. In the US, recommendations have been developed by an expert panel convened under the direction of the National Institutes of Health (NIH) and the American Academy of Pediatrics (**Table 1**).

The goal of nutritional therapy is to keep blood phenylalanine controlled while providing a nutritionally sound diet. This necessitates the use of a special medical food (most often as a formula) that provides amino acids other than phenylalanine. A medical food is required because the phenylalanine restriction needed to maintain blood levels within the desired range is so severe that the amount of natural protein

Table 1 Treatment goals for PKU

Age (years)	*Phenylalanine level (μmol l^{-1})*
0–12	120–360
12–adult	120–900
	(120–600 preferred in adolescents)
Maternal PKU	120–360

allowed in the diet would not support normal growth and development. Several medical foods are currently available. When PKU was first treated, only one medical food was commercially available: a protein hydrolysate from which most of the phenylalanine had been removed. Now, medical foods for PKU use synthetic L-amino acids (other than phenylalanine) as the protein source and are phenylalanine free. The medical foods vary in the amount of amino acids that they contain; in addition, most also provide carbohydrate and fat, vitamins and minerals, but others do not. The amount of medical food prescribed is intended to meet protein needs at various ages in the life cycle (see **Table 2**).

Introduction of Dietary Therapy

Infant formulas for PKU come in a powdered form and are mixed with water and taken as a substitute for regular infant formula or breast milk. In some clinics, only phenylalanine-free formula is given for a few days so that blood phenylalanine will quickly decrease to an acceptable level. A prescribed amount of breast milk or standard infant formula, however, should be shortly introduced into the diet. Whole protein is needed to meet phenylalanine requirements and prevent phenylalanine deficiency, which will lead to muscle protein catabolism and inadequate weight gain. For formula-fed infants, both standard infant formulas and PKU medical foods are used in prescribed amounts and are bottle fed. Breast-feeding of an infant with PKU is possible and, as with all infants, should be encouraged whenever possible. Mature breast milk contains approximately 46 mg 100 ml^{-1}of phenylalanine compared to approximately 59 mg 100 ml^{-1} in cows' milk protein-based formula and approximately 88 mg 100 ml^{-1} in soy-based formulas. Therefore, breast-fed infants may initially have slightly lower plasma phenylalanine levels. If a mother chooses to continue breast-feeding, she is advised about the proper ratio of breast milk to PKU medical food to feed her infant. The key to either method is frequent monitoring of blood phenylalanine and adjusting the diet based on phenylalanine intake, weight gain, and blood levels. Guidelines for the frequency of monitoring were also recommended by the NIH consensus panel (**Table 3**). The method used for monitoring varies

Table 2 Recommended daily nutrient intakes (ranges) for infants, children, and adults with PKU

Age	*Nutrient*				
	PHE	*TYR*	*Protein*	*Energy*	*Fluid*
Infants	(mg kg^{-1})	(mg kg^{-1})	(g kg^{-1})	(kcal kg^{-1})	(ml kg^{-1})
0 to <3 months	25–70	300–350	3.50–3.00	120 (145–95)	160–135
3 to <6 months	20–45	300–350	3.50–3.00	120 (145–95)	160–130
9 to <12 months	15–35	250–300	3.00–2.50	110 (135–80)	145–125

Table 3 Monitoring for PKU

Age (years)	*Frequency of testing for phenylalanine*
0–1	Weekly
1–12	Twice monthly
12–adult	Monthly
Maternal PKU	Twice weekly

Adapted from NIH Consensus Development Conference Statement (2001) Phenylketonuria, screening and management. *Pediatrics* **108**(4): 972–982.

depending on the resources available at individual PKU clinics: either frequent visits to the clinic for blood drawing or filter paper samples (as used for newborn screening) that can be collected at home and then mailed to the clinic or, in some cases, to the newborn screening program, for analysis. Because of the time delay in the latter method, it is more suitable for use after the initial stabilization period.

When an infant with PKU is 4–6 months old, solid food is introduced. Since nearly all food contains some phenylalanine, it must be measured and counted. Lists of the phenylalanine content of foods are available and are essential to diet management. The phenylalanine content of foods is listed in milligrams; in some clinics, an exchange system is used where one exchange is equal to a given amount of phenylalanine (often 15 mg per exchange, but in some cases 20 or 50 mg). Since the total amount of phenylalanine taken daily remains the same (adjusted for weight gain), adjustments are made in the amount of regular infant formula or breast milk given to the infant once solid foods are started. This process continues until all of the phenylalanine requirement is provided as food. In general, infants with PKU begin with fruit and small amounts of infant cereal. As the infant's appetite increases, other foods are added, but the choices are limited to fruits, vegetables and, in some cases, small portions of bread and cereal products. For some individuals with PKU, the phenylalanine restriction is severe enough to preclude any regular grain products. Instead, specialty low-protein foods are available, often through mail order. A whole array of low-protein breads, cereals, crackers, bagels, pasta, cakes, cookies, and even low-protein cheeses and peanut butter are critical to proper diet management. These foods provide much needed variety and calories to the diet. High-protein foods such as meat, fish, poultry, dairy, nuts, eggs, and legumes are not allowed on a PKU diet. Thus, the phenylalanine-free medical food continues to be the main source of protein for life.

A wide variety of medical foods are now available for children and adults with PKU in order to meet different tastes and caloric needs. Some of the medical foods for children, teens, and adults are packaged in pouches or sachets for convenience, and several are available in bar, capsule, or tablet form to promote ease of use. Nevertheless, many individuals with PKU struggle with this aspect of the diet. If the full amount of medical food is not taken, nutritional intake is inadequate and may lead to catabolism of lean body mass, which in turn leads to poor control of blood phenylalanine.

Once established, the amount of dietary phenylalanine an individual is allowed remains the same, except for periods of rapid growth, when more phenylalanine may be necessary. A typical phenylalanine intake for a child with severe PKU is $250\,mg\,day^{-1}$, and for a child with moderate PKU is $400\,mg\,day^{-1}$. Thus, in addition to achieving the correct amount of medical food, the crux of the diet is to provide the prescribed amount of phenylalanine while making the diet taste and appear as appetizing and socially acceptable as possible. Families require a good deal of support in doing this. Internet-based support groups, newsletters, regional networks, family gatherings, as well as camps for children with PKU provide a link for families and a forum for exchange of practical information and emotional support. PKU clinic personnel are another source of support and reliable information on medical advances in treating PKU.

All patients with PKU should have their blood phenylalanine and other amino acids monitored regularly as long as they remain on the diet; they should have regular physical examinations, especially for assessment of growth parameters in children and adolescents, and review of the dietary intake since the previous visit. Extensive dietary counseling is an ongoing process. It is also recommended that adult patients who are not following phenylalanine-restricted diets with prescribed medical foods should be seen at least once a year for nutritional assessment, as they often tend to self limit their protein intake and may have inadequate diets.

Adequacy of Nutritional Therapy

Carefully executed diet therapy for individuals with PKU is widely considered to be safe as well as efficacious in preventing mental and neurological impairment. However, it cannot be assumed that largely synthetic diets supplemented with individual vitamins, minerals, and trace elements will confer the same benefits as diets composed of whole foods. Synthetic diets may have an inherent inability to supply all essential nutrients. In addition, patients who are noncompliant or partially compliant with their intake of medical food are at increased

nutritional risk. Formerly treated patients who are 'off diet' tend to select high-carbohydrate diets and continue their habit of avoiding high-protein foods such as meat, milk, and eggs. Micronutrients previously supplied by the medical food, such as vitamin B_{12}, zinc, and iron, may not be replaced in adequate amounts on such a self-selected diet.

Growth

A strict PKU diet supplies 80–90% of its prescribed protein via a phenylalanine-free medical food. Most of the nitrogen in medical foods is supplied via essential amino acids. Meals that supply most of the protein as L-amino acids result in more rapid absorption and oxidation than observed after consumption of whole-protein meals. L-amino acids also may not be as efficiently absorbed as whole protein. Owing to these reasons, protein requirements for patients with PKU are considered to be greater than those given in the WHO guidelines and recommended daily intakes (RDIs). Normal growth and protein status has been observed in infants consuming at least 3 g protein $kg^{-1}\,day^{-1}$. Long-term inadequate protein intake will result in impaired growth in infants and children, low plasma prealbumin concentrations, radiological bone changes (osteopenia), and reduced phenylalanine tolerance. Because phenylalanine is an essential amino acid, it is crucial to prevent its deficiency. Phenylalanine deficiency will result in catabolism of body protein stores and subsequent elevation of blood phenylalanine levels, anemia, and mental retardation as well as the above symptoms accompanying overall inadequate protein intake.

Fatty Acids

Diet-treated children and adults with PKU consume very small amounts of animal fats, including fish-derived oils and long-chain polyunsaturated fatty acids (LC PUFAs.) In infants, small amounts of cows' milk-based formula are typically used to supply phenylalanine requirements. The majority of fatty acids supplied are typically not longer than 18 carbons long. While many standard infant formulas in Europe and the US are now supplemented with docosohexanoic acid (DHA) and arachadonic acid (ARA), metabolic formulas are not. Fatty acids are a structural component of all cell membranes. Alpha linolenic acid-derived compounds are essential for proper development of the central nervous system and retina. Linoleic acid-derived compounds play a role in promoting normal growth, skin, and reproduction. Breast milk contains formed DHA and ARA, and some studies indicate that breast-fed infants have better visual and cognitive development than unsupplemented formula-fed infants. The diets of children with PKU provide similar energy, higher carbohydrate, and lower lipid (with high unsaturated/saturated ratio) and cholesterol content than controls. Circulating plasma lipid levels of treated PKU patients contain lower concentrations of arachadonic acid (ARA), docosahexanoic acid (DHA), and eicosapentanoic acid than controls. Erythrocyte membranes of patients contain relatively high amounts of ARA and relatively low amounts of DHA. In theory, patients receiving adequate amounts of the essential fatty acid precursors linoleic and alpha linolenic acids would be able to synthesize LC PUFAs via elongation and desaturation reactions. It is unclear whether the amount of LC PUFAs synthesized would be adequate for optimal tissue function. Especially in infants, DHA and ARA may be partially essential nutrients. Trials of LC PUFA supplementation in PKU patients are underway. A number of widely available PKU formulas for older children and adults do not supply fat. Patients prescribed these formulas are presently advised to regularly include good sources of linoleic and alpha-linolenic acids in their diets. Flax, canola, and walnut oils are good sources.

In theory, patients with poorly controlled phenylalanine levels cannot efficiently build reserves of DHA and ARA from precursors. Carnitine-dependent mitochondrial enzymes that also use a cofactor, alpha tocopherolquinone, perform elongation and desaturation reactions. Phenyllactate and phenylpyruvate, metabolic byproducts of phenylalanine, may inhibit the synthesis of the cofactor alpha tocopherolquinone. This process may be at least partly responsible for the mental retardation and microcephaly observed in untreated PKU patients and poorly controlled maternal PKU.

Iron, Zinc, Vitamin A, and selenium

Some diet-treated patients with PKU have exhibited altered iron, zinc, vitamin A, and selenium status. With the exception of selenium, aberrations have been demonstrated even when patients consumed close to or greater than the RDI levels of the vitamin/mineral in question. The mechanisms of these changes are unclear and may be multifactorial. The actual impact of these changes on the health of the individual patients is unknown.

Low serum ferritin but appropriate hemoglobin and mean erythrocyte volumes have been noted, even in patients consuming close to three times the recommended dietary allowance (RDA) for iron. Iron absorption or bioavailability may be inhibited by the presence of calcium and phosphorous salts, diets high in PUFAs, and dietary fiber. The presence of alterations in the PUFA composition of gut cell

membranes could affect iron absorption. In vitamin A-deficient rats, anemia occurred, which was not remedied by the administration of oral iron. This suggests that vitamin A deficiency in PKU patients could result in anemia unresponsive to iron therapy. The iron status of diet-treated patients should be serially monitored.

Low serum zinc has occurred in infants and children receiving greater than or equal to 70% of the RDA for zinc. Low serum zinc occurred more often in patients receiving casein hydrolysates than in patients receiving L-amino acids alone. Serum zinc may not be an accurate marker for assessment of zinc deficiency. Zinc absorption in general is inhibited by a PUFA-rich diet, fiber, phosphorous, and large amounts of iron. Competitive inhibition between calcium and zinc also occurs.

Low plasma retinol levels have been observed in infants and young children despite consumption of up to three times the RDA for vitamin A. Retinol is transported on retinol-binding protein (RBP); zinc is needed for the synthesis of RBP. Prealbumin is a carrier for RBP. RBP and zinc levels have been normal in nearly all patients with low retinol levels. Low prealbumin levels or abnormal release of RBP from prealbumin may be responsible for the low serum retinol levels. In fact, a number of children have low prealbumin levels despite receiving adequate protein and energy intakes.

Until recently, selenium was not routinely added to PKU formulas. In the past it was supplied to patients via contamination of foods grown in selenium-containing soil. Low serum, whole blood, urine, and hair levels of selenium have been observed in some patients with PKU on strict diet therapy. Low activity of the selenium-containing enzyme glutathione peroxidase also occurs. Clinical symptoms of selenium deficiency in the patients studied have not been reported.

Bone mineral density

Osteopenia is prevalent in diet-treated persons with PKU from early life. Reduced bone mineral density and/or bone mass has been detected in up to approximately 50% of patients screened by various methods. These methods have included DEXA (dual energy X-ray absorptiometry), pQCT (peripheral quantitative computed tomography), and SPA (single photon absorptiometry). The defect seems to be characterized by a reduction in the speed of bone mineralization, especially after 8 years of age. Osteoporosis is an important cause of morbidity and mortality in older adults in the general population. Reduction in bone mass increases the risk of fracture. A reduction of one standard deviation in spine bone mass is associated with a bone fracture rate of 2.0–2.5. Some authors have reported an increased fracture rate in children over 8 years of age with PKU.

The pathogenesis of osteopenia in PKU is under study. Discrepant associations have been reported between osteopenia and blood phenylalanine levels, serum vitamin and mineral levels, protein, vitamin and mineral intakes, serum markers of bone formation and PTH, and ratio of urinary minerals, to creatinine. One theory is that impaired mineralization is a direct effect of the lifelong disease process of PKU. The total and the bone-specific fraction of alkaline phosphatase are reduced in some patients. This reduction may affect osteoblast activity and impact bone formation and turnover. High blood phenylalanine levels have not been consistently correlated with osteopenia. High blood levels of phenylalanine and phenylalanine metabolites would result in their increased urinary excretion. Chelating of minerals with phenylalanine and phenylalanine derivatives could theoretically result in significant mineral losses.

Osteopenia may be an accumulated result of lifelong diet treatment or poor diet compliance at vulnerable stages of bone development. Compliant patients tend to have low variation in their lifelong intake of whole protein, as controlled amounts of whole protein are required to maintain good metabolic control. Compliant patients tend to have similar trends in overall intakes. Lack of adequate trace elements, whole protein, vitamins, and/or minerals may be culprits. Impaired absorption of the synthetic diet or the type of medical food used (hydrolysate versus elemental formulation) may exert an independent effect. Inadequate intakes of calcium and phosphorous are known risk factors for the development of osteoporosis in nonaffected persons. Tailoring medical foods to specifically deliver the amounts of calcium and phosphorous recommended in the new RDIs may help to prevent osteopenia.

Trials of calcitriol (1-25 (OH)2 D) supplementation in estrogenic patients with PKU are in progress. Calcitriol has been chosen as most patients already receive expected sun exposure from participating in normal outdoor activities, and their intakes of dietary vitamin D generally meet or exceed the RDA. Clairol has been shown to be a useful treatment; treated patients require close monitoring of urinary calcium excretion and blood calcium levels.

Maternal PKU

For women with PKU who intend to become pregnant, following a strict phenylalanine-restricted

diet and controlling blood phenylalanine to 120–360 mol l^{-1} is critical to offspring health. Women with PKU who have high blood phenylalanine levels are at high risk of having children with microcephaly, mental retardation, low birth weight, and congenital heart anomalies. In an International Study of Maternal PKU, women who had good metabolic control by 10 weeks' gestation had babies with good birth outcomes and development. In women with poor control, the degree of microcephaly and mental retardation was proportional to the level of blood phenylalanine. Congenital heart disease, on the other hand, was not directly related to the degree of metabolic control, suggesting that etiology is multifactorial, although in this study, no serious heart defects occurred when mothers were in good metabolic control by 10 weeks' gestation. The recommendation is for women to be on the diet for PKU and in good metabolic control before conceiving in order to prevent damage to the fetus. Nevertheless, many women come to medical attention during pregnancy, indicating the need for better strategies for keeping women on the diet for life or helping them return to the diet before pregnancy. While blood phenylalanine during pregnancy was the best predictor of outcome in maternal PKU in the Collaborative Study, other nutritional factors, including sufficient energy, protein, vitamin B_{12} and fat, also played an important role.

Alternative Therapies

Tetrahydrobiopterin (BH4)

Tetrahydrobiopterin (BH4) is the cofactor for phenylalanine hydroxylase. Some mutations for PAH are considered to be relatively milder than others; a number of studies have shown that certain of these mutations result in enzyme activity that may be improved by the addition of BH4 to the diet. In these cases, the degree of phenylalanine restriction needed to maintain good control could be liberalized, although not eliminated altogether.

Large Neutral Amino Acid Supplementation

The large neutral amino acids (LNAAs), phenylalanine, tyrosine, tryptophan, and the branched-chain amino acids share the same L-amino acid transport system across the blood–brain barrier. Therefore, high levels of phenylalanine in the blood impede the transport of these other amino acids into the central nervous system (CNS). Tyrosine and tryptophan are important neurotransmitter precursors, relative deficiency or imbalance of which may contribute to the neuropsychiatric symptoms seen in some adult PKU patients who have resumed an unrestricted diet. Treatment with supplemental LNAAs (in tablet form) theoretically will increase the competition with phenylalanine for transport into the CNS. A net reduction in phenylalanine and an increase in CNS tyrosine and tryptophan may result in improvement in symptoms. Long-term outcome data are not yet available. This treatment is not suitable for children or women in the childbearing years who might be contemplating pregnancy.

Nutritional Requirements

S A Atkinson, McMaster University, Hamilton, ON, Canada

Optimal nutritional support of infants in the first year of life is essential to attain normal trajectories of growth and development. Additionally, evidence supports the thesis that during critical periods of early development nutrition may be key to 'programming,' possibly through modification of gene expression or differential cell proliferation, that subsequently impacts on risk for chronic diseases in later life. Information on early nutrition programming is not sufficient to be used as a basis to set dietary standards for infants. However, the importance of adopting the quantity and quality of nutrients in human milk as a gold standard in the determination of nutrient recommendations has been reinforced by several agencies worldwide, such as the pioneering partnership between the Food and Nutrition Board of the Institute of Medicine in the United States and Health Canada.

Recommended nutrient intakes or dietary standards are produced by many countries as well as key international agencies such as the FAO/WHO. For infants, the recommended intakes are usually intended for term-born, healthy, and normally growing infants who have a birth weight of more than 2500 g (and thus not small for gestational age). In this article, the nutrient requirements outlined reflect recent reports of the Dietary Reference Intakes (DRIs) for the United States and Canada as published by the Institute of Medicine. For a summary of the range of recommended nutrient intakes for infants that reflect a review of several international reports, the reader is referred to the March of Dimes document, *Nutrition Today Matters Tomorrow* (Appendix D-2).

The key changes in the derivation of the DRIs for infants compared to previous dietary standards from the United States and Canada include adoption of human milk as the reference model for setting recommended nutrient intakes for infants; simplification of age groupings within the first year; no specific provision of dietary recommendations for formula-fed infants; and gender-specific DRI values for fewer nutrients and only where data were available to support such gender specificity. Another major change from previous dietary standards is that upper levels (ULs) for nutrient intake were defined for the first time. Unfortunately, for infants, few ULs were established due to a paucity of pertinent knowledge; even for ages 1–18 years, the UL values were mostly extrapolated from adult values.

This article provides an overview of key concepts and examples of the DRIs specific for infants, future needs for additional research, and practical aspects of meeting the dietary recommendations for infants.

Dietary Reference Intakes for Infants

For infants, evaluation of evidence to establish the DRIs consistently revealed a paucity of appropriate studies on which to base an Estimated Average Requirement (EAR) or UL. A Recommended Dietary Allowance (RDA) could not be calculated if a value for the EAR was not established, in which case the recommended intake was based on an Adequate Intake (AI). The nutrient recommendations for infants from birth through 6 months of age for all nutrients except for energy and vitamin D were set as an AI, a value that represents "the mean intake of a nutrient calculated based on the average concentration of the nutrient in human milk from 2 to 6 months of lactation using consensus values from several reported studies," multiplied by an average volume (0.780 l/day) of human milk. The predicted daily volume of breast milk ingested by an infant was based on observational studies that used test weighing of full-term infants. For infants aged 7–12 months, the AI for many nutrients was based on mean observed nutrient intake from human milk in the second 6 months (0.6 l/day) in addition to published values for intake of nutrients from complementary or weaning foods if such data were available.

Assuming an adequate intake of milk for all infants was considered a valid approach since there is evidence that the volume of milk produced during the early months of lactation is very consistent

among women irrespective of racial, cultural, or nutritional diversity or variations in body size. The volume of milk produced increases with greater size of the infant, when twins are nursing, and in response to greater frequency of nursing.

Using consensus values for the nutrient content of human milk was deemed appropriate since for many nutrients—energy, macronutrients, and macrominerals—maternal diet does not influence the nutrient content of the milk. The exceptions to this include the fatty acid profile, selenium, iodine, and the water-soluble vitamins. Although human milk is known to contain many nonnutrient bioactive factors, such as immune and growth factors and live enzymes, these were not considered to impact on nutrient needs *per se*.

For nutrients for which intake data were not available for ages older than 6 months, the EAR or AI was derived by extrapolation from estimates of intakes from older children or adults using the formula with adjustments for metabolic body size, growth, and variability:

$$\mathrm{EAR}_{\text{infant or child}} = \mathrm{EAR}_{\text{child or adult}} \times (F)$$

where $F = (\text{weight}_{\text{infant or child}}/\text{weight}_{\text{child or adult}})^{0.75}$ (1 + growth factor); or occasionally by extrapolating up from intake of breast-fed infants with similar adjustments using the formula

$$\text{AI } 6-11 \text{ months} = \text{AI } 0-5 \text{ months} \times F$$

where $F = (\text{weight}_{6-11 \text{ months}}/\text{weight}_{0-5 \text{ months}})^{0.75}$

For a few nutrients, such as iron and zinc, sufficient metabolic data were available to derive an EAR using modeling or factorial methods.

Because no specific AIs were derived for formula-fed infants, it is incumbent upon industry to design formulas with a quantity and quality of nutrients that when fed will provide an amount of nutrients that meets the RDA or AI. An approach to establishing the amount of nutrient needed by formula-fed infants is addressed under the section titled "Special Considerations" in each DRI report.

When possible, a DRI called the tolerable upper level was defined as "the highest level of daily nutrient intake that is likely to pose no risk of adverse health effects for almost all individuals in the general population" (Institute of Medicine, 2002). Chronic consumption of nutrients above the UL increases the potential risk of adverse effects, the latter varying by nutrient. For infants, data were only available to reliably estimate ULs for vitamins A and D and the minerals fluoride, selenium, zinc, and iron. Although adequate data were not available to define a UL for infants for other nutrients, it is important to note that intake for nutrients for which a UL does not exist should only be consumed from food or formula and not from supplements. Also notable is that the UL for iron for infants is only relevant to intake from supplements and not foods.

Summary of DRIs for infants

Macronutrients: Energy, Carbohydrate, Fat, Protein, and Amino Acids

Energy The estimated energy requirement (EER) for infants was derived by summing predicted total energy expenditure (TEE) and energy deposition for growth. Because the energy needs for growth decelerate with advancing age, an equation for EER was established for three age intervals during the first year of life (**Table 1**). The TEE is calculated using an equation (**Table 1**) based on energy expenditure measured by doubly labeled water and adjusted for weight of the child. The EER is then the sum of TEE for an individual child plus the predicted energy deposition for age (**Table 1**). No adjustment for physical activity was included in the EER for infants. Examples of the EER for males and females using reference weights are shown in **Table 1** for infants at five ages during the first year. At most ages beyond the first 2 months of life, the values for EER exceed the average energy provided (500 kcal) by human milk assuming a volume of intake (0.780 l/day) from human milk.

Table 1 DRI estimated energy requirement (EER) for infants[a]

Equations	
0–3 months	(89 × weight of infant (kg) − 100) + 175 (kcal for energy deposition)
4–6 months	(89 × weight of infant (kg) − 100) + 56 (kcal for energy deposition)
7–12 months	(89 × weight of infant (kg) − 100) + 22 (kcal for energy deposition)

Calculated EER for age using reference weights for age

Age (months)	*Males (kcal/day)*	*Females (kcal/day)*
1	472	438
3	572	521
6	645	593
9	746	678
12	844	768

[a]From the Institute of Medicine (2002) *Dietary Reference Intakes for Energy, Carbohydrates, Fiber, Fat, Protein, and Amino Acids (Macronutrients)*. Washington, DC: National Academy Press.

Carbohydrate The AI for carbohydrate for infants through 1 year of age is based on the average carbohydrate intake from human milk and complementary foods for the 7- to 12-month age group (**Table 2**). Although the carbohydrate from human milk is almost exclusively lactose and that from infant formula may be lactose, sucrose, or glucose polymers alone or in combination, there is no evidence that non-lactose-containing formulas vary from lactose contained in human milk with regard to available energy.

Fat As for other nutrients, the AI for fat intake is based on the average intake of fat from human milk alone or in addition to complementary foods after 7 months of age (**Table 2**). Although infant formulas are designed to contain a percentage of energy as fat similar to human milk (approximately 50%), the type of fat in formulas varies widely, including such sources as safflower, sunflower, soybean oil, and coconut and palm oils, usually in some combination.

Linoleic acid (n-6) and α-linolenic acid (n-3) The n-6 fatty acids are essential for infants, and in extreme long-term deficiency skin lesions and delayed growth may develop. Linoleic acid serves as a precursor of arachidonic acid (AA), which is required for synthesis of prostaglandins and other eicosanoids. The n-3 fatty acids are also essential as a precursor of docosahexenoic acid (DHA), which comprises a large percentage of the fatty acids incorporated into developing brain and retina, and of eicosapentenoic acid, which is the substrate for eicosanoid synthesis. Human milk is a natural source of both fatty acid families, including the long-chain polyenoic derivatives DHA and AA. The pattern of all fatty acids in human milk, including the polyenoic fatty acids, is dependent on maternal diet. The AI established for infants for n-6 and n-3 fatty acids is based on the average content in human milk reported for North American women with the addition of that from complementary foods during months 7–12 (**Table 2**).

Feeding of mother's milk compared to cow milk-based infant formula has been associated with a positive benefit to developmental outcomes (cognitive, motor, and vision) in both retrospective and prospective studies (but not randomized trials for obvious ethical reasons). To date, investigations of the nutrient(s) possibly responsible for the observed benefits of mother's milk on neurodevelopment have focused on the long-chain polyenoic fatty acids DHA and AA. These fatty acids represent the greatest proportion of polyenoic fatty acids contained in phospholipids of neural and retinal tissues, and they are present naturally in human milk. Until very recently, DHA and AA were not provided in infant formulas, but such formula is now marketed globally.

A positive benefit of breast-feeding compared to formula feeding on short-term visual and developmental outcomes in term and premature infants has been observed in several studies. However, the evidence for a benefit is more consistently observed in premature than in term infants, perhaps due to a greater immaturity of their enzymatic pathway to convert α-linolenic and linoleic acids to the long-chain polyenoic derivatives. Due to the conflicting evidence, specific requirements for DHA and AA for term infants were not included in the recent DRI report.

Protein For infants age 0–6 months, the AI for protein is based on the intake from human milk (**Table 2**). For infants age 7–12 months, sufficient information was available from nitrogen balance studies and protein deposition to derive an EAR based on the factorial method. For both males and females, this averaged 1.1 g protein/kg body weight/day. The RDA was set as the EAR + 2 standard deviations (based on coefficients of variation observed in adults), which yielded a value for protein intake of 1.5 g/kg/day. Because the absorption and digestibility of protein contained in infant formula may be less efficient than from human milk, the quantity of protein contained in infant formulas may have to be adjusted depending on the protein source used.

Amino acids The DRI for the essential (indispensable) amino acids for infants was derived from the content of human milk for ages 0–6 months. For older infants, an EAR was derived for these amino acids using a factorial estimate that was based on

Table 2 DRI for macronutrients for infants—carbohydrate, protein, fat, and essential fatty acids[a]

Nutrient[b]	*0–6 months*	*7–12 months*
Carbohydrate, AI (g/day)	60	95
Protein		
AI (g/day)	9.1	—
RDA (g/day)	—	13.5
Total fat, AI (g/day)	31	30
Linoleic acid (n-6), AI (g/day)	4.4	4.6
α-Linolenic acid (n-3), AI (g/day)	0.5	0.5

[a]From the Institute of Medicine (2002) *Dietary Reference Intakes for Energy, Carbohydrates, Fiber, Fat, Protein, and Amino Acids (Macronutrients)*. Washington, DC: National Academy Press.
[b]No upper levels of nutrients were set for any macronutrients.
AI, Adequate Intake; RDA, Recommended Dietary Allowance.

Table 3 DRI for indispensible (essential) amino acids[a]

Amino acid[b]	*0–6 months*[c]	*7–12 months*
	AI (mg/kgday)	*RDA (mg/kg/day)*
Histidine	23	32
Isoleucine	88	43
Leucine	156	93
Lysine	107	89
Methionine + cysteine	59	43
Phenylalanine + tyrosine	135	84
Threonine	73	49
Tryptophan	28	13
Valine	87	58

[a]From the Institute of Medicine (2002) *Dietary Reference Intakes for Energy, Carbohydrates, Fiber, Fat, Protein, and Amino Acids (Macronutrients)*. Washington, DC: National Academy Press.
[b]No upper levels were set for any of the indispensable amino acids.
[c]AI values shown as amino acid in mg/kg/day can be converted to mg amino acid/day by multiplying by the reference weight of 6 kg for infants 0–6 months of age.

the amino acid needs for growth or protein deposition, with adjustments for efficiency of protein deposition and maintenance requirement. The RDA was determined by adding the coefficient of variation derived for maintenance and protein deposition to the value for the EAR. No values were set for UL for any of the amino acids. A summary of the AI and RDA for the indispensable amino acids of infants is provided in **Table 3**.

Other macronutrients For infants, no DRI was set for saturated fat, monounsaturated fat, *trans* fatty acids, and cholesterol or dietary fiber. Although some dietary fiber is present in the diet after solid foods are introduced, there are no data on fiber intakes in such young age groups and no theoretical basis exists on which to establish a need for fiber at less than 1 year of age.

Macrominerals: Calcium, phosphorus, magnesium, and fluoride The AI for infants for the "bone" minerals are summarized in **Table 4**. The content of human milk was used as the basis to derive the AI for calcium, phosphorus, and magnesium for infants age 0–6 months and with the addition of intake from complementary foods for those age 7–12 months. For fluoride, intake from human milk was the reference for the first 6 months only. After 6 months, the AI for fluoride was set at 0.05 mg/kg/day and adjusted to a reference weight for age, based on the well-documented evidence of the benefit of fluoride intake for the prevention of dental caries (**Table 4**).

Table 4 DRI for minerals for infants—calcium, phosphorus, magnesium, and fluoride[a]

Nutrient	*0–6 months*	*7–12 months*
Calcium		
AI (mg/day)	210	270
UL	ND	ND
Phosphorus		
AI (mg/day)	100	275
UL	ND	ND
Magnesium		
AI (mg/day)	30	75
UL	ND	ND
Fluoride		
AI (mg/day)	0.01	0.5
UL (mg/day)	0.7	0.9

[a]From the Institute of Medicine (1997) *Dietary Reference Intakes for Calcium, Phosphorus, Magnesium, Vitamin D and Fluoride*. Washington, DC: National Academy Press.
AI, Adequate Intake; ND, not determinable due to lack of data of adverse effects in infants; RDA, Recommended Dietary Allowance; UL, upper limit.

Microminerals/trace elements The AI for iron for ages 0–6 months is based on the concentration of iron in human milk albeit low (approximately 0.35 mg/l) but assumes the infant is born with maximal iron stores due to transplacental transfer of iron from an iron-replete mother. If the latter conditions do not apply, then an exogenous source of iron such as iron drops may be required. For infants age 7–12 months, an EAR and RDA were developed based on a factorial modeling method that summed basal loss of iron with needs for growth, increasing hemoglobin mass, and iron stores. This value was then adjusted for iron bioavailability using a factor of 10% for infants due to a medium bioavailability of iron from infant cereals, which are generally the major dietary source of iron in weaning foods before meats are introduced (**Table 5**). A UL was established (**Table 5**) for iron based on the risk of adverse gastrointestinal side effects from supplemental (not food) iron.

For zinc, an AI was based on the human milk model only for the 0- to 6-months age group (**Table 5**). The zinc content of human milk declines rapidly during the first 6 months (from 4 to 1.2 mg/l), so the AI was based on a milk zinc concentration of 2.5 mg/l. This value cannot be directly applied to infants being fed cow milk- or soy-based infant formulas because zinc absorption is significantly lower from these compared to human milk. The EAR for the 7- to 12-months age group was set using a factorial method that summed obligatory losses with requirements for growth and adjusted for fractional absorption of dietary zinc from human milk and complementary foods. The RDA

AI, Adequate Intake; ND, not determinable due to lack of data of adverse effects in infants; RDA, Recommended Dietary Allowance; UL, upper limit.

was derived by adding twice the coefficient of variation of 10% to the EAR (2.5 mg/day of zinc) for infants 7–12 months (**Table 5**). A UL was set for zinc on the basis of the possibility of an adverse effect of high zinc intakes on copper status.

For the trace elements chromium, copper, iodine, manganese, molybdenum, and selenium, an AI was set for infants age 0–6 months based on the human milk model (**Table 5**). For the age group 7–12 months, data on intake from complementary foods were only available to set an AI for chromium, copper, and selenium (**Table 5**). For iodine and molybdenum, the AI represents an extrapolation up from the AI values for the age group 0–6 months based on differences in metabolic body weight ($kg^{0.75}$). For manganese, the AI represents an extrapolation down from the AI for adults as described previously (**Table 5**). Due to lack of relevant information no UL values for infants younger than 1 year of age were established for chromium, copper, iodine, manganese, or molybdenum, but intakes of these nutrients should be limited to foods and not supplements. A UL was established for selenium due to the known toxicity of chronic excess selenium ingestion, which presents clinically as brittleness and loss of nails and hair. The UL was set for infants based on the highest known intake of selenium from human milk and adjusting for a reference infant weight (**Table 5**). The UL value pertains to intake from both foods and supplements.

The trace elements arsenic, boron, nickel, silicon, and vanadium are recognized as having a role in human metabolism, but due to lack of information DRI values, including UL, could not be established for infants.

Globally, deficiencies of iron, iodine, and zinc in infants are still widespread despite international efforts to develop sustainable food fortification and supplementation programs. In North America, the prevalence of iron deficiency anemia is relatively low at 4–5% owing to the promotion of breast feeding and the widespread fortification of infant formulas and cereals with iron. In developing countries, prevalence of anemia can be 50% or more by one year of age. Premature and/or low birth weight (<2.5 kg) infants represent a particular risk group for iron deficiency owing to a major reduction in transplacental transfer of iron when birth occurs during the third trimester of pregnancy, the period when most iron is transferred to the fetus as long as the mother is not iron deficient. Infants of low birth weight require iron supplementation in a liquid form until complementary foods containing iron can be introduced. Use of weaning foods that are not iron-fortified and that often contain phytic acid, a strong inhibitor of iron absorption, is a key causative factor for high rates of anemia in many developing countries.

Fat-soluble vitamins A, K, E, and D For vitamins A, K, and E, the AI for infants 0–6 months of age was based on the human milk model as previously described (**Table 6**). For vitamins A, K, and E, the AI for infants 7–12 months of age was extrapolated up from the values for 0–6 months using a reference weight for infants at this age. There are two important points with respect to the AI established for vitamin K. First, the AI was set assuming infants had received a prophylactic injection of vitamin K just after birth. Since vitamin K is not readily transferred to the fetus while *in utero*, and human milk is relatively low in vitamin K, newborn infants, at least in North America, routinely receive an injection of vitamin K within a few hours after birth. Second, the AI set for ages 7–12 months may be lower than the actual intake of vitamin K once a child's diet of

complementary food becomes varied. Any evaluation of dietary intake of vitamin K should use the recently updated vitamin K values for raw and cooked foods available from the USDA National Nutrient Database for Standard Reference, Release 17 (http://www.nal.usda.gov/fnic/foodcomp/Data/SR17/wtrant/wt_rank.html). Although carotenoids are present in human milk, a factor to calculate their bioconversion to vitamin A is not known so their contribution to vitamin A was not included.

For vitamin D, it was determined that a dietary (or supplement) intake of 100 IU would likely prevent rickets but not maintain normal circulating concentrations of 25-hydroxyvitamin D. Thus, assuming that most infants obtain minimal or no vitamin D via exposure to sunlight, an AI of 200 IU (5 μg) was established. This amount of vitamin D was also recommended for infants 7–12 months of age assuming most infants could maintain normal vitamin D status with this intake. The AI for vitamin D set by the Institute of Medicine was adopted by the American Academy of Pediatrics (AAP). The AAP recommended a minimum intake of 200 IU vitamin D per day for all infants beginning during the first 2 months of life in recognition of the risk in vitamin D-deficiency rickets in the United States, especially among infants who are breast fed for a number of months without vitamin D supplementation. In Canada, a recent recommendation by Health Canada (2004) was for all breast fed infants to receive 10 μg (400 IU)/day of vitamin D from birth until their diet included equal amounts of vitamin D from other food sources. Considerations for this recommendation (rather than 5 μg (200 IU)/day of the DRI) included lack of sun exposure owing to Canada's northern geographic latitude, current practices related to protection from the sun, and an increasing prevalence of vitamin D deficiency rickets in infants.

Water-soluble B vitamins, folate, choline, and vitamin C The AIs for infants age 0–6 months for most water-soluble vitamins were based on the content of human milk (**Table 7**). This approach may be problematic for water-soluble B vitamins, in which milk content is dependent on maternal intake of vitamins. An example of clinical relevance is the vegan mother

AI, Adequate Intake; UL, upper limit.

who may have subclinical vitamin B_{12} deficiency and produce B_{12}-deficient milk. For vitamin C, the effect of maternal supplementation on milk content remains uncertain, but available reports do not indicate that excessive amounts of vitamin C are secreted in milk, even in mothers taking supplements of 1000 mg or more. For age 7–12 months, the AI for thiamin, riboflavin, niacin, folate, pantothenic acid, and choline was derived by extrapolation down from values for older children or adults due to a lack of information of dietary intake of these nutrients from solid foods. Tolerable ULs for infants were not established for any of the water-soluble vitamins.

Water and electrolytes Optimal water intake in infants is more critical than at any other period of life. Not only do infants have higher total body water content per body mass than children or adults but also they have a higher water turnover rate, a less well-developed sweating mechanism, and little ability to indicate when they are thirsty. The AI for water intake of infants age 0–6 months is 0.7 l/day and is based on the water content of human milk. Assuming infants are breast-fed on demand, infants will drink to meet thirst needs; thus, even in hot and humid climates supplemental water should not be required. The AI for water intake of 0.8 l/day set for 7–12 months is based on the sum of the water content of human milk, complementary foods, and beverages, the latter obtained from reported food intakes from surveys in the United States.

For sodium and potassium, the AI of 0.12 g/day and 0.4 g/day, respectively, is based on the human milk model. For 7–12 months, the AI for sodium is 0.37 g/day and for potassium is 0.7 g/day based on the sum of observed intakes from human milk and complementary foods. No ULs were established for infants due to lack of data on adverse effects of these nutrients on infant health. However, particularly because the renal excretory capacity of young infants may not be able to handle excess amounts of ingested electrolytes, the DRI report notes that intake of sodium, chloride, and potassium should be limited to human milk (or infant formula) and solid foods appropriate for age.

Assessment of Growth as an Indication of Adequate Nutrition

Assessment of growth in weight, length and head circumference is an internationally accepted measure of health and nutritional status of infants, albeit not an indicator that is nutrient specific. The interpretation of growth measures requires comparison with reference data from normal populations of infants that have been complied into growth charts with centiles indicated. The growth charts from the Center for Disease Control in the United States as revised in 2000 (http://www.cdc.gov/nchs/about/major/nhanes/growthcharts/charts.htm), were adopted for use in the USA and Canada as well as by the World Health Organization (WHO) for use internationally. The growth charts as shown in **Figures 1–6** may be downloaded from the CDC website and copied. Weight gain of exclusively breast fed infants is more rapid than formula-fed infants in the first 2 to 3 months but they weigh less from 6 to 12 months. The longitudinal data that form the basis of the growth charts for infants from birth to 36 months growth represent a mix of both breast and formula fed infants from the American population. A Working Group of WHO has undertaken a project to develop growth charts specifically for exclusively or predominantly breast fed infants but these are not yet available.

Research Needs

The paucity of sound evidence on which to provide a substantial basis for estimating the nutrient requirements for infants is highlighted at the end of each chapter in the DRI reports. Since infants and children are not just "little adults," the DRI values must be carefully defined for the specific stages of growth and development and with consideration for nutritional programming that occurs in early life in response to dietary exposures as our knowledge of this area becomes more complete.

Practical Aspects of Meeting the Nutrient Needs of Infants

Adequate amounts of breast milk meet the nutrient needs of most infants for the first 6 months of life. However, there is not universal agreement on the optimal duration of exclusive breast feeding and the precise timing or the order of introduction of complementary foods. Internationally, recommendations from most health agencies state that the ideal feeding of infants is exclusive breast feeding for the first 6 months of life with appropriate introduction of foods from 6 months onward including partial breast feeding through 2 years of age or beyond. When assessing intakes of infants fed marketed formulas, it must be kept in mind that intakes of most nutrients will exceed the new DRI values for AI given that these are based on the composition of human milk. In many cases, the greater concentration of nutrients in infant formula is appropriate due

to lower digestibility or bioavailability of nutrients from cow milk- or soy-based protein in formulas compared to human milk.

The introduction of complementary foods, especially solids and eventually finger foods, is important for infants to develop normal oral and motor skills related to eating and to attain adequate intakes of nutrients that may be low in breast milk (e.g., protein or iron). In a report by the March of Dimes, three common inappropriate complementary feeding practices were delineated: (i) introducing foods too early or too late, (ii) introducing foods of low nutrient density, and (iii) feeding contaminated foods. It is noted in the report that early introduction of foods may reduce the intake of breast milk due to limited gastric capacity of very young infants or precipitate an allergic reaction in infants with a family history of food allergy or atopy. By delaying introduction of foods beyond 6 months, there is increasing risk of deficiencies of nutrients known to be relatively low in breast milk and yet essential to support rapid growth of infants, such as iron and zinc. The choice of first foods is important so that they contain adequate energy and micronutrients to meet the needs of infants. For example, reduced-fat cow milk (skim 2%, and 1% fat) should not be fed to infants before 2 years of age. Excessive amounts of fruit juices or 'empty calorie' fast foods should not be fed to infants. To achieve adequate intakes of micronutrients such as iron, choice of nutrient-fortified foods (e.g., iron-fortified infant cereal or other weaning food) may be required in areas where natural sources of micronutrients are not available. Finally, both solid and liquid foods offered to infants need to be free of contamination since the transmission of infections through food is thought to be a primary cause of diarrhea in young infants, particularly in developing countries.

The March of Dimes report (2002) outlined three key recommendations for ensuring optimal nutrition of term-born infants through breast-feeding and complementary feeding practices. The rationale for each recommendation and suggestions for implementation strategies on a global basis are provided in the report. The three key recommendations are as follows:

> Recommendation 1: Promote and support exclusive breast feeding for 6 months, with the introduction of complementary foods and continued breast feeding thereafter—up to 2 years of age or longer as mutually desired by the mother and infant.
>
> Recommendation 2: Promote and support programs to ensure that pregnant women and breast feeding mothers receive adequate nutrient intakes.
>
> Recommendation 3: Promote the appropriate introduction of safe, nutritionally adequate, and developmentally appropriate complementary foods.

The recommendations from the March of Dimes report are universally applicable and will ensure that infants attain nutrient intakes that match the nutrient requirements as set out in dietary standards such as the DRI reports.

Feeding Problems

R M Katz, Johns Hopkins University School of Medicine and Mount Washington Pediatric Hospital, Baltimore, MD, USA
L Schuberth, Kennedy Krieger Institute, Baltimore, MD, USA
C S Gulotta, Johns Hopkins University and Kennedy Krieger Institute, Baltimore, MD, USA

Feeding is the process by which growing children accept and digest food in amounts adequate to meet their nutritional needs. What seems at first glance to be a simple intuitive act is actually a complex process requiring successful caregiver interaction, adequate oral motor skills, and intact gastrointestinal motility and absorption. The term 'feeding disorder' is applied to situations in which young children are unable or unwilling to eat enough to maintain their nutritional needs. The *Diagnostic and Statistical Manual of Mental Disorders*, a compendium of diagnoses and the related criteria, more specifically defines pediatric feeding disorders as "persistent failure to eat adequately as reflected in significant failure to gain weight or significant weight loss over at least one month." Feeding disorders are surprisingly common in children, and it has been reported that 25–35% of normal children will have mild feeding disorders and up to 70% of premature infants will have more severe feeding problems. Clinical manifestations include food refusal/selectivity, gagging, vomiting, swallowing difficulty, poor weight gain, or failure to thrive. These can be grouped into medical, oral motor, and behavioral categories, although many children have overlapping problems.

Certain groups may be at a higher risk for feeding difficulties. For example, children with food allergy may have accompanying gastroesophageal reflux and motility disorders, which then result in food refusal. A variety of medical conditions, such as cardiopulmonary, genetic, and metabolic disorders, can lead to poor appetite and slow weight gain. Oral motor and/or swallowing problems are commonly seen in children with congenital and acquired neurologic conditions such as cerebral palsy, structural abnormalities, or traumatic brain injury. Premature and medically fragile infants may miss sensitive periods of oral motor development resulting in delayed acquisition of feeding skills. This early interruption of feeding skills can lead to serious feeding disorders and food refusal due to lack of experience and impaired oral sensitivity.

Lastly, behavioral difficulties such as food refusal or selectivity are not always isolated problems. More often, they develop when medical illness adversely affects feeding patterns and caregiver interactions. If a child is failing to thrive, the most immediate solution to address the lack of weight gain and growth is to start nasogastric or gastrostomy tube feeding. However, this supplemental feeding often results in a decrease in oral intake, which ultimately impacts on hunger, experience, and endurance. Medical issues (i.e., reflux, cleft palate, etc.) that occur very early in infancy can be the initial cause for food refusal. Consequently, for the majority of children with a feeding disorder, an early avoidance pattern is established. The parent–child interaction usually exacerbates this pattern. For example, because of severe reflux the child learns to associate eating with pain. Consequently, when the parent tries to feed the child, he or she will often encounter severe refusal behavior, which leads most parents to terminate the meal prematurely. At this point, the child not only has associated food with pain but also has learned that by having severe food refusal the meal will be terminated. Even when the reflux is medically managed, the child will still have the learned history of pain associated with eating, and the child will also have the new history of having refusal behaviors to escape the meal.

Normal Development of Feeding and Swallowing

In order to understand feeding and swallowing disorders, one must recognize that there are dynamically changing developmental skills and social abilities in the growing child. Progression through the normal stages of feeding (**Table 1**) requires the attainment of physical abilities such as postural stability, oral motor coordination, and sensory awareness. In addition, factors such as emerging cognitive skills and

Table 1 Normal infant feeding

Age	*Stage*
Birth–12 months	Suck/swallow liquids (breast or bottle)
4–6 months	Pureed solids by spoon (cereal, fruits, vegetables, and meats)
8–9 months	Cup drinking liquids
	Ground or junior foods by spoon
	Finger feeding soft dissolvables
10–12 months	Soft table food
24 months	Self-feed with utensils

socialization play an important role in an effective caregiver–child feeding interaction.

The Swallowing Process

Understanding the mechanisms involved in eating can also be useful in understanding why a child is refusing to eat. The swallowing process is usually divided into three phases: oral, pharyngeal, and esophageal. In the newborn and young infant, all phases are driven reflexively by typical rooting and sucking behavior. As children age, the oral phase of chewing and managing food comes under more voluntary control, requiring cortical integration of sensory/motor input to coordinate the complex patterns of jaw, tongue, and oral movements. Factors such as smell, taste, and emotion become increasingly important. Once the process of chewing is completed, the tongue and soft palate propel the bolus toward the pharynx, initiating the pharyngeal phase of swallowing. As food progresses through the pharynx, a complex sequence of movements allows the safe passage of food around the airway into the esophagus. Closure of the mouth and nasal/laryngeal passages prevents aspiration while elevation and anterior displacement of the larynx opens the upper esophageal sphincter. This automatically generates a pressure gradient, which propels the bolus toward the esophageal opening. Once the food progresses to the esophageal phase, the subsequent movements are almost entirely automatic and no longer subject to cortical control. After passing the lower esophageal sphincter, food normally enters the stomach, beginning the gastrointestinal and absorptive phase of feeding. Food is emptied from the stomach based on the volume, nutrient composition, and caloric density of the meal.

Classification of Feeding Disorders in Children

A single underlying cause for why children refuse to eat enough to sustain normal growth is rarely evident, and therefore this problem presents a significant diagnostic and therapeutic challenge to clinicians and parents. Given the complexity of this challenge, numerous attempts at classifying feeding disorders have been made based on the apparent etiology, physical condition, or associated behaviors. Because most feeding disorders are the result of multiple factors (i.e., physical, motivational, skill, and parent/child relationships), a more functional classification has been developed that allows differentiation of patient types by symptoms rather than an arbitrary disease-based diagnostic approach (**Table 2**).

Table 2 Common feeding disorder symptoms

Food refusal—partial/total
Liquid dependent
Enteral tube dependent
Food selectivity
Texture
Type

Children with food refusal who require any kind of enteral tube feed would be categorized as 'food refusal—enteral tube dependent,' whereas a child who drinks more than 80% of his or her calorie requirement would be considered 'food refusal—liquid dependent.' Another feeding problem category is 'food selectivity—type.' In this category, children would eliminate 75% of the four basic food groups. Typically, a child with this categorization would have the skill to eat but would choose to only eat one or two different foods and restrict all other foods. The child may or may not be able to sustain normal growth with this kind of diet. 'Food selective—texture' describes a child who does not eat an age-appropriate texture of food due to lack of skill or oversensitivity to a particular food texture—for example, a 5-year-old child who only eats pureed foods when he or she should be able to handle regular textured food. Again, the child may or may not sustain normal growth.

Assessment

An appropriate assessment of a child's feeding disorder is a critical first step in initiating treatment. The management of complicated feeding disorders usually requires a multidisciplinary team devoted to establishing diagnosis, assessment of need, and developing a thorough treatment plan. This team may include a variety of pediatric specialists, including physicians (e.g., general pediatricians, developmental pediatricians, pediatric gastroenterologists, allergists, and otolaryngologists), nurse practitioners, nutritionists,

occupational therapists, speech therapists, psychologists, and social workers. The assembled team must begin its approach to diagnosis and therapy with complete history taking by all interested parties. This includes a careful prenatal, birth, and neonatal history. In addition to determining the nutritional and medical status of the child, an appropriate psychological and developmental pediatric evaluation must be performed.

Physicians

An important goal of the physician history taking is to assess for any comorbid conditions that would require treatment prior to the implementation of a therapeutic treatment program for the food refusal (**Table 3**). As part of the initial evaluation, an observation of a feeding session between the child and primary caregiver will often provide insight into the feeding problem, especially from an oral motor/sensory and behavioral perspective. Clinical signs of oral motor dysfunction, length of meals, and nature of the caregiver–child interaction are all noted. Observation of the muscle tone, posture, and positioning as well as special seating systems and feeding devices is routine because this can provide insight into the child's overall neurological functioning. Physical examination of the child includes a general survey examination for the determination of any underlying medical disorders that may preclude safe feeding. This includes evaluation of tongue and jaw movement, dentition, airway sounds, speech, and oral cavity assessment. Additionally, a complete physical examination including cardiac, pulmonary, and abdominal exams is mandatory.

Table 3 Medical conditions associated with pediatric feeding disorders

Disorders of the oral and pharyngeal phases of swallowing
Anatomic lesions
– Cleft lip and/or palate
– Pierre–Robin sequence
– Choanal atresia
– Laryngeal clefts
– Macroglossia
– CHARGE association
Acquired structural abnormalities
– Dental caries
– Tonsillar hypertrophy
– Viral/inflammatory stomatitis
– Retropharyngeal mass
– Candida stomatitis
Cardiopulmonary effects
– Chronic lung disease
– Complex congenital heart disease
– Reactive airway disease
– Tachypnea
Neuromuscular disorders
– Familial dysautonomia
– Cerebral palsy
– Pseudo-bulbar palsy
– Bulbar atresia or palsy
– Cranial nerve anomalies
– Muscular dystrophic disorders
– Arnold–Chiari malformation
– Myelomeningocele
– Intracranial mass lesions

Disorders of the esophageal phase of swallowing
Anatomic lesions
– Esophageal atresia
– Cricopharyngeal achalasia
– Tracheoesophageal fistula
– Esophageal mass
– Esophageal stricture
– Esophageal web
– Esophageal rings
– Vascular rings/aberrant vessels
– Foreign bodies

Disorders of the lumen
– Peptic esophagitis
– Candida esophagitis
– Viral esophagitis
– "Pill" esophagitis
– Inflammatory bowel disease
– Behcet syndrome
Motility disorders
– Achalasia
– Diffuse esophageal spasm
– Chronic pseudo-obstruction
– Systemic lupus erythematosis
– Polymyositis
Genetic disorders
– Prader–Willi syndrome
– Trisomy 21
– Cornelia de Lange syndrome
– Velocardiofacial syndrome
– Rett syndrome
Metabolic disorders

Diagnostic Testing

Diagnostic evaluations may be warranted to better assess swallowing and anatomy (**Table 4**). The modified barium swallow study (MBS) is the procedure of choice to assess oral, pharyngeal, and upper esophageal phases of swallowing. Seat positioning, food texture, and rate and amount of food presented can be manipulated during the performance of the MBS

Karyotype

to determine the safest and most efficient method of feeding. Clinical evaluation prior to the MBS is essential so that appropriate food textures and liquid consistencies are available at the time of the study. Changes in head and neck position, such as chin tuck, should be tried before the actual study is performed to better correlate clinical and radiologic findings.

Additionally, a standard upper gastrointestinal contrast series utilizing barium is required for assessment of anatomy of the gastrointestinal tract. Children with repetitive vomiting or abdominal pain require endoscopic evaluation, and many will also need colonoscopy to rule out the possibility of underlying inflammatory bowel disease. Some children will need cranial imaging, such as computed tomography or magnetic resonance imaging, to search for evidence of intracranial mass lesions, hydrocephaly, or posterior fossa anomalies such as the Chiari malformation. Fiberoptic endoscopic evaluation of swallowing (FEES) allows for direct visualization of the hypopharynx and larynx during swallowing by use of a flexible laryngoscope. This will allow evaluation of the valleculae and pyriform sinuses as well as the assessment of anatomy during swallowing and potential aspiration problems. This procedure, however, does not provide information on the oral phase of swallowing. FEES may also be combined with sensory testing to induce a laryngeal adductor response. Lastly, increasingly important is the need for allergy evaluation, including consultation by an allergist. Appropriate skin testing may be necessary as well as appropriate RAST testing to search for response to food allergy.

Feeding Specialist

The generic term 'feeding specialist' refers to the team member whose responsibilities include assessing and treating oral motor and swallowing dysfunction and performing MBS studies when warranted. This may be either an occupational therapist or a speech/language pathologist depending on the training and local facility. Occupational therapists can also evaluate fine motor, sensorimotor, and visual motor function as well as positioning and the need for adaptive equipment. Speech/language pathologists can evaluate and make recommendations for communication skills when necessary.

Nutritionists

Nutritionists dedicated to pediatric care are also essential in the diagnostic team functioning. The role of the nutritionist in the assessment of current nutritional status, anticipated growth, and recommended caloric intake that would be age and diagnosis appropriate is essential.

Psychologists/Behavioral Therapists

Behavioral therapists help to provide detailed observation and an analysis of variables that may be contributing to food refusal behaviors. An integral part of the therapist's approach is performing an in-depth assessment of the child's behavior patterns with regard to eating. The goal of an assessment is to help the therapist identify what behaviors have been shaped in a child with regard to eating patterns and to help identify rewards preferred by the child to help reinforce or shape new eating patterns. The behavioral therapist then designs a treatment plan oriented toward shaping new child behaviors, and ultimately the therapist teaches the parents how to implement these strategies in the home environment.

Social Workers

Because the medical issues, behavioral needs, and family psychodynamics play a central role in the development of abnormal feeding patterns, a clinical social work evaluation is necessary for assessment and treatment of underlying familial interactions and support systems. These assessments and planning help to ensure continued success once the child has returned to the home environment.

Treatment of Feeding Disorders

The goal of all therapy is directed toward allowing parents to safely feed their children in a developmentally appropriate manner. The physician in the

treatment team must ensure that all appropriate diagnostic studies have been performed to determine if an underlying medical condition has predisposed a child to developing an unusual feeding pattern. This includes appropriate utilization of consultants and diagnostic modalities (**Table 4**). Once these studies have been performed, the physician must coordinate all the resources and direct care so that feeding therapy may proceed with minimal risk to the patient—keeping the child safe from aspiration and other complications.

The initial, and perhaps most important, part of any therapeutic approach to introducing or increasing oral food intake is to establish the safety of eating as well as the types and textures of food the child can consume most efficiently. Approaches to therapy are often described as nutritive or nonnutritive. Nonnutritive oral stimulation is performed to decrease hypersensitivity, facilitate management of secretions, establish or retrain the swallowing mechanism, maintain coordination of breathing and swallowing, and develop oral movement for sound production and communication.

Objectives for a nutritive approach include increasing oral intake, advancing food texture, transitioning to utensil use, and improvement of self-feeding. Oral motor techniques to improve muscle tone and postural control as a foundation for feeding and swallowing are largely based on a neurodevelopmental framework. The use of adaptive seating systems is a key component to feeding a child with physical disabilities that require external devices to provide head, neck, and trunk support. Attention must be paid to how positioning affects the feeding process because a change in head and neck posture and oral motor structures may affect oral motor control.

Once airway safety, positioning, and sensitivity have been controlled, a variety of treatment approaches have been suggested for children with pediatric feeding disorders. These range from individual child psychotherapy to interactional therapy between child and caregiver. However, the most widely employed treatments for feeding disorders are behavioral interventions usually included within an interdisciplinary team approach that also addresses physiology, oral motor functioning, parent–child interactions, and community or social support.

Behavioral interventions for pediatric feeding disorders are the most common modality of therapy and are often a mixture of antecedent and consequence-based treatment packages. Antecedent interventions include the establishment of a systematic feeding routine (i.e., the same time and place to eat), reducing or increasing the level of texture of food (i.e., puree vs chopped fine), and presenting a preferred food along with a nonpreferred food. Consequence-based treatments include rewarding appropriate eating behavior and/or ignoring (i.e., escape extinction) or punishing food refusal behavior. Thus, if a child accepts a bite, he or she is rewarded with attention or an arbitrary reinforcer, such as a toy or music. If the child engages in food refusal behavior, such as batting at the spoon or turning his or her head away from the food, the consequence is to ignore or extinguish the food refusal behavior and continue to present the bite to the child until it is accepted. If the child continues to refuse by expelling the food, this refusal behavior is ignored/extinguished by re-presenting the expelled bite of food to the child. In some cases, a child refuses food by holding the bite of food in his or her mouth. This form of food refusal behavior can also be ignored or extinguished by moving or redistributing the food from between the child's cheek and teeth onto the tongue, where it is more likely to be swallowed. Finally, training the parents in the use of the various feeding techniques is critical in maintaining long-term treatment gains. Skill-based parent training involving step-by-step criteria-based training has been shown to be superior to didactic methodology. Parent training, including instruction, discussion, handouts, role-playing, feedback, and the practice of techniques with a trained clinician, can result in increased parent treatment integrity.

Conclusion

Despite the increased awareness of feeding disorders in young children, there remain many challenges in implementing the specialized treatment necessary for these children. Foremost among these challenges is the financial burden associated with diagnosis and therapy. Children who cannot or will not eat require a systematic diagnostic and therapeutic approach by a team of dedicated professionals. The goal of safe oral feeding is attainable in most children when those involved in the care of children understand the complexity of eating and the associated medical and psychological conditions that comprise a feeding disorder. Helping these children to eat will allow independence from artificial sources of nutrition, such as gastrostomy feeds and parenteral nutrition, and ultimately reduce the total cost of health care for these children.

Nutritional Interactions

H Ghattas, London School of Hygiene and Tropical Medicine, London, UK

Introduction

Immunological competence (the ability of the immune system to mount a response in the presence of a pathogen) and nutritional status are major determinants of morbidity and mortality, particularly in children of the world's least developed countries. Communicable and nutritional deficiency diseases are often grouped together in mortality statistics, as many infection-related deaths occur in individuals who are also malnourished, making it difficult to disentangle infectious causes from malnutrition-related causes of death. It is estimated that infectious and nutritional deficiency diseases are responsible for 32% of global mortality and up to 59% of deaths in the world's poorest countries (World Health Organization 2004).

The relationship between malnutrition and infection has often been described as synergistic, and is the result of multifaceted interactions between nutritional intake, nutritional status, immunity, and vulnerability to infections. However, the role of nutrition in host resistance to infection is such that both nutrient deficiencies and excesses can increase susceptibility to infection.

The Cycle of Malnutrition and Infection

Malnutrition and infection interact in a cycle of adverse events (**Figure 1**) whereby malnutrition impairs immunocompetence by affecting both nonimmunological defense mechanisms (such as epithelial membrane integrity) and immunological defenses (e.g., cytokine activity, neutrophil function, T-cell maturation) thereby increasing host

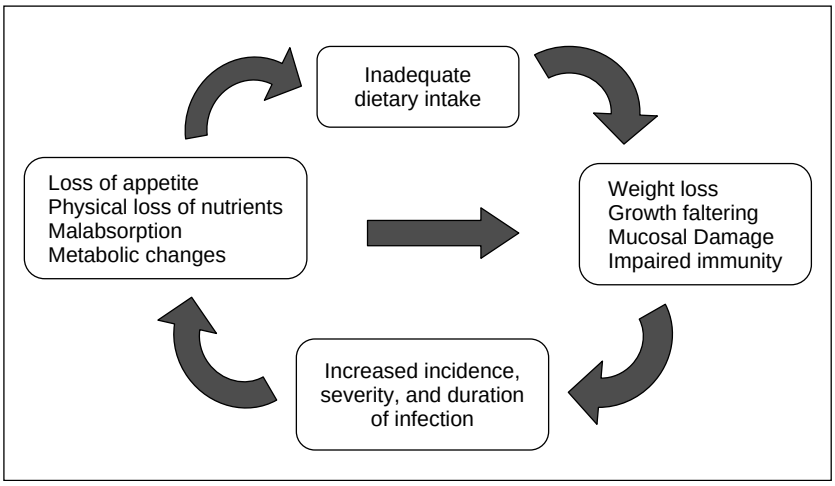

Figure 1 The cycle of malnutrition and infection. (Reproduced from Tomkins A and Watson F (1989) *Malnutrition and Infection: A Review. Nutrition Policy Discussion Paper No.5 (ACC/SCN State of the Art Series).* Geneva: United Nations.)

susceptibility to infection. Conversely, infection can affect energy requirements and appetite, and can lead to weight loss in adults and growth faltering in children. This occurs through a simultaneous increase in energy requirements during the acute phase response of an infection, anorexia (primarily mediated by interleukin (IL)-1 released by infected macrophages), physical loss of nutrients from the intestine, and malabsorption. The resulting deterioration in nutritional status is associated with additional mucosal damage, which can in turn further prolong and increase the severity of the infection as well as leaving the individual susceptible to further pathogenic invasion, thus bridging the vicious cyclical relationship between malnutrition, impaired immunity, and infection.

The Effect of Infection on Nutritional Status

Infection triggers several processes that lead to the deterioration of nutritional status (**Figure 2**). The innate response to an acute infection induces a catabolic response that increases basal metabolism (therefore increasing energy expenditure), places individuals in negative nitrogen balance (as a result of amino acid mobilization from peripheral muscle for gluconeogenesis), and leads to loss of body weight. This primarily occurs in the febrile stage of an infection during which the increase in body temperature is accompanied by an increase in basal energy requirements. This energy is required to fuel the increased rates of enzymatic reactions that occur when body temperature is elevated and to provide energy for the synthesis of proteins involved in the response to infection, e.g., acute phase proteins and immunoglobulins. The latter explains why energy metabolism can also be increased in subclinical nonfebrile infections.

The acute phase reaction is mainly driven by cytokines produced by infected leucocytes. Interleukin-1 (IL-1) is the primary mediator of the acute phase response and stimulates endocrine changes that lead to amino acid mobilization as well as the initiation of anorexia (loss of appetite). This can be compounded by physical discomfort associated with eating or swallowing that can occur in certain infections. For example, dehydration due to diarrhea can lead to mouth dryness, and opportunistic oral infections may occur following acute infections. Nutritional intake can be further reduced as a result of the cultural practice of withdrawal of food from individuals with signs of infection (such as fever or diarrhea).

Amino acid mobilization during the acute phase response to infection is also accompanied by redistribution of other nutrients among tissues as well as vitamin (e.g., retinol, folate, riboflavin, ascorbic acid) and mineral (e.g., potassium, zinc, copper) losses from the body. These changes reflect a shift in the transport of nutrients by nutrient transport proteins, the synthesis of which is reduced in response to infection, in order to prioritize the synthesis of acute phase proteins by the liver. Consequently, plasma nutrient concentrations fall due to reduced circulating levels of nutrient transport proteins.

Reductions in circulating levels of iron also occur through the sequestration of iron by the reticuloendothelial system as well as the release of the iron-binding protein lactoferrin by neutrophils, increased storage of iron as ferritin in the liver and spleen, and reduced intestinal iron absorption. This is

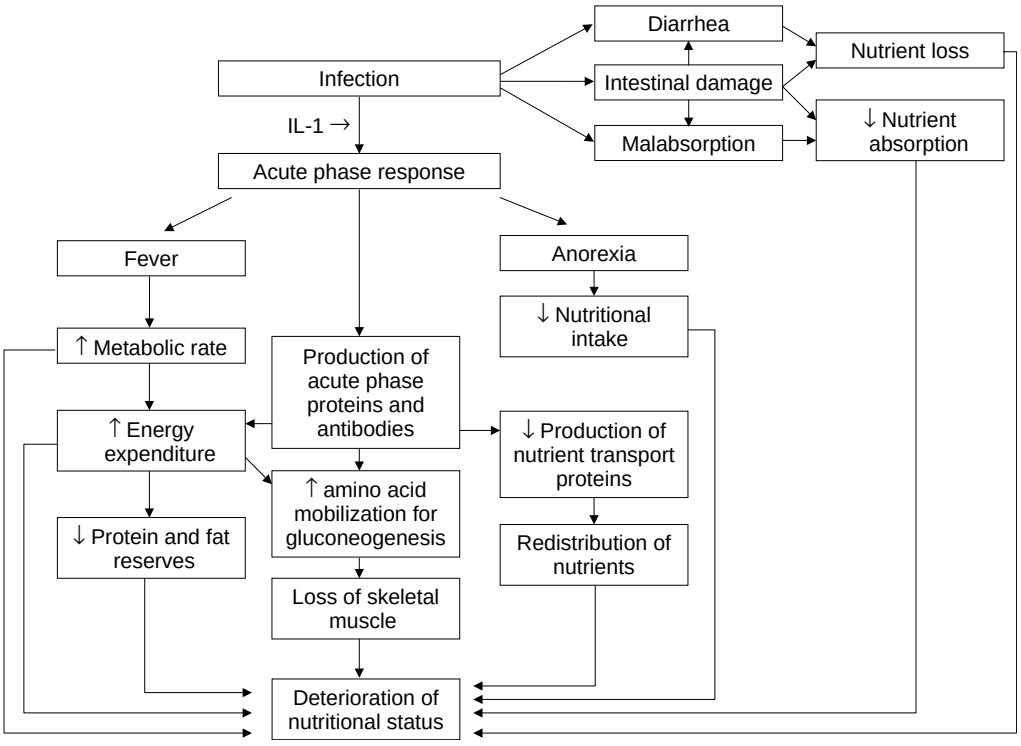

Figure 2 The effect of infection on nutritional status.

a protective mechanism that deprives microorganisms of the iron required for microbial growth and replication, therefore restricting further spread of infection.

Serum retinol levels are also reduced in a range of infections including acute respiratory infections, gastroenteritis, measles, malaria, pneumonia, and hookworm infection. Retinol depletion in measles infection has been shown to be closely related to the severity of infection.

Direct nutrient losses also occur in infection through diarrhea and nutrient malabsorption. Various infections of the gastrointestinal (GI) tract can cause diarrhea including viral, bacterial, protozoan, and helminthic infections, although non-GI infections such as malaria may also precipitate diarrheal episodes. GI infections can damage the gastrointestinal epithelium leading to flattening of microvilli, this decreases the absorptive surface area of the intestine resulting in malabsorption and electrolyte imbalance.

Table 1 lists examples of major infections, how they affect nutritional status, and the ways in which these infections may be modulated by certain nutrients.

The Effect of Nutrition on Immunity and Infection

In nutritionally compromised individuals with infection, a persistent catabolic state prevails, impairing the capacity for recovery from infection, as several recovery processes are dependent on active protein synthesis, for example, tissue repair, replacement of structural and functional proteins, and synthesis of immunoproteins. Additionally, the coexistence of malnutrition and infection increases susceptibility to secondary infection.

Severe Malnutrition and Reductive Adaptation

The acute phase response to an infection is muted in severe protein-energy malnutrition in part of a process referred to as 'reductive adaptation,' whereby the structure and function of cells or tissues cannot be maintained due to the limited supply of energy resulting from decreased nutritional intake. Protein synthesis from amino acids is highly energy-dependent and proteins have a wide variety of structural and functional roles in the body, including the cytokines that initiate the acute phase reaction (IL-1, Il-6, tumor necrosis factor (TNF-α)). Severely malnourished individuals are therefore immunocompromised, in that they cannot produce an adequate immune response to infection. The generalized responses to infection such as fever and increased pulse, as well as localized responses such as inflammation and delayed cutaneous hypersensitivity, may also not manifest. Silent infections must therefore always be suspected and treated in severe malnutrition.

Table 1 Major infections: their effect on nutritional status and ways in which these infections may be modulated by nutrition

Nutritional modulation	*Infection*	*Nutritional effects*
• Zinc: ↓ incidence and morbidity • Ascorbic acid: may have protective effect (conflicting results)	Acute Respiratory infections (ARI)	• Anorexia • Dysphagia
• Vitamin A: ↓ incidence of diarrhea • Breast feeding: ↓incidence of diarrhea • Malnutrition → ↓ epithelial integrity and ↑ diarrhea • Zinc: ↓ duration and mortality	Diarrheal diseases	• Nutrient losses • Intestinal damage and malabsorption • Dehydration • Electrolyte imbalance • Nutrient deficiencies (e.g., vitamin A)
• Vitamin A: ↓ morbidity and mortality in HIV + children • ↓ plasma selenium associated with ↑ HIV severity • Ascorbic acid: may ↓ HIV viral load • Zinc supplementation → conflicting results in HIV • Vitamin A: in lactation may ↑ MTCT[a]	Human immunodeficiency virus (HIV)	• Anorexia • Wasting syndrome • When treated with HAART[b] can lead to metabolic changes and lipodystrophy
	Intestinal parasites	• Nutrient losses • Malabsorption • Anorexia • Anemia (in hookworm and *Trichuris*) • Impaired growth and weight loss
• Vitamin A: ↓ malaria-anemia • Iron: ↓ malaria-anemia but may ↑ morbidity	Malaria	• Anemia • ↑ Protein metabolism • Anorexia • Fever → ↑ energy needs • ↓ Plasma retinol • Malaria in pregnancy → low-birth-weight baby
• Vitamin A: ↑ measles specific Ab in response to measles vaccination • Vitamin A: ↓ morbidity	Measles	• Anorexia • Buccal mucosal lesions → ↓ intake • ↑ Catabolism → growth faltering and weight loss • ↓ Plasma retinol
	Tuberculosis (TB)	• ↑ Energy metabolism • ↑ Protein breakdown • Anorexia • Anemia

[a]MTCT: mother to child transmission.
[b]HAART: highly active anti-retroviral therapy.

Malnutrition and the Breakdown of Defenses

The skin and mucous membranes provide the first layer of physical and chemical defense against an invading pathogen, and the mucosae are the major sites of entry of infectious agents into the host. The structural integrity of these barriers is compromised in malnutrition through the reduced production of mature epithelial cells, and the decreased secretion of mucin, gastric acid, lysozyme, and secretory immunoglobulins. This results in reduced gastric acidity and intestinal villous atrophy, which facilitate pathogen entry into the host. The host gut-associated lymphoid tissue (GALT) is the principal site of stimulation of mucosal immune responses and the gastrointestinal epithelium functions in the transport of nutrients as well as in immunological surveillance. Reduced epithelial integrity therefore impairs mucosal immune function and can further exacerbate nutritional status.

Lymphoid organs and cell-mediated immunity are also affected by malnutrition. In the context of malnutrition-related immunodeficiency, changes in both thymic morphology and function have been observed. These include thymic involution, thymus atrophy, circulation of immature lymphocytes, and increased thymocyte apoptosis. Similar changes occur in the spleen and lymph nodes. Where innate immunity is an organism's first level of defense in response to an infective agent, adaptive immunity and hence thymic involvement may be considered to be less crucial in the short term. The case has

therefore been made that when faced with a stress such as malnutrition, adaptive immunity becomes less of a priority and is shut down in order to prioritize other more critical organ functions. It has been suggested that critical periods in lymphoid organ development, such as the fetal and neonatal phases of development, may be particularly susceptible to malnutrition-induced changes, which may be irreversible and have long-term consequences on host resistance to immunity.

Cell-mediated immunity depends on thymus-derived T lymphocytes, which may be reduced in both number (lymphopenia) and function (impaired maturation) in malnutrition. This may result from reduced production of thymocytes by the thymus or from impaired T-cell differentiation and proliferation. Lymphocyte response to mitogens is undermined in both protein-energy and specific micronutrient deficiencies.

Moreover, neutrophil activity and bactericidal capacity are decreased in undernutrition. The neutrophil respiratory burst (which involves the production of toxic metabolites including hydrogen peroxide, superoxide anion, and nitric oxide that cause direct damage to bacteria) is impaired.

Complement proteins are also reduced in malnutrition. However, B-lymphocyte function and humoral immunity appear unaffected and normal antibody response to infectious agents is seen (except antibody responses that are highly dependent on T-cell help). However, secretory immunoglobulin (Ig) A responses may be decreased in malnutrition, possibly due to reduced secretion of IgA from damaged or atrophied mucosal surfaces.

Low Birth Weight

Low birth-weight babies are born with low nutrient reserves, an immature immune system, and small sized lymphoid organs. Studies have also linked low birth weight to reductions in T-cell counts, altered proportions of lymphocyte subsets, and reduced *in vitro* lymphocyte proliferation in infants and children. Additionally, mucosal surfaces (of the gastrointestinal and respiratory tract) are underdeveloped, thereby weakening the first layer of defense against an invading pathogen. Low birth-weight infants have increased neonatal mortality, mainly from diarrhea, pneumonia, and measles, and there is evidence that they remain at an increased risk of infection past the first year of life.

Breast feeding and Immunity to Infection

Human milk is the first form of nutrition for a neonate. Mammary glands are part of the integrated mucosal immune system and produce antibodies against mucosal pathogens that the mother is exposed to and which the infant is most likely to encounter. Breast milk contains several factors that protect against infections in the breast-fed infant either through passive immunity or by activating the infant's immune system. These include secretory IgA and IgM antibodies specific to maternal pathogenic encounters, short-chain fatty acids (SCFA), which can inhibit bacterial growth, block bacterial toxins and activate eosinophils, bactericidal lactoferrin, lysozymes, and mucins, as well as lymphocytes (both T cells and B cells), which may transfer primed immunity to the infant.

Additionally, cytokines and other growth factors in human milk contribute to the activation of the lactating infant's immune system, rendering breast-fed infants less susceptible to diarrheal diseases, respiratory infections, otitis media, and other infections and may impart long-term protection against diarrhea. Breast feeding also reduces mortality from diarrhea and respiratory infections. However, human immunodeficiency virus (HIV) infection (and other viral infections) can be transmitted from a virus-positive mother to her child through breast milk, and breast-feeding is responsible for a significant proportion of childhood HIV infection.

Key Nutrients Involved in Host Resistance to Infection

Ascorbic acid (vitamin C) Ascorbic acid is rapidly mobilized and utilized in infection and high levels of ascorbic acid are found in leucocytes. Studies in humans and animals have found a reduced T-cell response, delayed cutaneous hypersensitivity, and reduced epithelial integrity in vitamin C deficiency. Vitamin C supplementation is associated with increased lymphocyte proliferation in response to mitogen, increased phagocytosis by neutrophils, and decreased serum lipid peroxides. A role for vitamin C has been suggested in the treatment of autoimmune diseases as well as in delaying the progression of HIV to AIDS; however, further research is required to confirm such a role. The effectiveness of ascorbic acid in preventing and reducing the duration of acute respiratory infection also remains controversial. Claims that high intakes of vitamin C can prevent the common cold have not been corroborated, although there is evidence of a decrease in duration and alleviation of symptoms of the common cold.

Iron The effects of iron on infection are bipolar, with both deficiency and excess leading to increased

susceptibility to infection. Iron deficiency has been found to impair cell-mediated immunity (CMI), neutrophil function, natural killer (NK) cell activity, and bactericidal activity of macrophages, and to delay the development of CMI. The assessment of iron status in infection is however complicated by the redistribution of iron-binding proteins in the inflammatory response, making it difficult to interpret studies that find associations between measures of iron deficiency and infection.

Excess iron has immunosuppressive effects and can promote bacterial growth. Iron overload (hemochromatosis) decreases the phagocytic capacity of macrophages, alters lymphocyte subset distribution, and increases incidence of infection. Free iron acts as a catalyst in the production of reactive oxygen species (ROS) thereby increasing lipid peroxidation and cell membrane damage (of both host and microbial cells).

Invading organisms compete with the host for available iron necessary for cell function and proliferation. Pathogen replication and virulence is increased when iron supplements are administered to individuals with both iron deficiency and infection, leading to increased morbidity and mortality from infection (there is accumulating evidence for such an effect in malaria, tuberculosis, and HIV). In malaria, iron supplementation reduces malaria anemia but some studies have found increased incidence and severity of the disease, although this may be related to mode and dosage of iron administration.

The detrimental effect of iron supplementation in infection remains controversial; however, the variation in the response to supplementation may be explained by polymorphisms in genes that affect iron metabolism. For example, studies have shown poorer prognosis in HIV-infected patients with the haptoglobin (Hp) 2-2 phenotype (characterized by high serum iron, transferrin saturation and ferritin levels).

Retinol (vitamin A) Vitamin A is essential for the maintenance of mucosal surfaces and plays a role in cytokine regulation. Vitamin A supplementation has been reported to reduce child mortality from diarrheal diseases and HIV/AIDS, and to decrease the prevalence, severity, and duration of diarrheal episodes (particularly in nonbreastfed infants). Vitamin A is also involved in increasing levels of long-term measles-specific antibodies in response to measles vaccination and in reducing measles-related morbidity.

However, vitamin A does not necessarily play a beneficial role in all infections and supplementation may not always achieve the desired outcome; for example, the role of vitamin A supplementation in reducing malaria morbidity and increasing resistance remains contentious. Despite evidence for reductions in malaria-anemia, supplementation studies in respiratory infections have found no beneficial effect and a recent study found increased mother to child transmission of HIV when HIV-infected mothers were supplemented with vitamin A.

Selenium The role of selenium in resistance to infection mainly derives from its antioxidant function, but an increasing number of studies have shown that selenium also functions in both cell-mediated immunity and humoral immunity. Selenium containing proteins (selenoproteins) are the major modulators of the effects of selenium on immunity. Of these, the selenium-dependent glutathione peroxidases have an antioxidant function, and play a regulatory role in the synthesis pathways of both anti-inflammatory and proinflammatory eicosanoids.

Selenium deficiency leads to impaired antioxidant capacity, resulting in cell damage as well as a diminished respiratory-burst reaction (a microbicidal reaction in neutrophils and monocytes/macrophages). Low serum selenium levels are associated with severity of HIV, and selenium supplementation may be beneficial in HIV infection where it has been shown to reduce oxidative stress and to modulate cytokine production. Keshan disease, a juvenile cardiomyopathy with a viral etiology, is precipitated by selenium deficiency.

Selenium appears to be able to modulate pathogens as well as the immune response, as demonstrated by the increased virulence of Coxsackie virus and influenza A in response to selenium deficiency.

Zinc Zinc acts as a cofactor for many enzymes and plays a role in cellular DNA synthesis, RNA transcription, cell division, and activation. Zinc modulates both humoral and cell-mediated immunity and zinc deficiency is marked by lymphoid organ atrophy, lymphopenia, decreased T-helper 1 cell function, impaired B-cell function, and reduced phagocytic capacity.

Zinc supplementation has been found to improve infectious morbidity in individuals with sickle cell disease. In malnourished children, zinc supplementation improves epithelial integrity, decreases the duration of diarrheal episodes and mortality from diarrhea, decreases the incidence of respiratory tract infection respiratory morbidity, and improves T-cell-mediated immunity. Maternal zinc deprivation results in small thymus and spleen size in the neonate.

Results of zinc supplementation studies in HIV-positive individuals are conflicting with both benefits and adverse effects reported. The role of zinc in

reducing the severity and duration of the common cold is also still contested. High doses of zinc however have been associated with increased mortality in severe malnutrition and sepsis indicating a potential detrimental effect associated with pharmacological (versus physiological) doses of zinc.

Multiple micronutrients Much of the research in the field of nutrition–infection interactions has focused on the effect of single nutrient deficiencies on immunity, and how single nutrient supplementation may modulate infectious outcomes. However, micronutrient deficiencies often occur concurrently and significant interactions exist between different micronutrients, whereby large supplementation doses of one nutrient may inhibit uptake of another. Recent studies have shown beneficial effects of a multiple micronutrient supplement including vitamins B-complex, C, E, and folate on lymphocyte counts and birth outcomes of pregnant HIV-positive women. Few other studies have investigated the effects of multiple micronutrient supplementation on infectious outcomes, although these are warranted in populations where multiple micronutrient deficiencies coexist with infection.

The effects of nutrition on immune function are mainly modulated through the action of nutrients as essential cofactors and substrates in biosynthetic pathways or as antioxidants; with cell-mediated immunity and mucosal immunity being the most cited immunological outcomes affected by nutrition. **Table 2** lists the key nutrients involved in host defense against infection and their major effects on infectious outcomes.

Table 2 Role of key nutrients in host defense against infection

Nutrient	*Effect on infection*
Ascorbic acid	• Prevents oxidative damage in infection • Role in reducing ARI is controversial • May improve HIV outcome
Iron	• ↓ Malaria-anemia • Supplementation may ↑ morbidity from malaria, TB, and HIV
Retinol (vitamin A)	• ↓ Child mortality from diarrhea and AIDS • ↓ Prevalence of diarrhea • ↑ Measles-specific antibodies, ↓ measles morbidity • Benefits in malaria controversial • ↑ Mother-to-child transmission of HIV
Selenium	• Deficiency can precipitate Keshan disease • Deficiency ↑ virulence of Coxsackie virus and influenza A • Deficiency may ↑ severity of HIV
Zinc	• ↑ Epithelial integrity • ↓ Diarrheal duration and mortality • ↓ Incidence of and morbidity from respiratory tract infection • High doses associated with ↑ mortality in severe malnutrition and sepsis

Confounding Factors in the Nutrition-Infection Relationship

Infection and malnutrition are interdependent indices; however, the nature of the interaction between nutrition and immunity is complex and is confounded by factors that affect both nutritional status and immunocompetence (**Figure 3**).

Despite the clinical evidence for increased frequency and severity of infections in malnourished individuals, the major factor confounding the relationship between nutrition and immune status is that the environmental conditions of poverty simultaneously lead to both malnutrition and increased exposure to infections. The increase in morbidity and mortality from infectious diseases in malnourished children is often attributed to mucosal and epithelial damage caused by malnutrition, whereas this damage may be caused by the infection itself, making it difficult to confirm a causal path in the malnutrition–infection paradigm.

Furthermore, studies investigating the effects of single nutrient deficiency on infection are often confounded by coexisting nutritional deficiencies, and although nutrition can modulate immunocompetence, susceptibility to secondary opportunistic infection can be independent of nutritional status.

Additionally, the assessment of nutritional status is complicated by the presence of infection, as is the diagnosis of infection in malnourished individuals. During the acute phase response to infection, the plasma concentrations of many micronutrients are altered making it difficult to assess nutritional status, whereas the metabolic and physiological changes (reductive adaptation) that occur in severe malnutrition impair immune responses, making it difficult to diagnose infection.

Conclusions

Owing to the complex nature of the interaction between nutritional status and host-susceptibility to infection, establishing a better understanding of the underlying mechanisms behind the nutrition–infection relationship is crucial to the formulation of intervention strategies to reduce morbidity and mortality from communicable and nutritional deficiency diseases in developing countries.

Metabolic and Nutritional Changes in Patients with Infection

An increased blood glucose concentration is the most common abnormality in the infected hospitalized patient. This section discusses the metabolic abnormalities in glucose, protein, and fat metabolism as well as abnormalities in specific nutrients in this population. Specific nutritional treatment plans are presented. In addition, the host response to injury and why

patients may not be able to become anabolic with conventional nutritional support are discussed. The acute phase response typifies the host's response to infection. Mechanisms to blunt the catabolic state are important because the extent of muscle wasting and weight loss is inversely correlated with long-term survival. The potential uses of conventional nutritional support and newer nutritional adjunctive techniques utilized for patients are discussed.

Glucose Utilization in Injury and Infection

In nearly all studies of glucose metabolism in patients with infection, injury, or cancer, there is a significant reduction in glucose utilization. This occurs even when the insulin concentrations are in the physiological range. This effect is not overcome even with administration of supraphysiological insulin concentrations. In sepsis, the insulin resistance associated with injury is due to defective insulin-mediated activation of the glycogen storage pathway. By approximately 7 h after the onset of injury, there is a reduction in glucose utilization via the nonoxidative pathway. This injury response persists until the source of injury, infection, or tumor is removed.

Hepatic Glucose Metabolism

During infection, the liver increases glucose production to defend against hypoglycemia. In fact, the increase in hepatic glucose production is the major reason why patients with infection have an elevated blood glucose concentration. For example, patients with active malaria can have an increase in fasting glucose concentration due to an increase in gluconeogenesis and overall glucose production. Approximately 75% of cancer patients, like patients with infection, also have an elevated rate of glucose production. Cancer patients also have a mild form of injury; approximately 75% have an elevated rate of hepatic glucose production. In 18 studies, hepatic glucose production for normals ranges between 1.6 and 3.0 mg/kg/min, with an average of 2.1 mg/kg/min. Glucose production for cancer patients without weight loss ranges from 1.7 to 5.1 mg/kg/min, with a mean of 2.75 mg/kg/min. This is a 30% increase in the fasting rate of hepatic glucose production. For cancer patients with weight loss, glucose production ranges from 2.3 to 3.3 mg/kg/min, with a mean of 2.96 mg/kg/min. This represents a 41% increase in the rate of hepatic glucose production. Not all cancer types have an elevation in hepatic glucose production. For example, head and neck cancer patients may not have an elevation in fasting hepatic glucose production, but it is commonly elevated in lung cancer patients, probably because they have an increased injury response. In cancer patients, the etiology for the elevated rate of fasting hepatic glucose production is not known. Early studies tested whether excessive growth hormone (GH) release in cancer patients might be responsible. However, there was no direct correlation between GH secretion pattern and hepatic glucose production. Furthermore, the administration of GH to cancer patients for a 3-day period failed to increase the rate of glucose production. Koea and Shaw suggested that the rate is related to the bulk of the tumor, and others have suggested it is related to cytokines or other factors. Earlier studies on normal volunteers demonstrated that the loss of the first-phase insulin response causes a delay in the normal inhibition of glucose production. Although the latter effect may explain postprandial hyperglycemia, it is an unlikely explanation for fasting hepatic glucose production.

Gluconeogenesis is elevated in head and neck cancer patients and also in lung cancer patients. Gluconeogenesis accounts for approximately 50% of the overall glucose production after an overnight fast. It was demonstrated that glucose carbon recycling was elevated in five of seven published studies. Glucose carbon recycling is an indicator of increased gluconeogenesis. The ability to measure gluconeogenesis was not possible in humans until recently, when a method using [U-^{13}C] glucose and isotopomer analysis was developed. The Cori cycle is increased in cancer patients and has been estimated to account for 300 kcal of energy loss per day. In 70% of published studies, cancer patients have a significant elevation in the rate of gluconeogenesis compared to normal weight-matched controls. Gluconeogenesis was directly related to the morning blood cortisol concentration in both the normal volunteers ($r = 0.913$, $p < 0.01$) and the cancer patients ($r = 0.595$, $p < 0.05$). In the septic host, the increase in glucose production is likely due to an elevation of multiple counterregulatory hormones (cortisol, GH, catecholamines, and glucagon) and cytokines (interleukin-1 (IL-1), tumor necrosis factor-α (TNF-α), etc.).

It is important to note that unlike diabetic patients with an elevated blood glucose concentration, cancer patients with an elevated glucose production rate frequently have a normal blood glucose concentration. Fasting glucose concentrations may be 110–120 mg/dl, which may be overlooked as a subtle indicator of an elevated glucose production rate. The increased rate may contribute to an increased energy cost. Data indicate that the resting energy expenditure is elevated in lung cancer patients and those with other types of cancer compared to weight-matched controls. As expected, energy expenditure is increased in most critically ill patients a few days after admission. However, the precise measurement of energy expenditure is difficult in this setting. Early

in the course of critically ill patients, one should focus on excellent blood glucose control. A total caloric intake of 20–25 kcal/kg/day should be provided to the nonthermal injured patient. Protein intake should be 1.5 g/kg body weight/day.

Unlike the normal fasting blood glucose that is seen in cancer patients, patients with injury or infection most commonly have an increase in blood glucose. This has been associated with a large increase in hospital mortality (**Table 1**). Hyperglycemia as a marker of intensive care unit (ICU) mortality may be greater in surgical patient compared to medical ICU patients. In a prospective randomized clinical trial in which intravenous insulin was provided to surgical patients, preventing the increase in blood glucose associated with injury and infection, there was significantly reduced mortality.

Protein Metabolism

Sepsis is associated with an increase in skeletal muscle catabolism and a reduction in the rate of skeletal protein synthesis. Both contribute to a large loss of lean body mass during injury and infection. Skeletal protein breakdown occurs more in the fast-twitch or white muscle fibers than in the red fibers. In addition to sepsis, injury and cancer are also associated with muscle wasting and malnutrition. The etiology is multifactorial, including poor dietary intake, insulin resistance, elevated resting energy expenditure, and other unknown factors. Muscle wasting is due to a combination of increased skeletal muscle protein catabolism and reduced skeletal muscle protein synthesis. For example, in an experimental model of cancer cachexia, protein synthesis was reduced in rats with several tumor types and it occurred at small tumor burdens. In humans with renal cell cancer, the rate of muscle protein synthesis was reduced. In this cancer host, the loss of skeletal muscle appears to be due in part to a reduced protein synthesis and in part to a normal rate of protein catabolism. This can occur even in the face of an adequate dietary intake.

Whole body protein metabolism can be measured in many ways. The most common isotope is that of the essential amino acid leucine. In the majority of studies on cancer, injury, and infected patients, the rate of plasma amino acid appearance or turnover is elevated. This rate of plasma appearance is a reflection of multiple sites of protein metabolism. The most important are the skeletal muscle, liver, and gastrointestinal (GI) mucosa. Other sites also play an important role, as does the tumor. Studies have demonstrated that the rate of plasma amino acid appearance is related to the bulk of the tumor mass. Measurements of protein metabolism in tumor tissue have demonstrated that the tissue has a very high fractional protein synthesis rate of 50–90% per day. This is similar to that of the liver, and it contrasts with a rate of 1–3% for the skeletal muscle. However, since the body is composed mostly of skeletal muscle, its overall contribution to whole body amino acid metabolism is large and it contributes to a significant proportion of plasma amino acid appearance rates. Data suggest that the increase in the protein catabolism in humans is via the effect of cytokines (IL-1, IL-6, and TNF) and the glucocorticoids, which are known to stimulate the ubiquitin–proteasome pathway of skeletal muscle protein catabolism. Earlier work demonstrates that TNF administration reduces skeletal muscle amino acid content by 20%, but it has no effect on skeletal muscle protein synthesis. The loss of amino acids without stimulation of protein synthesis suggests that TNF stimulates protein catabolism via a loss of amino acids from inside the skeletal muscle. This effect of TNF wanes after 6 h since animals studied at 60 h have a 30% increase in the rate of protein synthesis and a normal skeletal muscle amino acid content. The increased rate of protein synthesis probably reflects the recovery of the depleted amino acid pool due to

Table 1 Mean blood glucose concentrations, hospital mortality

Patients	*Controls*		*IV insulin*		*Reference*

[b]Three-year mortality.
*$p < 0.01$ vs mortality at baseline.

earlier administration of TNF. The increased intracellular concentration of amino acids in the skeletal muscle may stimulate synthesis. The direct effect of TNF 60 h after a single administration is not likely since it has a short half-life. Chronic administration results in a reduction in whole body protein synthesis and a net loss of skeletal muscle protein but an increase in liver protein synthesis. An increase in the thyroid hormone triiodothyronine also plays an important role in promoting protein breakdown in both the ubiquitin–proteasome pathway and the lysomal pathway. However, under most conditions, patients with malignancy have either a normal or a reduced triiodothyronine concentration. Similar processes are responsible for the loss of protein seen in infection.

Data suggest that humans make and break down approximately 300 g of protein per day, which is exchanged and reused. This is meditated by the flow of amino acids into and out of cells. Since the amino acid pool is small (only 60 g), the turnover is large. An average person ingests approximately 70 g of protein per day and loses approximately 70 g per day in the form of nitrogen. The cellular proteins, including muscle and extracellular proteins, are approximately 10 400 g. These proteins are broken down and reused at various rates. The key to a small intake of amino acids in the diet is the reutilization of amino acids locally inside the cell and the maintenance of the plasma amino acid pool. The amino acid pool is only 0.6% of the whole body amino acid content, but it plays a vital role in the maintenance of protein synthesis.

Cancer patients who have an elevated plasma amino acid appearance rate survive and those with a normal rate have a worse survival. In one study, stage D colorectal cancer patients who were able to sustain an increased whole body protein metabolism over a 3-month period, as measured by amino acid kinetics, survived and those who had a normal or reduced rate died. Although fasting plasma glucose concentrations were greater in the survivors (100 ± 2 vs 92 ± 3 mg/dl), there was no difference in glucose production rate, age, and body weight. Carcinoembryonic Antigen (CEA) concentrations were higher in the patients who died, which suggests that they had a larger tumor burden. There may be subgroups of patients who are able to mount an acute phase response, which may improve survival. It is not known why some patients mount an increased amino acid appearance rate with cancer, and further research is needed to confirm that it may predict survival. Historically, an elevated plasma amino acid appearance rate was believed to represent protein wasting, but recent data suggest that an elevated rate of whole body protein metabolism may not reflect a maladaptive processes but rather a healthy response to the tumor. An adequate acute phase response to tumor may reflect a greater fight against cancer. The absence of a response may be unfortunate, as data from patients with colorectal carcinoma suggest. Unfortunately, there are no similar data from infected patients for this comparison.

Lipid Metabolism

Energy in the body is stored mainly in body fat, which is depleted during the wasting process. This process is normally increased during fasting without tumor or injury. When the patient has a tumor, there is a metabolic response to the injury that also promotes lipid mobilization. Several authors have implicated a lipid mobilization factor as being responsible for this process, which is believed to occur in both infection and cancer. Data suggest that this factor may also be responsible for the depletion of liver glycogen in cancer cachexia. This factor(s) increases lipolysis and plasma triglyceride concentrations. The former effect may be due to an increase in the hormone-sensitive lipase and the latter effect due to inhibition of lipoprotein lipase activity. However, the exact factor(s) that is responsible for these effects is not known.

Cancer patients with weight loss have an increase in whole body lipid turnover measured by radioactively labeled fatty acids. However, when weight loss is prevented, there is no increase in the rate of lipolysis. Similarly, the rates of lipid oxidation are normal in cancer patients compared to weight-matched controls. In more severe injury, as seen in sepsis, the rate of lipolysis is increased.

Hormonal Response to Injury, Infection, and Cancer

Infection, cancer, or any injury to the body result in an increase in counterregulatory hormones as well as insulin concentration. As a result of cancer, sepsis, or injury, many patients develop the syndrome of insulin resistance even though they had no history of diabetes prior to cancer. In cancer patients, when the overall injury is smaller, many studies have failed to demonstrate an elevation in counterregulatory hormones. Mild elevations in cortisol concentrations may contribute to the protein catabolism and increased gluconeogenesis. When serum insulin is measured with a sensitive assay, cancer patients demonstrate a small but significant elevation in serum insulin concentration. This is consistent with the observation that these patients have insulin resistance. Cancer patients, like diabetics, have a reduced glucose utilization and loss of the first-phase insulin

response, and many have an increased fasting hepatic glucose production rate. As mentioned previously, underweight cancer patients frequently have increased fatty acid oxidation and plasma fatty acid appearance rates. Triglyceride hydrolysis involves much more than fat oxidation, so albumin-bound fatty acids are used partially for energy but many are utilized for reesterification or substrate cycling back to triglyceride.

The rise in serum cortisol as the host's response to the tumor is one of many factors that are responsible for the development of insulin resistance. Insulin resistance is easy to diagnosis because the patient's fasting glucose will be elevated. An elevated fasting glucose level of approximately 110 mg/dl is a good marker of insulin resistance. This is not likely seen in mild injury alone unless the patient has a predisposition to the development of diabetes mellitus. Although insulin resistance is present, the presence of frank diabetes (blood glucose level >126 mg/dl or >7 mm) is not common in cancer or mild injury. It is more common in patients with severe infection or injury. Although most of the counterregulatory hormones are usually normal, serum cortisol and/or glucagon can be mildly elevated. Newer glucagon assays measure the normal value as 35–45 ng/ml, so a significant increase in injury can be detected, which was difficult to do with the older Unger assay. Recent data from pancreatic cancer patients have shown elevated glucagon concentrations, which may be contributing to the development of diabetes. Earlier work found that GH secretion was increased in cancer patients by 24-h analysis and by random sampling. However, after careful study, the increase in GH does not appear to have a major influence on hepatic glucose metabolism. Although there may be a small effect on glycogen breakdown, the major effect is likely via inhibition of glucose utilization in the skeletal muscle.

The sick euthyroid state, in which total triiodothyronine (T_3) concentrations are reduced in severely injured and infected patients, is common. This is likely a normal response to conserve energy in the injured person as the body's ability to convert the stored form of a thyroid hormone (thyroxine (T_4)) into the active form of thyroid hormone, T_3, becomes impaired. T_4 is converted to an inactive thyroid hormone known as reverse-T_3 hormone (rT_3). This event may have evolved as a necessary energy-saving response during a severe injury or illness to reduce the known contribution of T_3 to resting energy expenditure. The low T_3 syndrome is an adaptive way to reduce the normal day-to-day effect of T_3 on resting energy expenditure. This process can occur in the aggressive cancers, for which the patient's response is similar to that of an injury response.

In septic and injured patients, all counterregulatory hormones are routinely elevated, contributing to an increase in protein catabolism, glucose production, gluconeogenesis, and glycogen breakdown and a major reduction in glucose utilization and anabolism.

Acute Phase Response

The development of injury, infection, or cancer cachexia elicits an acute phase response. This is one of the most basic responses of the body to defend itself against injury. Phylogenetically, this response could be considered the most primitive response of the body. This stereotypical response is similar for injury from an accident, burn, infection, foreign objects, and, in some cases, from a tumor. Unfortunately, this response does not occur for most tumors, but it is seen when the malignancy presents with infection, such as in lung cancer, or in other more aggressive malignancy, such as seen in leukemia. The host develops a response that includes reductions in serum iron and zinc levels, increased serum copper and ceruloplasmin levels, alterations in amino acid distribution and metabolism, an increase in acute phase globulin synthesis, and gluconeogenesis. Although not common, fever can occur, and a negative nitrogen balance results. The tumor can elicit a sequence of events that include changes in cytokine levels as well as several classical hormone levels. For example, a malignant process in the lung will attract monocytes that will be transformed into macrophages at the tissue site of tumor. These macrophages will secrete proteins known as cytokines and other peptides that can attract other white blood cells and initiate an inflammatory response common to many types of injury. Cytokines include TNF-α and IL-1 to IL-20. TNF and other cytokines circulate to the liver, inhibit albumin syntheses, and stimulate the synthesis of acute phase proteins. Acute phase proteins include C-reactive protein, which promotes phagocytosis, modulates the cellular immune response, and inhibits the migration of white blood cells into the tissues; α_1-antichymotrypsin, which minimized tissue damage due to phagocytosis and reduces intravascular coagulation; and α_2-macroglobulin, which forms complexes with proteases and removes then from circulation, maintains antibody production, and promotes granulopoiesis and other acute phase proteins. Unfortunately, the majority of tumors do not elicit a large acute phase response. This limited response may result in a decreased inflammatory and tumorcidal effect.

Urine Urea Nitrogen Loss as a Marker of Catabolism

As part of the host response to injury, infection, or tumor, patients frequently lose protein in the urine in the form of nitrogen. For example, 16 g of urea nitrogen in the urine per day represents a 1-lb loss of lean body mass, such as muscle tissue. In some aggressive cancers, urea nitrogen loss can be as high as 24 g per day. The loss of 1 g of urinary urea nitrogen is equal to 6.25 g of dry protein. A total of 6.25 g of dry protein is equal to approximately 1 oz. of lean body mass. A loss of 16 g of urinary urea is equal to the loss of 1 lb of skeletal muscle or lean body mass per day. Specific areas of lean body mass loss that may result in a functional impairment of the respiratory muscles include the diaphragm, heart muscle, and GI mucosa. The loss of lean body mass in these areas can contribute to the development of respiratory failure, heart failure, and diarrhea, respectively. The rapid development of malnutrition can occur in patients with infection due to large losses of lean body mass per day.

Vitamin Deficiencies

Reduced serum concentrations of several vitamins, including vitamins C and E, have been reported in patients with sepsis. In one study, the administration of additional vitamin E and C resulted in a significant reduction in 28-day mortality (67.5 vs 45.7). Clearly, cancer patients with a poor intake can have deficiencies of many vitamins. For example, cancer patients have been noted to have significant reductions in plasma levels of many of vitamins, especially folate, vitamin A, and vitamin C.

Vitamin C and Vitamin A Patients with a premalignant lesion called leukoplakia also have reductions in plasma levels of retinol (vitamin A), β-carotene, and vitamin C. A study of healthly elderly demonstrated that approximately 20% had a reduced vitamin C level (<0.5 mg/dl) and 10% had a reduced serum vitamin A level (<33 μg/dl). The replacement of multiple vitamins and minerals with 80 mg of vitamin C and 15 000 IU of vitamin A per day for 1 year resulted in a significant reduction in the number of days associated with an infection-related illnesses (48 ± 7 to 23 ± 5 days per year). The multiple vitamin and mineral supplement improved the lymphocyte response to phytohemagglutin and the natural killer cell activity. In another study, the administration of a multivitamin for 1 year demonstrated a 41% reduction in infectious illnesses. In addition, there was a 63% reduction in infection-related absenteeism compared to that of placebo-treated individuals. The administration a MVI to pregnant HIV mothers also reduced HIV progression and mortality (24.7 vs 31.1% mortality, $p < 0.05$).

Vitamin deficiency states are difficult to diagnose. Plasma levels of vitamins are not the best way to assess deficiency. Vitamin C decreases during injury. Although plasma vitamin C concentrations reflect whole body stores, the measurement of plasma vitamin A (retinol) is not the best marker of an actual deficiency state. Liver vitamin A measurements may be a better marker. Patients who die of cancer and subsequent infections have an 18% incidence of moderate liver deficiency of vitamin A at autopsy. Serum vitamin A (retinol) levels are low in up to 92% of patients with serious infections. This depletion of liver stores of vitamin A may be due to excessive loss of retinol in the urine in patients with sepsis. In contrast to what is noted in patients with cancer or serious infections, trauma patients who die within 7 days of hospitalization only have a 2% incidence of severe liver vitamin A deficiency. Vitamin A can be provided by supplementation dietary intake, parenteral intake, or intramuscular vitamin A administration. In addition to the changes in folate, vitamin A, and vitamin C mentioned previously, excessive losses of several vitamins have been observed in patients receiving medications that interfere with normal utilization or elimination (**Table 2**).

Table 2 Drug-induced nutrient deficiencies

Drug	*Nutrient(s) affected*
Steroids	Vitamin A, potassium
Phenothiazines	Vitamin B_2
Tricyclic antidepressants	Vitamin B_2
Hydralazine	Vitamin B_6
Isoniazid	Vitamin B_6, niacin
Penicillamine	Vitamin B_6
Ammonium chloride	Vitamin C
Aspirin	Vitamin C
Phenobarbital and phenytoin	Vitamin C, vitamin D
Tetracycline	Vitamin C
Coumadin	Vitamin K
Estrogen and progesterone compounds	Folic acid, vitamin B_6
Aminoglycoside	Magnesium, zinc
Platinum	Magnesium, zinc
Diphenylhydantoin	Niacin
Antacid	Phosphorus, phosphates
Diuretics	Sodium, potassium, magnesium, zinc
Laxatives	Sodium, potassium, magnesium
Cholestyramine	Triglycerides, fat-soluble vitamins

Mineral Deficiencies

Multiple elevated cytokines are likely responsible for the commonly observed reduction in serum mineral concentrations. This is known as part of the cytokine-mediated inflammatory response. In addition, in patients with injury, infection, or cancer, the reduced mineral content may also occur secondary to poor oral intake, increased requirements, and excessive urinary and stool losses.

Magnesium Total body stores are 2028 g of magnesium. Communications with several experts on magnesium and current work on the antiarrhythmic actions of magnesium suggest a that the commonly used normal values for serum magnesium levels should be increased from 1.7–2.3 mg/dl to 2.0–2.6 mg/dl. Large losses can occur in conditions such as diarrhea, in which the stool may have up to 12 meq of magnesium per liter and the urine may have up to 25 meq per day. Large urinary losses can occur in cancer patients given aminoglycides, diuretics, and ketoconazole. Furthermore, large losses can occur in some of the intestinal fluids (**Table 3**) in cancer and other operative patients who develop GI fistulas.

Zinc Total body stores are only 2 or 3 g of zinc. Zinc concentration in the blood decreases as an early response to cytokines. This is commonly seen in many different types of injury as well as in cancer patients. There are minor tissue stores of zinc in skin, bone, and intestine. Zinc is redistributed to liver, bone marrow, thymus, and the site of injury or inflammation. This redistribution is mediated by IL-1 and the other cytokines secreted from macrophages. In hospitalized cancer patients, a reduced serum zinc concentration ($<70\,\mu g/dl$) is not uncommon. The administration of approximately 50 mg of zinc per day is associated with a normalization of the zinc level after 3 weeks of feeding. Fifteen percent of healthy elderly have been found to have reduced serum zinc levels ($<67\,\mu g/dl$). The replacement of a multivitamin with 14 mg of zinc per day for 1 year resulted in a significant reduction in the number of days associated with infection-related illnesses (48 ± 7 to 23 ± 5 days per year). This vitamin and mineral supplementation improved the lymphocyte response to phytohemagglutin and the natural killer cell activity. There was no change in the placebo-treated group. Zinc supplementation in hospitalized patients may help with normal immune response for minor infection and wound healing. Zinc is needed for cell mitosis and cell proliferation. It has also been demonstrated to improve wound healing in patients provided 600 mg of zinc sulfate (136 mg of elemental zinc) orally per day who had a serum zinc level on admission of less than 100 μg/dl. In this double-blind study, the healing rate increased more than twofold in those randomized to receive zinc supplementation. In addition, large losses of zinc can occur via intestinal losses (**Table 3**). It is important to note that intestinal fluids can contain up to 17 mg of zinc per liter, so the replacement rate of zinc should take into account the abnormal sources of zinc loss as well as the routine nutritional requirements.

Copper Total body stores are very small at 60–80 mg. Serum copper status is normal or increased compared to that of serum zinc, and cytokines are also believed to be responsible for these changes. The benefits of or rational for these increased concentrations are not known.

Iron Total body stores are 3.5–4.5 g of iron. An increase in cytokines also contributes to the observed decrease in serum iron concentration. This is a mediated response to cancer, injury, or infection. The exact mechanism is not known, but iron is stored in Kupffer cells of the liver until the injury wanes. This is probably a beneficial effect

Table 3 Electrolyte contents of body fluids

Body fluid	*Electrolyte and mineral concentration (meq/l)*					
	Sodium	*Potassium*	*Chloride*	*Bicarbonate*	*Magnesium*	*Zinc (mg)*
Bile	145	5	100	15–60	1–2	—
Colonic fluids	50	30–70	15–40	30	6–12	17
Diarrheal fluids	50	35	40	45	1–13	17
Duodenum	130	5–10	90	10	1–2	12
Ileal fluids	140	10–20	100	20–30	6–12	17
Pancreatatic juice	140	5	75	70–115	0.5	—
Saliva	10	20–30	15	50	0.6	—
Stomach fluids	100	10	120	0	0.9	—
Urine	60–120	30–70	60–120	—	5	0.1–0.5
Urine post Lasix	15× normal	2× normal	—	—	20× normal	—

since many microbes use iron as a source of energy. Iron administration should be restricted in patients who have a serious infection because it has been shown to cause harm with fungal, parasitic, malarial, or other types of low-grade or quiescent infections.

Summary

Vitamins and minerals act as cofactors for essential processes in health and in illness. The requirements for the healthy person have been well established and are published as the recommended daily requirements (**Tables 4** and **5**). The exact needs for the infected, injured, or cancer patient are not well documented and evaluations are in progress. Reduced levels of vitamin C, vitamin A, copper, manganese, and zinc have been observed, and all of these are associated with poor wound healing. Wound dehiscence is eight times more common with decreased vitamin C levels. This is probably due to the fact that vitamin C enhances capillary formation and decreases capillary fragility, is a necessary component of complement, and is key to the hydroxylation of proline and lysine in collagen synthesis. Vitamin A enhances collagen synthesis and crosslinking of new collagen, enhances epithelialization, and antagonizes the inhibitory effects of glucocorticoids on cell membranes. Manganese is a cofactor in the glycosylation of hydroxylysine in procollagen. Copper acts a cofactor in the polymerization of the collagen molecule and as a cofactor in the formation of collagen crosslinks.

Table 4 Adult daily vitamin nutritional requirements (RDA, 1989)

Nutrient	*Oral*	*Intravenous*	*Special requirements (diagnosis)*
Vitamin A	3300 IU/day	3300 IU/day (1 mg)	5000+ IU/day (serious infections)
Vitamin B (Biotin)	100 μg/day	60 μg/day	
Vitamin B (Folic acid)	0.2 mg/day	0.4 mg/day	5 mg/day (ICU patients/thrombocytopenia)
Vitamin B (Niacin)	20 mg/day	40 mg/day	
Vitamin B_1 (Thiamin)	1.5 mg/day	3 mg/day	50 mg/day (alcoholics/Wernike–Korsakoff)
Vitamin B_2 (Riboflavin)	1.8 mg/day	3.6 mg/day	
Vitamin B_6 (Pyridoxine)	2 mg/day	4 mg/day	
Vitamin B_{12}	2 μg/day	5 μg/day	
Vitamin C	60 mg/day	100 mg/day	
Vitamin D	400 IU/day	200 IU/day (5 μg)	
Vitamin E	10 mg/day	10 mg	
Vitamin K	80 μg/day	[a]	
Pantothenic acid	7 mg/day	15 mg/day	

[a]Vitamin K is routinely given as 10 mg SQ on admission and then every Monday.

Table 5 Daily nutritional requirements

Nutrient	*Adult daily nutritional requirements*		
	Oral	*IV*	*Special requirements (diagnosis)*
Macronutrients			
Protein	1.5–2.0 g/kg	1.5–2.0 g/kg	2–3 g/kg (thermal injury)
Glucose	20–25 kcal/kg	20–25 kcal/kg	3000 kcal goal in alcoholic liver disease patients
Lipid	4% of kcals	4% of kcals	Can administer up to 60% of calories to prevent hyperglycemia
Micronutrients			
Sodium	60–150 meq	60–150 meq	
Potassium	40–80 meq	40–80 meq	
Chloride	40–100 meq	40–100 meq	
Acetate	10–40 meq	10–40 meq	
Phosphorus	10–60 mmol	10–60 mmol	
Calcium	5–20 meq	5–20 meq	100 meq or more severe hypocalcemia and hungry bone syndrome
Magnesium	10–20 meq	10–20 meq	50–100 meq (cardiac arrthymias, diarrhea)
Zinc	3 mg	2.5–4 mg	10–100 mg (diarrhea, fistula, wounds)
Copper	1.5–3 mg	1–1.5 mg	
Chromium	50–200 μg	10–15 μg	40 μg (diarrhea, gastrointestinal losses)
Molybdenum	75–250 μg	100–200 μg	
Manganese	2–5 mg	150–800 μg	
Selenium	40–120 μg	40–120 μg	120–200 μg (thermal injury, wounds)

Nutritional Assessment and Predictors of Hospital Outcome

Markers of Nutritional Assessment

Conventional nutritional assessment in injured, infected, or cancer patients is of clinical value. Body weight and history of weight loss is one of the best indicators of survival in patients with infection or cancer. In addition, serum albumin concentration upon admission is probably one of the best predictors of hospital survival (**Table 2**). Serum albumin is commonly used as an indicator of nutritional status. Its level provides the clinician with an index of visceral and somatic protein stores for most medical illnesses. A level less than 3.0 is considered malnutrition and may also be called hypoalbuminemic malnutrition or protein malnutrition. Exceptions to this include the isolated starved state such as anorexia nervosa, severe edema, and the rare case of congenital analbuminemia. Serum albumin has a 21-day half-life, and this can reflect processes that have been ongoing for a few weeks. The benefit of serum albumin is that it is also an inverse acute phase reactant. The further it declines, the more severe the injury response on top of the severity of malnutrition at the time of the injury or cancer.

Predictors of Clinical Outcome

The best marker of injury is serum albumin concentration. It is an excellent predictor of survival in patients with cancer and other types of illnesses (**Table 6**). More than 20 studies have shown that a serum albumin level below normal can be used to predict disease outcomes in many groups of patients. One of the first studies in this area was a Veterans Administration study in which 30-day mortality rates were evaluated for a total of 2060 consecutive medical and surgical admissions. Investigators found that 24.7% of the patient population had a low albumin level defined as 3.4 g/dl or lower. The 30-day mortality rate for hypoalbuminemia patients was 24.6% compared to 1.7% for patients with a normal albumin level. These investigators demonstrated an excellent correlation between serum albumin levels and 30-day mortality rates. A 1-g decrease in serum albumin levels (3.5 to 2.5 g/dl) translated into a 33% increase in mortality. Patients with an average albumin level of 1.8 g/dl had a mortality rate of 65%. It is interesting to note that of 15 hypoalbuminemia patients in this study who were provided with total parenteral nutrition, only 1 died (7% mortality).

Protein malnutrition is associated with a greater risk for infection, especially fungal infections. In one

study, the most important risk factor for the development of candidemia was malnutrition. A reduced serum albumin level is an independent risk factor for nosocomial infections. The greater the protein malnutrition, the greater the risk for nosocomial infections.

In summary, serum albumin concentrations provide the clinician with a tool to help predict recovery or mortality. Albumin levels should be monitored at regular intervals (every 3 or 4 days) for hospitalized patients who are ill and at risk for malnutrition. Once hypoalbuminemia is documented, it is not an ideal indicator of nutritional rehabilitation since it returns to normal slowly (21-day half-life) and lags behind other indices of nutritional status, such as transferrin (7-day half-life), prealbumin (1-day half-life), or retinol binding protein (4-h half-life). Albumin replacement does not reverse the metabolic process that the hypoalbuminemia state represents. The reduced level of protein reserves in the patient and the severity of the metabolic injury or cancer are the two most important determinants of serum albumin level.

Nutritional Diagnoses Commonly Seen in Hospitalized Patients

The diagnosis of malnutrition is made by taking a good history and obtaining a physical exam. It is important to ask the patient if he or she has been able to maintain his or her appetite and body weight during the past several months. A history of a recent hospitalization is also important to note due to the common development of protein malnutrition during hospital stay. The physical exam involves inspection of the muscle mass, especially noting a loss of temporals muscle, 'squaring off' of the deltoid muscle, and loss of the thigh muscles. Obtaining a measured body weight should be standard on all admissions, and this weight should be followed on a daily basis.

Up to 50% of hospitalized surgical and medical patients have either hypoalbuminemia or marasmic-type malnutrition. Hypoalbuminemia or protein malnutrition can be diagnosed with the measurement of reduced albumin, transferrin, prealbumin, or retinol binding protein levels. Albumin levels are most commonly used to make the diagnosis. Marasmic malnutrition is the diagnosis for anyone who has lost 20% of usual body weight during the preceding 3–6 months or who is less than 90% of ideal body weight. Of these two types of malnutrition, protein malnutrition is most common. The presence of hypoalbuminemia malnutrition in one study was associated with a 4-fold increase in dying and a 2.5-fold increased risk of developing a nosocomial infection and sepsis. As indicated in **Table 6**, a low serum albumin level predicts a significant increase in mortality across many diseases.

Loss of Lean Body Mass

The use of body weight as an index of muscle mass in the cancer patient is very difficult due to the possible fluid shifts that occur in the extracellular compartment. Body weight can be divided into three compartments: extracellular mass, lean body mass, and fat mass. Extracellular mass is known to increase in malnutrition and as a result of hypoalbuminemia. An increase in extracellular fluid occurs more commonly in the malnourished patient. A large portion of the fluid shift noted in cancer patients is due to a reduction in the plasma colloid oncotic pressure. Lean body mass is the mixture of skeletal muscle, plasma proteins, skin, skeleton, and visceral organs. The skin and skeleton account for 50% of the lean body mass. Currently, there are no convenient markers to determine the loss of nitrogen from either skin or skeleton. The plasma proteins account for only 2% of the lean body mass, but albumin measurement can reflect the overall status of the lean body mass. The viscera accounts for 12% of the lean body mass, and decreases in some of visceral sizes (gut atrophy and cardiac atrophy) are noted in cancer patients. Unfortunately, there is no convenient marker of loss of lean body mass that originates from the visceral organs. On the other hand, urine creatinine is a marker of skeletal muscle mass. The skeletal muscle accounts for 35% of the lean body mass, and it provides the major storage area for amino acids needed during illness. The standard way to assess the size of the skeletal mass is to determine the creatinine height index by collecting 24-h urine and comparing the value to normal values of creatinine excretion for age, sex, and height. A simplified way is to collect 24-h urine and divide the total amount by the ideal body weight based on the patient's height. The normal value for an adult male is 23 mg/kg of ideal body weight, and that for a female is 18 mg/kg. A value of 10% less than normal would be consistent with a 10% loss in the muscle mass for unit height. A value of 20% less than the lower range of normal would classify patients as having mild muscle loss. A 20–40% loss would classify them as having a moderate loss, and a 40% or greater reduction in the creatinine per weight would document severe muscle loss. The most accurate estimate is to obtain urine creatinine over a 3-day period and to repeat at intervals to

document the loss of muscle mass over an extended period of time. Dietary creatine and creatinine intake has only a minor influence (<20%) on urinary creatinine in the normal eating individual. Changes in dietary intake may influence the accuracy of the collection, but repeating the values over 3 days will help average variations in dietary intake. Impairment of renal function reduces the normal creatinine excretion and excludes the creatinine height index as a marker of muscle mass.

Elevated Resting Energy Expenditure

Resting energy expenditure (REE) is directly linked to the size of the lean body mass. REE is difficult to determine accurately in volunteers since the method of indirect calorimetry has variations when the same individual is restudied. Several studies have demonstrated an elevated rate of energy expenditure when compared to controls of similar weight. The use of D_2O^{18} has helped in the estimate of energy expenditure and will improve our understanding of energy expenditure in the future.

Nutritional Feeding of the Patient: Enteral versus Parenteral

Vitamins and Minerals

The standard oral and intravenous vitamin intake and what is currently being given at Harbor-UCLA Medical Center and UCLA Medical Center are listed in **Table 4**. Also included are the few exceptions to the routine intravenous amounts for both **Tables 4** and **5**. The mineral and trace element requirements are listed in **Table 5**. These vitamin, mineral, and trace mineral recommendations are for hospitalized cancer patients and noncancer patients who are hospitalized. They should not have oliguric renal failure or cholastatic liver disease. In acute oliguric renal failure, vitamins A and D should be reduced or eliminated from the enteral or parenteral solutions. Potassium, phosphorus, magnesium, zinc, and selenium should be reduced or eliminated. Iron and chromium are known to accumulate in renal failure and should be removed from the parenteral or enteral formulations. In cholastatic liver disease, the trace elements copper and manganese are excreted via the biliary tree in the bile and should be reduced or eliminated to prevent toxicity. In comparison, large amounts of electrolytes and minerals can be lost in gastrointestinal fluids and in urine (**Table 3**). It is essential to replace the estimated amounts lost on a daily basis in the parenteral nutrition.

Enteral versus Parenteral Feeding

In all situations, if the gut is functional, then it should be used as the route of calorie administration. Gut atrophy predisposes bacterial and fungal colonization and subsequent invasion associated with bacteremia. Sepsis due to microbial or toxin translocation into the portal system is a frequent source of fever evaluations that do not indicate an obvious source of infection. Utilization of the GI track can reduce the incidence of bacterial translocation.

Enteral Products

Enteral nutrition is best taken by mouth if the patient can ingest the required amount. If the patient cannot, then either supplements or full tube feeding is the method of choice. Protein in the peptide form is better absorbed than the free amino acid form due to specific transporters in the small intestines for amino acids, dipeptides, and tripeptides. Feeding tube placement is best in the small bowel up to the ligament of Treitz. This can be obtained best by the direct use of fluoroscopy or may be obtained by the passage of the feeding tube into the small bowel by a corkscrew technique, in which the distal tip of the feeding tube is bent at an approximately 30° angle with the wire stilet in place. Upon placement into the stomach, the tube is rotated so that the tip may pass via the pylorus into the small bowel. The infusion of enteral products into the small bowel will reduce the incidence of aspiration because the infusion is below the pylorus. Intubated patients have a low risk for aspiration due to the endotracheal cuff, so placement of a feeding tube into the small bowel is less essential.

Supplementation of enteral products with higher than standard amounts of the amino acid arginine has been done to enhance immune function. Published data on its beneficial effect in surgical patients have demonstrated some benefit; however, data from nonsurgical patients suggest harm. Immunonutrition should not be given to patients with severe infection, especially patients with pneumonia.

Branched-chain amino acid-enriched enteral products are available and have been shown to improve mental function and mortality in patients with hepatic encephalopathy. Albumin synthesis is also stimulated by branched-chain-enriched amino acid solutions. However, additional branched-chain amino acids did not improved morbidity or mortality in trauma or septic patients randomized to receive branched-chain-enriched amino acids compared to conventional feeding.

Glutamine-enriched enteral formulas are very common. There are many enteral products used in hospitalized patients and for home enteral nutritional support. These can be found at several enteral nutrition pharmaceutical Web sites.

The choice of lipid composition in enteral products is a field that is rapidly evolving, and this is an important decision to be made by the clinician depending on the type of disease being treated. The use of omega-3-enriched fatty acids in the enteral product (fish oil-enriched) has been associated with an ability to modify the inflammatory response that may be related to the increased arachondic acid metabolism and a decrease in the omega-6 pathway fatty acid metabolism. Unfortunately, most commercially available enteral products that have omega-3 fatty acids also have other additives, such as arginine, glutamine, and nucleotides, so that the benefits attributed to the use of an omega-3-enriched fatty aid enteral diet await future clinical studies.

Energy Intake for Patients with Malnutrition

The diagnosis of protein malnutrition can be made when the serum albumin level is less than 2.8 g/dl. Many of these patients have a 20% weight loss during the preceding 3 months, or they have a reduced ideal body weight (<90% for height). Patients at high risk for the development of malnutrition are those who are unlikely to ingest a minimum of 1500 kcal by day 5.

There are currently only three studies that support the importance of energy intake in malnourished patients. Elderly hospitalized patients who consume less than 50% of their estimated maintenance caloric requirement have an 8-fold increase in hospital mortality (11.8 vs 1.5%). This suggests that an intake of less than 1000 kcal may not be helpful. In a prospective study providing approximately 400 additional calories as 'sip feeds,' reduced mortality was seen in severely malnourished (body mass index <5th percentile), medically ill elderly patients. In this study, patients were randomized to receive 120 ml of enteral supplements provided by the registered nurse three times per day or provided no additional sip feeds. Patients who received the sip feeds had a significantly better energy intake (1409 kcal) than nonsupplemented patients (1090 kcal), and they had an increased overall weight gain compared with a loss in the controls. Patients in the severely undernourished group who received intervention had a significant reduction in mortality compared to controls (15 vs 35%, $p < 0.05$). The less malnourished or normals did not demonstrate the same benefit. In the third study, patients with less than 25% of recommended calorie intake (<600 kcal) had a 3.7-fold increased rate of nosocomial bloodstream infections. Candida and coagulase-negative *Staphylococcus* accounted for 63% of the nosocomial infections, with candida accounting for 29%.

Iodine is classified as a nonmetallic solid in the halogen family of the Periodic Table of the elements and therefore is related to fluorine, chlorine, and bromine. The halogen family lies between the oxygen family and the rare gases. Iodine sublimates at room temperature to form a violet gas; its name is derived from the Greek *iodes*, meaning 'violet-colored.' Iodine was discovered by Bernard Courtois in Paris in 1811, the second halogen (after chlorine) to be discovered. It took nearly 100 years to understand its critical importance in human physiology. In 1896, Baumann determined the association of iodine with the thyroid gland, and in 1914 Kendall, with revisions by Harrington in 1926, described the hormone complexes synthesized by the thyroid gland using iodine that are so integral to human growth and development.

As the biochemistry of iodine and the thyroid was being established, the scarcity of the element in the natural environment became evident and the link between deficiency and human disease was revealed. Enlargement of the thyroid, or goitre, is seen in ancient stone carvings and Renaissance paintings, but it was not until years later that the link with lack of iodine was firmly established. Even with this knowledge, many years passed before preventive measures were established. From 1910 to 1920 in Switzerland and the USA work was done on the use of salt fortified with iodine to eliminate iodine deficiency, with classic work being done by Dr David Marine in Michigan. Recently the linkage of iodine deficiency with intellectual impairment has brought iodine into the international spotlight.

Recent work has demonstrated that the halogens, including iodine, are involved through the halo-peroxidases in enzymatic activity and production of numerous active metabolites in the human body. While the importance of iodine for the

thyroid has been known for some time, recent research on halogen compounds in living organisms suggests additional more complex roles including antibiotic and anticancer activity. Yet it is the critical importance of iodine in the formation of the thyroid hormones thyroxine (T_4) and triiodothyronine (T_3) that makes any discussion of this element and human physiology of necessity bound up with a review of thyroid function.

Existence of Iodine in the Natural Environment

The marine hydrosphere has high concentrations of halogens, with iodine being the least common and chlorine the most. Halogens, including iodine, are concentrated by various species of marine organisms such as macroalgae and certain seaweeds. Release from these organisms makes a major contribution to the atmospheric concentration of the halogens. Iodine is present as the least abundant halogen in the Earth's crust. It is likely that in primordial times the concentration in surface soils was higher, but today the iodine content of soils varies and most has been leached out in areas of high rainfall or by previous glaciation. Environmental degradation caused by massive deforestation and soil erosion is accelerating this process. This variability in soil and water iodine concentration is quite marked, with some valleys in China having relatively high iodine concentrations in water, and other parts of China with negligible amounts in soil and water. **Table 1** shows the relative abundance of various halogens in the natural environment, while **Figure 1** illustrates the cycle of iodine in nature.

Table 1 Relative abundance of halogens in the natural environment

Element	*Abundance in oceans (ppm)*	*Abundance in Earth's crust (ppm)*	*Abundance in human body (mol)*
Fluorine	1.3	625	0.13
Chlorine	19 400	130	2.7
Bromine	67	2.5	0.0033
Iodine	0.06	0.05	0.00013

Commercial production of iodine occurs almost exclusively in Japan and Chile, with iodine extracted from concentrated salt brine from underground wells, seaweed, or from Chilean saltpetre deposits.

Absorption, Transport, and Storage

Iodine is usually ingested as an iodide or iodate compound and is rapidly absorbed in the intestine. Iodine entering the circulation is actively trapped by the thyroid gland. This remarkable capacity to concentrate iodine is a reflection of the fact that the most critical physiological role for iodine is the normal functioning of the thyroid gland. Circulating iodide enters the capillaries within the thyroid and is rapidly transported into follicular cells and on into the lumen of the follicle. This active transport is likely to be based on cotransport of sodium and iodine, allowing

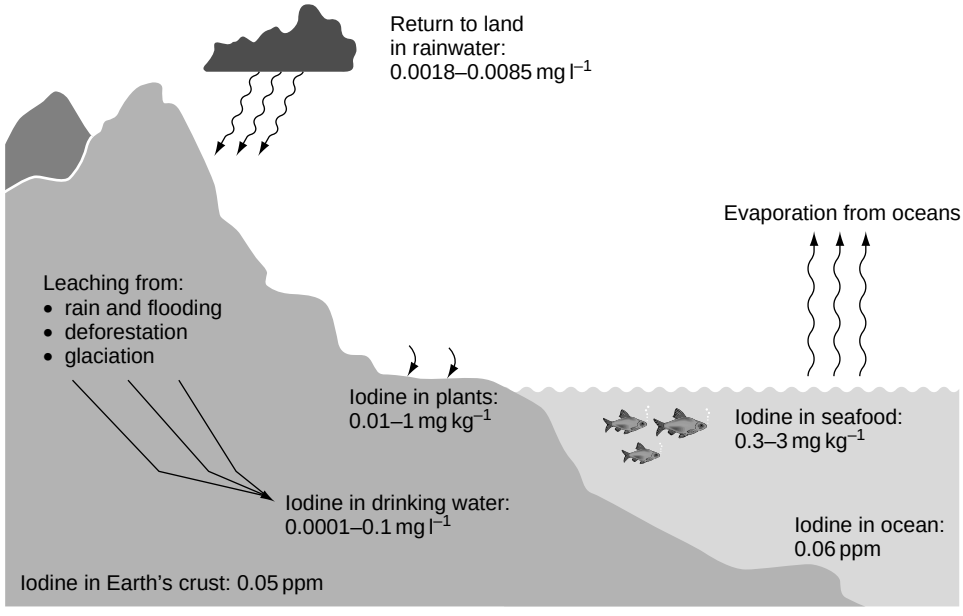

Figure 1 Cycle of iodine in nature.

iodine to move against its electrochemical gradient. Several anions, such as thiocyanate, perchlorate, and pertechnetate, inhibit this active transport. There is evidence that the active transport clearly demonstrated in the thyroid gland is also true for extrathyroidal tissues, including the salivary glands, mammary glands, and gastric mucosa.

In addition to trapping iodine, follicular cells also synthesize the glycoprotein, thyroglobulin (Tg), from carbohydrates and amino acids (including tyrosine) obtained from the circulation. Thyroglobulin moves into the lumen of the follicle where it becomes available for hormone production. Thyroid peroxidase (TPO), a membrane-bound hem-containing glycoprotein, catalyzes the oxidation of the iodide to its active form, I_2, and the binding of this active form to the tyrosine in thyroglobulin to form mono- or diiodotyrosine (MIT or DIT). These in turn combine to form the thyroid hormones triiodothyronine (T_3) and thyroxine (T_4). Thyroglobulin is very concentrated in the follicles through a process of compaction, making the concentration of iodine in the thyroid gland very high. Only a very small proportion of the iodine remains as inorganic iodide, although even for this unbound iodide the concentration in the thyroid remains much greater than that in the circulation. This remarkable ability of the thyroid to concentrate and store iodine allows the gland to be very rapidly responsive to metabolic needs for thyroid hormones. **Figure 2** shows the structures of the molecules tyrosine and thyroxine.

Formation of thyroid hormones is not restricted to humans. Marine algae have an 'iodine pump' that facilitates concentration; invertebrates and all vertebrates demonstrate similar mechanisms to concentrate iodine and form iodotyrosines of various types. Although the function of these hormones in invertebrates is not clear, in vertebrates these iodine-containing substances are important for a variety of functions, such as metamorphosis in amphibians, spawning changes in fish, and general translation of genetic messages for protein synthesis.

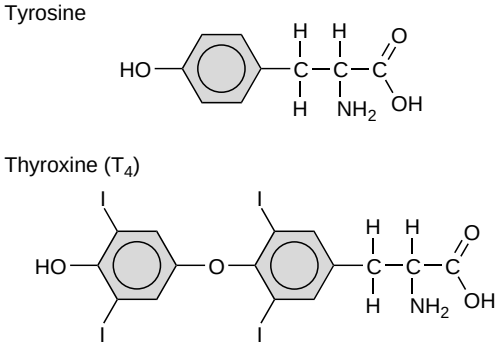

Figure 2 Structures of tyrosine and thyroxine (T_4).

Metabolism and Excretion

Once iodine is 'captured' by the thyroid and thyroid hormones formed in the lumen of the follicles, stimulation of the gland causes release of the hormones into the circulation for uptake by peripheral tissues. Both production and release of the hormones are regulated in two ways. Stimulation is hormonally controlled by the hypothalamus of the brain through thyroid releasing hormone (TRH) which stimulates the pituitary gland to secrete thyroid stimulating hormone (TSH), which in turn stimulates the thyroid to release T_3 and T_4. In addition to the regulation of thyroid hormones by TSH, iodine itself plays a major role in autoregulation. The rate of uptake of iodine into the follicle, the ratio of T_3 to T_4, and the release of these into the circulation, among other things, are affected by the concentration of iodine in the gland. Thus, an increase in iodine intake causes a decrease in organification of iodine in the follicles and does not necessarily result in a corresponding increase in hormone release. Recent research suggests that this autoregulation is not entirely independent of TSH activity and that several other factors may contribute. However, regardless of the mechanism, these regulatory mechanisms allow for stability in hormone secretion in spite of wide variations in iodine intake.

When stimulated to release thyroid hormones, thyroglobulin is degraded through the activity of lysosomes and T_3 and T_4 are released and rapidly enter the circulation. Iodide freed in this reaction is for the most part recycled and the iodinated tyrosine reused for hormone production. Nearly all of the released hormones are rapidly bound to transport hormones, with 70% bound to thyroxine binding globulin (TBG). Other proteins, such as transthyretin (TTR), albumin, and lipoproteins, bind most of the remainder; with significant differences in the strengths of the affinity for the hormones, these proteins transport the hormones to different sites.

This remarkable ability of the thyroid to actively trap and store the iodine required creates a relatively steady state, with daily intake used to ensure full stores. T_4, with a longer half-life, serves as a reservoir for conversion to the more active hormone, T_3, with a much shorter half-life of 1 day. Target organs for thyroid hormone activity all play a role in the complex interplay between conversion of T_4 to T_3 deiodination, and metabolism of various other proteins involved with thyroid function. The liver,

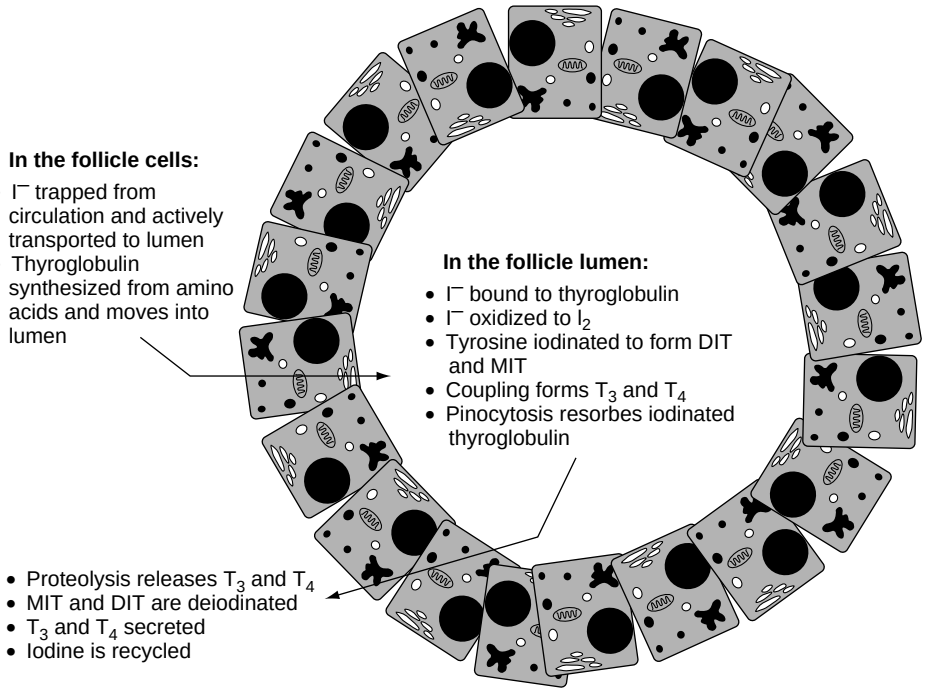

Figure 3 Thyroid follicle (courtesy of Kiely Houston).

which is estimated to contain 30% of the extrathyroidal T_4, is responsible, through the activity of the liver cell enzyme, deiodinase, for ensuring adequate supply of T_3 to peripheral tissues and degradation of metabolic by-products. The kidney demonstrates a strong ability to take up the iodothyronines. Iodine is ultimately excreted in the urine, with average daily excretion rates of approximately 100 μg per day. This accounts for the vast majority of iodine excretion, with negligible amounts excreted in feces. **Figure 3** illustrates a thyroid follicle and summarizes iodine transport.

Metabolic Functions

Separating the role of iodine from the complex and pervasive function of the thyroid gland is difficult since iodine is a critical component of the hormones that mediate these functions, and whatever other roles iodine may have are poorly understood. Thyroid hormones affect a wide range of physiological functions, from liver and kidney to heart and brain. Earlier work supported a role for thyroid hormones in affecting the energy generating capacity of cells through biochemical changes in mitochondria. More recent work has shown, however, that these hormones act on specific genetic receptors in cell nuclei, and perhaps through other extranuclear mechanisms. The nuclear receptors belong to a large family of receptors that bind other extranuclear molecules including vitamins A and D and steroids. Through this interaction, along with a number of other proteins, thyroid hormones modify genetic expression. A great deal of research currently focuses on these thyroid hormone receptors, and the effect primarily of T_3 on the physiological function of the target organ through genetic transcription. These receptors are present in pituitary, liver, heart, kidney, and brain cells.

In the pituitary gland, thyroid hormones, along with many cofactors, regulate the synthesis and secretion of growth hormone by increasing gene transcription. Similarly, as part of the feedback loop for hormone regulation and release, thyroid hormones affect transcription of TSH in the pituitary. In cardiac and skeletal muscle, thyroid hormones affect production of the muscle tissue myosin in a variety of ways, depending on the stage of life and specific muscle tissue affected. In addition, the hormones affect muscle contraction through genetic alteration of calcium uptake within the cell. Carbohydrate metabolism and formation of certain fats (lipogenesis) are affected through hormone-induced changes in gene transcription in liver cells.

In the adult brain, receptors have been identified, but the specific genes affected by thyroid hormones have not yet been located. However, in the developing brain of the fetus and neonate, the effects of thyroid hormones are significant even though the

Table 2 Estimated iodine concentrations in selected organs

Total body	*Thyroid gland*	*Brain*	*Liver*	*Blood*
15–20 mg	8–12 mg (for a 15–25 g gland)	0.02 $\mu g\,g^{-1}$ (wet weight)	0.2 $\mu g\,g^{-1}$ (wet weight)	0.08–0.60 $\mu g\,dl^{-1}$ (plasma inorganic iodide)

exact mechanisms are still not fully understood. The effects of thyroid hormones on brain development are suggested by failure in development of the nerve elements, failure of differentiation of cerebellar cells, and reduced development of other brain cells, in hypothyroid states. It is this early effect that has recently elevated the status of iodine from an element whose deficiency caused goitre to one whose deficiency is the leading cause of mental impairment worldwide.

In addition to these nuclear mechanisms, several alternative pathways have been suggested, some based on earlier historical studies. The thermogenic effects of thyroid hormones were originally felt to be a direct action on mitochondria, though this has recently been questioned. Thyroid hormones stimulate glucose transport, and again though originally attributed to a direct action on the plasma membrane, recent evidence suggests a genetic mechanism. There may also be a direct effect of thyroid hormones on brain enzymatic activity.

The overall effect of these cellular and systemic actions is to stimulate respiratory and other enzyme synthesis, which results in increased oxygen consumption and resultant increased basal metabolic rate. This affects heart rate, respiratory rate, mobilization of carbohydrates, cholesterol metabolism, and a wide variety of other physiological activities. In addition, thyroid hormones stimulate growth and development and, as noted earlier, are critical for the normal proliferation, growth, and development of brain cells. **Table 2** shows the estimated iodine concentration in selected organs.

Iodine Deficiency and Excess

Iodine Deficiency

Iodine deficiency is the most common cause of preventable mental retardation in the world. This fact, along with the recognition that iodine deficiency is not limited to remote rural populations, has stimulated agencies and governments to mobilize resources to eliminate this problem. This global effort, focusing primarily on iodization of salt for human and animal consumption, is slowly succeeding in eliminating a hidden set of disorders that have plagued mankind for centuries.

Unlike many nutritional deficiencies that are more directly related to socioeconomic status, insufficient intake of iodine is a geographical disease, related to lack of iodine in the environment. Iodine originally present in soil was subjected to leaching by snow and rain, and while a portion of the iodine in the oceans evaporates and is returned to the soil in rainwater, this amount is small. Thus, many areas have insufficient iodine in the environment, and this is reflected in plants grown in that environment. The diets in many developing countries are limited in variability and contain few processed foods. This places large populations at risk of iodine deficiency. The World Health Organization (WHO) estimates that at least 1572 million people are at risk in 118 countries, with 43 million affected by 'some degree of mental impairment.'

In the most simplistic physiological model, inadequate intake of iodine results in a reduction in thyroid hormone production, which stimulates increased TSH production. TSH acts directly on thyroid cells, and without the ability to increase hormone production, the gland becomes hyperplastic. In addition, iodine trapping becomes more efficient, as demonstrated by increased radioactive iodine uptake in deficient individuals. However, this simplistic model is complicated by complex adaptive mechanisms which vary depending on the age of the individual affected. In adults with mild deficiency, reduced intake causes a decrease in extrathyroidal iodine and reduced clearance, demonstrated by decreased urinary iodine excretion, but iodine concentration in the gland may remain within normal limits. With further reduction in intake, this adaptive mechanism is overwhelmed, and the iodine content of the thyroid decreases with alterations in iodination of thyroglobulin, in the ratio of DIT to MIT, and reduction in efficient thyroid hormone production. The ability to adapt appears to decrease with decreasing age, and in children the iodine pool in the thyroid is smaller, and the dynamics of iodine metabolism and peripheral use more rapid. In neonates, the effects of iodine deficiency are more directly reflected in increased TSH. Diminished thyroid iodine content and increased turnover make neonates the most vulnerable to the effects of iodine deficiency and decreased hormone production, even with mild deficiency.

A number of other factors influence iodine balance. Active transport of iodide is competitively inhibited by several compounds, including complex ions such as perchlorate, and by thiocyanate, a metabolic product of several foods. Other compounds, such as propylthiouracil, affect coupling reactions and iodination, doing so regardless of iodine intake, e.g., without blocking iodide transport. Several pharmaceuticals affect peripheral hormone action. Dietary goitrogens, as these compounds have been called, include cassava, lima beans, sweet potatoes, cabbage, and broccoli; these contain cyanide compounds that are detoxified to thiocyanate, which may inhibit iodide transport. Cabbage and turnips, and other plants of the genus *Brassica*, also contain thionamide compounds which block iodination. Certain industrial waste products, such as resorcinol from coal processing, contain phenols that cause irreversible inhibition of TPO and block iodination. In some countries the staple diet includes such goitrogens, and iodine deficiency may be exacerbated, as has been well documented for cassava. While this may be a significant problem in some geographical areas, in most instances adequate dietary iodine can reverse the goitrogenic effect.

The most important clinical effect of deficiency relates to the fact that thyroid hormone is required for the normal development of the brain in both humans and other animals. Numerous studies have demonstrated reduced psychomotor skills and intellectual development in the presence of iodine deficiency, and most experts now believe that there is a continuum of deficits, from mild impairment in IQ to severe mental retardation. Studies in China demonstrated shifts in IQ point distributions in rural communities that were deficient, suggesting an impact of deficiency of 10–15 IQ points. In Europe, where mild deficiency still exists, studies have demonstrated decreased psychomotor, perceptual integrative motor ability as well as lower verbal IQ scores in schoolchildren. Studies in Iran showed similar findings. A recent meta-analysis of 18 studies demonstrated a strong relationship, with an overall 13.5 IQ point difference between deficient and non deficient populations. These findings, coupled with the high prevalence of deficiency in many countries, have major implications for development.

The most severe effect of iodine deficiency is cretinism, which is rare in areas of mildly endemic deficiency but may have reached 5–10% or more in areas with severe deficiency. There are general classifications of cretinism, the symptoms of which frequently overlap. Neurological cretinism presents as extreme mental retardation, deaf-mutism, and impaired motor function including spastic gait. Myxoedematous cretinism presents as disturbances of growth and development including short stature, coarse facial features, retarded sexual development, mental retardation, and other signs of hypothyroidism. It appears likely that severe deficiency resulting in decreased maternal T_4 may be responsible for the impaired neurological development of the fetus occurring early in pregnancy. The effect of deficiency on the fetus after 20 weeks' gestation may result in hyperstimulation of the developing fetal thyroid, with the extreme manifestation being thyroid failure causing myxoedematous cretinism. Other factors may affect thyroid hormone metabolism. Selenium deficiency, when present with iodine deficiency, may alter the clinical manifestations. Selenium deficiency decreases the activity of the enzyme, glutathione peroxidase (GPX), which, along with thyroid hormone synthesis, reduces hydrogen peroxide (H_2O_2). Combined with iodine deficiency and reduced hormone synthesis, it has been speculated that selenium deficiency may contribute to accumulation of H_2O_2 which may in turn lead to cell damage and contribute to thyroid failure. Selenium is also essential for the deiodinase enzyme activity affecting thyroid hormone catabolism, and deficiency may actually increase serum thyroxine. The balance between these two effects is still not fully understood. The study of cretinism has been critical to the evolution of our understanding of the critical role of iodine for normal mental development.

Iodine deficiency has a number of other effects, including development of goitre, clinical or subclinical hypothyroidism, decreased fertility rates, increased stillbirth and spontaneous abortion rates, and increased perinatal and infant mortality. This spectrum of clinical effects, collectively called 'iodine deficiency disorders,' underlines the importance of iodine in human health.

The most effective method to eliminate iodine deficiency in populations is through iodization of salt. The most classic success of salt iodization was demonstrated in Switzerland. Salt is universally consumed, and in most countries the amount consumed is relatively constant between 5 and 10 g per person per day. Iodine is usually added as iodide or iodate (which is more stable) to achieve 25–50 ppm iodine at consumption. This provides about 150–250 μg of iodine per person per day.

The challenge for national iodine deficiency elimination programs is to mobilize the various sectors that must be involved in a sustainable national program, including education, industry, health, and the political arena. There must be an appropriate regulatory environment, effective demand creation,

adequate production to make iodized salt available, and quality assurance of both the product and all program elements to ensure that the program is sustained forever. Success in these efforts has the potential to have a greater impact on development than any public health program to date.

Iodine Excess

Iodine is used in many medications, food preservatives, and antiseptics with minimal adverse effects on populations. Pure iodine crystals are toxic, and ingestion can cause severe stomach irritation. Iodine is allergenic, and acute reactions to radiographic contrast media are not rare. Yet because of the thyroid's unique ability to regulate the body's iodine pool, quite a wide range in intake is tolerated without serious effects, particularly when the exposure is of limited duration.

When ingestion of iodine is in excess of the daily requirement of approximately 150 μg per day, changes in thyroid hormones can occur. A variety of clinical problems can occur, and these differ depending on the dose, the presence of thyroid disease, and whether the individual has been deficient in the past. In iodine-replete individuals without thyroid disease, goitre can result, and rarely, hypothyroidism, although the latter is more common in individuals with other illnesses such as lung disease or cystic fibrosis. The relationship of iodine excess to other diseases such as Hashimoto's thyroiditis remains controversial. In the US iodine levels were quite high from 1960 to 1980, with estimates for adult males as high as 827 μg per day. There was no immediate evidence of an impact on thyroid disease, although longer term longitudinal data are lacking. Effects usually remain subtle and transient, even with ingestion of up to 1500–4500 μg per day.

In the presence of thyroid disease, and in areas with endemic iodine deficiency, suddenly raising daily iodine intake may precipitate hyperthyroidism, and this has been the subject of some concern as salt iodization efforts proceed with fledgling quality assurance. This effect is felt to be related in part to autonomous nodules in the gland that synthesize and release excess thyroid hormone. The exact prevalence of iodine-induced hyperthyroidism in deficient areas is not clear. Many countries initiating salt iodization programs have reported increases in the incidence of toxic nodular goitre and iodine-induced thyrotoxicosis, usually in older people. While this may be a significant clinical problem, the risk is estimated to be between 0.01 and 0.06% and must be considered in the light of the benefit from correction of deficiency.

Assessment of Iodine Status

A standard set of indicators of iodine status has been established by the WHO in response to the need to determine prevalence in countries with endemic deficiency. These indicators reflect iodine status as mediated through the response of the thyroid gland to fluctuations in iodine intake. There are several additional indicators that are used to assess thyroid function, such as T_4 and T_3, but these are less accurate in reflecting iodine status since conversion of T_4 to T_3 and cellular uptake is so responsive to peripheral need.

Urinary iodine reflects iodine sufficiency, and output decreases with diminished intake. Since this indicator reflects the amount of iodine per unit volume of urine, its accuracy is impaired by variable fluid intake and factors affecting the concentration of the urine. Therefore, as a measure of iodine status in an individual, it is less accurate than as a measure of iodine status of a population. Median urinary iodine values are used extensively to assess population prevalence of iodine deficiency.

Thyroid size, either estimated by palpation or using ultrasound volume determination, reflects iodine status since deficiency results in thyroid enlargement, or goitre. Due to the relative ease of palpation, that measure has been a traditional standard to assess populations for iodine deficiency and has been particularly useful in schoolchildren. In adults, where long-standing thyroid enlargement from iodine deficiency may be minimally responsive to corrected iodine intake, palpation may be misleading and could overestimate the current level of iodine sufficiency. In children, palpation becomes increasingly difficult and significantly less accurate when deficiency is mild. Ultrasound volume determination provides a more accurate estimate of thyroid size. For any measure of thyroid size, other factors besides iodine deficiency can cause enlargement, including iodine excess, carcinoma, and infection. In areas of the world where deficiency is a problem, the prevalence of these other diseases compared with goitre from iodine deficiency is negligible.

TSH is produced in response to decreased iodine intake and diminished thyroid hormone production and is used as a measure of iodine status. TSH is best measured in neonates—in the developed world for surveillance against congenital hypothyroidism, and in endemic countries to estimate the magnitude of iodine deficiency. Neonatal TSH has been a useful advocacy tool to demonstrate to policy makers that iodine deficiency is not limited to rural remote populations but affects children born in big city

Table 3 WHO criteria for iodine deficiency as a public health problem in populations

Indicator	*Population assessed*	*Mild deficiency (%)*	*Severe deficiency (%)*
Goitre by palpation	Schoolchildren	5–19.9	≥30
Thyroid volume by ultrasound (>97th percentile)	Schoolchildren	5–19.9	≥30
Median urinary iodine ($\mu g\,l^{-1}$)	Schoolchildren	50–99	<20
TSH (>5 $mU\,l^{-1}$ whole blood)	Neonates	3–19.9	≥40

hospitals. However, with the complexity of the interactions between TSH and other hormones, TSH has not been shown to be as useful in older children or adults in estimating prevalence of iodine deficiency. Also, use of iodine containing antiseptics affects TSH distributions in neonates.

Uptake of radioactive iodine isotopes can be used to scan the gland, and determine the affinity of the gland to introduced iodine, and is a measure of deficiency. The most common isotope used is ^{123}I because of its relatively short 13-h half-life and γ photon emission. Uptake is increased in iodine deficiency. Isotopes can also be used to examine the organification of iodine in the formation of thyroid hormones. This is an impractical method for surveying populations. **Table 3** provides the WHO criteria for defining iodine deficiency as a public health problem.

Requirements and Dietary Sources

The daily requirement for iodine in humans has been estimated based on daily losses, iodine balance, and turnover, with most studies ranging from 40 to 200 μg per day, depending on age and metabolic needs, as shown in **Table 4**.

Natural sources of iodine include seafood, seaweeds, and smaller amounts from crops grown on soil with sufficient iodine, or from meat where livestock has grazed on such soil. The contribution of the latter two is small, and in most countries other sources are required. Iodine added to salt, as noted above, is the primary source for many populations. **Table 5** shows sample iodine content for various sources.

Table 4 Recommended dietary intake

Age	*WHO recommended intake (μg per day)*	*US RDA 1989 (μg per day)*
0–6 months	40	40
6–12 months	50	60 (at age 1 year)
1–10 years	70–120	60–120
11 years–adult	120–150	150
Pregnancy	175	175
Lactation	200	200

In the US and Britain, as well as in other developed countries, most dietary iodine comes from food processing. Intake can vary, as illustrated in **Table 6**. Iodophors used as antiseptics in the dairy and baking industries provide residual iodine in milk and processed foods. In addition, iodine is present in several vitamin and pharmaceutical preparations.

Iodine as a trace element in low concentrations in most environments plays a critical role in the normal growth and development of many species. In humans, iodine is critical for brain development and correction of global deficiencies is an unparalleled opportunity to improve the well-being of our global community.

Table 6 Iodine intake from average US and British diets

Country	*Milk (μg per day)*	*Grains (μg per day)*	*Meat, fish, and poultry (μg per day)*
US	534	152	103
Britain	92	31	36

Table 5 Sample iodine content for various sources

Water	*Cabbage*	*Eggs*	*Seafood*	*Sugar*	*Iodized salt*
0.1–2 $\mu g\,l^{-1}$ in endemic area	0–0.95 $\mu g\,g^{-1}$	4–10 $\mu g\ egg^{-1}$	300–3000 $\mu g\,kg^{-1}$	<1 $\mu g\,kg^{-1}$ in refined sugar	20–50 ppm (at household level, depending on climate, and currently subject to review)
2–15 $\mu g\,l^{-1}$ in nonendemic area				30 $\mu g\,kg^{-1}$ in unrefined brown sugar

Deficiency Disorders

B S Hetzel, Women's and Children's Hospital, North Adelaide, SA, Australia

Iodine deficiency is discussed as a risk factor for the growth and development of up to 2.2 million people living in iodine-deficient environments in 130 countries throughout the world. The effects of iodine deficiency on growth and development, called the iodine deficiency disorders (IDD), comprise goiter (enlarged thyroid gland), stillbirths and miscarriages, neonatal and juvenile thyroid deficiency, dwarfism, mental defects, deaf mutism, and spastic weakness and paralysis, as well as lesser degrees of loss of physical and mental function.

Iodine deficiency is now accepted by the World Health Organization as the most common preventable cause of brain damage in the world today.

Since 1990, a major international health program to eliminate iodine deficiency has developed that uses iodized salt. The progress of this program and the continuing challenge are discussed as a great opportunity for the elimination of a noninfectious disease, which is quantitatively a greater scourge than the infectious diseases of smallpox and polio.

History

The first records of goiter and cretinism date back to ancient civilizations, the Chinese and Hindu cultures and then to Greece and Rome. In the Middle Ages, goitrous cretins appeared in the pictorial art, often as angels or demons. The first detailed descriptions of these subjects occurred in the Renaissance. The paintings of the madonnas in Italy so commonly showed goiter that the condition must have been regarded as virtually normal. In the seventeenth and eighteenth centuries, scientific studies multiplied and the first recorded mention of the word 'cretin' appeared in Diderot's *Encyclopédie* in 1754. The nineteenth century marked the beginning of serious attempts to control the problem; however, not until the latter half of the twentieth century was the necessary knowledge for effective prevention acquired.

Mass prophylaxis of goiter with iodized salt was first introduced in Switzerland and in Michigan in the United States. In Switzerland, the widespread occurrence of a severe form of mental deficiency and deaf mutism (endemic cretinism) was a heavy charge on public funds. However, following the introduction of iodized salt, goiter incidence declined rapidly and cretins were no longer born. Goiter also disappeared from army recruits.

A further major development was the administration of injections of iodized oil to correct iodine deficiency in Papua New Guinea for people living in inaccessible mountain villages. These long-lasting injections corrected iodine deficiency and prevented goiter for 3–5 years, depending on the dosage.

Subsequently, the prevention of cretinism and stillbirths was demonstrated by the administration of iodized oil before pregnancy in a controlled trial

in the Highlands of Papua New Guinea. This proved the causal role of iodine deficiency.

To further establish the relation between iodine deficiency and fetal brain development, an animal model was developed in the pregnant sheep given an iodine-deficient diet. Subsequently, similar models were developed in the primate marmoset monkey and in the rat.

Studies with animal models confirmed the effect of iodine deficiency on fetal brain development (as already indicated by the results of the field trial with iodized oil in Papua New Guinea). The combination of the controlled human trials and the results of the studies in animal models clearly indicated that prevention was possible by correction of the iodine deficiency before pregnancy.

This work led Hetzel to propose the concept of the IDD resulting from all the effects of iodine deficiency on growth and development, particularly brain development, in an exposed population that can be prevented by correction of the iodine deficiency. Iodine deficiency is now recognized by the World Health Organization (WHO) as the most common form of preventable mental defect.

Although the major prevalence of iodine deficiency is in developing countries, the problem continues to be very significant in many European countries (France, Italy, Germany, Greece, Poland, Romania, Spain, and Turkey) because of the threat to brain development in the fetus and young infant.

Ecology of Iodine Deficiency

There is a cycle of iodine in nature. Most of the iodine resides in the ocean. It was present during the primordial development of the earth, but large amounts were leached from the surface soil by glaciation, snow, or rain and were carried by wind, rivers, and floods into the sea. Iodine occurs in the deeper layers of the soil and is found in oil well and natural gas effluents, which are now a major source for the production of iodine.

The better known areas that are leached are the mountainous areas of the world. The most severely deficient soils are those of the European Alps, the Himalayas, the Andes, and the vast mountains of China. However, iodine deficiency is likely to occur to some extent in all elevated regions subject to glaciation and higher rainfall, with runoff into rivers. It has become clear that iodine deficiency also occurs in flooded river valleys, such as the Ganges in India, the Mekong in Vietnam, and the great river valleys of China.

Iodine occurs in soil and the sea as iodide. Iodide ions are oxidized by sunlight to elemental iodine, which is volatile so that every year approximately 400,000 tons of iodine escapes from the surface of the sea. The concentration of iodide in the seawater is approximately 50–60 μg/l, and in the air it is approximately 0.7 μg/m^3. The iodine in the atmosphere is returned to the soil by rain, which has a concentration of 1.8–8.5 μg/l. In this way, the cycle is completed (**Figure 1**).

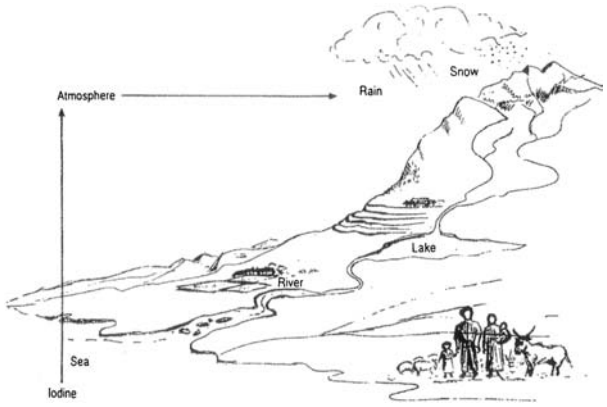

Figure 1 The iodine cycle in nature. The atmosphere absorbs iodine from the sea, which then returns through rain and snow to mountainous regions. It is then carried by rivers to the lower hills and plains, eventually returning to the sea. High rainfall, snow, and flooding increase the loss of soil iodine, which has often been already denuded by past glaciation. This causes the low iodine content of food for man and animals. (Reproduced from Hetzel BS (1989) *The Story of Iodine Deficiency: An international Challenge in Nutrition.* Oxford: Oxford University Press.)

However, the return of iodine is slow and the amount is small compared to the original loss of iodine, and subsequent repeated flooding ensures the continuity of iodine deficiency in the soil. Hence, no natural correction can take place and iodine deficiency persists in the soil indefinitely. All crops grown in these soils will be iodine deficient. The iodine content of plants grown in iodine-deficient soils may be as low as 10 μg/kg compared to 1 mg/kg dry weight in plants in a non-iodine-deficient soil.

As a result, human and animal populations that are totally dependent on food grown in such soil become iodine deficient. This accounts for the occurrence of severe iodine deficiency in vast populations in Asia that live within systems of subsistence agriculture in flooded river valleys (India, Bangladesh, Burma, Vietnam, and China).

Iodine Deficiency Disorders

The effects of iodine deficiency on the growth and development of a population that can be prevented by correction of iodine deficiency, denoted by the term IDD, are evident at all stages, including

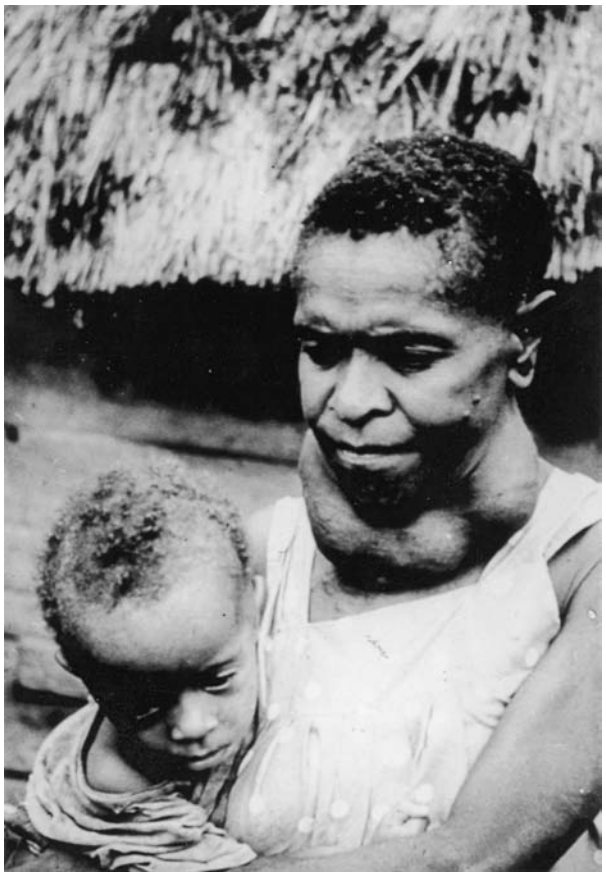

Figure 2 A mother and child from a New Guinea village who are severely iodine deficient. The mother has a large goiter and the child is also affected. The larger the goiter, the more likely it is that she will have a cretin child. This can be prevented by eliminating the iodine deficiency before the onset of pregnancy. (Reproduced from Hetzel BS and Pandav CS (eds.) (1996) *SOS for a Billion: The Conquest of Iodine Deficiency Disorders*, 2nd edn. Oxford: Oxford University Press.)

particularly the fetus, the neonate, and in infancy, which are periods of rapid brain growth. The term goiter has been used for many years to describe the enlarged thyroid gland caused by iodine deficiency (**Figure 2**). Goiter is indeed the obvious and familiar feature of iodine deficiency, but knowledge of the effects of iodine deficiency on brain development has greatly expanded in the past 30 years so that the term IDD was introduced to refer to all the effects of iodine deficiency on growth and development, particularly brain development, in a population that can be prevented by correction of the deficiency (**Table 1**).

The following sections discuss in detail the IDD at various stages of life: the fetus, the neonate, the child and adolescent, and the adult (**Table 1**).

The Fetus

Iodine deficiency of the fetus is the result of iodine deficiency in the mother (**Figure 2**). The condition is associated with a greater incidence of stillbirths, abortions, and congenital abnormalities, which can be prevented by iodization.

Another major effect of fetal iodine deficiency is the condition of endemic cretinism, which is quite distinct from the condition of sporadic cretinism or congenital hypothyroidism due to a small or absent thyroid gland.

Endemic cretinism-associated with an iodine intake of less than 25 μg per day, in contrast to a normal intake of 100–150 μg per day, has been widely prevalent, affecting up to 10% of populations living in severely iodine-deficient regions in India, Indonesia, and China. In its most common form, it is characterized by mental deficiency, deaf mutism, and spastic diplegia (**Figure 3**). This form of cretinism is referred to as the nervous or neurological type, in contrast to the less common hypothyroid or myxedematous type characterized by hypothyroidism with dwarfism (**Figure 4**).

In addition to Asia, cretinism also occurs in Africa, (Zaire, now the Republic of the Congo), South America in the Andean region (Ecuador, Peru, Bolivia, and Argentina), and the more remote areas of Europe. In all these areas, with the exception of the Congo, neurological features are predominant. In the Congo, the hypothyroid form is more common, probably due to the high intake of the root vegetable cassava, which contains substances inhibiting the function of the thyroid gland.

However, there is considerable variation in the clinical manifestations of neurological cretinism,

Table 1 Spectrum of Iodine Deficiency Disorders

Fetus	Abortions
	Stillbirths
	Congenital anomalies
	Neurological cretinism
	Mental deficiency, deaf mutism, spastic diplegia, squint
	Hypothyroid cretinism
	Mental deficiency, dwarfism, hypothyroidism
	Psychomotor defects
Neonate	Increased perinatal mortality
	Neonatal hypothyroidism
	Retarded mental and physical development
Child and adolescent	Increased infant mortality
	Retarded mental and physical development
Adult	Goiter with its complications
	Iodine-induced hyperthyroidism
All ages	Goiter
	Hypothyroidism
	Impaired mental function
	Increased susceptibility to nuclear radiation

Reproduced with permission from Oxford University Press and the World Health Organization, WHO/UNICEF/ICCIDD (2001).

Figure 3 A mother with her four sons, three of whom (ages 31, 29, and 28 years) are cretins born before iodized salt was introduced, and the fourth is normal (age 14 years), born after iodized salt became available in Chengde, China. (Reproduced from Hetzel BS and Pandav CS (eds.) (1996) *SOS for a Billion: The Conquest of Iodine Deficiency Disorders*, 2nd edn. Oxford: Oxford University Press.)

Figure 4 A hypothyroid cretin from Sinjiang, China, who is also deaf mute. This condition is completely preventable. (Right) The barefoot doctor of her village. Both are approximately 35 years old. (Reproduced from Hetzel BS (1989) *The Story of Iodine Deficiency: An international Challenge in Nutrition.* Oxford: Oxford University Press.)

which include isolated deaf mutism and mental defect of varying degrees. In China, the term cretinoid is used to describe these individuals, who may number 5–10 times those with overt cretinism.

The Neonate

Apart from the question of mortality, the importance of the state of thyroid function in the neonate relates to the fact that at birth the brain of the human infant has only reached approximately one-third of its full size and continues to grow rapidly until the end of the second year. The thyroid hormone, dependent on an adequate supply of iodine, is essential for normal brain development, as has been confirmed by animal studies.

Data on iodine nutrition and neonatal thyroid function in Europe confirm the continuing presence of severe iodine deficiency. This affects neonatal thyroid function and hence represents a threat to early brain development. These data have raised great concern about iodine deficiency, which is also heightened by awareness of the hazard of nuclear radiation with carcinogenic effects following the Chernobyl disaster in the former Soviet Union (**Table 1**).

These observations of neonatal hypothyroidism indicate a much greater risk of mental defects in iodine-deficient populations than is indicated by the presence of cretinism. Apart from the developing world, there has been a continuing major problem in many European countries, such as Italy, Germany, France, and Greece, and Romania, Bulgaria, and Albania still have very severe iodine deficiency with overt cretinism.

The Child

Iodine deficiency in children is characteristically associated with goiter. The goiter rate increases with age and reaches a maximum at adolescence. Girls have a higher prevalence than boys. Goiter rates in schoolchildren over the years provide a useful indication of the presence of iodine deficiency in a community.

In a review of 18 studies, a comparison was made between IQ scores in iodine-deficient children and carefully selected control groups. The iodine-deficient group had a mean IQ that was 13.5 points lower than that of the non-iodine-deficient control group. Detailed individual studies demonstrating these defects in Italian and Spanish schoolchildren as well as those from Africa, China, Indonesia, and Papua New Guinea have been published. There is a serious problem in Europe as well as in many developing countries.

The Adult

Long-standing large goiter may require surgery to reduce pressure in the neck. Long-standing goiter may also be associated with iodine-induced hyperthyroidism (IIH) due to an increase in iodine intake. IIH is associated with nervousness, sweating, and tremor, with loss of weight due to excessive levels of circulating thyroid hormone. This condition no longer occurs following correction of iodine deficiency and therefore is within the spectrum of IDD.

In northern India, a high degree of apathy has been noted in whole populations living in iodine-deficient areas. This may even affect domestic animals such as dogs. It is apparent that reduced mental function is widely prevalent in iodine-deficient communities, with effects on their capacity for initiative and decision making. This is due to the effect of hypothyroidism on brain function. This condition can be readily reversed by correction of the iodine deficiency, unlike the effects on the fetus and in infancy, so that villages can come to life.

Thus, iodine deficiency is a major block to the human and social development of communities living in an iodine-deficient environment. Correction of the iodine deficiency is indicated as a major contribution to economic development. An increase in physical and mental energy leads to improved work output, improved learning by children, and improved quality of life. Improved livestock productivity (chickens, cattle, and sheep) is also a major economic benefit.

Magnitude of the Problem

The number of cases of IDD throughout the world was estimated by WHO in 1990 to be 1.6 billion, including more than 200 million cases with goiter and more than 20 million cases with some degree of brain damage due to the effects of iodine deficiency in pregnancy. Recent estimates of the population at risk have been increased to 2.2 billion, with the recognition that even mild iodine deficiency in the mother has effects on the fetus. There are now estimated to be 130 IDD-affected countries, including the most populous: Bangladesh, Brazil, China, India, Indonesia, and Nigeria. Therefore, there is a global scourge of great magnitude, which provides one of the major challenges in international health today.

Correction of Iodine Deficiency

Iodized Salt

Since the successful introduction of iodized salt in Switzerland and the United States in the 1920s, successful programs have been reported from a number of countries, including those in Central and South America (e.g., Guatemala and Colombia) and Finland and Taiwan. However, there has been great difficulty in sustaining these programs in Central and South America mainly due to political instability. Following the breakup of the Soviet Union, iodine deficiency recurred in the Central Asian republics.

The difficulties in the production and quality maintenance of iodized salt for the millions who are iodine deficient, especially in Asia, were vividly demonstrated in India, where there was a breakdown in supply. These difficulties led to the adoption of universal salt iodization (USI) for India and subsequently for many other countries. This policy includes legislation to provide for compulsory iodization of all salt for human and animal consumption, and this legislation makes it illegal for noniodized salt to be available for human or animal consumption.

In Asia, the cost of iodized salt production and distribution is on the order of 3–5 cents per person per year. This must be considered cheap in relation to the social benefits that have already been described.

However, there is still the problem of the iodine in the salt actually reaching the iodine-deficient subject. There may be a problem with distribution or preservation of the iodine content: It may be left uncovered or exposed to heat. Thus, it should be added after cooking to reduce the loss of iodine.

Potassium iodate is the preferred vehicle compared to potassium iodide because of its greater stability in the tropical environment. A dose of 20–40 mg iodine as potassium iodate per kilo is recommended to cover losses to ensure an adequate household level. This assumes a salt intake of 10 g per day; if the level is below this, then an appropriate correction can readily be made by increasing the concentration of potassium iodate.

Iodized Oil

Iodized oil by injection or by mouth is singularly appropriate for isolated communities characteristic of mountainous endemic goiter areas. The striking regression of goiter following iodized oil administration, with improved well-being from correction of hypothyroidism, ensures general acceptance of the measure (**Figure 5**).

Iodized oil is more expensive than iodized salt but is used especially for severe iodine deficiency in remote areas. It provides instant correction of the deficiency and the consequent prevention of brain damage.

Figure 5 Subsidence of goiter in a New Guinea woman 3 months after the injection of iodized oil. This is accompanied by a feeling of well-being due to a rise in the level of the thyroid hormone in the blood. This makes the injections very popular. (Reproduced from Hetzel BS (1989) *The Story of Iodine Deficiency: An international Challenge in Nutrition.* Oxford: Oxford University Press.)

In a suitable area, the oil (1 ml contains 480 mg iodine) should be administered to all females up to the age of 40 years and all males up to the age of 20 years. A dose of 480 mg will provide coverage for 1 year by mouth and for 2 years by injection.

Iodized Milk

This is particularly important for infants receiving formula milk as an alternative to breast-feeding. An increase in levels from 5 to 10 μg/dl has been recommended for full-term infants and 20 μg/dl for premature infants. However, breast-fed infants will be iodine deficient if the mother is iodine deficient.

Iodized milk has been available in the United States, the United Kingdom and Northern Europe, Australia, and New Zealand as a result of the addition of iodophors as disinfectants by the dairy industry. This has been a major factor in the elimination of iodine deficiency in these countries. However, in most countries of Southern Europe and Eastern Europe, this has not occurred and the risk of iodine deficiency continues. Recently, the use of iodophors has been phased out, with a substantial decrease in the level of urine iodine excretion. Recurrence of iodine deficiency has been confirmed in Australia and New Zealand.

The Role of the United Nations

In 1990 the United Nations Sub-Committee on Nutrition recognized IDD as a major international public health problem and adopted a global plan for the elimination of IDD by the year 2000 proposed by the International Council for Control of Iodine Deficiency Disorders (ICCIDD) working in close collaboration with UNICEF and WHO.

The ICCIDD, founded in 1986, is an independent multidisciplinary expert group of more than 700 professionals in public health, medical, and nutritional science, technologists, and planners from more than 90 countries.

In 1990, the World Health Assembly and the World Summit for Children both accepted the goal of elimination of IDD as a public health problem by the year 2000. These major meetings included government representatives, including heads of state at the World Summit for Children, from 71 countries, and an additional 88 countries signed the plan of action for elimination of IDD as well as other major problems in nutrition and health.

Since 1989, a series of joint WHO/UNICEF/ICCIDD regional meetings have been held to assist countries with their national programs for the elimination of IDD. The impact of these meetings has been that governments now better realize the importance of iodine deficiency to the future potential of their people.

A dramatic example is provided by the government of the People's Republic of China. As is well-known, China has a one child per family policy, which means that an avoidable hazard such as iodine deficiency should be eliminated. In China, iodine deficiency is a threat to 40% of the population due to the highly mountainous terrain and flooded river valleys—in excess of 400 million people at risk. In recognition of this massive threat to the Chinese people, in 1993 the government held a national advocacy meeting in the Great Hall of the People sponsored by the Chinese Premier, Li Peng. The commitment of the government to the elimination of iodine deficiency was emphasized by Vice Premier Zhu Rongyi to the assembly of provincial delegations led by the provincial governors and the representatives of international agencies.

In 1998, an international workshop was held in Beijing by the Ministry of Health of China with the ICCIDD. Dramatic progress was reported, as indicated by a reduction in mean goiter rate (from 20 to 10%) with normal urine iodine levels. Severe iodine deficiency has persisted in Tibet due to difficulty in the implementation of salt iodization. In other provinces, excess iodine intake was noted in 10% of the population. The need for continuation of monitoring with urine iodine was emphasized at the meeting. Tibet is now receiving special assistance with a program supported by WHO, UNICEF, and the Australian Aid Program (AusAID).

Elimination of Iodine Deficiency Disorders at the Country Level

It is now recognized that an effective national program for the elimination of IDD requires a multisectoral approach as shown in **Figure 6**, which provides a model in the form of a wheel.

This wheel model represents the continuous feedback process involved in the national IDD control (elimination) program. All actors in the program need to understand the whole social process. The wheel must keep turning to maintain an effective program.

The wheel model also shows the social process involved in a national IDD control program. The successful achievement of this process requires the establishment of a national IDD control commission, with full political and legislative authority to carry out the program.

The program consists of the following components:

1. Assessment of the situation requires baseline IDD prevalence surveys, including measurement of urinary iodine levels and an analysis of the salt economy.
2. Dissemination of findings implies communication to health professionals and the public so that there is complete understanding of the IDD problem and the potential benefits of elimination of the most common preventable cause of brain damage.
3. Development of a plan of action includes the establishment of an intersectoral task force on IDD and the formulation of a strategy document on achieving the elimination of IDD.

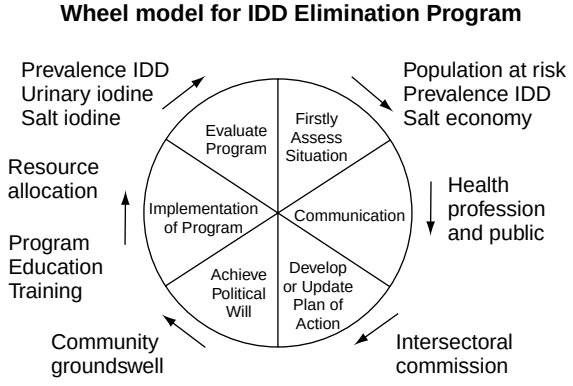

Figure 6 Wheel model for the iodine deficiency disorders (IDD) elimination program. The model shows the social process involved in a national IDD control program. The successful achievement of this process requires the establishment of a national IDD control commission, with full political and legislative authority to carry out the program. (Reproduced from Hetzel BS (1989) *The Story of Iodine Deficiency: An international Challenge in Nutrition.* Oxford: Oxford University Press.)

4. Achieving political will requires intensive education and lobbying of politicians and other opinion leaders.
5. Implementation requires the complete involvement of the salt industry. Special measures, such as negotiations for monitoring and quality control of imported iodized salt, will be required. It will also be necessary to ensure that iodized salt delivery systems reach all affected populations, including the neediest. In addition, the establishment of cooperatives for small producers, or restructuring to larger units of production, may be needed. Implementation will require training in management, salt technology, laboratory methods, and communication at all levels.

   In addition, a community education campaign is required to educate all age groups about the effects of iodine deficiency, with particular emphasis on the brain.
6. Monitoring and evaluation require the establishment of an efficient system for the collection of relevant scientific data on salt iodine content and urinary iodine levels. This includes suitable laboratory facilities.

Striking progress with USI has occurred, as indicated by the WHO/UNICEF/ICCIDD report to the 1999 World Health Assembly. Data show that of 5 billion people living in countries with IDD, 68% now have access to iodized salt. Of the 130 IDD-affected countries, it was reported that 105 (81%) had an intersectoral coordinating body and 98 (75%) had legislation in place.

Criteria for tracking progress toward the goal of elimination of IDD have been agreed on by ICCIDD, WHO, and UNICEF. These include salt iodine (90% effectively iodized) and urine iodine in the normal range (median excretion, 100–200 μg/l).

The major challenge is not only the achievement but also the sustainability of effective salt iodization. In the past, a number of countries have achieved effective salt iodization, but in the absence of monitoring the program lapsed with recurrence of IDD. To this end, ICCIDD, WHO, and UNICEF offer help to governments with partnership evaluation to assess progress toward the goal and also provide help to overcome any bottlenecks obstructing progress.

The Global Partnership

Since 1990, a remarkable informal global partnership has come together composed of the people and countries with an IDD problem, international agencies (particularly UNICEF, WHO, and

ICCIDD), bilateral aid agencies (Australia (AusAID) and Canada (CIDA)), the salt industry (including the private sector), and Kiwanis International. Kiwanis International is a world service club with 500,000 members throughout the world that has achieved a fundraising target of $75 million toward the elimination of IDD through UNICEF.

This partnership exists to support countries and governments in their elimination of IDD.

A more recent development is the establishment of the Global Network for the Sustainable Elimination of Iodine Deficiency, in collaboration with the salt industry.

The achievement of the global elimination of iodine deficiency will be a great triumph in international health in the field of noninfectious disease, ranking with the eradication of the infectious diseases smallpox and polio.

However, the goal of elimination is a continuing challenge. Sustained political will at both the people and the government level is necessary to bring the benefits to the many millions who suffer the effects of iodine deficiency.

Nomenclature

Endemic Occurrence of a disease confined to a community

Endemic Cretinism A state resulting from the loss of function of the maternal thyroid gland due to iodine deficiency during pregnancy characterised by mental defect, deaf-mutism and spastic paralysis in its fully developed form

Goiter An enlarged thyroid gland most commonly due to iodine deficiency in the diet

Hypothyroidism The result of a lowered level of circulating thyroid hormone causing loss of mental and physical energy

Hyperthyroidism The result of excessive circulating thyroid hormone with nervousness, sweating, tremor, with a rapid heart rate and loss of weight

ICCIDD International Council for Control of Iodine Deficiency Disorders-an international non-government organization made up of a network of 700 health professionals from more than 90 countries available to assist IDD elimination programs in affected countries

IDD Iodine Deficiency Disorders referring to all the effects of iodine deficiency in a population that can be prevented by correction of the iodine deficiency

IIH Iodine Induced Hyperthyroidism-due to increase in iodine intake following long standing iodine deficiency. The condition is transient and no longer occurs following correction of iodine deficiency

Iodization The general term covering fortification programs using various agents (iodide, iodate) or various vehicles (salt, oil, bread and water)

Iodized Oil Iodine in poppy seed oil-lipiodol is extensively used in radiology as a radio-contrast medium to demonstrate holes (cavities) in the lung. Available both by injection (lipiodol) and by mouth (oriodol) for the instant correction of iodine deficiency

Iodized Salt Salt to which potassium iodate or potassium iodide has been added at a recommended level of 20–40 milligrams of iodine per kilogram of salt

Kiwanis International A World Service Group including more than 10,000 clubs and over 500,000 members based in the USA

Thyroid size Measured by ultrasound-a much more sensitive and reproducible measurement than is possible by palpation of the thyroid

Thyroxine Thyroid Hormone (T_4) an amino acid which includes four iodine atoms

Triiodothyronine A more rapidly active thyroid hormone (T_3) which includes 3 iodine atoms on the amino acid molecule

UNICEF United Nations Children's Fund

USI Universal Salt Iodization-iodization of all salt for human and animal consumption which requires legislation and has been adopted by a number of countries

WHO World Health Organization-the expert group on health within the UN System

IRON

J R Hunt, USDA-ARS Grand Forks Human Nutrition Research Center, Grand Forks, ND, USA

Iron, the Earth's most abundant metal and fourth most common element, is also the essential nutrient that is most commonly deficient in human diets. At the beginning of the 21st century, the World Health Organization recognizes iron deficiency as one of the 10 greatest global health risks, ranked according to the number of lost healthy life years. Iron deficiency impairs reproductive performance, cognitive development, and work capacity. Effectively resolving this problem with preventative nutritional strategies remains an unmet challenge.

Iron Chemistry and Physiology

Body Content, Forms, and Function

Iron, the 26th element of the periodic table, has a molecular weight of 55.85. Two common aqueous oxidation states, ferrous (Fe^{2+}) and ferric (Fe^{3+}), enable iron to participate in oxidation/reduction reactions that are essential to energy metabolism by accepting or donating electrons. However, this property also enables free iron to catalyze oxidative reactions, resulting in reactive and damaging free radicals. Accordingly, body iron must be chemically bound to facilitate appropriate physiological function, transport, and storage, with minimal opportunity for free ionic iron to catalyze harmful oxidative reactions.

Most of the body's iron functions in heme protein complexes that transport oxygen as hemoglobin and myoglobin. Approximately two-thirds of the body iron is in hemoglobin, a 68,000 MW structure containing four subunits of heme, a protoporphyrin ring with iron in the center (**Figure 1**), and four polypeptide chains (two chains each of α- and β-globin). For transport by hemoglobin, oxygen bonds directly to the iron atom, stabilized in a Fe^{2+} oxidation state surrounded by the protoporphyrin ring and histidine residues. Hemoglobin iron easily binds and releases oxygen, circulating in blood erythrocytes. Myoglobin, consisting of a single heme molecule and globin, enables oxygen transfer from erythrocytes to cellular mitochondria in muscle cytoplasm.

Smaller quantities of iron in the heme form function in mitrochondrial cytochromes involved with electron transfer, oxygen utilization, and the production of ATP. A small fraction of body iron functions in heme-containing hydrogen peroxidases such as catalase that protect against excessive hydrogen peroxide accumulation by catalyzing its conversion to hydrogen and oxygen.

Iron also functions in non-heme proteins that contain an iron–sulfur complex, a cubical arrangement of four iron and four sulfur atoms. This is the principal form of iron in mitochondria, functioning in enzymes of energy metabolism such as aconitase, NADH dehydrogenase, and succinate dehydrogenase. In both mitochondria and cytosol, aconitase

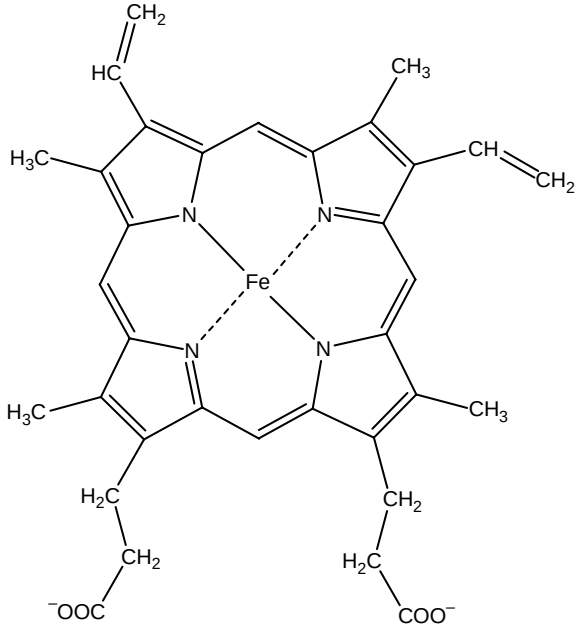

Figure 1 Heme (ferroprotoporphyrin 9).

is sensitive to iron concentrations. When iron is abundant, the aconitase enzyme assumes the full iron–sulfur cubic structure that is associated with carbohydrate metabolism. However, when iron concentrations are reduced, the protein loses aconitase activity and functions as an iron binding protein (IRP). IRPs interact with iron response elements (IREs) of the mRNA to regulate the synthesis of proteins involved with iron transport, storage, and use, in response to changes in cellular iron concentrations.

Absorption, Excretion, Transport, and Storage

Absorption Both heme and non-heme (inorganic) iron are absorbed in an inverse proportion to body iron stores (indicated by serum ferritin; **Figure 2**). Heme iron is absorbed more efficiently than the non-heme form. Non-heme iron absorption can vary from 0.1 to >35% and that of heme iron from 20 to 50%, depending on body iron status (stores, erythropoiesis, and hypoxia) and dietary bioavailability. These ranges indicate greater control of non-heme compared to heme iron absorption. When iron stores are high, absorption of non-heme iron can be minimized more completely, and when iron stores are low, non-heme iron is absorbed nearly as efficiently as heme iron. Because there is considerably more non-heme iron in the diet (~85–100%), this form accounts for most of the physiological control of iron absorption in relation to iron needs.

The upper portion of the duodenum, with its low pH luminal conditions, is the primary site for both heme and non-heme iron absorption (**Figure 3**). Non-heme iron absorption is better understood

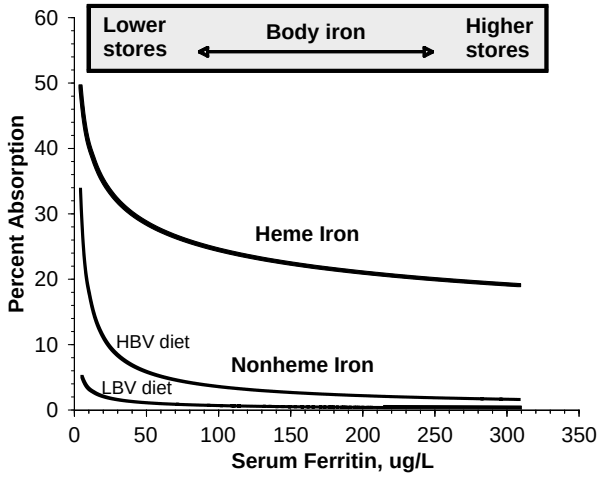

Figure 2 Heme and non-heme iron absorption as influenced by body iron stores and dietary bioavailability. HBV and LBV indicate high and low dietary bioavailability, respectively.

than heme iron absorption, and only receptors for mucosal uptake of non-heme iron have been identified. The globin proteins of hemoglobin are proteolytically digested in the intestinal lumen, producing peptide remnants that may enhance the absorption of the heme molecule by preventing heme polymerization. The heme molecule is absorbed as an intact porphyrin structure, possibly involving endocytosis. In the mucosal cell, heme iron is split into ferrous iron and bilirubin by heme oxygenase, adding to a common pool of cellular iron for transport into plasma or intracellular storage and exfoliation.

Non-heme iron is best absorbed if presented to the intestinal villi as soluble ions (preferably reduced, ferrous ions) or as low-affinity, low-molecular-weight iron ligands. Stomach acid facilitates these conditions. Ascorbic acid concurrently ingested with iron helps to maintain the iron in a soluble, reduced, low-molecular ligand form in the intestinal lumen. Mucin, an intraluminal protein, has been proposed to bind iron and facilitate duodenal uptake.

Proteins involved in mucosal uptake and transfer of non-heme iron as well as possible regulatory molecules have been identified (**Figures 3 and 4**). These include duodenyl cytochrome *b* (Dcytb), which converts ferric to ferrous iron at the apical mucosal surface. A divalent metal transporter (DMT-1) transfers ferrous iron into the mucosal cell. Mutations in DMT-1 impair iron absorption and produce microcytic anemia in rodents. Ferrous iron has the highest affinity for DMT-1, but it will also transport other divalent ions, such as manganese, lead, cadmium, zinc, and copper. This may contribute to competitive inhibition observed in the absorption of these metals. Ferric iron is transported into the mucosal cell by mobilferrin, followed by ferroreduction with the protein paraferritin. Iron transported into the enterocyte may be further transported to the body at the basolateral membrane, completing absorption, or may be held and returned to the intestinal lumen with cellular desquamation. Ireg-1, or ferroportin, is involved in efflux of iron from the mucosal cell at the basolateral membrane. A mutation in Ireg-1 results in an uncommon form of hemochromatosis, an iron storage disorder. The mRNA for both DMT-1 and Ireg-1 contain an IRE, enabling regulation of mRNA translation by intracellular iron concentrations. Dcytb, DMT-1, and Ireg-1 are all upregulated in iron deficiency. Intestinal transfer of iron to the circulation also involves hephaestin, an intestinal ferroxidase with a protein sequence similar to that of ceruloplasmin (a copper-containing ferroxidase in serum). A defective hephaestin gene in mice results in anemia and

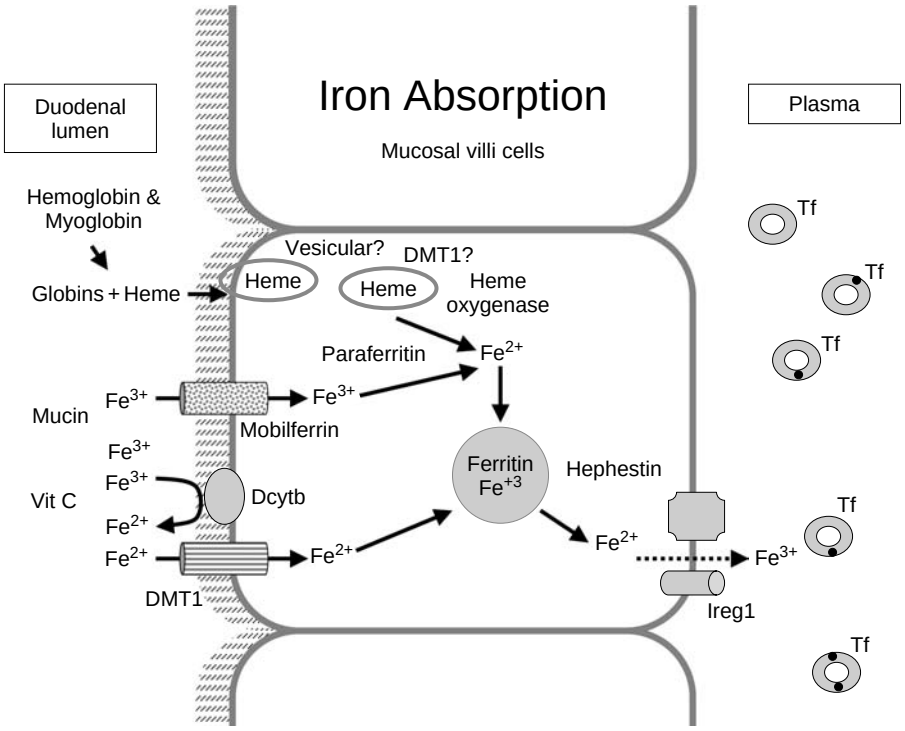

Figure 3 Absorption of iron in the intestinal mucosa.

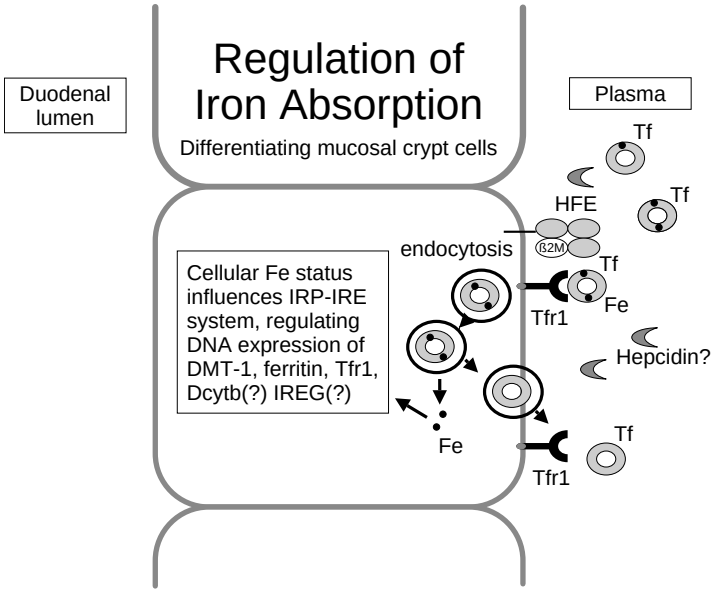

Figure 4 Regulation of iron absorption in the mucosal crypt cells before differentiation and development into actively absorbing intestinal villi cells.

accumulation of iron in intestinal cells. However, unlike Dcytb, DMT-1, or Ireg-1, hephaestin is not preferentially expressed in the duodenum, the main site of iron absorption.

Iron absorption is responsive to recent iron intake, iron stores, erythropoiesis, hypoxia, pregnancy, and inflammation. A newly identified peptide, hepcidin, may be related to several of these stimuli of regulatory control. Hepcidin is an antimicrobial peptide found in human blood and urine that apparently serves as a signal for limiting iron absorption. Control of absorption also likely involves the HFE protein located in the basolateral membrane of intestinal crypt cells. A specific point mutation in

the HFE gene is associated with the most common form of hemochromatosis, a disorder involving excessive iron absorption and accumulation. The HFE protein interacts with β_2-microglobin and transferrin receptor, apparently influencing iron uptake from serum transferrin, the primary protein involved in serum iron transport (**Figure 4**). Knowledge of the control of iron absorption is growing rapidly.

Transport Transferrin transports essentially all of the 3 or 4 mg of iron in blood serum, including dietary iron absorbed from the duodenum as well as iron from macrophages after the degradation of hemoglobin. Each transferrin molecule binds two iron atoms; the transferrin in serum is normally approximately one-third saturated with iron. The amount of iron that can be bound by transferrin is measured as the total iron binding capacity (TIBC). In iron deficiency, serum iron is reduced, and TIBC is elevated; expressing serum iron as a fraction of the TIBC defines the transferrin saturation, which is reduced in iron deficiency. As iron deficiency develops, these measures of iron transport signal iron deficiency before the functional pool of circulating hemoglobin is reduced (**Figure 5**).

Membrane transferrin receptors enable the cellular uptake of iron. Transferrin receptors complex with transferrin, the complex is internalized by endocytosis, and the iron is released to the cell from transferrin upon vesicular acidification (**Figure 4**). Transferrin receptors are abundant in erythrocyte precursors, placenta, and liver, and the number of receptors changes inversely with cellular iron status. Serum transferrin receptors are a soluble, truncated form of the cellular receptors, present in proportion to the cellular receptors, which serve as a clinical indicator of cellular iron status that is useful in distinguishing between iron deficiency and other causes of anemia.

Other proteins involved in iron transport include lactoferrin, which is structurally similar to transferrin and occurs in body fluids such as milk and semen. Haptoglobin and hemopexin proteins clear hemoglobin and heme, respectively, from circulation as they are released from senescent red blood cells.

Storage Iron is primarily stored in liver, spleen, and bone marrow in the form of ferritin or hemosiderin. Ferritin is a water-soluble protein complex of 24 polypeptide subunits in a spherical cluster with a hollow center that contains up to 25% iron by weight, or 4000 atoms of iron per molecule.

	Excessive Body Iron	Adequate Iron	Low Iron Stores	Iron Deficiency	Iron Deficiency Anemia
Serum Ferritin	↑	---	↓	↓↓	↓↓

Total Iron Binding Capacity	---	---	---	↑	↑
Erythrocyte Protoporphyrin	---	---	---	↑	↑↑
Hemoglobin, Hematocrit	---	---	---	---	↓

Figure 5 Clinical indicators of body iron status.

Hemosiderin is a water-insoluble complex, immunologically similar to ferritin, containing up to 35% iron. Ferritin and hemosiderin each account for approximately half of the storage iron in liver.

Excretion The approximately 1 mg of iron lost daily by men and postmenopausal women represents mainly obligatory fecal losses from exfoliated mucosal cells, bile, and extravasated red cells, with minor additional amounts in desquamated skin cells and sweat. Urine contains minimal amounts of iron.

Adolescent girls and premenopausal women excrete considerable amounts of iron through menstruation. The menstrual losses of individual women vary considerably; half of women lose less than 14 mg of iron per menstrual period, but the distribution is highly skewed, and 5% lose 50 mg or more. Iron deficiencies among women in prosperous countries are commonly attributable to these high iron excretion rates rather that to differences in dietary intakes.

Body iron balance The body contains 2–4 g of total iron, or approximately 50 mg/kg in men and 40 mg/kg in women. Red blood cells contain approximately two-thirds of body iron and have an average life span of 120 days; consequently, approximately 20 mg of iron daily is efficiently recycled from senescent to newly formed erythrocytes through the reticuloendothelial system.

In contrast to other nutrients, controlled through both absorption and excretion, body iron balance is controlled almost exclusively by absorption. Approximately 10–20 mg iron is consumed daily from food. Average absorption and excretion of iron for adult men or postmenopausal women is approximately 1 mg daily. Menstruation can more than double iron losses in women of child-bearing age, increasing their requirement for absorbed iron. Iron balance is also challenged by the growth demands of pregnancy and early childhood.

Clinical Assessment of Iron Status

With adequate iron status, there is sufficient iron to meet all of iron's functional roles and a small reserve of storage iron that can be mobilized when needed (**Figure 5**). Excessive body iron, stored in liver and bone marrow, is marked by elevated serum ferritin and also serum iron and transferrin saturation. Ferritin in plasma corresponds well with body iron stores, but its use as an indicator is limited under inflammatory conditions. Iron deficiency occurs when iron stores are depleted and the iron transported for physiological function is reduced. Iron deficiency without anemia is commonly detected from abnormal values for two out of three blood indices, usually serum ferritin, transferrin saturation, and free erythrocyte protoporphyrin (**Figure 5**). As iron deficiency becomes more severe, iron deficiency anemia results, with small, pale erythocytes and reduced blood hemoglobin and hematocrit. Measurement of hemoglobin in reticulocytes, or immature red blood cells, is a possible new tool to assess developing anemias. The ratio of serum transferrin receptor to serum ferritin provides a single, sensitive indicator of iron status across the full range of body iron status, except under conditions of inflammatory stress.

Iron Nutrition

Iron Deficiency

Iron deficiency is the most common of nutrient deficiencies, affecting as many as two-thirds of all children and women of child-bearing age worldwide. Iron deficiency severe enough to cause anemia affects 20–25% of infants and as many as 40% of women and 25% of men. Iron deficiency occurs in industrially developed as well as developing populations. In the United States, 9–11% of toddlers, adolescent girls, and women of child-bearing age have iron deficiency, and 2–4% have iron deficiency anemia. The prevalence of iron deficiency is approximately doubled in US black and Hispanic women.

Consequences of Iron Deficiency

Iron deficiency adversely affects pregnancy, impairs early childhood development and cognitive function, and reduces the ability to do physical work. These serious problems are almost exclusively associated with iron deficiency severe enough to cause anemia; however, small reductions in exercise capacity, detectable in a laboratory setting, are also detectable in women with low iron stores and no anemia.

Physical work capacity Iron deficiency anemia adversely affects physical work capacity, reflecting the element's key role in oxygen and energy utilization. Maximal oxygen consumption during exercise is reduced, in association with decreased muscle myoglobin and other iron-containing enzymes. Iron supplementation has improved productivity among Guatemalan sugar and coffee plantation workers, Indian tea pickers, and Indonesian road construction workers and rubber tappers. Iron supplementation programs are clearly cost-effective in addition to providing a positive impact on human health and well-being.

Cognitive development In infants, iron deficiency anemia has been associated with reduced mental and motor test scores and behavioral changes such as being more hesitant and wary. This impaired mental and motor functioning appears to persist after treatment with iron, emphasizing the need for early detection and treatment and preferably prevention of iron deficiency during early development.

Reproduction Iron deficiency anemia has been associated with greater perinatal maternal and infant mortality, premature birth, and low birth weight. Iron supplementation during pregnancy has not been completely effective in preventing maternal anemia, leading to suggestions for promoting adequate iron stores in all women of child-bearing age prior to conception.

Other Iron deficiency increases the susceptibility to lead poisoning. It may also impair resistance to infection and regulation of body temperature. Iron deficiency has been associated with the eating of non-food material (pica) or ice (pagophagia). Clinical signs may include spoon-shaped fingernails and abnormalities of the mucosa of the mouth and gastrointestinal tract.

Recommended Dietary Intakes

The US and Canadian recommended iron intakes are intended to meet the requirements of 97.5% of the healthy population, replacing excreted iron and maintaining essential iron functions with a minimal supply of body iron stores. They also assume a relatively high bioavailability of the dietary iron. The recommended 8 mg daily for adult men and postmenopausal women can easily be met with varied Western-style diets. More careful food choices are needed to obtain the 18 mg recommended to meet requirements for 97.5% of adult menstruating women. This higher recommendation reflects the high menstrual iron losses of some women; the median iron requirement is 8.1 mg for menstruating women.

During pregnancy, dietary iron recommendations are increased to 27 mg daily, based on the iron content of the fetus and placenta (approximately 320 mg) as well as the expanded blood volume associated with a healthy pregnancy. Meeting this recommendation generally requires iron supplementation. Supplementation with 30–60 mg daily is commonly recommended. Lactation has minimal impact on maternal iron balance and recommendations.

The high iron requirements of early growth put infants and toddlers at risk of iron deficiency. Breast-feeding is recommended for the first year of life. Although iron in breast milk is relatively low (0.35 mg/l, or 0.27 mg daily), it is well absorbed, possibly because of lactoferrin. Breast milk alone is assumed to be adequate for the first 6 months of infancy, with the addition of iron-rich foods in the next 6 months. When prepared formula is used, iron fortification of the formula is recommended.

Dietary recommendations at other ages reflect the increased needs of active growth periods, such as adolescence. Western dietary recommendations have been based on mixed diets with a relatively high bioavailability of iron and may need to be increased twofold or more for low meat, plant-based diets with greater phytic acid content (see Bioavailability).

Other factors that may increase dietary requirements include achlorhydria, which decreases iron absorption, hookworm or other parasites that increase gastrointestinal blood loss, or intrauterine contraceptive devices that may increase menstrual losses by 30–50%. In contrast, hormonal contraceptives reduce iron requirements by reducing menstrual losses by approximately 50%.

Dietary Iron

Food Sources

Typical Western diets contain approximately 6 mg iron per 1000 kcal. Men and women consume approximately 16–18 and 12–14 mg daily, respectively. In the United States, 24% of dietary iron is supplied by breads, pasta, and bakery products. An additional 21% comes from (mostly fortified) cereal products. Other abundant dietary sources are red meats (9% from beef), poultry, legumes, and lentils. In countries such as the United States, fortification practices increase the influence of grain and cereal products as sources of iron. In countries without fortification to at least replace the iron lost during milling, the refinement of grain products considerably reduces dietary iron content. The populations of developing countries that eat little meat and do not include legumes or lentils as a dietary staple are at increased risk of inadequate iron intake.

Bioavailability

In underdeveloped countries, diets may be inadequate in both iron content and bioavailability (the amount that is absorbed and utilized by the body). However, the bioavailability of iron can be more important than the iron content in determining the amount of iron absorbed from food. Diets with similar total iron contents can differ 8- to 10-fold

in the amount of absorbable iron. Dietary iron bioavailability is high from refined Western diets containing meat, poultry, and fish and abundant sources of ascorbic acid with low consumption of phytic acid from whole grains and legumes and limited drinking of coffee and tea with meals. On average, men absorb 1 mg daily from such diets, and women, with their lower iron stores, absorb approximately 2 mg. Individuals may absorb considerably more or less, depending on their body iron stores (**Figure 2**).

Despite the considerable differences in dietary iron bioavailability observed with absorption measurements, dietary changes are slow to influence biochemical indices of iron status. However, people following vegetarian diets for years have lower iron stores than their omnivorous counterparts, and consumption of red meat is often a predictor of iron status in epidemiological studies.

Heme iron Approximately 10%, or 1 or 2 mg, of the iron in a mixed, Western diet is in the well-absorbed heme form. Heme iron accounts for approximately 40% of the iron in meat, poultry, or fish flesh. There is little to no heme iron in organ meats, dairy products, or foods of plant origin. Heme iron is absorbed as an intact porphyrin structure. Heme iron absorption is enhanced by meat, poultry, or fish and is reduced by calcium consumed concurrently, but it is not influenced by the other enhancers and inhibitors of non-heme iron absorption.

Non-heme iron Non-heme iron accounts for 85–100% of dietary iron. In contrast to heme iron, the absorption of non-heme iron is substantially influenced by dietary enhancers and inhibitors consumed concurrently. These factors appear to affect the solubility of a single exchangeable pool of non-heme iron absorbed from the intestinal digestate.

Absorption of non-heme iron is enhanced by ascorbic acid, which reduces ferric iron to ferrous iron, resulting in a soluble iron–ascorbic acid complex. Enhanced absorption has been demonstrated with synthetic as well as several food sources of ascorbic acid. The enhancement increases logarithmically with the dose, approximately doubling absorption with as little as 25 mg of ascorbic acid and increasing absorption by nearly 10-fold with 1000 mg of ascorbic acid.

Non-heme iron absorption is also enhanced by concurrently consuming meat, poultry, or fish. Despite intensive study, the factor responsible for this enhancement by animal flesh has not been identified and may involve the general matrix of low-molecular-weight peptides released during digestion.

Non-heme iron absorption is reduced by phytic acid (inositol hexaphosphate), present in legumes, rice, and grains, that binds iron and makes it insoluble. Both phytate and iron are concentrated in the aleurone layer and germ of grains, and they are reduced with milling, which increases the bioavailability of the remaining iron. An additional unidentified factor in soy beans, independent of the phytic acid, also impairs iron absorption. Polyphenols in grains, fruits, and vegetables, and including the tannins in tea and coffee, also inhibit non-heme iron absorption. Ascorbic acid consumed concurrently can partially reduce the inhibition of non-heme iron absorption by both phytic acid and polyphenols. Calcium in supplemental quantities inhibits both heme and non-heme iron absorption from foods. Supplemental zinc also inhibits non-heme iron absorption.

Supplementation and Fortification

The serious international problem of iron deficiency has been met with poor success by supplementation and fortification efforts. Both approaches suffer from difficulties in delivery and acceptance. Supplements that readily ionize into the ferrous form, such as ferrous sulfate, ferrous fumerate, or ferrous gluconate, are highly bioavailable but may cause gastrointestinal discomfort. Iron injections are poorly tolerated and can result in serious infections. Because daily supplementation reduces the physiological efficiency of iron absorption, routine weekly iron supplementation with 60 mg iron has been suggested in developing countries for women of childbearing age, beginning in adolescence. Menstruating women in more prosperous countries are advised to obtain assessment from a health professional before taking iron supplements in excess of 20 mg daily.

Fortification of staple foods with 3–10 mg iron daily, depending on the needs of the population, is a long-term preventative strategy. In the United States, bread and cereal products are routinely fortified with 20 mg iron per pound (460 g) of flour, and additional fortification at the option of food suppliers is common. However, fortification is difficult when food processing is decentralized, as is common in poor populations. Food fortification carries the additional challenge that the chemical forms of iron most bioavailable also tend to be the most reactive with the food fortified, resulting in adverse changes in flavor, color, and shelf life. Promising approaches include the fortification of food sauces with iron chemically bound with amino acids or with EDTA (sodium iron ethylenediaminetetraacetic acid), which are well absorbed even in the presence

of phytic acid. Elemental iron powders, commonly referred to as carbonyl, electrolytic, and reduced forms of iron, are relatively inert in foods and inexpensive, but their bioavailability may be 30–80% less than iron from ferrous sulfate, depending on the dissolution in the gastrointestinal tract. Ferric orthophosphate and ferric pyrophosphate do not adversely affect foods but are poorly bioavailable; however, efforts are under way to enhance their bioavailability by reducing the particle size and encapsulating the particles with various lipids or carbohydrates to prevent agglomeration.

Excessive Intakes

An extensive biological control system limits the occurrence of free ionic iron that can readily participate in toxic, free radical-producing reactions. Large quantities of ingested iron are acutely toxic, and accidental ingestion of medicinal iron preparations is a leading cause of poisoning deaths in young children. Iron supplementation is also associated with gastrointestinal irritation. Iron supplements adversely affect absorption of zinc. Iron absorption is well controlled, but iron overload can result from excessive parenteral iron administration or blood transfusions. Dietary iron overload, possibly exacerbated by genetic factors, occurs in sub-Saharan tribes that consume a high-iron traditional beer prepared and stored in iron containers. Genetic factors can substantially influence body iron retention, as indicated by hemochromatosis, a relatively frequent iron storage disorder of northern European descendants characterized by excessive iron absorption and leading to life-threatening iron damage of organs in adulthood. The possible association of high iron stores with increased risk of diseases related to oxidative stress, including cardiovascular disease, diabetes, and cancer, is an area of epidemiological investigation.

KETOSIS

D H Williamson†, Radcliffe Infirmary, Oxford, UK

This article is a revision of the previous edition article by D H Williamson, pp. 1160–1167, © 1999, Elsevier Ltd.

The two ketone bodies, acetoacetate ($CH_3COCH_2COO^-$) and D-3-hydroxybutyrate ($CH_3CHOHCH_2COO^-$), are the only freely soluble lipids in the circulation.

The name ketone bodies originates from the German *Ketonkörper* (literally, ketones excreted from the body) and refers to their discovery in the urine of diabetic patients in the latter half of the nineteenth century. In reality, the term is a misnomer because 3-hydroxybutyrate is not a ketone. It arose because the reagent originally used reacted positively with ketones in diabetic urine. Acetone (CH_3COCH_3), the product of the spontaneous decarboxylation of acetoacetate, is also a ketone and is present in blood and urine when the plasma concentration of acetoacetate is elevated. It is excreted via the kidneys and lungs and is responsible for the sweet smell on the breath in ketotic states.

The association of ketone bodies with the pathology of diabetes resulted in the view that they were toxic waste products. It is only in the past 30 years that this view has been convincingly reversed. Two factors led to this change, namely the development of an enzymatic method for the determination of acetoacetate and 3-hydroxybutyrate, which in turn allowed the dramatic finding of Cahill and colleagues in 1967 that adult human brain removed appreciable amounts of ketone bodies from the circulation in prolonged starvation.

†Deceased.

The aim in this contribution is to review (a) the formation of ketone bodies in physiological and pathological situations, and (b) the function of ketone bodies as physiological substrates and signals.

Formation of Ketone Bodies

It is well established that in humans and other mammals the only organ that contributes significant amounts of ketone bodies to the blood is the liver; this organ, unlike peripheral tissues, is unable to utilize ketone bodies to any appreciable extent. More recently it has been found that during the suckling period (high-fat diet) the intestine also has the capacity (about 10% of the liver) to produce ketone bodies. Whether ketone bodies are used *in situ* or are transported via the portal blood to supplement the existing hyperketonemia is an open question.

The main blood-borne substrates for the synthesis of ketone bodies (ketogenesis) are the nonesterified fatty acids; others of lesser importance are the branched-chain amino acids, leucine and isoleucine. In addition, acetate (sources: intestinal fermentation, in vinegar or an oxidation product of ethanol) is a ketogenic substrate.

Long-chain fatty acids contained in dietary lipids do not enter the portal blood directly but are esterified in the intestinal cells, packaged with proteins and phospholipids to form chylomicrons (large lipoproteins), and transported via the lymphatic system to the thoracic duct where they enter the blood. In contrast, the short- and medium-chain fatty acids (below C_{14}) contained in dairy products or in clinical medium-chain triacylglycerol preparations are directly absorbed as the respective fatty acids and are transported to the liver via the portal blood (**Figure 1**). The long-chain

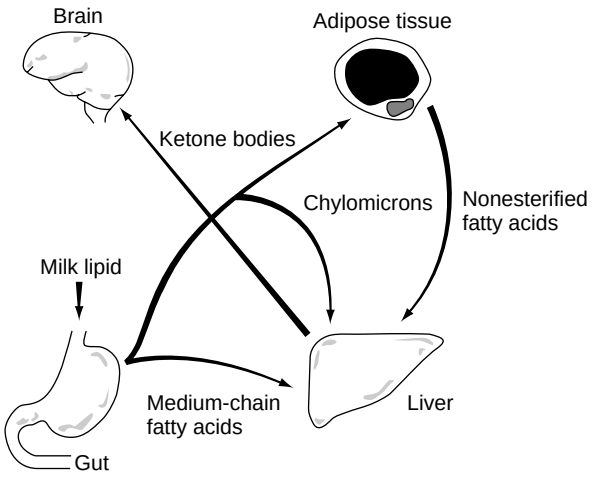

Figure 1 Intertissue fluxes of substrates in the suckling neonate. Thickness of line denotes rate of flux.

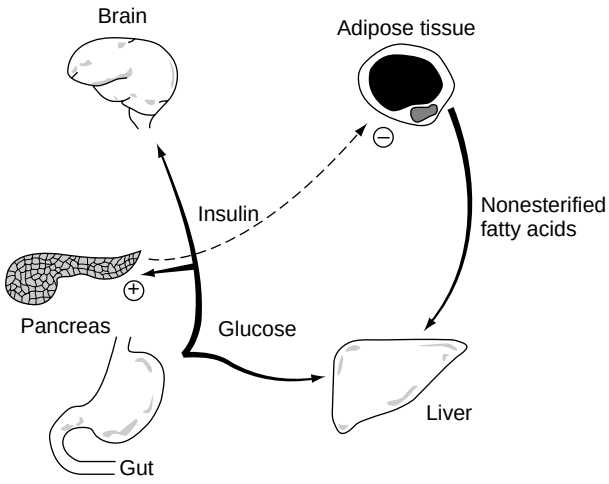

Figure 2 Intertissue fluxes of substrates in the fed state. Thickness of line denotes rate of flux.

fatty acids in the plasma are bound to albumin and are released from adipose tissue triacylglycerol stores by the process of lipolysis.

Extrahepatic Regulation

A key factor in the regulation of ketogenesis is the availability of nonesterified long-chain fatty acids to the liver, which in turn is controlled by their release from adipose tissue. The enzyme responsible for the initiation of the hydrolysis of stored triacylglycerols to fatty acids is hormone-sensitive lipase. As its name implies, this enzyme is exquisitely sensitive to hormones: adrenaline (in the plasma) and noradrenaline (released from sympathetic nerve endings) are activators, whereas insulin inhibits the activity. In small mammals glucagon is also an activator of the enzyme, but this does not seem to be the case in the human.

Insulin has an additional effect on the net release of long-chain fatty acids from adipose tissue in that it stimulates their reesterification to triacylglycerols. Thus after a high-carbohydrate meal, when insulin secretion and its concentration in the plasma is high, the release of fatty acids from adipose tissue is suppressed and their concentration in the plasma is low (**Figure 2**). In contrast, during stress, when adrenaline and noradrenaline are elevated, the release of fatty acids is increased and their plasma concentration is high.

In experimental animals increased plasma ketone body concentrations (hyperketonemia) can inhibit adipose tissue lipolysis (a) indirectly by increasing the secretion of insulin or (b) by a direct effect on the tissue (**Figure 3**). This can be viewed as a feedback mechanism for controlling the rate of ketogenesis via fatty acid supply to the liver, but whether this is important in the human is not known. In contrast, the supply of short- and medium-chain fatty acids to the liver is mainly dependent on the dietary intake and on the proportion that escapes further metabolism in the intestinal tract; there is no known involvement of hormones in the process.

Intrahepatic Regulation

There are situations (e.g., stress) where the supply of fatty acids to the liver may be increased, but there is no necessity to increase the availability of ketone bodies to the peripheral tissues. Consequently, there is a requirement that the rate of hepatic ketogenesis should be controlled independently of the supply of fatty acids. However, it must be stressed that without an increase in the supply of fatty acids the rate of ketogenesis cannot increase.

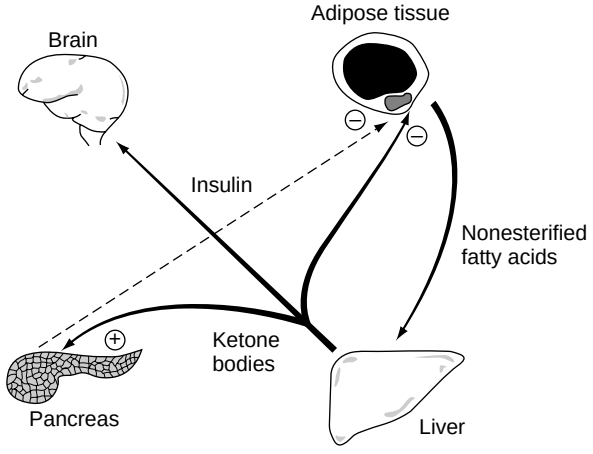

Figure 3 Role of ketone bodies as feedback regulators.

Much of the current interest is concerned with how the intrahepatic metabolism of fatty acids (**Figure 4**) is regulated. Long-chain fatty acids entering the liver have three main fates:

1. They can be re-esterified to phospholipids and triacylglycerols and then be secreted as very low-density lipoproteins (VLDL).
2. They can be oxidized via the mitochondrial β-oxidation complex to acetyl-CoA. The latter can combine with another molecule of acetyl-CoA in the reaction catalysed by acetoacetyl-CoA thiolase and then enter the hydroxymethylglutaryl-CoA pathway to form acetoacetate.
3. The acetyl-CoA derived from the fatty acids can be completely oxidized in the tricarboxylate cycle.

The short- and medium-chain fatty acids cannot be re-esterified to any appreciable extent in mammalian liver and therefore they are either metabolized to ketone bodies or completely oxidized. In addition, unlike the long-chain fatty acids, they are transported directly into the mitochondrial matrix without the need to be converted first to the corresponding acyl-CoA derivatives.

The role of malonyl CoA The entry of free long-chain fatty acids into the hepatocyte is via a specific carrier on the plasma membrane. Once inside the cytosol the long-chain fatty acids are bound to binding proteins, converted to the acyl-CoA derivatives, and then can either be esterified or enter

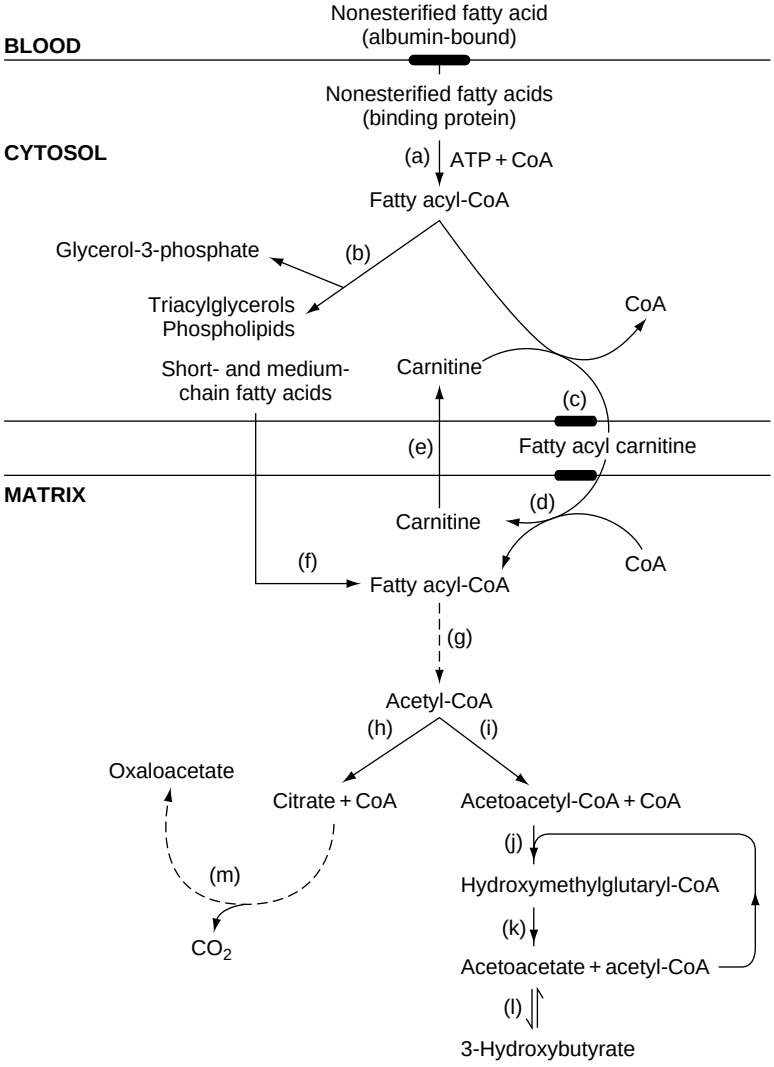

Figure 4 Pathway of fatty acid catabolism in liver. Enzymes involved: (a) long-chain fatty acyl-CoA synthetase; (b) glycerol-3-phosphate acyl-CoA transferase; (c) CAT I; (d) CAT II; (e) carnitine exchange; (f) short- and medium-chain fatty acyl-CoA synthetase; (g) fatty acid oxidation complex; (h) citrate synthase; (i) acetoacetyl-CoA thiolase; (j) hydroxymethylglutaryl-CoA synthase; (k) hydroxymethylglutaryl-CoA lyase; (l) hydroxybutyrate dehydrogenase; (m) tricarboxylate cycle.

the mitochondria via a complex transport system, the carnitine–acyl-CoA transferase (CAT) system. This consists of two proteins: CAT I located on the outer mitochondrial membrane and CAT II on the inner mitochondrial membrane (**Figure 5**). The overall action of the two enzymes results in the transfer of a long-chain fatty acyl-CoA to the mitochondrial matrix and the return of free carnitine to the cytosol via an exchange mechanism. Although carnitine is not consumed in the reaction, the available concentration can be critical. In nutritional carnitine deficiency there is impairment of long-chain fatty acid oxidation and ketogenesis.

The activity of CAT I is the key to the intrahepatic regulation of fatty acid metabolism in most situations. Its activity increases in ketogenic situations. More importantly, CAT I is inhibited by malonyl-CoA and the sensitivity of CAT I to this inhibitor changes in various pathophysiological situations such as fasting or diabetes.

As malonyl-CoA is a key intermediate in the synthesis of fatty acids (lipogenesis) from products (pyruvate and lactate) of glucose metabolism, this interaction provides a regulatory link between lipid and carbohydrate metabolism (**Figure 5**). Thus on high-carbohydrate diets, when the rate of hepatic lipogenesis, and consequently the cytosolic concentration of malonyl-CoA, is high, the activity of CAT I will be inhibited and fatty acids will be diverted to esterified products and secretion as VLDL rather than oxidation and conversion to ketone bodies. Conversely, on high-fat diets or in starvation, when lipogenesis is inhibited, malonyl-CoA concentration is low and CAT I is active. The sensitivity of CAT I to malonyl-CoA generally correlates with the prevailing concentration of the latter.

The short- and medium-chain fatty acids do not utilize the CAT I and II system to enter the mitochondrial matrix and therefore their oxidation is not greatly influenced by the prevailing 'carbohydrate status' (amount of glycogen, direction of carbohydrate flux, glycolysis, or gluconeogenesis) of the liver (**Figure 5**).

Insulin can rapidly depress the rate of ketogenesis *in vitro*. This effect is thought to result mainly from its stimulatory action on a key enzyme of lipogenesis, acetyl-CoA carboxylase, which in turn increases the concentration of malonyl-CoA. Glucagon and the catecholamines have the opposite effect. Thus hormonal effects can be exerted at both the extrahepatic (lipolysis) and intrahepatic (modulation of lipogenesis) levels.

Intramitochondrial regulation Once the fatty acyl-CoA molecule is attached to the mitochondrial β-oxidation complex there appears to be little regulation exerted until release of the acetyl-CoA fragments. As indicated above, the acetyl-CoA can enter the tricarboxylate cycle and be oxidized to CO_2 or can be converted to ketone bodies via the hydroxymethylglutaryl-CoA pathway.

It appears that in most experimental situations the complete oxidation of fatty acids proceeds at a low, but relatively similar, rate and it is the activity of the

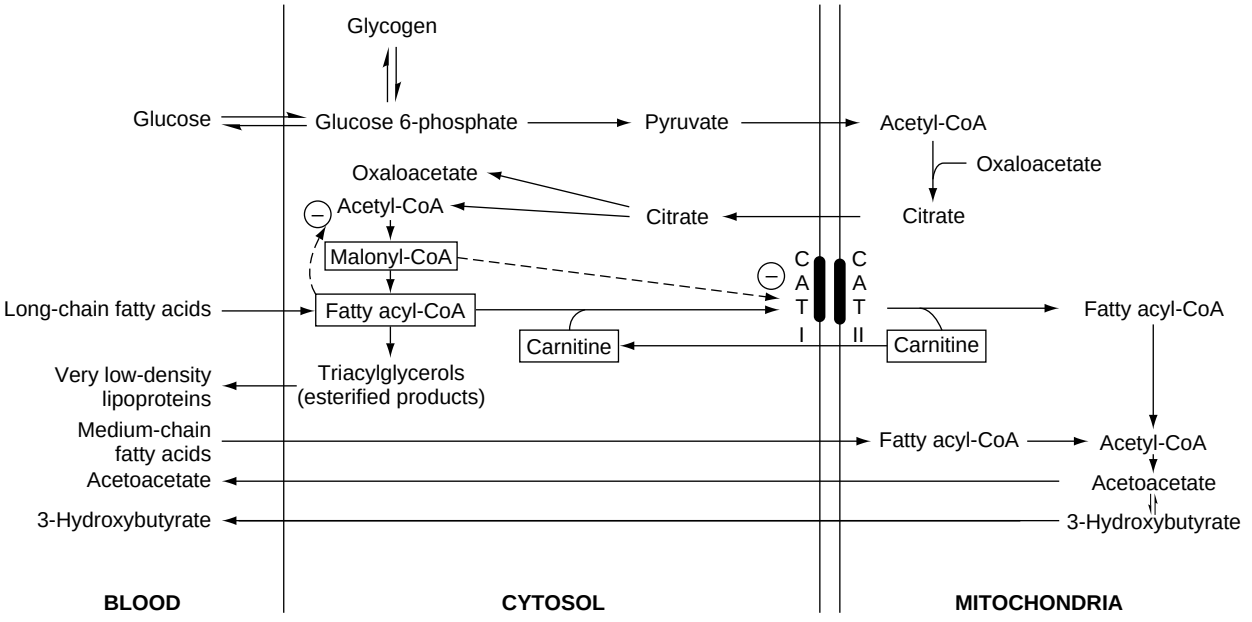

Figure 5 Interrelationship between hepatic carbohydrate metabolism, lipogenesis, and ketogenesis. Circled minus signs indicate inhibition by the metabolite.

hydroxymethylglutaryl-CoA pathway that shows larger changes. This has led to the view that the pathway might be regulated by mechanisms other than substrate supply.

Studies on the expression of 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) synthase have shown that both the mRNA coding for the protein and the amount of protein increase during the onset of ketogenic states (fasting, diabetes) and that these changes are rapidly reversed (refeeding, insulin treatment). However, the finding that rates of ketogenesis from medium-chain fatty acids (CAT I and II) do not alter greatly with change in physiological state, if the rate of fatty acid supply is held constant, would seem to rule out appreciable regulation within the hydroxymethylglutaryl-CoA pathway. Indeed, current thinking suggests that the activity of CAT I is the primary intrahepatic site for the regulation of fatty acid oxidation and ketogenesis. If there is another important site, particularly during situations associated with the reversal of ketogenesis, it is likely to be proximal to the step catalysed by this protein (e.g., the supply of fatty acids to the liver). Thus *in vivo* there is little doubt that the primary step that controls ketogenic flux is the rate of long-chain fatty acid release from adipose tissue.

Function of Ketone Bodies

The major role of ketone bodies is to supply an alternative oxidizable substrate to glucose for the brain in situations where the availability of the latter is impaired (e.g., starvation). In addition, ketone bodies can act as precursors for the acetyl-CoA required in neural lipid synthesis (myelin). Other mammalian tissues, including heart, skeletal muscle, kidney, and lactating mammary gland, can utilize ketone bodies but, in contrast to glucose utilization, no energy can be obtained in the absence of oxygen. In these tissues metabolism of ketone bodies results in the inhibition of glucose utilization and inhibition of the oxidation of pyruvate. The net result is a sparing of carbohydrate for the brain and the strictly glycolytic tissues (erythrocytes, retina).

Pathways of Ketone Body Utilization

Mitochondrial pathway The major site of ketone body utilization in peripheral tissues is the mitochondria (**Figure 6**). Although transporters for ketone bodies have been described on the plasma and inner mitochondrial membranes of some tissues, these do not appear to limit the flux. The initiating enzyme for acetoacetate metabolism is 3-oxoacid-CoA transferase:

$$\text{Acetoacetate} + \text{succinyl-CoA} \rightleftharpoons \text{acetoacetyl-CoA} + \text{succinate}$$

The resulting acetoacetyl-CoA is cleaved to two molecules of acetyl-CoA by acetoacetyl-CoA thiolase; they are then oxidized in the tricarboxylate cycle.

3-Hydroxybutyrate is converted to acetoacetate by 3-hydroxybutyrate dehydrogenase:

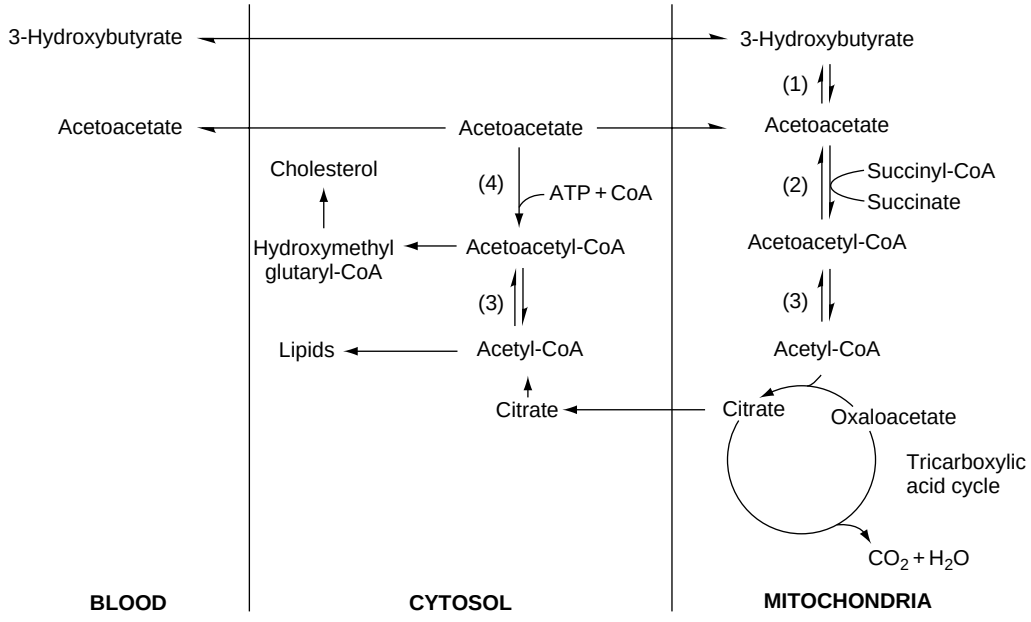

Figure 6 Pathways of ketone body utilization in peripheral tissues. (1) Hydroxybutyrate dehydrogenase, (2) 3-oxoacid-CoA transferase; (3) acetoacetyl-CoA thiolase; (4) acetoacetyl-CoA synthetase.

$$\text{3-Hydroxybutyrate} + NAD^+ \rightleftharpoons \text{acetoacetate} + NADH + H^+$$

The ready reversibility of the three enzymes of the mitochondrial pathway (**Figure 6**) means that if the overall system is near equilibrium within the cell *in vivo*, the utilization of the ketone bodies will be dependent on their respective concentrations and on the rate of removal of the products. Thus acetoacetate utilization will be promoted when mitochondrial acetyl-CoA is decreased, whereas an increase in the latter will have the opposite effect. Similarly, oxidation of hydroxybutyrate will increase if the concentrations of $NADH_2$ and acetoacetate fall. Unlike the hepatic hydroxymethylglutaryl-CoA pathway for ketogenesis, which is essentially irreversible, the free reversibility of this pathway in peripheral tissues can be viewed as means of buffering the mitochondrial acetyl-CoA pool and hence energy production. Some of the acetyl-CoA can be transported to the cytosol in the form of citrate to act as a precursor for lipogenesis (**Figure 6**).

Cytosolic pathway The cytosol of tissues where active lipogenesis occurs (adipose tissue, developing brain, lactating mammary gland, and liver) contains an enzyme, acetoacetyl-CoA synthetase, which converts acetoacetate to acetoacetyl-CoA (**Figure 6**):

$$\text{Acetoacetate} + ATP + CoA \rightarrow \text{acetoacetyl-CoA} + AMP + \text{pyrophosphate}$$

Its activity is at least an order of magnitude lower than that of the mitochondrial 3-oxoacid-CoA transferase, whereas its affinity for acetoacetate is appreciably higher. The presence of acetoacetyl-CoA thiolase in the cytosol allows the conversion of acetoacetate to acetyl-CoA and then to lipids without the involvement of the mitochondria.

Brain cytosol also contains 3-hydroxy-3-methylglutaryl-CoA synthase, allowing acetoacetate to act as a direct precursor for sterol synthesis. Evidence from *in vivo* experiments with ^{14}C-labelled acetoacetate has confirmed the existence of this pathway in developing brain and liver. The cytosolic route for acetoacetate utilization can be seen as a mechanism for directing this substrate to lipid or sterol synthesis rather than to oxidation.

Ketosis

The concentration of ketone bodies in the blood at any time represents a balance between the rate of hepatic ketogenesis and the rate of utilization by peripheral tissues. It is generally assumed that an increase in ketogenesis leads to a rise in blood ketone bodies, which in turn results in their increased utilization. In rare situations, such as congenital absence of key enzymes involved in ketone body utilization (e.g., 3-oxoacid-CoA transferase) or inhibition of these enzymes by pharmacological agents, blood ketone bodies may increase without any concomitant increase in ketogenesis.

The concentration of ketone bodies in the blood is exquisitely sensitive to changes in pathophysiological state. It is therefore useful to define *normoketonemia* in mammals as a concentration of total ketone bodies in blood below $0.2\,mmol\,l^{-1}$, *hyperketonemia* as above this level, and *ketoacidosis* (ketosis; by analogy to the definition of lactic acidosis) as above $7\,mmol\,l^{-1}$. In adult mammals there are small but characteristic diurnal variations in ketone body concentrations. Larger increases in concentration occur in man in response to change in pathophysiological state (**Table 1**). The concentrations span a 200-fold range and it is this which underlines the important role of ketone bodies as substrates and signals.

Physiological Ketosis

Physiological hyperketonemia is found in the suckling neonate (high-fat diet of the milk; **Figure 1**), postexercise (depletion of hepatic glycogen reserves), and after prolonged fasting (more than 24 h; **Figure 7**). All these situations have in common a low hepatic carbohydrate status (depletion of glycogen and/or activation of gluconeogenesis) and therefore from a physiological standpoint one would expect an increased rate of ketogenesis. Comparison of the factors which can influence ketogenesis in suckling and fasting (**Table 2**) shows the expected broad agreement.

Table 1 Range of blood ketone body concentrations in humans

Situation	*Ketone body concentration (mmol l^{-1})*
Fed normal diet	about 0.1
Fed high-fat diet	up to 3
Fasted: 12–24 h	up to 0.3
Fasted: 48–72 h	2.0–3.0
Postexercise	up to 2
Late pregnancy	up to 1
Late pregnancy: fasted 48 h	4.0–6.0
Neonate: 0–1 days	0.2–0.5
Neonate: 5–10 days	0.7–1.0
Hypoglycemia	1.0–5.0
Untreated diabetes mellitus	up to 25

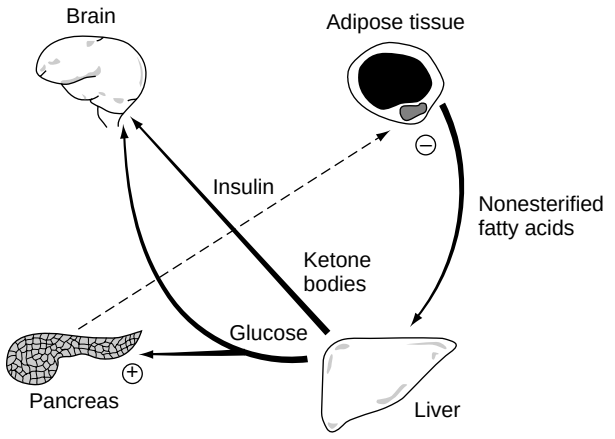

Figure 7 Intertissue fluxes of substrates in the starved state. Thickness of line denotes rate of flux.

More detailed information on the hierarchy of the regulatory factors during onset and reversal of ketogenesis has been obtained for the fasting state by measurements at short time intervals. The first event after withdrawal of food is a lowering of plasma insulin accompanied by an increase in plasma fatty acids (stimulation of lipolysis). However, for an appreciable period (8–10 h) there is no increase in blood ketone bodies or in the *in vitro* rates of hepatic ketogenesis (measured with saturating fatty acid concentrations). The major increment in ketogenic rate occurs at the nadir of the hepatic malonyl-CoA concentrations and when the sensitivity of CAT I to malonyl-CoA is starting to increase rapidly. This long time lag before a change in sensitivity of the protein to malonyl-CoA inhibition is thought to be due to the time required to bring about alterations to the lipid environment of the outer mitochondrial membrane.

Confirmation of this view is that on refeeding, when insulin rapidly increases and plasma fatty acids decrease with a parallel decrease in blood ketone bodies, there is again a time lag before malonyl-CoA concentrations rise and a longer one before sensitivity returns. In physiological and nutritional terms this delay of return to the normal fed settings of intrahepatic regulation makes excellent sense. It is only when the refeeding consists primarily of large amounts of carbohydrate that the starved liver needs to inhibit the activity of CAT I to prevent the oxidation of newly synthesized fatty acids. If the meal consists mainly of lipid with little carbohydrate the activity of CAT I needs to remain high to allow oxidation of the excess fatty acids. Thus the liver must sense a prolonged increase in plasma insulin before the high activity of CAT I is suppressed.

Table 2 Comparison of factors influencing ketogenesis in suckling and fasted states

Factor	*Suckling*	*Fasted*
Plasma nonesterified fatty acids	Increased	Increased
Plasma insulin	Decreased	Decreased
Plasma glucagon	Increased	Increased
Hepatic carnitine	Increased	Increased
Hepatic lipogenesis	Decreased	Decreased
Hepatic malonyl-CoA	Decreased	Decreased
Hepatic CAT I activity	Increased	Increased
Sensitivity to malonyl-CoA	Decreased	Decreased

Pathological ketosis

The major example of pathological ketosis is of course insulin-dependent or type 1 diabetes. Essentially the changes in this condition are similar to those that occur during fasting, but they are more pronounced. Insulin is absent or very low in the plasma and therefore there is no antagonistic action to restrain the opposing hormones, adrenaline, noradrenaline, and glucagon. Consequently, lipolysis in adipose tissue is greatly stimulated and plasma fatty acids increase to high levels.

The lack of insulin and the large flux of fatty acids to the liver means that lipognesis is inhibited at the level of acetyl-CoA carboxylase and there is the expected decrease in malonyl-CoA concentration. In addition, the sensitivity of CAT I to inhibition by malonyl-CoA is considerably decreased. The level of expression of hepatic CAT I and II proteins also increases several-fold in diabetes. Thus the liver is in the ideal mode for producing excessive amounts of ketone bodies.

It has been suggested that diversion of oxaloacetate to hepatic glucose synthesis (which is also increased in insulin deficiency) may also play a role in the increased rate of ketogenesis by diverting acetyl-CoA from the tricarboxylate cycle. However, present evidence suggests that this makes a minor contribution. Although the excessive output of ketone bodies by the liver undoubtedly makes the major contribution to their high levels in the blood, it is likely that there is also a degree of underutilization by peripheral tissues. The net result is ketoacidosis and excretion of large amounts of energy as ketone bodies in the urine.

A rare, but intriguing, example of pathological ketosis (ketone bodies up to $10\,mmol\,l^{-1}$) is the inborn error of hepatic glycogen synthase deficiency (**Figure 8**). Here glycogen is virtually absent from the liver so that after short-term fasting (5–10 h) the glucose falls to hypoglycemic levels, plasma insulin is decreased, plasma fatty acids increase, and

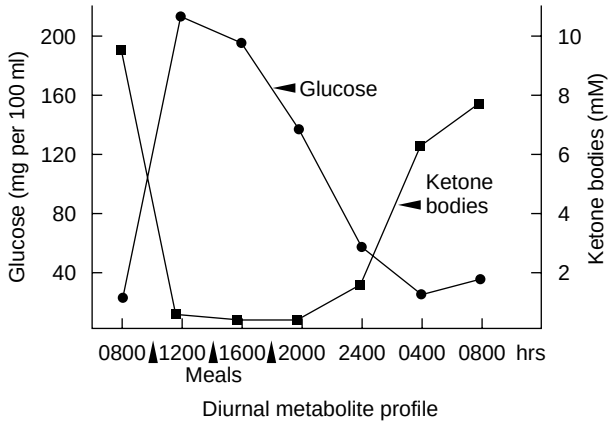

Figure 8 Diurnal blood metabolite profile of a child with glycogen synthetase deficiency. Values taken from Aynsley-Green A, Williamson DH and Gitzelmann R (1977) *Archives of Disease in Childhood* **52**: 573–579. (With permission from BMJ Publishing Group.)

ketogenesis is switched on. On consuming a meal the pattern is reversed until the blood glucose falls again. This case illustrates the importance of hepatic glycogen (and its mobilization) in the smooth transition of substrate supply from the fed to the fasted state. Treatment in this case was to recommend the consumption of more frequent high-carbohydrate snacks. It is of interest that this particular child suffered no ill effects from the daily exposure to high concentrations of ketone bodies, underlining their role as normal substrates for the brain when available.

Metabolic Acidosis

The great disadvantage of ketone bodies is that both acetoacetate and hydroxybutyrate are relatively strong acids. When they increase to high concentration there is the expected decrease in the blood pH, the plasma hydrogen carbonate concentration, and the partial pressure of carbon dioxide in blood and body fluids. The symptoms of acidosis include malaise, weakness, anorexia, and vomiting and these may eventually lead to coma. Treatment of diabetic ketoacidosis is to give insulin as soon as possible, usually as a continuous intravenous infusion. This rapidly decreases the raised plasma fatty acids and more slowly lowers the blood glucose and ketone bodies. Prolonged starvation, where the blood ketone bodies may reach 8–10 $\text{mmol}\,\text{l}^{-1}$, does not usually cause a serious disturbance of the acid–base balance. Loss of ketone bodies via the urine occurs but is not excessive. The nonenzymic decarboxylation of acetoacetate to acetone and carbon dioxide can be seen as a primitive mechanism for removing the potential acidotic effects of ketone bodies. The fact that acetone can be converted to glucose by the liver at low rates is an extra bonus.

The other common form of metabolic acidosis is lactic acidosis. This can arise because of infection, tissue hypoxia (anaerobic glycolysis), can be drug induced (ethanol, hypoglycemic biguanides), or can arise because of a congenital defect (pyruvate dehydrogenase or pyruvate carboxylase deficiency). In addition to the acidosis caused by lactic acid or ketone bodies there is a group of organic acidurias (some 25–30 different types) in which an inborn error results in the accumulation of an organic acid in the blood and urine. However, frank acidosis is not always associated with these conditions. The key investigation is chromatographic identification of the organic acid.

Physiology

J L McManaman and M C Neville, University of Colorado, Denver, CO, USA

Lactation is a uniquely mammalian physiological process in which the caloric and nutrient reserves of the mother are transformed into a complex fluid capable of supporting the nutritional demands of newborns for sustained periods. Milk, the product of lactation, is a mixture of solutes whose composition reflects the activities of distinct secretion and transport processes of the mammary gland and mirrors the differing nutritional requirements of mammalian neonates. In humans, this fluid is capable of providing the full-term infant with all the nutrients required for the first 4–6 months of life as well as offering significant protection against infectious disease. Although artificial formulas are widely utilized for human infant nutrition in developed countries, many components of human milk, including critical growth factors, long-chain polyunsaturated fatty acids, antiinfectious oligosaccharides and glycoconjugates, and the protein lactoferrin, are not duplicated in formula. Although it is likely that such substances are beneficial even to healthy infants in well-protected environments, they are particularly important to infants living in conditions of inadequate sanitation, as well as to preterm infants and infants with feeding problems. Despite the obvious importance of milk to neonatal nutrition and the selective advantage of lactation in mammalian evolution, the physiological mechanisms underlying milk secretion and utilization are not well understood and the molecular mechanisms involved in the production of individual milk components are still poorly characterized. In this article, the functional anatomy of the mammary gland is described, followed by a brief description of human milk composition and a review of the transport mechanisms involved in the secretion of individual milk components. We then summarize the functional differentiation of the mammary gland and the initiation of lactation—a process that involves a series of carefully programmed functional changes that transform a prepared, but nonsecretory, gland into a fully functioning organ during the first week postpartum in humans.

Functional Anatomy of Lactation

The lactating mammary gland consists of an arborizing ductal network that extends from the nipple and terminates in grape-like lobular clusters of alveoli forming the lobuloalveolar unit, which is the site of milk secretion. A stylized diagram of these structures is shown in **Figure 1**. Alveoli are composed of a single layer of polarized secretory epithelial cells that possess specialized features indicative of highly developed biosynthetic and secretory capacities, including numerous mitochondria, an extensive rough endoplasmic reticulum network, and a well-developed Golgi apparatus. Secretory components including lipid droplets and casein containing secretory vesicles are found juxtaposed to the apical membrane of these cells. The epithelial cells are connected to each other through a junctional complex composed of adherens and tight-junctional elements that function to inhibit transfer of extracellular substances between the vascular system and milk compartments during lactation (**Figure 2**). The basal portion of alveolar epithelial cells is surrounded by a meshwork of myoepithelial cell processes that contract to bring about milk

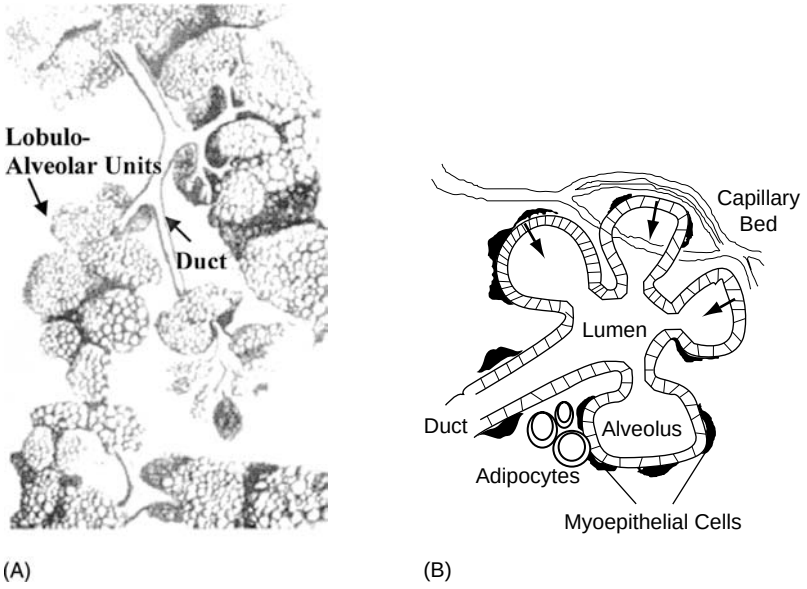

Figure 1 (A) Camera lucida drawing of a section of the breast of a woman who died 2 days after last suckling her infant. The drawing clearly shows collecting ducts and the grape-like lobuloalveolar units, which are engorged with milk. (From Dabelow A (1941) *Morphology Journal* **85**: 361–416.) (B) Cross-sectional diagram showing the relationship of the lobuloalveolar unit composed of milk secreting alveoli and ducts to the other cellular compartments of the mammary gland. Arrows indicate milk secretion by the alveolar epithelial cells into the lumen.

ejection and by a connective tissue stroma that supports and separates the lobules. The stromal component also contains lymphatics and becomes extensively vascularized during lactation to sustain the biosynthetic demands of alveolar epithelial cells. In nonpregnant, nonlactating animals the stroma contains a large adipose component.

New York: Plenum Press.)

The nipple, which is the termination point of the mammary ductal network, is innervated by the fourth intercostal nerve. Afferent sensory stimuli from suckling are transmitted to the spinal cord and the brain, resulting in release of prolactin and oxytocin from the pituitary. Prolactin, secreted from the anterior pituitary, acts directly on alveolar epithelial cells to foster synthesis and secretion of milk components. Oxytocin, secreted from the posterior pituitary, stimulates contraction of the myoepithelial cells that surround the alveoli and ducts. This process, called the 'letdown reflex,' forces the milk from the alveoli through ductules into ducts draining several clusters of alveoli. In the human, the small ducts converge into 15–25 main ducts that drain sectors of the gland and open directly on the nipple. The secretory product is stored in the alveolar space until myoepithelial cell contractions force it through the ducts toward the nipple, where it is available to the suckling infant.

Milk Composition

The major macronutrients in milk are lactose (a disaccharide unique to milk); lipids; proteins, including casein, α-lactalbumin, lactoferrin, secretory immunoglobulin A (sIgA), and many others present at much lower concentrations; and minerals

such as sodium, chloride, calcium, and magnesium. Minor nutrients in milk are enzymes, vitamins, trace elements, and growth factors. The lipid content of milk varies considerably between species. In human and cow's milk, the fat accounts for approximately 4% of milk volume, whereas in whales and seals it can account for as much as 60% of milk volume. Milk fat is primarily composed of triglycerides, a major source of neonatal calories, but it also contains cholesterol and phospholipids, essential for early neonatal development. Casein micelles form a separate phase that can be pelleted by high-speed centrifugation or acidification. These micelles have a high calcium and phosphate content. The aqueous fraction of milk, often called whey, is a true solution that contains all the milk sugar as well as the major milk proteins lactoferrin, α-lactalbumin, and sIgA and nonprotein nitrogen compounds (mostly urea); the monovalent ions sodium, potassium, and chloride; citrate; calcium; free phosphate; and most of the water-soluble minor components of milk.

The casein fraction from cow's milk, usually obtained by rennin precipitation, is used in cheese making, whereas the whey has a multiplicity of uses, most notably as the base for infant formula. Urea and other nonprotein nitrogen components of milk are a source of nitrogen for amino acid and protein synthesis. Isotope utilization studies indicate that on average 10–20% of urea nitrogen is converted into protein by breast-fed infants. Significantly higher utilization rates, however, have been measured in children recovering from infection, suggesting that alterations in urea nitrogen utilization may be a homeostatic response. Human and bovine milk differ primarily in their concentrations of lactose, mono- and divalent ions, and casein levels and the existence of antiinfectious agents in human milk (**Table 1**). These differences are related to the specific needs of these species. Human milk, for example, possesses higher concentrations of lactose and lower divalent ion concentrations than cow's milk. The high lactose concentration provides a large amount of 'free water,' via osmotic regulation, that serves as a reserve for temperature regulation via sweating in human infants. Human milk also contains a number of agents that protect against gastrointestinal and respiratory infections, including oligosaccharides that interact specifically with pathogen receptors, lactoferrin and sIgA. Bovine milk, on the other hand, contains high concentrations of casein, which provides protein and associated calcium and phosphate needed to support rapid growth of young calves.

Table 1 Comparison of the macronutrient contents of human and bovine milk

Component	*Human milk*	*Bovine milk*
Carbohydrates (g/dl)[a]		
Lactose	7.3	4.0
Oligosaccharides	1.2	0.1
Proteins (g/dl)[a]		
Caseins	0.2	2.6
α-Lactalbumin	0.2	0.2
Lactoferrin	0.2	Trace
Secretory IgA	0.2	Trace
β-Lactoglobulin	0	0.5
Nonprotein nitrogen (NPN) (g/l)		
Total NPN	0.42[b]	0.29[c]
Urea	0.16[b]	0.14[c]
Milk lipids (%)[a]		
Triglycerides	4.0	4.0
Phospholipids	0.04	0.04
Minerals and other ionic constituents (mM)[a]		
Sodium	5.0	15
Potassium	15.0	43
Chloride	15.0	24
Calcium	7.5	30
Magnesium	1.4	5
Phosphate	1.8	11
Bicarbonate	6.0	5

Synthesis and Secretion of Milk Components

Solutes enter milk through five general pathways (**Figure 2**). Endogenously generated substances, including the major milk proteins, oligosaccharides, and nutrients such as lactose, citrate, phosphate, and calcium, are secreted through an exocytotic pathway (pathway I). Lipids and lipid-associated proteins are secreted by a process that is unique to mammary epithelial cells (pathway II). The transcytosis pathway (pathway III) transports a wide range of macromolecular substances derived from serum or stromal cells, including serum proteins such as immunoglobulins, albumin, and transferrin; endocrine hormones such as insulin, prolactin, and insulin-like growth factor-1; and stromal-derived agents such as IgA, cytokines, and lipoprotein lipase. In addition, various membrane transport pathways (pathway IV) exist for the transfer of ions and small molecules, such as glucose, amino acids, and water,

across basal and apical plasma membranes. Finally, there is a paracellular pathway (pathway V) that provides a direct route for entry of serum and interstitial substances into milk. This pathway, however, closes during the first few days of lactation in the human. Transport through these pathways is affected by the functional state of the mammary gland and regulated by direct and indirect actions of hormones and growth factors. The general cellular and physiological properties of these pathways are summarized next.

Exocytotic Pathway (I)

Like exocytotic secretion mechanisms found in other cells, proteins, oligosaccharides, and nutrients such as lactose and citrate are packaged into secretory vesicles within the Golgi that are then transported to the apical region of the cell, where they fuse with the apical plasma membrane, discharging their contents into the extracellular space. A unique feature of this pathway in the mammary gland is the presence of high concentrations of lactose, phosphate, citrate, and calcium within the vesicles. Lactose is synthesized in the Golgi from UDP-galactose and glucose, which have entered from the cytoplasm using specific transporters, by the enzyme β-galactosidase, with α-lactalbumin acting as a cofactor. The high concentration of lactose present in the Golgi during lactation osmotically stimulates the influx of water that contributes to the fluidity of milk. Casein micelle formation begins in the terminal Golgi with condensation, and simultaneous phosphorylation, of casein molecules. Addition of calcium, possibly in the secretory vesicle, leads to maturation of casein micelles into particles sufficiently dense to be seen in the electron microscope. This complex thus delivers an efficient package of protein, calcium, and phosphate that provides the nutrients necessary for bone growth, among other things. Calcium enters the cytoplasm from the plasma by a poorly defined transport process. Cytoplasmic calcium is then transported into secretory vesicles by an ATP-dependent Ca^{2+} pump localized on Golgi and secretory membranes. The phosphate in secretory vesicles is derived from the hydrolysis of UDP-galactose during the synthesis of lactose. Citrate is generated endogenously within the cytoplasm of alveolar epithelial cells and transported into the Golgi lumen by an undefined process.

Lipid Secretion Pathway (II)

Estimates of the quantity of milk lipid secretion during lactation in humans and rodents indicate that in many species the lactating mammary gland may be one of the most lipogenic organs in the body. In a fully lactating woman secreting 800 ml/day of milk containing 4% fat, the mammary gland synthesizes approximately 32 g of triglyceride daily or approximately 6 g, 10% of the weight of the woman, in a typical 6-month lactation. The fatty acids for triglyceride synthesis are synthesized from glucose or derived from the plasma lipids by the action of lipoprotein lipase. Once available in the mammary alveolar cells, fatty acids are either bound to a fatty acid binding protein or activated by combination with coenzyme A (CoA) and then bound to an acyl-CoA binding protein. Activated fatty acids are joined with glycerol-3-phosphate by transacylases located in the endoplasmic reticulum to form triglycerides, which enter the cytoplasm as protein-coated structures called cytoplasmic lipid droplets. These structures are translocated to the apical membrane, where they are enveloped by a novel budding process that leads to their release as membrane-bound lipid droplets known as milk fat globules.

The fatty acid composition of milk triglycerides reflects differences in maternal diet. Medium-chain (C_{8-14}) fatty acids are synthesized only in the mammary gland using glucose (or acetate in ruminants) as substrate, whereas long-chain fatty acids are derived from the plasma. Nigerian women who have high-carbohydrate, low-fat diets have significantly more medium-chain fatty acids in their milk than Western women who consume a high-fat diet (**Table 2**).

Transcytosis Pathway (III)

Transport of proteins and other macromolecules by transcytotic pathways involves endocytic uptake of substances at the basal membrane, formation and maturation of endosomes, and sorting to lysosomes for degradation or to the apical recycling compartment for exocytosis at the apical membrane. The best studied molecule in this regard is immunoglobulin A (IgA). IgA is synthesized by plasma cells in the interstitial spaces of the mammary gland or elsewhere in the body and binds to receptors on the basal surface of the mammary alveolar cell; the entire IgA–receptor complex is endocytosed and transferred to the apical membrane, where the extracellular portion of the receptor is cleaved and secreted together with the IgA. It is thought that many other proteins, hormones, and growth factors that find their way into milk from the plasma are secreted by a similar mechanism.

Transmembrane Pathway (IV)

Transport processes for sodium, potassium, and chloride exist on the basal and apical plasma

Table 2 Major fatty acids of human and bovine milk (wt%)

Fatty acid	*Human milk*		*Bovine milk*

membranes of alveolar epithelial cells. Uptake mechanisms for calcium, phosphate, and iodide, however, are thought to be limited to the basal membrane. The mammary epithelial cells possess a GLUT1 glucose transporter and a sodium-dependent glucose transporter. The GLUT1 transporter is thought to mediate glucose transport at the basal and Golgi membranes, but it does not contribute to glucose transport at the apical membrane. Both sodium-dependent and sodium-independent amino acid transport mechanisms analogous to those found in other organs are located in the basolateral component of the mammary epithelium. It is unclear if apical membranes have similar transport mechanisms for amino acids, and it is unknown how amino acids get into milk.

Paracellular Transport Pathway (V)

Pathway V (**Figure 2**) involves passage of substances between epithelial cells rather than through them, and for this reason it is designated the paracellular pathway. During full lactation the passage of even low-molecular-weight substances between alveolar cells is impeded by the gasket-like tight junction structures that join the epithelial cells tightly, one to another. During pregnancy, with mastitis and after involution the tight junctions become leaky and allow components of the interstitial space, such as sodium and potassium, to pass unimpeded into the milk, a fact that is sometimes useful in diagnosing breast-feeding problems.

Regulation of Milk Synthesis, Secretion, and Ejection

Milk volume production is a primary indicator of lactational function; the most precise methods for measuring the volume of milk produced involve weighing infants before and after each feed for 24 h or longer or using an isotope dilution technique with stable isotopes. Clinically, the amount of milk that can be expressed with a breast pump or the change in infant weight after a single feed can be used as a rough index. The volume of milk secreted by women exclusively breast-feeding a single infant at 6 months postpartum is remarkably constant at approximately 800 ml/day in populations throughout the world. Mothers of twins, and occasionally even triplets, are able to produce volumes of milk sufficient for complete nutrition of their multiple infants,

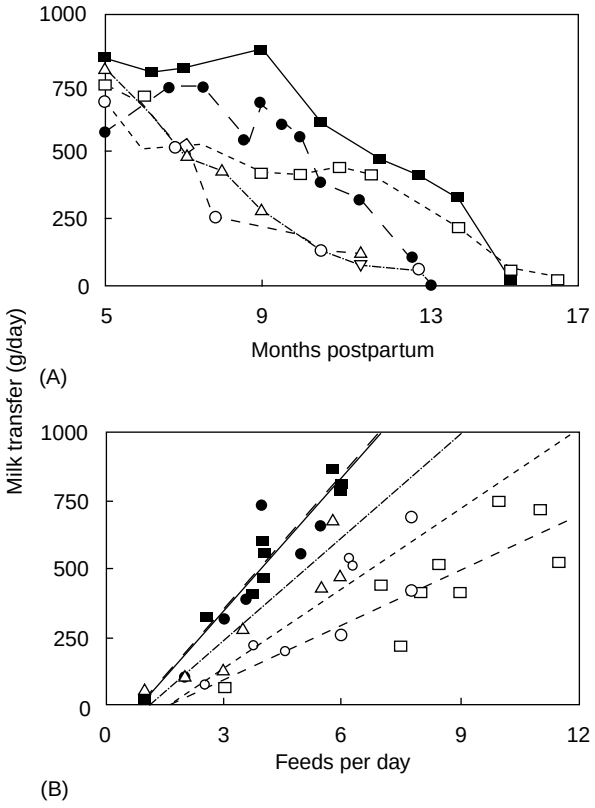

Figure 3 Changes in milk volume during weaning and in response to increased feeding frequency. (A) Milk volume transfer as a function of time postpartum. (B) Relation between feeding frequency (feeds/day) and the milk volume. Data are from five breast-feeding dyads; each symbol represents an individual dyad. (Reproduced with permission from Neville MC *et al.* (1991) *American Journal of Clinical Nutrition* **54**: 81–92.)

and studies of wet nurses indicate that at least some women are capable of producing up to 3.5 l of milk per day. On the other hand, if infants are supplemented with foods other than breast milk, milk secretion is proportionately reduced. This point is illustrated in **Figure 3**, which shows that milk volumes gradually decline during weaning and increase as feeding frequency increases. These observations illustrate the important principle that the volume of milk secretion in lactating women is regulated by infant demand. If milk cannot be removed from the breast, local mechanisms bring about an inhibition of milk secretion and downregulation of milk synthetic machinery. With partial removal of milk on a consistent basis, these local factors adjust milk secretion to a new steady-state level. If milk removal ceases for extended periods, involution sets in and the gland loses its competency to secrete milk.

Hormonal Control of Milk Synthesis and Secretion

In most species, the presence of high levels of plasma prolactin appears to be essential for lactation. In rats, the ergot alkaloid bromocriptine (an inhibitor of prolactin release from the pituitary) inhibits lactation, and in women it inhibits the onset of lactation when given in appropriate doses. How prolactin influences lactation is not known in any detail. However, it appears to promote mammary epithelial cell survival. In addition, it is an osmoregulator in some species of fish, birds, and amphibians and may function to maintain solute transport in the mammary gland.

Local Control of Synthesis and Secretion

Two local mechanisms have been postulated to regulate milk volume production. In one, it is thought that buildup of a specific inhibitory substance occurs in milk as it accumulates in the lumen of the mammary gland. However, the identity of this factor, called feedback inhibitor of lactation, has not been defined. In the second, it is thought that a stretch response of alveoli regulates milk production. Understanding this regulation may be very important in helping women to increase their milk supply, particularly in the postpartum period; therefore, further research is needed.

Regulation of Milk Ejection

When the infant is suckled, afferent impulses from sensory stimulation of nerve terminals in the areolus travel to the central nervous system, where they promote the release of oxytocin from the posterior pituitary. This neuroendocrine reflex can be conditioned, and in the woman oxytocin release is often associated with such stimuli as the sight or sound, or even the thought, of the infant. The oxytocin is carried through the bloodstream to the mammary gland, where it interacts with specific receptors on myoepithelial cells, initiating their contraction and expelling milk from the alveoli into the ducts and subareolar sinuses. The passage of milk through the ducts is facilitated by longitudinally arranged myoepithelial cell processes whose contraction shortens and widens the ducts, allowing free flow of milk to the nipple. Milk is removed from the nipple not so much by suction as by the stripping motion of the tongue against the hard palate. This motion carries milk through the teat into the baby's mouth. The letdown response is decreased by psychological stress or pain, which interfere with oxytocin release. Oxytocin also appears to be involved in regulating maternal behavior in laboratory animals and may play a similar role in humans.

Initiation of Lactation

Pregnancy transforms the mammary gland from a simple ductal tree into a highly efficient exocrine organ with expansive lobuloalveolar structures. This

transformation is hormonally regulated and involves changes in the cellular composition of the mammary gland and alterations in the structural, cellular, and biochemical properties of alveolar cells that are critical to development of efficient solute transport and secretory functions. Alveolar epithelial cells begin to differentiate into secretory cells at midpregnancy in most species. The differentiation process occurs heterogeneously and has been divided into initiation and activation phases based on differences in the composition of mammary secretions, gene expression, and structural and functional properties of alveolar cells. Alveolar cells become capable of limited secretion of some milk components during the initiation phase, which in humans is detected by measurement of increased concentrations of lactose and α-lactalbumin in the plasma. Copious milk secretion, however, is induced during the secretory activation phase (sometimes called lactogenesis II) that occurs in response to the decrease in serum progesterone levels. In rodents and ruminants, this decrease is closely associated with parturition; in humans it occurs after parturition.

Changes in Milk Composition during Secretory Activation

Secretory activation is reflected in dramatic modifications of the solute composition of milk and increased secretory volume, which in turn reflect the maturation of secretory mechanisms and transport pathways during this period. In women, there are three temporally distinct changes in milk composition at the onset of lactation. The earliest is a decrease in sodium and chloride concentrations and an increase in the lactose concentration of milk (**Figure 4**). These modifications occur immediately after delivery and are largely complete by 72 h postpartum. They precede increases in milk volume by at least 24 h and can be explained by closure of the tight junctions that block the paracellular pathway. Blocking this pathway prevents lactose, made by the epithelial cells, from passing from the lumen of the alveolus to the plasma, and it prevents sodium and chloride from directly entering the lumen from the interstitial space. These changes result in decreased concentrations of sodium and chloride and increased concentrations of lactose in the mammary secretion. The increased lactose concentration is reflective of decreased water entering the lumina as monovalent ion secretion decreases rather than an increase in the lactose secretion rate.

Secondarily, there are transient increases in the rates of secretion of sIgA and lactoferrin into milk of women soon after delivery. The concentrations of these two important protective proteins remain high, comprising

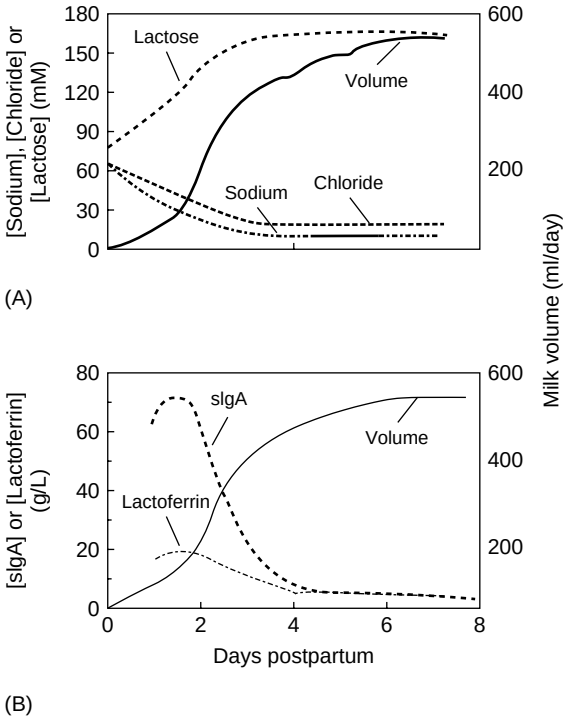

Figure 4 Changes in milk composition and volume in women during secretory activation and early lactation. (Reproduced with permission from McManaman JL and Neville MC (2003) *Advanced Drug Delivery Reviews* **55**: 630–641.)

as much as 10% of milk, for the first 48 h after birth. The concentration of each protein decreases rapidly after day 2, both from dilution as milk volume secretion increases and from actual decreases in their rates of secretion, particularly of immunoglobulins. Although both these proteins are found at high concentrations in colostrum, they are likely to be secreted by different mechanisms; lactoferrin, an endogenous protein of alveolar cells, is secreted by the exocytotic pathway (pathway I), whereas sIgA, a plasma-derived protein, is secreted by receptor-mediated transcytosis (pathway III). In addition, the peak secretion rate of lactoferrin occurs at the same time as that of lactose and the major milk proteins, whereas sIgA secretion peaks 1 day earlier, indicating the possibility that the exocytotic and transcytosis pathways are regulated differently during early lactation.

The third phase occurs approximately 36 h postpartum and is associated with massive and concerted increases in milk volume and the rates of synthesis and/or secretion of almost all the components of mature milk, including, but not limited to, lactose, protein (mainly casein), lipid, calcium, sodium, magnesium, potassium, citrate, glucose, and free phosphate. Considering that the secretion of these substances involves the actions of several distinct transport pathways and biosynthetic

processes, such tightly synchronized increases imply the presence of a common activation switch for coordinating their activities.

Hormonal Control of Secretory Activation

The decrease in progesterone around parturition is generally agreed to be required for the onset of milk secretion. In humans, it is known that removal of the placenta, the source of progesterone, is necessary for the initiation of milk secretion. In swine, timing of the increase in milk lactose correlates closely with timing of the decrease in plasma progesterone at parturition. Exogenous progesterone prevents lactose and lipid synthesis in mammary glands of pregnant rats and sheep after removal of their ovaries, the source of progesterone in these species. Progesterone also suppresses β-casein expression in the rat mammary gland during pregnancy and the decrease in progesterone levels is linked to increased β-casein synthesis at parturition. Receptors for progesterone are not detected in lactating mammary tissues, which explains why progesterone does not inhibit established lactation. It is likely that the decline in progesterone is insufficient to activate secretion and that the actions of other hormones, including prolactin and glucocorticoids, are necessary to complete this process. In all *in vitro* mammary systems, insulin and corticoids, in addition to prolactin, are necessary to maintain synthesis of milk components. Further more, cortisol replacement is required for maintenance of milk production in adrenalectomized animals. An early notion that a surge of glucocorticoids is the initiator of lactation is likely incorrect since the increase in cortisol seen in unanesthetized women associated with the stress of labor is complete by the time milk volume begins to increase to any extent. Because secretory activation proceeds at parturition in severely diabetic rats, a role for insulin in lactogenesis as opposed to metabolic adjustments during lactation seems improbable. In summary, the most reasonable interpretation of the data from both animal and human studies is that the hormonal trigger for lactogenesis is a decrease in progesterone in the presence of maintained prolactin. Since postpartum prolactin levels are similar in both breast-feeding and non-breast-feeding women, the basic process appears to be initiated whether or not breast-feeding occurs. The caveat, of course, is that the mammary epithelium must be sufficiently prepared by the hormones of pregnancy to respond with milk synthesis.

Delays in Secretory Activation

A delay in the onset of milk secretion is a problem for the initiation of breast-feeding in a significant number of parturient women. A number of pathological conditions may delay secretory activation in women, including cesarean section, diabetes, obesity, and stress during parturition. The role of cesarean section is controversial, but if there is one it is likely to have only a modest effect. However, poorly controlled diabetes, stress from delivery, or obesity are associated with significant decreases in early milk production. Because each of these conditions is related to higher blood glucose, hyperglycemia may be an underlying factor in the delay in lactation. However, once it is established, diabetics do not have a problem in maintaining lactation. Thus, compensatory factors may override initiation defects to ensure infant nutrition in these disorders.

Dietary Requirements

N M F Trugo and C M Donangelo, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil

Introduction

Milk secretion imposes a considerable nutritional demand on lactating women. The challenge to the maternal organism to sustain milk production and nutrient composition while maintaining an adequate nutritional status is high and must be met by increased dietary intake of energy and nutrients. Otherwise, maternal nutrient depletion may occur due to excessive mobilization of maternal stores. Owing to the major gaps in the knowledge on maternal nutrient requirements and the impact of lactation on maternal nutrient status, and the quantitative and qualitative importance of milk production for the incremental nutrient requirements, the recommended nutrient intakes for lactating women are based mainly on the volume of milk secreted and its nutritional content. The high nutritional demands for milk production result in recommended intakes of most nutrients for lactation that are higher (10%–90%) than in nonreproductive stages.

The dietary recommendations for lactating women considered in this article are those of the FAO/WHO Reports on fats (1994) and micronutrients (2001), and the Dietary Reference Intakes (DRIs) of the Institute of Medicine (US) on micronutrients (1997, 1998, 2000, 2001) and macronutrients (2002). The rationale for recommended nutrient intakes, and the nutrient requirements and dietary recommendations for energy, fat, protein, calcium, zinc, folate, and vitamin A are specifically addressed.

Rationale for Recommended Nutrient Intakes

Recommendations on dietary nutrient intakes for lactating women by different scientific authorities are typically based on the estimated total amount of each nutrient secreted daily into breast milk, taking into account, where known, the efficiency of milk synthesis and the bioavailability of the nutrient in the maternal diet. This estimate for each nutrient is then added to the recommended nutrient intake for non-pregnant, non-lactating women.

The onset of lactation after parturition is brought about by the major hormonal changes that occur in this period. During the first 2–7 days post-partum a thick yellow fluid (colostrum) is secreted. With the progress of lactation, the volume of milk secreted increases and its nutrient composition changes, with an increase, decrease or no change in concentration, depending on the nutrient. After about 21 days the milk secreted is considered mature milk. The volume of breast milk secreted daily increases rapidly in the first post-partum days, being ~500 ml on day 5, ~650 ml at 1 month, and ~750 ml at 3 months, remaining relatively stable during full lactation but decreasing during weaning. In industrialized countries, the average volume of breast milk produced is 750–800 ml day^{-1} in the first 4–5 months post-partum and decreases to 600 ml day^{-1} during 6–12 months after delivery. In this period, the volume of milk produced may be even lower and more variable, depending on the weaning practices adopted.

The FAO/WHO and DRI committees considered 750 and 780 ml, respectively, as the average milk volume produced during full lactation and the basis for recommendations. For most nutrients, average concentration in mature milk multiplied by the average milk volume was used to estimate the total amount of nutrient secreted daily into breast milk. A correction factor was then applied to account for the nutrient bioavailability in the maternal diet and, where known, for the anabolic cost of milk synthesis, and the final value was added to the recommended intake of nonpregnant, nonlactating women. The stage of lactation was considered to be a factor for some nutrients and, where applicable, separate values were given according to the period of time post-partum.

The volume of milk secreted during lactation is not influenced by maternal nutritional status, unless maternal undernutrition is severe. The composition of breast milk for most nutrients is adequate to support infant growth and development in a wide range of maternal nutritional status. However, maternal diet and nutritional status do have an influence on the concentration of some micronutrients such as vitamin A, thiamin, riboflavin, vitamins B_6 and B_{12}, iodine, and selenium. Also, the fatty acid composition of breast milk can be affected by maternal diet.

An important step taken by the DRI committees when setting recommendations was taking maternal age into account, thus giving separate values for adolescent ($\leq$18 years) and adult (19–50 years) lactating women. For some nutrients, adolescent lactating women may have greater requirements than adult women because they are still growing and they need to cover their own nutrient demands. Recommendation of intakes during lactation of calcium, phosphorus, magnesium, iron, and zinc are higher for adolescent than for adult women.

In general, there is considerable uncertainty in establishing dietary nutrient recommendations for lactation due to high intra- and interindividual variability in breast milk volume output and in several specific nutrient concentrations in breast milk, and to temporal changes in milk volume and nutrient concentrations during the lactation period. The composition of breast milk is affected by several factors depending on the nutrient, such as stage of lactation, changes during nursing, diurnal rhythm, maternal diet, gestational age at birth, and parity. Moreover, the total amount of nutrients secreted into breast milk depends on the extent and duration of breast feeding. In addition, physiological adaptation to the increased nutrient lactation demands such as increased nutrient absorption and conservation, and use of maternal nutrient stores, which are quite specific for each nutrient and not easily quantified, contributes to the degree of uncertainty. Maternal age and maternal nutritional status during pregnancy and lactation may influence the homeostatic adaptations during lactation such as the efficiency of nutrient absorption and the degree of mobilization of maternal nutrient stores. These factors are not well known and are difficult to quantify.

Requirements and Dietary Recommendations

Macronutrients

Energy The dietary energy intake recommended for healthy adults of normal weight (body mass index between 18.5 and 25 $kg\,m^{-2}$) is the energy required to maintain energy balance, considering gender, age, weight, height, and level of physical activity. The energy requirements of lactating women include the additional energy that is necessary for milk production. The stage and extent of breastfeeding affect the incremental energy requirements for lactation.

The energy density of human milk is mainly determined by its fat content, which represents 50–60% of the total energy in mature milk and is the most variable energy-yielding component. Protein and lactose contribute to approximately 5% and 38% of energy, respectively. The mean energy density of representative 24-h pooled mature milk samples from well-nourished women ranges from 0.64 to 0.74 $kcal\,g^{-1}$ (2.7–3.1 $kJ\,g^{-1}$).

The estimated energy requirements (EER) for lactating women by the DRI committee are based mainly on studies done in the 1990s, using the doubly labeled water method. The main findings in women who were fully breastfeeding their infants up to 6 months of age were: total energy expenditure of 2109–2580 $kcal\,day^{-1}$ (8860–10840 $kJ\,day^{-1}$) or 35.8–41.0 $kcal\,kg^{-1}\,day^{-1}$ (150–172 $kJ\,kg^{-1}\,day^{-1}$), milk energy output of 483–538 $kcal\,day^{-1}$ (2030–2260 $kJ\,day^{-1}$), and energy mobilization from tissue stores of 72–287 $kcal\,day^{-1}$(300–1200 $kJ\,day^{-1}$). It was concluded that the energy requirements of lactating, well-nourished women are met primarily from the diet and partially by mobilization of tissue stores, without evidence for adaptations in basal metabolism and physical activities. The EER for lactating adult women during the first 6 months of lactation is calculated as the sum of the EER obtained from the equation for adult nonlactating women (using current age, weight, and physical activity level), and the milk energy output (500 $kcal\,day^{-1}$ or 2100 $kJ\,day^{-1}$), subtracting the energy derived from tissue mobilization during lactational weight loss (170 $kcal\,day^{-1}$ or 714 $kJ\,day^{-1}$). The committee considered a milk production rate of 0.78 $l\,day^{-1}$ from birth through 6 months of age, with a milk energy density of 0.67 $kcal\,g^{-1}$ (2.8 $kJ\,day^{-1}$), and an average maternal weight loss of 0.8 $kg\,month^{-1}$. For the second 6 months of lactation, the incremental EER is calculated considering a milk energy output of 400 $kcal\,day^{-1}$ or 1680 $kJ\,day^{-1}$ (milk production rate of 0.6 $l\,day^{-1}$) and no maternal weight loss. The EER for lactating adolescents (14–18 years) is calculated in the same manner as for adult lactating women, but using the appropriate equation to estimate the EER of nonlactating adolescents.

The acceptable macronutrient distribution ranges as percentage of total dietary energy for lactating women are the same as for the general adult population: 10–35% protein, 20–35% fat, and 45–65% carbohydrates. Natural simple sugars, such as those present in fruit, and complex carbohydrates (polysaccharides), such as in cereals (rice, wheat), cereal products (flour, pasta) and starchy roots, should be the preferred sources of carbohydrates in the diet. Added sugars, usually sucrose, should not be higher than 25% of dietary energy. Many of the energy-yielding carbohydrate food sources are also sources of dietary fiber, which are beneficial in reducing the risk of coronary heart disease, ameliorating constipation, and other ways. A total fiber intake of 29 $g\,day^{-1}$ is recommended for lactating women. Whole grain cereals, nuts, legumes, and fruit are good fiber and energy sources, and are also nutrient-rich foods. Restriction of energy intake during lactation to values below 1800 kcal (7500 kJ) per day may lead to low intakes of several micronutrients such as calcium, magnesium, zinc, folate, vitamin B_6, and vitamin A.

Fat Total fat content in human milk is affected by several factors, including stage of lactation, moment of feeding, and parity, but maternal intake of energy, fat, and fatty acids and maternal status have little influence, except when there is a long-term or severe maternal undernutrition. Milk fat content is highly variable, being on average 35–40 $g\,l^{-1}$ in mature milk from well-nourished women delivering at term gestation. The content of individual fatty acids in milk is also highly variable, especially for the long-chain polyunsaturated fatty acids (LCPUFA; mainly C_{20} and C_{22}), and more dependent on maternal diet than total fat. Fatty acid intake and relative contribution of carbohydrate and fat to the total energy intake, as well as maternal body stores and endogenous synthesis, influence the fatty acid composition of human milk. In well-nourished mothers, the polyunsaturated essential fatty acids (EFA) linoleic acid (18:2*n*-6) and α-linolenic acid (18:3*n*-3) represent approximately 11 and 1% (wt/wt), respectively, of the total fatty acids in milk. LCPUFA of the *n*-6 and *n*-3 series account for 1.2 and 0.6%, respectively.

The adequate transfer of polyunsaturated fatty acids from maternal circulation to milk and the

maternal synthesis of LCPUFA, especially arachidonic acid (20:4*n*-6), dihomo-γ-linolenic acid (20:3*n*-6), eicosapentenoic acid (EPA, 20:5*n*-3), and docosahexenoic acid (DHA, 22:6*n*-3), from their respective EFA precursors, are important for infant growth, neurodevelopment, and visual function. These polyunsaturated fatty acids are structural components of all cell membrane phospholipids. Arachidonic acid and DHA are the two quantitatively most important LCPUFA in the brain and retina, and the LCPUFA with 20 carbon atoms are precursors for the synthesis of eicosanoids, a group of signaling molecules. The major part of the polyunsaturated fatty acids in human milk (70–85% in women on omnivorous diet) is derived from maternal body stores, which reflects long-term intake, and not from direct dietary transfer.

The metabolic fate of individual fatty acids depends on dietary energy and on energy balance. Therefore, the intake and requirements for fat, EFA, and LCPUFA are usually expressed as a percentage of the total energy in the diet (en %), rather than total intake (g). The fat intake recommended for lactating women is in the range of 20–35 en %, which is the same range as recommended for the adult population. Concerning the fatty acid intake, FAO/WHO recommends an additional maternal intake of 1–2 en % as EFA (3–4 g day^{-1}) during the first 3 months of lactation, and up to 4 en % (about 5 g day^{-1}) thereafter due to depletion of maternal fat stores. Based on the median linoleic and α-linolenic acid intakes of lactating women in the US, the DRI committee recommends an intake of 5–10 en % (average 13 g day^{-1}) of *n*-6 (as linoleic acid) and of 0.6–1.2 en % (average 1.3 g day^{-1}) of *n*-3 (as α-linolenic acid) polyunsaturated fatty acids throughout lactation, with a 10% contribution of LCPUFA of the *n*-6 and *n*-3 series to these ranges. The ratio of *n*-6:*n*-3 unsaturated fatty acids in the diet is important because these fatty acids are desaturated and elongated using the same series of enzymes. Increased intakes of linoleic acid result in decreased conversion of α-linolenic acid to EPA and DHA, whereas the conversion of linoleic acid to arachidonic acid is inhibited by EPA and DHA, and also by arachidonic acid, α-linolenic acid, and linoleic acid itself. The *n*-6:*n*-3 ratio recommended for adults by both DRI and FAO/WHO committees is 5:1 to 10:1. Vegetable oils are the main sources of *n*-6 fatty acids in the diet and also of *n*-3 fatty acids, although in lower amounts. Fish such as herring, mackerel, and salmon are good sources of *n*-3 fatty acids.

The intake of *trans* fatty acids (*trans* isomers of oleic and linoleic acid) present in hydrogenated food fats and oils, deep-fried foods, and meats are of special concern in lactating women when their intake is excessively high or when EFA intake is low during pregnancy and lactation. An inverse correlation of arachidonic acid and DHA with *trans* fatty acids in plasma lipids has been reported in infants, suggesting impairment in LCPUFA synthesis and metabolism.

Protein The average protein content in colostrum is 15–20 g l^{-1} decreasing to approximately 8–10 g l^{-1} in mature human milk during the first 6 months of lactation. The protein concentration in human milk is not affected by diet, body composition, or maternal undernutrition.

The recommended dietary allowance (RDA) of protein for adolescent and adult lactating women by the DRI committee is 1.1 g per kg of body weight per day. This corresponds to an increment of 25 g day^{-1} of protein intake above the RDA for nonlactating women, and it is the same as for pregnant women. Recent data have shown that protein intakes of 1 g kg^{-1} day^{-1} are able to maintain good milk production, and promote conservation of maternal skeletal muscle apparently by downregulating protein metabolism. The recommended range of percentage of energy from dietary protein is the same as for the general adult population (10–35%).

The factorial approach was used to estimate the protein RDA for lactation, assuming that the maintenance protein requirement of the lactating women is not different from that of the nonlactating women, and that the additional protein and/or amino acid requirements are proportional to milk production. The additional protein requirement for lactation is defined as the output of total protein and nonprotein nitrogen (converted in protein by multiplying by 6.25) in milk. Nonprotein nitrogen represents 20–25% of total milk nitrogen, mainly as urea. It is taken into account because it is assumed that the nitrogen needed to cover the total nitrogen loss in milk should be derived from dietary protein. The total nitrogen output in milk is converted to total protein output (approximately 10 g day^{-1}) and divided by the incremental efficiency of nitrogen utilization (0.47), which is assumed to be the same in adult and adolescent lactating women. The additional estimated average requirement due to milk production is 21.2 g day^{-1}. After correction by the coefficient of variation and rounding off, the RDA for lactation amounts to +25 g day^{-1}, which corresponds to +0.46 g protein kg^{-1} day^{-1} (based on a reference woman of 57 kg), above the RDA for nonlactating women.

Recommendations for individual indispensable amino acids for lactation by the DRI committee assume that the incremental needs correspond to the

amino acids secreted in milk, since there are no specific data on the amino acid requirements in lactating women. Therefore, the RDA of amino acids for lactation are calculated by adding the average amounts of amino acids in human milk in the first 6 months of lactation (expressed as milligrams per kilogram per day) to the respective RDA for the nonlactating women. Recommendations of indispensable amino acids for the lactating women are 36% (histidine) to 80% (tryptophan) higher than those for nonlactating women. The intake of good-quality protein such as in eggs, milk, meat, and fish provide the requirements for all indispensable amino acids. Individuals who restrict their diets to plant proteins (cereals, legumes, nuts, starchy roots, vegetables, and fruits) may be at risk of not getting adequate amounts of certain indispensable amino acids. However, adequate complementary mixtures of plant proteins, with increased digestibility through processing and preparation, can provide high-quality protein.

Micronutrients

Daily requirements for several micronutrients (riboflavin, vitamin B_{12}, vitamin C, vitamin A, vitamin E, copper, iodine, manganese, selenium, and zinc) are higher during lactation than during pregnancy, indicating that lactation is a very demanding process. The only micronutrient needed in lower amounts during lactation is iron, due to the small amount of iron secreted into breast milk and to the usual amenorrhea of nursing women. However, iron requirements may be high post-partum for women who need to replace major blood losses during delivery.

The recommended intakes for micronutrients during lactation established by FAO/WHO and DRI committees are summarized in **Table 1**. The

Table 1 Daily recommended micronutrient intakes for adult lactating women

Nutrient	*FAO/WHO*[a]		*IOM*[b]	
	Recommended value	*Per cent change*[c]	*Recommended value*	*Per cent change*[c]
Vitamin A (μg RAE day^{-1})	–	–	1300	↑ 86%
Vitamin A (μg RE day^{-1})	850	↑ 70%	–	–
Vitamin D (μg day^{-1})	5	No change	5	No change
Vitamin E (mg α-TE day^{-1})	7.5	No change	19	↑ 27%

percentages of change from the recommendations for nonpregnant nonlactating women are also shown. In order to meet these intakes, lactating women should be guided to consume daily a large variety of foods rich in micronutrients, since food diversification contributes to improve the intake of limiting nutrients. Micronutrients most commonly at risk of inadequate intakes by lactating women are calcium, zinc, folate, and vitamin A.

Calcium It is estimated that lactating women secrete an average of 200 mg of calcium per day into mature breast milk although this amount is variable among women, usually ranging from 150 to 300 mg day^{-1}. The maternal diet does not affect the milk calcium concentration except when maternal calcium intake is very low (<300 mg day^{-1}). The primary source of calcium for milk production appears to be the increased mobilization of calcium from maternal bone due to the increased bone resorption that occurs during lactation favored by the low estrogen concentration. This results in a net loss of maternal bone mass during lactation that is regained after weaning upon return of ovarian function. The decreased urinary calcium excretion during lactation also contributes to the calcium economy for milk secretion. The efficiency of intestinal calcium absorption is not increased during lactation and, therefore, does not contribute to the extra calcium needed for milk production.

Several studies have shown that the adaptive changes in calcium homeostasis during lactation are independent of maternal calcium intake. It was demonstrated that the loss of bone mass during lactation was not affected by calcium supplementation (1000 mg day^{-1}) of nursing women with habitual dietary calcium intakes of 300 mg day^{-1}, 800 mg day^{-1}, and 1200 mg day^{-1}. Since the loss of maternal bone calcium that occurs during lactation is not prevented by increased dietary calcium, and the calcium lost appears to be regained after weaning, the recommended intake of calcium of lactating women is the same as for nonpregnant nonlactating women of the same age, being 1000 mg day^{-1} and 1300 mg day^{-1} for adult and adolescent women, respectively. Even if not increased during lactation, the recommended calcium intake may be difficult to obtain by women with low habitual intake of dairy products. Therefore, lactating women should be guided to consume dairy products such as milk, yogurt, and cheese, and other calcium-rich foods such as fish with edible bones, broccoli, and kale.

Lactating adolescents are a group of special concern regarding calcium intake due to the already high calcium requirements of nonpregnant nonlactating adolescents. These young women are still increasing their own bone density besides the increased calcium requirement to support lactation. Studies are needed to investigate if these women are able to regain bone after weaning to the same level as when they were nonpregnant nonlactating and if they would benefit from increased calcium intake.

Zinc Zinc concentrations in human milk are highest in colostrum, decrease rapidly during the first 3 months post-partum, and more gradually at later stages of lactation. Typical milk zinc concentrations are 4 mg l^{-1} at 2 weeks, 3 mg l^{-1} at 4 weeks, 2 mg l^{-1} at 8 weeks and 1.2 mg l^{-1} at 24 weeks. These concentrations are not influenced by either maternal dietary intake or zinc supplementation at least in well-nourished women. Less is known about the effect of low maternal zinc intakes on milk zinc concentrations, but the available data indicate that concentrations in developing countries may be lower than those in developed countries at comparable times post-partum.

Average losses of zinc via the mammary gland range from 2.2 mg day^{-1} during the first month post-partum to 1 mg day^{-1} at 6 months. The average estimate of daily output of zinc in milk during the first 3 months of lactation is 1.6 mg day^{-1}, which would theoretically double the minimum endogenous zinc losses in lactating women compared to those of nonlactating nonpregnant women. However, maternal homeostatic mechanisms such as enhanced zinc absorption and reduced urinary zinc excretion contribute to compensate for the secretion of zinc into human milk, independent of maternal zinc intake. Intestinal conservation of endogenous fecal zinc appears to contribute to zinc homeostasis during lactation at low zinc intakes (<8 mg day^{-1}). Involution of the uterus, decreased maternal blood volume and increased resorption of trabecular bone in the postpartum period also contribute to mobilizable zinc pools to compensate for the increased needs. These sources appear to provide up to 0.5 mg day^{-1} of zinc during the first 3 months of lactation. Taking all these adaptation mechanisms into account, the average estimate of increased requirement for absorbed zinc during the first 6 months of lactation is 1.35 mg day^{-1}. Therefore, dietary zinc requirements during lactation are substantially increased compared to nonpregnant nonlactating women, both in adults and adolescents.

Bioavailability is an important factor in setting dietary zinc recommendations since the efficiency of dietary zinc utilization may vary up to fivefold depending on the overall composition of the diet, particularly the balance between promoters (animal

protein) and antagonists (phytic acid and possibly calcium, iron, and copper) of zinc absorption.

Dietary zinc recommendations during lactation are set at $12\,mg\,day^{-1}$ for adult lactating women consuming a mixed diet, but recommended intake may be as high as $19\,mg\,day^{-1}$ for nursing women with habitual diets of low zinc bioavailability, such as those based mainly on unrefined cereals and legume seeds, with high phytate:zinc ratio (>15), and low in animal protein. This high-zinc intake may be difficult to obtain using plant-based diets. Therefore, nursing women in developing countries and strict vegetarian women worldwide may be at risk of inadequate zinc status during lactation. Red meat, poultry, eggs, and seafood provide highly available zinc, and their consumption should be encouraged in lactating women.

Folate Concentration of folate in breast milk increases during the lactation period, with lower values for colostrum ($10–40\,\mu g\,l^{-1}$) than for mature milk ($79–133\,\mu g\,l^{-1}$). These concentrations are several-fold higher than in maternal plasma, independent of maternal folate status, suggesting that the mammary gland actively transports and regulates the secretion of this vitamin into milk. Folate concentration in breast milk is maintained with the concomitant depletion of maternal folate when maternal dietary intake is low. Maternal supplementation during lactation has little effect on milk folate but it benefits maternal folate status. Folate deficiency has been implicated in disorders such as neural tube defects, low infant birth weight, aborption, cervical dysplasia, atherosclerosis, and colon cancer.

Dietary folate requirements during lactation are based on the average milk folate concentration of $85\,\mu g\,l^{-1}$ and assume a 50% dietary absorption factor from a mixed diet, to account for dietary bioavailability. The average extra amount of dietary folate needed to cover the lactation needs is thus estimated as $133\,\mu g\,day^{-1}$, an increase of about 40% of the nonpregnant nonlactating average folate requirements. Dietary folate recommendations during lactation are set at $500\,\mu g\,day^{-1}$, as dietary folate equivalents (DFEs). A DFE is defined as 1 μg of food folate, or 0.6 μg of folic acid from fortified food or as a supplement taken with meals, or 0.5 μg of folic acid as a supplement taken on an empty stomach. Thus, in order to meet lactation requirements, much less of this vitamin is needed when given as pure folic acid than as natural food folate.

Present recommendations are very difficult to meet by dietary means and most nursing women worldwide appear to have a much lower dietary folate intake and, therefore, to be at risk for folate deficiency. Although folate is found in a variety of foods, such as fresh green vegetables, oranges, legumes and nuts, it is present in relatively small amounts, and several servings per day of these foods are needed to meet recommended intake. Moreover, considerable losses of folate occur during food harvesting, storage, and cooking. Fortification of cereal grains with folate has become mandatory or encouraged in many countries in order to reduce the risk of folate deficiency.

Vitamin A Vitamin A is present in human milk, primarily as retinyl esters (95%) and free retinol. Vitamin A activity is also provided as carotenoid precursors, mainly as beta-carotene, which accounts for up to 30% of total carotenoids in breast milk. Concentration of vitamin A in human milk is high in early lactation ($600–2000\,\mu g\,l^{-1}$) and declines thereafter ($200–1100\,\mu g\,l^{-1}$), being responsive to maternal intake, particularly in nursing women with poor vitamin A status. These women are at risk of providing insufficient amounts of vitamin A to their infants, as is often the case in developing countries.

Dietary recommendations of vitamin A during lactation are based on replacement of the amount of vitamin A secreted into breast milk during the first 6 months of lactation, while preserving maternal vitamin A stores. Because the bioconversion of carotenoids in human milk and in infants is still unknown, the contribution of maternal carotenoids in breast milk to meeting the vitamin A lactation requirement cannot yet be established.

Based on the average vitamin A milk concentration of $485\,\mu g\,l^{-1}$, an extra intake of 400 μg of retinol activity equivalents (RAE) per day is recommended for lactating women, which represents an increase of over 70% of recommended intakes for nonpregnant nonlactating adolescent and adult women. RAE is defined as 1 μg all-*trans*-retinol, 12 μg beta-carotene, and 24 μg alpha-carotene or beta-cryptoxanthin. The amounts of carotenoids equivalent to 1 RAE are double the equivalent to 1 RE (retinol equivalents). The new equivalency value (RAE) is based on recent studies demonstrating that bioconversion of carotenoids to vitamin A is 50% less than previously thought.

The vitamin A intake recommended for lactating women can be obtained as the preformed vitamin from foods of animal origin (primarily milk products, eggs, and liver) and as the carotenoid precursors by regular consumption of green leafy vegetables and ripe, colored fruits. However, meeting the recommended intake by consumption of plant foods alone, as is the case in many developing countries, may be difficult.

LACTOSE INTOLERANCE

D M Paige, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, USA

Lactose maldigestion and intolerance result from an inability to digest varying amounts of the milk sugar lactose. This is a result of an inadequate amount of the genetically regulated milk sugar enzyme lactase. The most common reason for lactose maldigestion is a decline of lactase activity with increasing age. Lactose maldigestion may also occur secondary to intestinal tract infection and diarrhea. A rare form of alactasia, an absence of the milk sugar enzyme, can occur at birth. The symptoms associated with lactose maldigestion are a result of the incomplete hydrolysis, or splitting, of the disaccharide lactose into its absorbable monosaccharide components, glucose and galactose. Lactose maldigestion may result in abdominal bloating and/or pain, flatulence, loose stools, and diarrhea, singly or in combination. The symptoms associated with lactose maldigestion result in lactose intolerance. The most common form of lactose maldigestion and lactose intolerance, as observed in the majority of the world's adult population, is due to genetically determined low lactase levels. Lactase deficiency due to genetic nonpersistence is reported in approximately 70% of the world's adult population.

The prevalence is lowest in people of Northern European descent (15%) and highest in many Asian populations (near 100%). The prevalence of lactase deficiency in individuals of African descent is approximately 70–80%. Similar levels are reported for Latinos and those of Eastern European and South American ancestry. Not all individuals with a reduced level of the enzyme lactase exhibit symptoms with the ingestion of dietary lactose. The presence or absence of symptoms varies with the amount and type of food consumed, intestinal transit time, and level of residual intestinal lactase. Individuals with low lactase levels may tolerate a

moderate intake of lactose. Lactase deficiency can generally be identified by a breath hydrogen test measuring the level of undigested lactose reaching the colon. Bacterial fermentation of the undigested lactose is responsible for the volume of breath hydrogen production. A lactose tolerance test measuring blood sugar rise has also been used. Individuals experiencing discomfort with lactose ingestion can elect to consume commercially hydrolyzed milk that is readily available, milk substitutes, or alternative food sources equally rich in calcium.

Historical and Geographic Perspective

The first herd animal kept by humans, sheep, seems to have been domesticated in approximately 10 000 BC. Herd animals were primarily used for meat and perhaps certain other purposes. The historical record suggests that herd animals during this period were not milked. Evidence that humans milked domesticated animals dates to approximately 4000 to 3000 BC in northern Africa and southwest Asia. Following that time, dairying spread across Eurasia and into sub-Saharan Africa. However, dairying was not adopted by all groups in Asia and Africa who had suitable herd animals. Even as late as 1500 AD, the beginning of the great European overseas expansion, there were sizable areas occupied by nonmilking groups. In Africa, the zone of nonmilking centered on the Congo Basin but extended beyond to cover approximately one-third of the continent. In Asia, the zone of nonmilking covered the bulk of the eastern and southeastern portions of the continent, including Thailand, Vietnam, China, and Korea, as well as the islands to the east. Moreover, dairying remained unknown in the Pacific region and in the Americas in pre-European times. In those days, the nonmilking peoples of Asia, Africa, and the Americas consumed mother's milk as infants but normally ingested no milk after weaning. Animal milk was not part of their diet.

It was striking that adults of all groups whose origins lay in the traditional zone of nonmilking were predominantly maldigesters, usually 70–100% of the individuals tested. Also striking was the fact that the peoples with low prevalences of lactose maldigestion (northwest Europeans and certain East African pastoral groups) came from a long tradition of consuming milk, much of it in lactose-rich forms. This suggested the geographic or culture–historical hypothesis. By that hypothesis, in the hunting and gathering stage, human groups everywhere were like most other land mammals in their patterns of lactase activity. That is, in the normal individual lactase activity would drop at weaning to low levels, which prevailed throughout life. With the beginning of dairying, however, significant changes occurred in the diets of many human groups. In some of these, moreover, there may have been a selective advantage for those aberrant individuals who experienced high levels of intestinal lactase throughout life. That advantage would have occurred only in certain situations: Where milk was a specially critical part of the diet, where the group was under dietary stress, and where people did not process all their milk into low-lactose products such as aged cheese. Under these conditions, most likely to occur among pastoral groups, such aberrant individuals would drink more milk, would benefit more nutritionally as a result, and would enjoy increased prospects of survival, well-being, and bearing progeny and supporting them. In a classical Mendelian way, the condition of high intestinal lactase activity throughout life, or lactase persistence, would come to be typical of such a group.

Lactase Nonpersistence

In its pure form, lactose cannot be transported across the mucosa of the small intestine. To be absorbed, it must be hydrolyzed by lactase to free glucose and galactose. These two simple sugars are rapidly and completely absorbed in the normal small intestine. The rate of lactase synthesis is high from birth until ages 3–5 years. Between ages 5 and 14 years, many people undergo a genetically programmed reduction in lactase synthesis that results in a lactase activity level only 5–10% of that of infancy. This reduction, known as lactase nonpersistence or primary lactase deficiency, is not related to the continued intake of milk or lactose. As noted, less than one-third of the world's adult population is genetically predisposed to maintaining a high degree of lactase activity or lactase persistence throughout adulthood.

Lactase persistence in the human population is inherited as a dominant genetic trait. It has been observed that lactose intolerance is 'ancient and globally distributed,' predating the appearance of a persistent lactase variant that was naturally selected in dairying regions. Hollox *et al.* report, "the continued adult production of lactase results from the persistent expression of the protein lactose–phlorizin hydrolase which is encoded by the lactase gene (LCT) on chromosome 2." Swallow notes, "the distribution of different lactase phenotypes in human populations is highly variable and is controlled by a polymorphic element *cis*- acting to the lactase gene. A putative causal nucleotide change

has been identified and occurs on the background of a very extended haplotype that is frequent in Northern Europeans, where lactase persistence is frequent."

Lactose Digestion and Gastrointestinal Function

Lactose is hydrolyzed at the intestinal jejunal brush border by the enzyme lactase into its absorbable monosaccharides glucose and galactose. Lactase activity is robust during infancy and, as is the case in humans and most mammals, declines after weaning. Accordingly, the general pattern of lactase nonpersistence is a continuous decline in genetically programmed populations. A shifting pattern of lactose digestion and gastrointestinal function is a result of lactase nonpersistence. The pattern can be described and monitored during three distinct clinical phases.

First, there is a decreasing ability to digest the large lactose load consumed during the screening test. It is important to recognize that this is not an all-or-none phenomenon but rather a slowly progressive decline in available lactase activity, and that this decline, as noted previously, can be influenced by transit time, the vehicle in which the lactose is consumed, and/or the intake of additional foods along with lactose.

Next, with the continued decline of lactase activity, a point is reached when available lactase activity is no longer sufficient to hydrolyze more modest levels of lactose. Therefore, the consumption of a glass of milk or another product containing the equivalent level of lactose will result in incomplete hydrolysis of the lactose consumed. The individuals so tested frequently do not recognize signs or symptoms associated with the incomplete digestion of lactose.

Finally, with the continued decline of lactase activity with increasing age, individuals become symptomatic as a result of the undigested lactose. The decline in available lactase activity reaches a recognizable clinical threshold with increasing age (**Figure 1**).

Initially, many reports treated the population studied as a single unit and paid incomplete attention to age-specific considerations. Distinctions between secondary lactose malabsorption due to short-term intestinal injury and primary lactose malabsorption that has a genetic basis were not always made. This introduced additional confounding variables. Differences in an individual's capacity to hydrolyze and tolerate a lactose challenge dose compared to his or her ability to utilize lesser amounts of lactose found in usually consumed amounts of milk created additional areas of confusion.

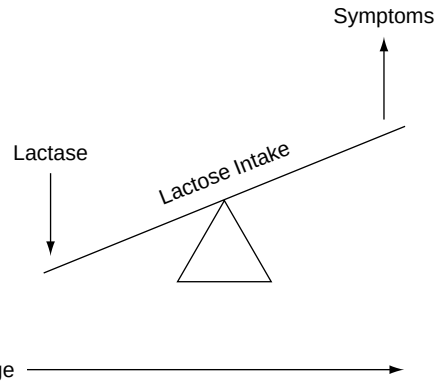

Figure 1 Symptoms associated with lactose maldigestion result from the decline in lactase levels with age and increase with the amount of lactose consumed.

When attention is paid to the many factors associated with lactose digestion from infancy to old age, it is possible to place many of the seeming contradictions into perspective. What may have appeared to be incongruities in reported data appear to merge into a relatively predictable pattern of lactose digestion.

Lactose maldigestion and intolerance are influenced by age, infection, size of the lactose bolus, gastric emptying time, intestinal transit time, individual sensitivities, eating habits, genetics, environment, food ideologies, and cultural patterns. Furthermore, symptoms of lactose malabsorption may also be the result of bacterial fermentation of undigested carbohydrate in the colon. The type and extent of the colonic bacterial profile and the absorption of hydrogen and the volatile fatty acids will influence individual reports of symptoms associated with lactose intolerance. Clearly, lactose malabsorption is not a homogeneous event. Neither is it an all-or-none phenomenon having its origins in a single etiology. Clinical expressions of lactose malabsorption, lactose intolerance, and milk rejection find their origins in one or more of the causes outlined previously (**Table 1**).

Prevalence

Children

A review of reported data on diverse populations supports the conclusion that in later childhood and adolescence an important transition in lactose digestion occurs. Older children and young adults are increasingly unable to digest even modest amounts of lactose. This results in increased symptom

Table 1 Patterns of lactose digestion by lactase status

Lactase status	*Test results*	*Symptoms*	*Lactose intolerance*	*Milk consumption*
Adequate	Normal (−)	0	0	Average (+)
Marginal lactase Deficiency	+	0/+	0/+	+ −
Moderate lactase Deficiency	+	0/+	0/+	+ −
Severe lactase Deficiency	+++	++	++	−

production, recognition of discomfort, and avoidance of lactose-containing products that provoke symptoms.

A progressive decrease in lactase is noted from approximately 1 to 5 years of age through adolescence. Reported rates in US African American children ranged from 27% lactose maldigestion following lactose testing using a lactose load equivalent to two 8-oz. glasses of milk at 1 or 2 years to 74% in 11- or 12-year-old children. The progressive decrease in the ability to hydrolyze a lactose challenge was observed in children of both high and low socioeconomic status. Studies of white children 1–12 years of age identified only 17% of children maldigesting a lactose challenge. Signs and symptom production associated with a reduction in lactose digestion in a child population is difficult to measure due to the nature of the symptoms being reported, the signs observed, and the subjective nature of the reports. This is reinforced by a report on 21 African American girls 11–15 years of age indicating 82% had evidence of lactose maldigestion with reports of gastrointestinal symptoms being negligible, and breath hydrogen excretion, while remaining high, varied between two time periods. Consistent with the previous data, milk consumption studies, both observed and reported, suggest a progressive decline in milk intake with increasing age in the African American population of children and parallel reports of children from other populations with a high prevalence of lactose maldigestion.

Adults

The progressive increase in prevalence of lactose maldigestion increases with age, reaching reported adult levels of approximately 70% of the world's adult population. The exceptions are populations of Northern and Central Europeans and some Middle Eastern populations as well as groups of primarily European descent in Australia, New Zealand, and North America. Thus, minority populations in North America and Europe, as well as adult populations in most developing countries, are lactose maldigesters (**Table 2**).

Reported milk drinking patterns of individuals classified as maldigesters vary considerably in adults. Data range from 50% reporting symptoms with one 8-oz. glass of milk to 75% reporting symptoms with two 8-oz. glasses of milk and 30% reporting not drinking any milk. Nevertheless, caution

Table 2 Prevalence of lactose maldigestion in selected populations

Population	*Country*	*% Lactose maldigestion*	*Population*	*Country*	*% Lactose maldigestion*
African American, 18–54 years	US	75	General, 21–65 years	Finland	15
Asian, 23–39 years	US	100	General, 20.3 years	Germany	70

Aboriginal	Australia	84	General, 15–64 years	Japan	100

must be exercised in interpreting reported symptoms and making the diagnosis of lactose intolerance. There can be considerable crossover between individuals who self-identify as intolerant to lactose and are not diagnosed as lactose intolerant versus those in whom the diagnosis was carefully established. More attention to identifying and categorizing symptoms better may help. A Finnish study noted flatulence as the most severe symptom in maldigesters, whereas abdominal bloating was most frequently reported by individuals self-identifying as lactose digesters. Moreover, microbiota may play a role in the presence and intensity of lactose-related symptoms. Data suggest that increased levels of colonic bacteria, as well as their diversity, may play a role as a result of increased fermentative capacity in reducing the symptoms associated with lactose intolerance.

Pregnant Women

The role of lactose digestion in pregnant women is of special interest. Despite the nutritional value of milk during pregnancy, the lactase levels in some individuals in a number of racial and ethnic groups may be insufficient to hydrolyze commonly consumed amounts of lactose, resulting in lactose maldigestion and possibly milk intolerance. The Institute of Medicine report notes that "lactose intolerance among pregnant African American women may result in their subsequent avoidance of milk." Other populations may also experience lactose maldigestion and intolerance to milk during pregnancy.

Studies of lactose maldigestion in pregnant women, as measured by breath hydrogen response to 240 ml of low-fat (1%) milk, reinforce the Institute of Medicine's concern with lactose digestion among pregnant African American women. The prevalence of lactose maldigestion in early (13–16 weeks), late (30–35 weeks), and 8 weeks postpartum was 66, 69, and 75%, respectively, and that of nonpregnant control women was 80% (**Table 3**).

Accordingly, health care providers instructing African American women on the optimal dietary pattern during pregnancy need to be mindful of a high rate of lactose maldigestion. Implications for fetal growth and development remain to be determined by further study. Also, health providers need to be aware that the presence or absence of symptoms may be unevenly reported by pregnant African American women, and symptoms do not represent a reliable guide to lactose digestion. Less than 25% of pregnant lactose maldigesting women reported any symptoms with 240 ml of low-fat (1%) milk. Symptoms may be further reduced when milk is consumed with other foods. Unanswered is the level of digestion and absorption of a range of nutrients in the consumed milk. Health care providers should discuss with the pregnant woman her ability to tolerate milk and, when appropriate, should educate her as to other food options. In this regard, Kingfisher and Millard report that "Euro-American staff tended to give advise that was biologically appropriate for them but not for many of their patients, a process reflecting biocentrism."

Table 3 Lactose maldigestion[a] in pregnant and nonpregnant African American women

African American women	*% Lactose maldigestion*
Early pregnancy (13–16 weeks)	66
Late pregnancy (30–35 weeks)	69
Postpartum (8 weeks)	75
Nonpregnant	80

[a]Breath hydrogen increase >20 ppm following the consumption of 240 ml of low-fat (1%) milk containing 12 g of lactose following an overnight fast.

Age-Specific Prevalence

Age-Specific prevalence data suggest a progressive decrease in lactose absorption with age in African American children studied in the United States. This progressive decrease was seen in a study of 409 African American children 13 months to 12 years of age. The population was stratified by age to have approximately equal representation in each 12-month category. The mean age of the children studied was 6.6 years. The study subjects were drawn from four well child clinic sites and a private pediatrician's office in Baltimore, Maryland. All subjects were in good health as determined by history and a review of recent clinic visits. The children were free of any overt intestinal or allergic disorders and had no recent history of gastroenteritis.

Secondary Lactase Deficiency

Secondary lactase deficiency is distinct from genetically determined loss of lactase with age. Secondary lactase deficiency is frequently associated with diseases of the small intestine. Enteric viruses, such as rotavirus and Norwalk agent, can induce lactase deficiency by penetration of the enterocyte in the small intestine Rotaviruses are a principal cause of diarrhea and lactose intolerance in infancy. Denudation of the brush border of the jejunal mucosa associated with diarrhea can lead to the loss of the other two disaccharides, maltase and sucrose. Continued diarrhea may also lead to severe complications such as monosaccharide intolerance. Giardiasis have also

been implicated as contributing to lactose maldigestion. An additional infection resulting in an interference with lactose digestion is *Ascaris lumbricoides*. Severe protein malnutrition is frequently associated with lactose maldigestion. Other disease conditions that give rise to secondary lactose maldigestion are celiac disease, gluten-induced enteropathy, and tropical and nontropical sprue. The mucosal brush border of the small intestine is severely damaged in each case.

Lactose Digestion and Diet

Calcium

Dietary calcium is an important element in skeletal development. Dairy products can account for up to three-fourths of dietary calcium in some populations. Milk is a rich source of calcium. Nevertheless, many minorities in the United States and population groups throughout the world drink decreasing amounts of milk after early childhood and little milk as adults. Given the high prevalence of lactose intolerance, alternatives to cow's milk should be identified for those who need them. Lactose-intolerant individuals ultimately attribute their discomfort to lactose-containing foods and voluntarily reduce or eliminate their milk intake. Data from national studies in the United States indicate that African American and Hispanic women have lower intakes of calcium compared to non-Hispanic women. An Institute of Medicine report concludes that the disparity in calcium intake "may be explained in part by the much higher prevalence of lactose intolerance among African Americans and Hispanics, sometimes resulting in their subsequent avoidance of milk." In general, populations at risk for lactose intolerance report a lower calcium intake as a result of the decline in the intake of milk and milk products. One solution to this problem is to educate lactose-intolerant groups about alternative calcium-containing foods, reinforce appropriate cultural patterns and dietary practices that include alternatives to milk, and identify other culturally acceptable calcium-containing foods. Meeting the calcium requirement with an alternative diet is a challenge but nevertheless is required for many in the community. Although milk may serve as a primary source of calcium, appreciable quantities of calcium can be found in nondairy foods.

Clearly, it is more difficult to meet the published calcium recommendation with a diet low in whole cow's milk. A review of the tables of food composition reveals a variety of foods that contain acceptable levels of calcium per 100 g portion or other standard portions (**Table 4**). Other lactose-modified dairy products, including hard cheeses, yogurts, and lactose-modified milk, are good calcium sources.

From Oski FA and Paige DM (1994) Cow's milk is a good food for some and a poor choice for others: Eliminating the hyperbole. *Archives of Pediatric and Adolescent Medicine* **148**: 104–107.

In addition, lactose digestive aids are available and are increasingly used, including lactase tablets, lactase preparations, lactose-free milk, and prehydrolyzed milk. Live culture yogurt is another alternative to milk. Lactose in yogurt is better digested than lactose in milk. Tolerance to yogurt is thought to be due to the microbial β-galactosidase activity that digests the lactose.

Osteoporosis

The role of lactose maldigestion, calcium intake, and osteoporosis has been studied. Osteoporosis and osteoporitic fractures are major public health problems. The role of lactose maldigestion and osteoporosis remains unsettled. For example, minority populations consuming small amounts of milk should be at greater risk for osteoporosis. Nevertheless, African American and Hispanic populations in the United States appear to have a lower risk of developing osteoporosis. Caucasian and Asian women were found to have the highest risk for osteoporosis, with fracture rates of 140.7/100 000 and 85.4/100 000, respectively. Hispanic and African American females had lower age-adjusted rates at 49.7/100 000 and 57.3/100 000, respectively. The paradox reinforces the complexity of the disease and the importance of biologic, genetic, and as yet undetermined factors in the eitology of osteoporosis.

Nutrition Policy

Apart from the nutritional implications outlined previously, there are policy considerations that require attention. Clearly, milk has important economic, nutritional, and emotional significance in Western culture, a culture strongly committed to the concept that milk is an ideal food. However, lactose digestion should be an important consideration in developing a suitable policy regarding the use of milk and dairy products by the lactose malabsorber and by ethnic or racial groups, among whom high rates of malabsorption prevail. Accordingly, a balance must be struck between dietary guidance and the interests of a diverse population with a large number of lactose maldigesters. For many, the continued use of a limited amount of milk may be appropriate and comfortable. For others, dietary modification and lactose reduction or elimination may be warranted. The substitution of low-lactose products or alternative foods may be nutritionally beneficial. The successful introduction of a lactose-reduced milk, Lact-Aid, into the US market in the 1970s by Alan Kligerman is one important example of a well-accepted milk product alternative. Traditional diets among lactose-maldigesting populations, using little or no milk or dairy products, should be respected.

Summary

The principles of genetics and evolution help to explain the emergence of the aberrant phenomenon of lactose tolerance. Darwin referred to food as a major factor in selective pressures. Lactose digestion is most effective in illustrating how a certain food, by indirectly favoring the survival of those able to digest that substance, can influence the evolutionary process of man.

Clinical and nutritional consequences of lactose digestion in adults must be examined in relation to malabsorption, intolerance, milk rejection, and symptoms and their recognition. Estimates of how frequently milk intolerance will be a clinically significant problem in adults vary with the nature of the associated gastrointestinal disorders and the format of the individual studies.

There is a series of interrelated physiologic events affecting the amount of undigested sugar and fluid that the small intestine, and subsequently the colon, must metabolize or reabsorb. A balance of these factors tends to prevent symptoms when the stomach, small intestine, and colon can compensate for the increased solute load, but abdominal discomfort or diarrhea occur when these small intestinal and colonic physiologic mechanisms are loaded beyond their capacity. The role of the colonic flora in metabolizing unabsorbed sugar and the importance of colonic salvage of unabsorbed carbohydrate are important variables in the symptom complex. Secondary lactase deficiency due to infectious gastroenteritis and malnutrition represents a distinct clinical syndrome and must be distinguished from lactose intolerance.

Dietary recommendations must take account of lactose maldigestion. Milk and dairy product

consumption will vary among lactose-maldigesting and milk-intolerant individuals. Lactose-reduced or lactose-free products are available to lactose-intolerant individuals who wish to drink milk and milk-based products. Nevertheless, dietary recommendations must be modified and respectful of those who do not drink milk. Accordingly, appropriate alternatives to milk and other lactose-containing foods must be identified and guidance provided in developing nutritionally equivalent diets.

LEGUMES

M A Grusak, Baylor College of Medicine, Houston, TX, USA

Published by Elsevier Ltd.

Legumes have been an important component of the human diet for several millennia and are used throughout the world today. They are a diverse group of plants that belong to the Fabaceae family (sometimes also referred to as the Leguminosae) and are estimated to include approximately 20,000 species in 700 genera. However, only a handful of these species have been developed as crops that are in common culture. Some of the more extensively grown legumes are listed in **Table 1**.

Legumes are consumed primarily as seed foods, but pods, leaves, and roots or tubers of various species are also eaten. The pod is an enveloping structure that protects the seeds as they develop and mature, and it is a characteristic feature of this group of plants. In fact, the name legume comes from the Latin word *legumen*, which means seeds that are harvested from pods. Other names used for legume seeds are pulse, which is derived from the Latin word *puls*, meaning pottage, or the phrase grain legume, used in reference to leguminous seeds. The more general phrase, food legume, is used to represent any vegetative or reproductive structures from legume plants that are utilized for human food.

An important nutritional aspect of legume foods is their high concentration of protein, which in most

Table 1 Commonly cultivated legume species

Scientific name	*Common names*
Arachis hypogea L.	Peanut, groundnut
Cajanus cajan (L.) Millsp.	Pigeon pea, red gram, Congo pea
Cicer arietinum L.	Chickpea, garbanzo, Bengal gram
Glycine max (L.) Merr.	Soybean, soya, edamame
Lablab purpureus (L.) Sweet	Hyacinth bean, Indian bean, Egyptian bean
Lathyrus sativus L.	Grass pea, chickling pea
Lens culinaris Medik.	Lentil
Lupinus albus L.	White lupine
Macrotyloma uniflorum (Lam.) Verdc.	Horse gram, Madras gram
Phaseolus lunatus L.	Lima bean, butter bean
Phaseolus vulgaris L.	Common bean, black bean, kidney bean, pinto bean, snap bean, string bean, French bean
Pisum sativum L.	Pea, garden pea, English pea
Psophocarpus tetragonolobus (L.) DC.	Winged bean, Goa bean, four-angled bean
Vicia faba L.	Broad bean, fava bean
Vigna aconitifolia (Jacq.) Marechal	Moth bean, mat bean
Vigna mungo (L.) Hopper	Urd bean, black gram
Vigna radiata (L.) Wilczek	Mung bean, green gram, golden gram
Vigna subterranea (L.) Verdc.	Bambara groundnut
Vigna umbellata (Thumb.) Ohwi and Ohashi	Rice bean, Mambi bean
Vigna unguiculata (L.) Walp. ssp. *unguiculata*	Cowpea, black-eyed pea, southern pea

legume seeds is at least twice that of cereal seeds. Legumes can produce more protein because the plants are generally well nourished with nitrogen, even in soils with limited inorganic nitrogen. Legume roots have the ability to form symbiotic associations with particular microbial species, in a structure called the root nodule. This symbiosis allows the plant to readily acquire atmospheric nitrogen and use it for the synthesis of amino acids. These protein precursors are transported to the developing seeds and are deposited there for later use. Legume seeds also contain a broad mix of energy reserves (starch or oil), minerals, and various phytochemicals—all of which are stored in seeds to provide nourishment to the young developing seedling.

As omnivores, humans have been able to take advantage of the nutrient and phytochemical reserves in legume seeds for dietary requirements and health benefits. This is especially important in the developing world, where malnutrition is an ever-present concern, and legumes can provide an inexpensive source of dietary protein (relative to animal food products), among other nutrients. The protein in legume seeds, although somewhat lacking in sulfur amino acids and tryptophan, is still an important complement to energy-rich carbohydrate staples, such as rice, wheat, maize, and various root and tuber crops. However, when eating legumes, we also must deal with the various antinutrients and toxic compounds found in seeds. These seed components include various enzyme inhibitors, tannins, phenolics, alkaloids, and neurotoxins. Some of these can cause debilitating consequences in humans, although cooking and other processing techniques can be used to reduce or alleviate their negative effects.

Legume Types

Legumes are grown throughout the world, with some adapted to warmer tropical and subtropical climates and others preferring temperate to cooler climates. The 20 species listed in **Table 1** are some of the more commonly cultivated legumes and include those whose annual production reaches levels that allow for worldwide marketing. In developing countries, many locally adapted legume species are cultivated on a small scale or are harvested from wild sources. These less cultivated legumes are usually harvested as mature seeds, but immature pods, leaves, roots, or tubers can also be collected.

Most of the common legume species are grown agronomically and harvested as mature seeds. These can be cooked and consumed in their entirety, or they are cracked and used as split seeds with the hulls (seed coats) removed. Seeds of some species are milled to produce a flour product, or they can be processed to yield protein isolate (e.g., soybean and lupine), extracted oils (e.g., soybean and peanut), or starch (e.g., pea).

For those legumes also cultivated as vegetable crops, immature seeds or immature pods can be harvested. These are canned, frozen, or sold as fresh products. Immature pods are nutritionally similar to leafy vegetables in that they contain various carotenoids and other phytochemicals; however, they also contain immature seeds that can provide a modest amount of protein. For some species, young tender leaves or whole shoots are also collected and used as vegetable greens that are eaten fresh or cooked. More detailed information is given on some of the common legume types in the following sections.

Bambara Groundnut

Bambara groundnut (*Vigna subterranea* (L.) Verdc.) is indigenous to west central Africa. Most of its current production is in Africa, but the plant is also cultivated in India, Southeast Asia, Australia, and Central and South America. The plant has an interesting growth habit in that after pollination, the developing pod and seeds are pushed into the ground, where they grow until full maturity. Plants are typically uprooted at harvest to collect the seeds and pods; because of this subterranean growth, they have acquired the common name groundnut. Mature seeds are boiled and consumed as a cooked seed, prepared as porridge, or milled into a flour to form cakes. Immature seeds are also harvested and cooked as a fresh vegetable.

Broad Bean

Broad bean (*Vicia faba* L.), also known as fava bean, is grown from tropical to temperate regions, with production occurring in North and South America, Europe, Africa, and China. This legume is grown for its enlarged, succulent, immature seeds that are removed from its thick, fleshy pod. Mature dry seed is also harvested. Although broad beans are widely consumed, they do contain storage proteins (vicine and convicine) whose metabolites can lead to acute hemolytic anemia in individuals with a deficiency in glucose-6-dehydrogenase (found predominantly in people of Mediterranean or African descent). Additionally, broad beans contain high levels of L-DOPA, a phenolic compound that can be converted to dopamine. Because of their L-DOPA content, broad beans should be avoided by individuals using monoamine oxidase inhibitors (MAOI-type drugs). The use of these drugs, in combination with high intakes of dopamine (or dopamine precursors), can lead to dangerous increases in blood pressure.

Chickpea

Chickpea (*Cicer arietinum* L.) is grown worldwide and is best adapted to cool, dry climates. Thus, it is a winter crop in some regions of the world. Two seed types are recognized: the large-seeded kabuli type, characterized by its beige-colored seed coat and ram's head shape, and the desi type, with its smaller size and dark-colored irregularly shaped seeds. Kabuli varieties are preferred for consumption as whole seeds, whereas desi types are typically processed into flour. Immature green pods and young tender leaves are also cooked and eaten as vegetables, especially in India.

Common Bean

Common bean (*Phaseolus vulgaris* L.) is grown in temperate zones as well as in temperate regions within the subtropics. As a dry seed, it is an important crop in Africa and in Central and South America. Many bean types are cultivated that exhibit vast differences in seed coat coloration and pod characteristics. Mature seeds are harvested as dry beans (e.g., black bean, pinto bean, and kidney bean); immature pods are used as a vegetable (e.g., snap bean and French bean). Pod types have been bred to have few fibers in the pod wall.

Cowpea

Cowpea (*Vigna unguiculata* (L.) Walp. ssp. *unguiculata*) is grown throughout the tropics and subtropics. It is an important crop in Africa, its probable center of origin, but is also grown in Brazil, India, Southeast Asia, and the United States. There are three major subspecies of *V. unguiculata*; in addition to ssp. *unguiculata*, there is appreciable production of ssp. *cylindrica* (common names: catjang cowpea and Bombay cowpea) and ssp. *sesquipedalis* (common names: yardlong bean and asparagus bean), especially in Asia. All types are harvested as vegetables (shoots, leaves, and immature pods) or as dry, mature seeds.

Grass Pea

Grass pea (*Lathyrus sativus* L.) is a hardy, cool-weather adapted legume that is cultivated in India, Africa, the Middle East, and South America. It is harvested primarily as a dry, mature seed, although young leaves and immature pods are edible. Grass pea is quite tolerant of limited moisture and does well in nutrient-poor soils; thus, in times of drought it is one of the few legumes that produces a harvest, and it is widely consumed by low-income populations during times of famine. Unfortunately, excessive or prolonged consumption of grass pea can lead to lathyrism, a debilitating muscle paralysis that is caused by a neurotoxin in the seeds.

Hyacinth Bean

Hyacinth bean (*Lablab purpureus* (L.) Sweet) is grown in India and in many tropical regions of the world. Mature seeds are consumed as a cooked food or a sprouted seed. The immature pods and seeds are also harvested as vegetable foods. Although this plant is cultivated as an annual, it will persist as a perennial, and when cultivation is extended it will form large, starchy roots that can be eaten. Some varieties (mostly dark-seeded types) contain high levels of a cyanogenic glycoside in their seeds.

When cyanogenic glycosides are hydrolyzed by plant enzymes during cooking, or possibly by intestinal enzymes after ingestion, cyanide can be released and lead to cyanide poisoning.

Lentil

Lentil (*Lens culinaris* Medik.) is another of the world's important pulse crops, especially for populations in developing countries. The plant is adapted to cool climates; Canada, India, and Turkey account for nearly 70% of its production. Lentils are harvested primarily as a dry, mature seed, but immature pods are also used as a vegetable in India.

Mung Bean

Mung bean (*Vigna radiata* (L.) Wilczek) is grown in tropical climates and is an important legume in India, China, and other Asian countries. Dry seeds are harvested and consumed as split, whole, boiled, or roasted forms. Immature pods are eaten, and there has been interest in developing the tuberous root as a food because of its high protein content (nearly 15%).

Pea

Pea (*Pisum sativum* L.) is grown primarily in cooler regions of the world. Different varieties have been developed to produce mature, dry seeds; succulent, well-developed immature seeds; or succulent, immature edible pods. Dry seed varieties are sometimes referred to as field peas. The names garden pea and English pea are used for the varieties harvested as immature seeds, whereas the edible pod types are commonly known as snow pea or sugar snap pea. In some Asian cuisines, the shoots of pea plants are also used as vegetable greens.

Peanut

Peanut (*Arachis hypogea* L.) is grown throughout the tropics, much of the subtropics, and even in some temperate zones. As with Bambara groundnut, its pods have a subterranean growth habit, and thus it also has acquired the common name, groundnut. Peanut is one of the few commonly grown legumes whose seeds contain high levels of oil. Most legume seeds have less than 5% oil, but for some peanut cultivars seed oil content is as high as 40–50%. Roasted seed and extracted oil is used and marketed worldwide; in some regions, young shoots and leaves of the plant are used as greens, and immature pods are consumed as a cooked vegetable. Although a nutritious legume, peanut has recently gained much attention and scientific interest due to the low, but nonetheless significant, incidence of individuals who are allergic to peanut proteins. For those extremely hypersensitive to this food, violent and life-threatening reactions can occur in response to exposure to as little as 0.1 mg of peanut. In fact, peanut is believed to be the most common cause of death due to foods.

Pigeon Pea

Pigeon pea (*Cajanus cajan* (L.) Millsp.) is broadly adapted to many climatic regions and soil types, and thus its production occurs over a huge area of crop land. It is an important food legume in India, other Asian countries, Africa, and South America. Mature grains are usually consumed as split, dehulled seeds. Immature seeds and pods are also consumed in large quantities.

Soybean

Soybean (*Glycine max* (L.) Merr.) is undoubtedly the most important food legume today, being a major source of protein and extracted oil. Soybean is believed to have originated in eastern Asia as a subtropical plant, but plant breeders have helped develop varieties adapted to several climatic zones. The crop is grown in many countries, but more than 70% of the world's production comes from the United States, Brazil, and China. Most soybeans are harvested as dry seed; a typical variety contains 20% seed oil and 35% protein (although some varieties can be as high as 45% protein). Both soy oil and soy protein isolate are found as ingredients in many processed foods. In eastern Asia, the immature seed is also harvested extensively and used as a vegetable.

Winged Bean

Winged bean (*Psophocarpus tetragonolobus* (L.) DC.) is adapted to tropical conditions and is grown in Southeast Asia, Papua New Guinea, various Pacific Islands, and Africa. The tender pods are the most widely consumed part of the plant, especially throughout Asia, but the leaves, stems, flowers, seeds, and tuberous roots are all nutritionally valuable and are used as food. Winged bean is another of the legumes with elevated seed oil content; varieties typically average 15% oil, with protein levels of 30–37%. The tuberous roots are a good source of energy in the form of starch, and they contain 8–10% protein.

Grain Legume Nutritional Value

As noted previously, many parts of legume plants are consumed by humans. However, the seeds are

the predominant food type across all species, and their nutritional value is discussed in the following sections.

Protein

Protein content in legume seeds is governed both by genotype and by environment. Seed protein levels can vary across varieties of a given species and even among seeds on an individual plant. In general, however, food legumes contain 20–30% protein by proximate analysis (**Table 2**). The exceptions to this are soybean and winged bean, which contain up to 37 and 45% protein, respectively.

Legume proteins are primarily of two types: storage proteins, which account for approximately 70% of total seed nitrogen, and enzymatic, regulatory, and structural proteins, which are present for normal cellular activities, including the synthesis of storage proteins. Legume storage proteins are soluble in dilute salt solutions but insoluble in water and therefore fall into the classical globulin group of protein fractions. Legume protein types are further characterized by their sedimentation coefficients, which in most species approach 11S and 7S; these are commonly referred to as the legumins and vicilins, respectively. Most legumes contain both types of storage protein, but the proportion of the two types varies from species to species.

In terms of protein quality, as defined by an optimal proportion of amino acids required by humans, legume proteins are deficient in the sulfur-containing amino acids and tryptophan but are rich in lysine. Cereals, on the other hand, are relatively deficient in lysine; thus, the combination of legumes with cereals often can improve the overall protein quality of the mixed foods. The nutritive value (or biological value) of legume proteins has been investigated quite extensively and has been shown to be rather low in some legumes, with the amount of utilizable protein ranging from 32 to 78%. In other words, not all of the protein available in a given legume (see **Table 2**) is converted into new protein when consumed by humans. The reasons for this are the general deficiency of essential amino acids (sulfur-containing and tryptophan) and the presence of many inhibitors of protease activity that are found in legume seeds. These enzyme inhibitors are primarily proteinaceous in character, and many have an effect on the digestive enzymes trypsin or chymotrypsin. The inhibition of these enzymes leads to a reduction in protein digestibility and thus the gut's ability to absorb amino acids. Fortunately, because many of these inhibitors are proteinaceous, cooking, heating, fermenting, and, in some cases, germination can inactivate and significantly lower their inhibitory effect. However, not all of the inhibitors found in legume seeds are proteins (e.g., other inhibitors include tannins and polyphenols).

Table 2 Protein contents of food legume seeds

Legume	*Protein range (% dry weight)*
Broad bean	22.9–38.5
Chickpea	14.9–29.6
Common bean	21.1–39.4
Cowpea	20.9–34.6
Grass pea	22.7–29.6
Horse gram	18.5–28.5
Lentil	20.4–30.5
Moth bean	21.0–31.3
Mung bean	20.8–33.1
Pea	21.2–32.9
Peanut	23.5–33.5
Pigeon pea	18.8–28.5
Rice bean	18.4–27.0
Soybean	33.2–45.2
Urd bean	21.2–31.3
Winged bean	29.8–37.4

Lipids

Grain legumes generally contain higher concentrations of lipids than cereals. In legumes, lipids are stored in oil bodies in the cotyledons (the bulk of the seed), whereas most oils in cereals are limited to the outer bran layer. Most common legumes contain 1–7% lipid, based on proximate analysis. Exceptions to this range are soybean, peanut, and winged bean, which average 20, 45, and 15%, respectively. Legumes are good lipid sources for humans because they contain high amounts of essential fatty acids. Although composition varies across species, most legumes contain some quantity of oleic, linoleic, and linolenic acids. Phospholipids and glycolipids are also found in legume seeds.

Carbohydrates

Legume seeds contain starch, mono- and oligosaccharides, and other polysaccharides. Total carbohydrates range from 25 to 65% across the commonly grown legume species. Starch is the predominant carbohydrate in most cases, with exceptions in the oilseeds soybean and peanut. Legumes generally contain low amounts of monosaccharides (usually 1% or less) and only slightly higher amounts of

disaccharides, such as sucrose (1–3%). However, some soybean varieties have been reported to contain as much as 7% sucrose.

Various oligosaccharides have been characterized in legume seeds, including raffinose, stachyose, and verbascose, which are galactosides of sucrose. Because humans do not express the enzyme α-galactosidase, these compounds remain undigested in the small bowel and pass through to the large bowel, where they can be fermented by anaerobic microbes. This leads to flatulence, or gas production, which is experienced following the consumption of some legumes. The concentration of raffinose-type oligosaccharides varies among legume species and, not surprisingly, the capacity to induce flatulence also varies.

Fiber

Legume seeds are a source of dietary fiber, containing both crude fiber and neutral detergent fiber. Most legumes contain 3–5 g of fiber per 100 g of dry seed, with most of the fiber found in the seed coat fraction. Exceptions are grass pea and hyacinth bean, which contain 8 and 10 g of fiber, per 100 g of dry seed, respectively. Compositionally, legume seeds contain varying quantities of lignin, cellulose, hemicelluloses, pectins, gums, and mucilage.

Minerals

Legume seeds contain a broad mix of minerals, many of which are essential both for plants and for animals. In fact, almost all essential minerals for humans can be found stored in the seeds. In comparison to cereals, legumes tend to have higher concentrations of calcium and potassium, as well as the micronutrients iron, zinc, and copper. Most of the calcium is sequestered as calcium oxalate crystals, however, and this form of calcium has extremely low bioavailability. Also, the majority of phosphorus in legume seeds is stored as phytic acid, which can complex calcium, iron, and zinc and thereby diminish their bioavailability. Other compounds found in legume seeds, including tannins, phenols, organic acids, protein, and fiber, can also interact with minerals and lower their bioavailability. Fortunately, certain processing procedures, such as fermenting or sprouting seeds, can reduce the levels of some of these mineral chelators. Due to these various problems, there is a significant effort under way in the plant science community to increase the absolute mineral levels in various legume seeds as well as to lower the levels of several major inhibitory compounds.

Vitamins

Most food legumes are good sources of thiamin, riboflavin, and niacin but are poor sources of ascorbic acid. This vitamin is present at only low levels in newly harvested dry seeds, and it disappears after long storage. In some species, varieties exist that produce green- or orange-colored cotyledons, and β-carotene, a pro-vitamin A carotenoid, can be found in some cases. The amounts of this vitamin precursor, however, are generally quite low. Tocopherols (vitamin E) are also found in some legume seeds, and folate, which is present in all legumes, can be quite high in certain species (e.g., lentil). Because folate is important in the prevention of neural tube defects, legume consumption is recommended for women of childbearing age, especially in regions of the world where folate fortification is limited.

Health-Promoting Phytochemicals

There is much interest in the role of various phytochemicals to promote good health and to reduce the risk of various cancers. As with many plant foods, legume seeds contain a number of these types of compounds. Prominent in this group are the isoflavonoids, such as genistein and daidzein, which are found at high levels in soybeans. Epidemiological studies have suggested a positive association between the consumption of soy isoflavones and reduced risk of breast and prostate cancer in humans. These and other related isoflavones are found in seeds of most of the commonly grown legumes. In addition, various saponins, catechins, epicatechins, and anthocyanidins have been measured in various legume seeds, and these compounds have also been suggested to have health-promoting qualities. Plant biochemists and human nutritionists are actively working to manipulate the levels of these and other compounds in legumes.

LIPIDS

Contents

Chemistry and Classification

J L Dupont, Florida State University, Tallahassee, FL, USA

Lipids are generally known as fats and oils in food and nutrition. They are unique in nutrition, as they are in all of biology, in that they are not soluble in water. Early work on the chemistry of living organisms led to the discovery that fatty substances were soluble in organic solvents, such as chloroform, ethyl ether, alcohols, and hydrocarbons. Those solubility characteristics are dependent on the neutral or polar attributes of particular lipids and define the structural and functional aspects of lipids in living systems. This article presents the classification of lipids in their chemical groupings, their characteristic chemical and physical properties, and their nomenclature. Major groups of lipids include fatty acids, acylglycerols, phospholipids and sphingolipids, and sterols. Some lipid compounds, such as fat-soluble vitamins and waxes, are not included.

Fatty Acids and Acylglycerols

Nomenclature

Fatty acids are hydrocarbons of chain length two or greater with a carboxyl group at one end. Hydrocarbon chains are termed acyl lipids, and fatty acids occur most abundantly esterified to glycerol as triacylglycerols (**Figure 1**). Nomenclature for fatty acids has evolved from studies of food or organ sources of the lipid, extraction and identification methods, and attempts at classification. **Table 1** lists fatty acids important in food and nutrition. The accepted shorthand description shows the number of carbons: number of double bonds, location of double bonds from the carbon at the methyl (n or omega) position, and *cis* or *trans* configuration (**Figure 2**). Saturated fatty acids (SFAs) have hydrogen atoms at every possible carbon site, and unsaturated fatty acids have double bonds. Fatty acids with double bonds may occur in isomeric forms. Geometric isomers are referred to as *cis* and *trans* rather than the convention Z and E preferred by chemists. For example, linoleic acid is 18:2 n-6, having 18 carbons, two double bonds located at the n (or omega) minus 6 and n minus 9 positions on the chain. Conventional carbon numbering is from the carboxyl end; therefore, linoleic acid can be written as *cis* 18:2 $\Delta^{9,12}$. Delta indicates numbering from the carboxyl carbon and the atom number from the carboxyl is sometimes used (C-9). Desaturase enzymes are named according to the delta number (i.e., Δ-9-desaturase). Commonly, the *cis* configuration is not noted because almost all natural fatty acids are in the *cis* configuration. Also, unless otherwise specified, the

t, *trans*.

double bonds are 3 carbons apart, referred to as 'methylene interrupted,' as contrasted with conjugated double bonds (**Figure 3**).

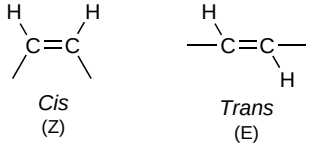

Figure 2 Structure of *cis* and *trans* double bonds.

Physical and Chemical Properties

Nonesterified fatty acids or free fatty acids have a polar (acidic) component and a neutral hydrocarbon component. The ratio of carbon to oxygen depends on the chain length and accounts for the solubility properties as well as the energy density of the lipid molecule. The hydrocarbon chain of the fatty acid is hydrophobic and the carboxyl end is hydrophilic, making the molecule amphipathic. This causes a dispersion of oil in water to form a mono molecular

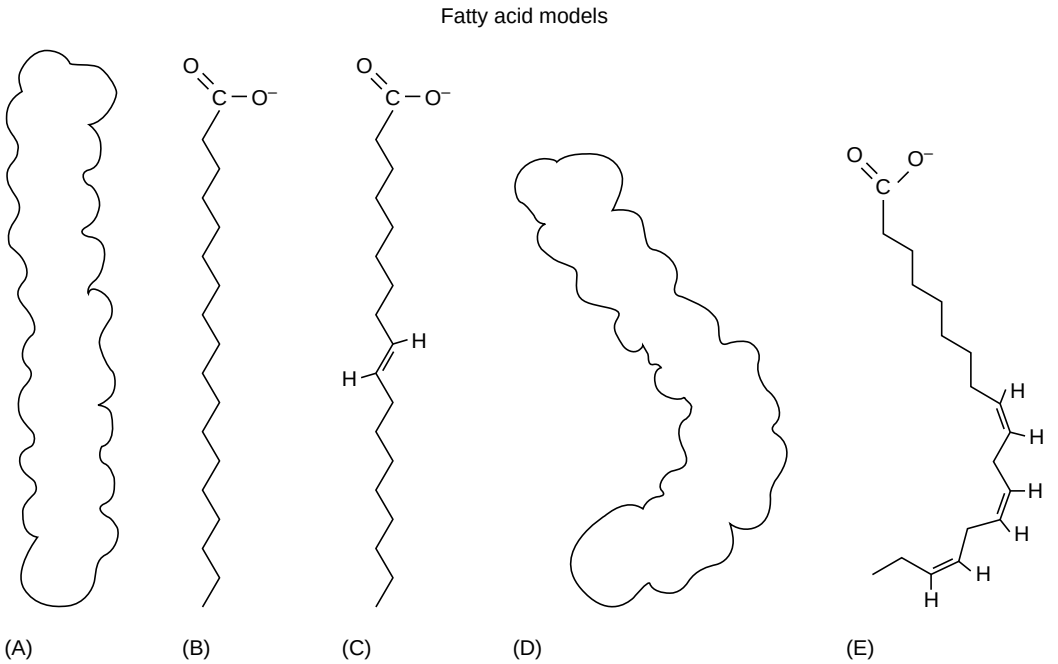

Figure 3 Space-filling and conventional models of fatty acids: (A) stearic acid (18:0), space-filling; (B) stearic acid, conformational; (C) elaidic acid (18:1n-9*t*) *trans*, conformational; (D) α-linolenic acid, all-*cis*, space-filling; (E) α-linolenic acid, conformational.

layer at the surface with the carboxyl end in contact with water and the hydrocarbon extending out of the water. The fatty acids may form a micelle (**Figure 4**) to separate the oil and water phases. These orientations of fatty acids and more complex lipids are a primary aspect of their participation in biological structures and functions. Furthermore, there is free rotation about the carbon–carbon bonds so the fatty acids and acylglycerols are capable of assuming a number of configurations.

Differences in the physical characteristics of fatty acids, particularly saturated compared with unsaturated, are extremely important in food and nutrition. SFAs with a chain length longer than 12 carbons are solid at usual ambient temperatures. As the chain lengthens, the melting point increases. On the contrary, mono- and polyunsaturated fatty acids (PUFAs) are liquid at room temperatures. Uses of fats in food products are based on these properties. Salad oils, margarines, and shortenings are examples of such differences. Hydrogenation of oils containing PUFAs was introduced to provide food fats that are resistant to rancidity and of a desirable plasticity. The chemical hydrogenation process yields mixtures of *cis* and *trans* fatty acids (**Figure 5**). The physical conformation of *trans* fatty acids is important for their functions in foods and nutrition (**Figure 3**). The melting points are similar to those of SFAs of similar length and their shapes are linear rather than bent as forced by the *cis* configuration. These physical characteristics affect their space-filling functions and the mobility of the molecule.

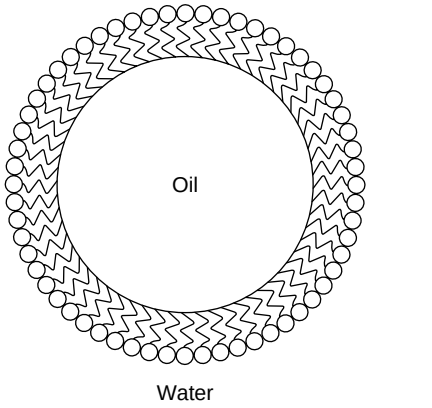

Figure 4 Micelle formed by oil dispersion in water.

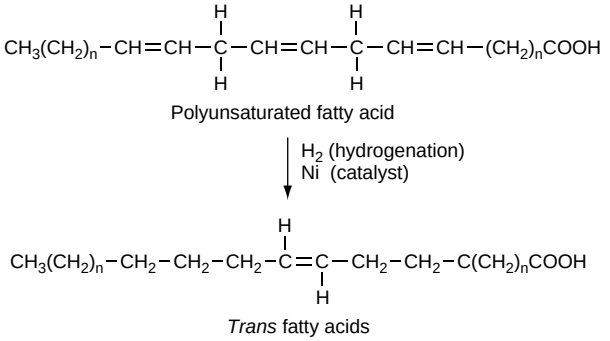

Figure 5 Hydrogenation of polyunsaturated fatty acids. *trans* fatty acids are produced when hydrogenation results in incomplete saturation of double bonds during chemical processing.

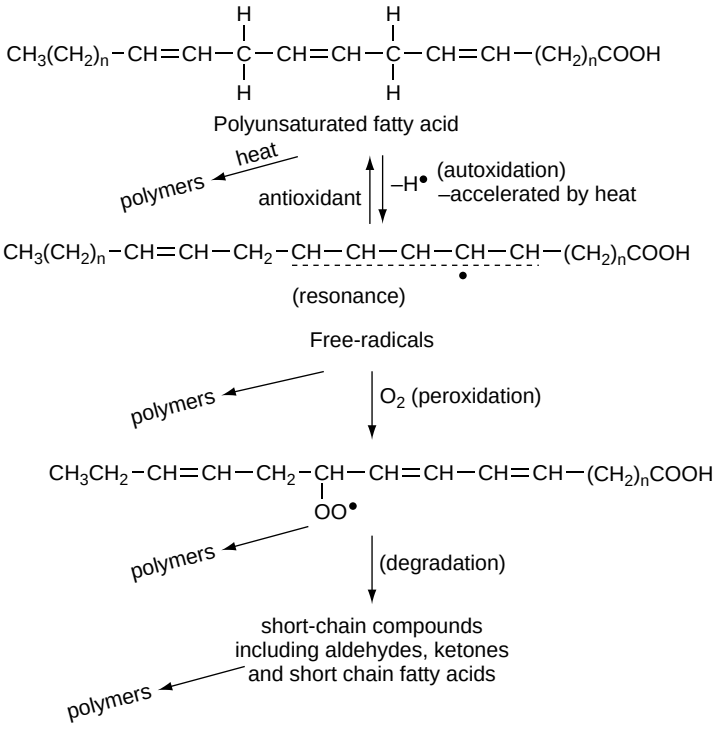

Figure 6 Autoxidation is caused by removal of a hydrogen from the methyl group between double bonds in polyunsaturated fatty acids. Resonating free radicals are produced and propagate peroxidation, degradation, and formation of polymers.

Polyunsaturated fatty acids with the methylene-interrupted double bond are also susceptible to oxidation (**Figure 6**). The hydrogen atoms on the methyl group between double bonds are susceptible to sequestration by oxidizing agents, such as iron or free radicals. This autoxidation results in a resonating free radical that is self-propagating and, with exposure to oxygen, yields peroxides. The peroxides may polymerize or degrade to smaller molecules. In foods, this process results in the condition of rancidity characterized by off flavors. In living systems, the products of peroxidation may cause reactions that damage proteins, membranes, and DNA resulting in pathological processes. Antioxidants are compounds that are capable of interrupting free radical propagation by reducing the peroxide to an alcohol without itself becoming a free radical. Tocopherols are a major antioxidant group in living systems and chemical antioxidants such as BHT (3,5-di-*t*-butyl-4-hydroxytoluene) are used in food products.

Another primary characteristic of naturally occurring PUFAs is that they cannot be synthesized by animals but are necessary for metabolism; therefore, they are an essential component of the diet. Animal organisms can introduce a double bond at the C-9 position but lack the enzymes to insert double bonds between the C-9 position and the methyl terminal carbon. The fatty acids are therefore considered to be in three families in relation to their biological functions: the monounsaturated (n-9 or omega-9) family and the polyunsaturated n-6 (omega-6) and n-3 (omega-3) families.

Phospholipids

The glycerol backbone is the central structure of phospholipids, as it is for acylglycerols. They are characterized by a phosphate group at the *sn*-3 position making phosphatidic acid (**Figure 7**).

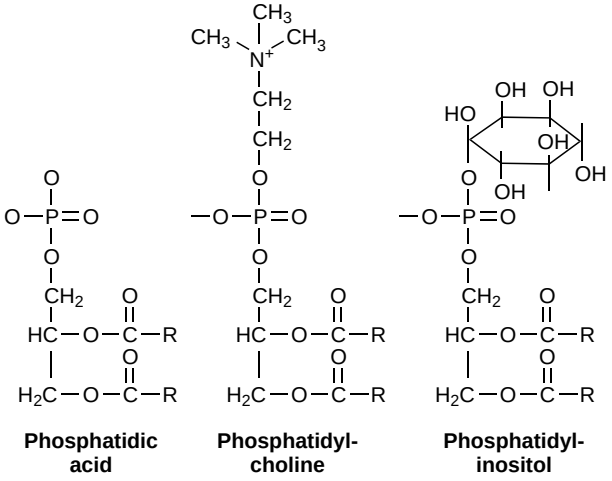

Figure 7 Structures of phospholipids.

Phosphoglycerides have fatty acids esterified at the 1 and 2 positions. A number of compounds may be esterified to the phosphate moiety, including choline, ethanolamine, serine, and *myo*-inositol. The compounds are called phosphatidylcholine, etc. These molecules are obviously amphipathic, having very polar constituents at the *sn*-3 position and acyl chains at the 1 and 2 positions. This attribute is very important to their function in biological membranes.

Sphingolipids

A group of acyl lipids has a sphingosine-based structure (**Figure 8**). The derivatives of sphingosine are cerebrosides and ceramides. They are characterized by having sugar molecules as part of their structure and thus are called glycosphingolipids. The most common sugar moiety is galactose. There is a large family of mono-, di-, and triglycosyl ceramides. Some of the glycosphingolipids have sialic (*N*-acetyl neurominic) acid linked to one or more of the sugar residues of a ceramide oligosaccharide. These are called mono-, di-, and trisialogangliosides and are abundant in membranes, particularly in nervous tissue. Their amphipathic structures are functional in membranes and in the water impermeability of skin.

Steroids

Sterols

Sterols are monohydroxy alcohols with a four-ring core structure or steroid nucleus (**Figure 9**). Cholesterol is the most abundant sterol in animal tissues. The tetracyclic structure is uniquely compact and rigid. The unesterified molecule has only one polar site, the hydroxyl on the number 3 carbon. When it is esterified to an acyl group, usually oleic acid, the cholesteryl ester is extremely hydrophobic. The free hydroxyl enables the cholesterol molecule to orient in membranes, a major function of

cholesterol. In brain and other nervous tissues, free cholesterol is the major component of myelin and renders the myelin sheath impermeable to electron transfer (dielectric).

Phytosterol and campesterol are the major sterols in plant tissues (**Figure 10**). The plant sterols and their stanol derivatives (saturated at the 5–6 carbons) along with cholestanol are active in regulating cholesterol absorption. All these sterols are consumed in the diet, and some are being added to foods as positive adjuncts to regulation of cholesterol metabolism.

Bile Acids

The most abundant derivatives of cholesterol are bile acids. Cholesterol is important in metabolism and is biosynthesized as well as consumed in the diet. It is the precursor for vitamin D (cholecalciferol) and for the adrenocortical hormones, such as estrogen, androgens, and progesterone. These compounds require very small amounts of the cholesterol precursor. The sterol nucleus cannot be broken by mammalian enzymes, except for the formation of cholecalciferol. Bile acids constitute approximately 50% of the excretion products of cholesterol metabolism and perform essential functions in digestion and absorption of dietary lipids. They are synthesized in the liver (**Figure 11**) and exist in metabolism as conjugates with taurine and glycine (**Figure 12**). As with other lipids in metabolism, the amphipathic properties of the compounds characterize their functions. The planar sterol moiety with an acid group at the 24 carbon is capable of separating water and lipid interfaces and is important in facilitating interaction between lipids and enzymes in digestion. The even greater contrast of polar and neutral within the same molecule is exemplified by the conjugated bile acids. They are also active in digestion and exist in all tissues, so they may have additional functions as amphipathic facilitators between enzymes and lipids.

Composition and Role of Phospholipids

A D Postle, University of Southampton, Southampton, UK

Phospholipids are amphipathic (amphipathic describes molecules with regions that are both water seeking (hydrophillic) and water repellent (hydrophobic). This is the fundamental physical property that drives the formation of biological membranes) lipids consisting of hydrophobic and hydrophilic regions. This amphipathic nature, which enables phospholipid molecules to assemble into bilayer and hexagonal membrane structures, is critically important for the functional viability of all eukaryote cells. Cellular membranes, composed primarily of phospholipid, separate the intracellular milieu from the extracellular environment and facilitate the formation of specialised intracellular organelles. For many years, phospholipids were considered to be important but relatively inert structural components of the cell. Recently, the central role of membrane phospholipid composition and turnover in the regulation of a wide range of cellular functions has become widely recognized. For instance, all membrane receptor events take place

within a phospholipid-rich environment, and it is therefore not surprising that cells have adopted hydrolysis of membrane phospholipids as a major signaling mechanism. Phospholipids have multiple roles, including the following:

1. They provide a structural framework to maintain cellular integrity and to compartmentalize diverse events within the cell.
2. They provide the appropriate physicochemical environment to optimize the activities of membrane-associated receptors, enzymes, and proteins.
3. They act as substrate molecules for a variety of phospholipase enzymes involved in signaling mechanisms.
4. They provide sites for binding of proteins involved in cellular signaling processes.
5. They exert a physicochemical detergent-like action to facilitate the physiological function of a variety of tissues, including the lungs, stomach, and synovial surfaces.
6. They regulate the synthesis and secretion of lipoproteins from the liver.

Phospholipid Structures

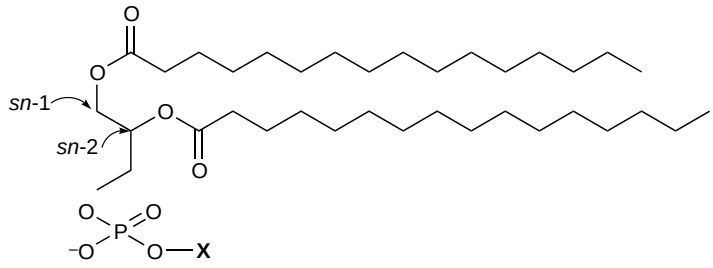
There are two major classes of phospholipid, depending on whether they contain a glycerol or sphingosyl backbone. Glycerophospholipids are molecules based on phosphatidic acid (3-*sn*-phosphatidic acid); the nature of the esterified group X defines the class of phospholipid (**Figure 1**). The most common substituent groups include nitrogenous bases, such as choline and ethanolamine, and polyalcohols, such as myoinositol and glycerol. Sphingophospholipids contain sphingosine (*trans*-D-erythro-1,3-dihyroxy 2-amino-4-octadecene). Sphingomyelin is the most abundant sphingophospholipid class, and it is the phosphorylcholine ester of *N*-acylsphingosine, also called ceramide. Sphingophospholipids are important components of all cell membranes and are structurally and metabolically closely related to glycosphingolipids such as glycosylceramides, gangliosides, and cerebrosides. Sphingomyelin is recognized as a major substrate for sphingomyelinase enzymes involved in generating intracellular ceramide and sphingosine, which are intimately involved in the regulation of programmed cell death (apoptosis). Sphingophospholipids contain principally saturated and monounsaturated fatty acids; little information is available on the nutritional effects on sphingophospholipid composition, and sphingomyelin metabolism has been recently reviewed.

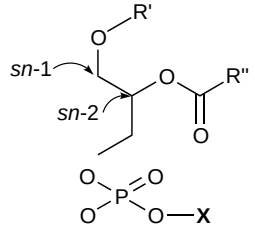
The distribution of phospholipids is heterogeneous within any cell both between different subcellular membranes and within individual membranes. For instance, mammalian cells maintain an enriched distribution of neutral lipids, such as phosphatidylcholine (PC) and sphingomyelin, in the outer leaflet of the plasma membrane and hence present an uncharged surface to the exterior of the cell (**Figure 2**). It is critically important to restrict the distribution of uncharged phospholipids to the interior of the cell because increased concentration of phosphatidylserine (PS) in the outer leaflet of the plasma membrane is the initial signal for both programmed cell death (apoptosis) and the clotting cascade.

Classification and Nomenclature of Glycerophospholipids

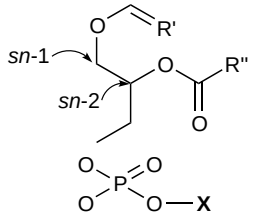
Glycerophospholipid classes are commonly referred to as phosphatidylcholine, phosphatidylethanolamine, etc. They are composed of a spectrum of molecular species (phospholipid molecular species are the individual different molecules within any different class of phospholipid determined by the combination of fatty acids esterified to the glycerol backbone. Any given mammalian cell contains up to 1000 individual phospholipid molecular species) defined by the substituent fatty acid groups attached to the *sn*-1 and *sn*-2 positions of the glycerol backbone. For example, the individual molecular species palmitoyloleoyl phosphatidylcholine can be named formally as either glycerol 1-hexadecanoate 2-9-octadecaenoate 3-phosphocholine or 1-hexadecanoyl-2-octadeca-9-enoyl-3-glycerophosphocholine. One shorthand designation for this molecule, adopted in this article, is PC16:0/18:1, where PC designates the phospholipid class, in this case phosphatidylcholine, and 16:0 and 18:1 (fatty acid nomenclature is based on total number of carbon atoms in the acyl chain, followed by total number of double bonds. For instance, 16:0 is saturated 16-carbon palmitic acid, whereas 20:4 is poplyunsaturated 20-carbon arachidonic acid) designate the fatty acids esterified at the *sn*-1 and *sn*-2 positions.

For phospholipids from cell membranes, saturated fatty acids are generally located at the *sn*-1 and unsaturated fatty acids at the *sn*-2 position, with notable exceptions. For instance, dipalmitoyl PC (PC16:0/16:0) is a major component of lung and surfactant PC, whereas significant amounts of didocosahexaenoyl phosphatidylethanolamine (PE22:6/22:6) are present in retinal PE. In addition, PC species with 18:1n-9 at the *sn*-1 position are minor components of many cells.





sn-1-alkyl-*sn*-2acyl species



sn-1alkenyl-*sn*-2-acyl species

Phospholipid	Headgroup(X)
Phosphatidylcholine (PC)	Phosphatidylethanolamine (PE)	Phosphatidylserine (PS)	Phosphatidylinositol (PI)	Phosphatidylglycerol (PG)	Phosphatidic acid (PA)	

Figure 1 Molecular structures of phospholipids. The class of phospholipid is defined by the nature of the nitrogenous base or polyol esterified to the phosphate group (X). The species distribution within any phospholipid class is determined by the fatty acyl substituents at the *sn*-1 and *sn*-2 positions of the glycerol backbone. The dipalmitoyl species would be designated PC16:0/16:0 if X was choline. If arachidonic acid was esterified at *sn*-2, then the molecule would be designated as PC1 6:0/20:4. In the diacyl species, fatty acids are attached by ester linkages. For *sn*-1-alkyl-*sn*-2-acyl species, the *sn*-1 fatty acid is attached by an ether bond. For *sn*-1-alkenyl-*sn*-2-acyl species, the *sn*-1 fatty acid is attached by a vinyl ether linkage.

In addition to diacyl species, with both fatty acids attached by ester bonds, there are a number of species with ether-linked fatty acids, principally in the *sn*-1 position. These ether phospholipids include 1-alkyl-2-acyl species, largely present in PC, and 1-alk-1-enyl species (plasmalogens), largely present in PE. These ether lipids are major components of many cell membranes, particularly neuronal and inflammatory cells, and there have been significant advances in understanding the biochemical pathways for their synthesis and catabolism. Some alkyl acyl PC species are substrates for the generation of the potent bioactive lipid platelet-activating factor (1-alkyl-2-acetyl-glycero-3-phosphocholine (PAF)), but the function of most ether lipids is largely unclear. One possibility is that generation of 1-alkyl-2-acyl-glycerol as a second messenger rather than diacylglycerol may contribute to differential regulation of protein kinase C isoforms, and antioxidant properties have been reported for plasmalogens.

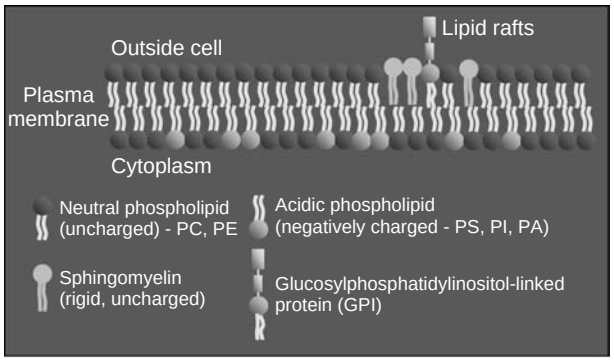

Figure 2 Topology of distribution of phospholipids within the plasma membrane of eukaryotic cells. The outer leaflet of the membrane bilayer is enriched in neutral PC and rigid components, such as sphingolipids and glucosylphosphatdylinositol-linked proteins. The distribution of charged acidic phospholipids, such as PS and PI, to the inner leaflet of the membrane is actively regulated by a combination of enzymes called flipases and scramblases.

Phospholipid Analysis

Historically, phospholipid compositions have been determined by thin-layer chromatography of different classes followed by gas chromatography of fatty acids. Such traditional analysis provides no direct information about the individual molecular species compositions of phospholipids, which are the functional, biologically relevant molecules. For instance, a fatty acid analysis of a phospholipid mixture as 50% 16:0, 50% 18:1 could represent either 16:0/18:1 or an equivalent combination of 16:0/16:0 and 18:1/18:1, which all have very different physical and functional properties. A variety of techniques have been established to provide such information, including high-performance liquid chromatography (HPLC), nuclear magnetic resonance, and mass spectrometry. In this article, compositional data are provided in terms of individual molecular species largely determined by sensitive electrospray ionization mass spectrometry (ESI-MS) methodologies. (Electrospray ionization mass spectrometry is a soft ionization technique that resolves intact molecular ions with minimal fragment formation. Best known for proteomic analysis, when applied to lipid analysis ESI-MS provides direct, very sensitive analysis of molecular species composition with a high degree of resolution.)

Phospholipid Composition

The glycerophospholipid composition of most cell types in the body is regulated within relatively restricted limits and is often specialized for the function of the cell involved. Moreover, most cells maintain distinct and different compositions of the various phospholipid classes. For example, ESI-MS analysis of total lipid extracts from a variety of mouse tissues shows that PC exhibits a wide variation of composition but that of phosphatidylinositol (PI) is relatively constant (**Figure 3**). PC species range from predominantly polyunsaturated in liver (**Figure 3A**) to disaturated and monounsaturated in lungs (**Figure 3B**) and brain (**Figure 3C**). Liver PC contains substantial amounts of species with either n-6 fatty acids (20:4n-6) or n-3 fatty acids (22:6n-3), whereas PC from pancreas, for instance, is essentially composed solely of species containing n-6 fatty acids (**Figure 3D**). This inherent variation in PC composition is emphasised by that of spleen (**Figure 3E**), which, like lung, is dominated by PC16:0/16:0 but also contains increased concentrations of monounsaturated and polyunsaturated species. In contrast, PI from all tissues measured was dominated by the single polyunsaturated stearoyl arachidonoyl species (PI18:0/20:4) (**Figures 3F–3J**). This diversity of composition is mirrored for the distinctive and different compositions of all the other phospholipid classes in most cell types and emphasizes the highly specific mechanisms that regulate phospholipid compositions *in vivo*. PE is typically enriched in arachidonoyl-containing species, whereas PS is generally dominated by the monounsaturated species PS18:0/18:1. It is important to recognize, for nutritional studies *in vitro*, that many of these tissue-specific distributions are lost or reduced for cells maintained in cell culture supplemented with fetal calf serum.

Phospholipid Synthesis

These compositions are mediated by interactions between phenotypic expression and cellular nutrition, which determine the specificities of the enzymes of phospholipid synthesis and hydrolysis and of the transfer proteins that exchange phospholipid species between different membranes. Regulation of synthesis is best characterized for the formation of PC in rat hepatocytes, where PC synthesis is essential for assembly and secretion of very low-density lipoprotein particles, and in the lung epithelial cells responsible for synthesis of pulmonary surfactant phospholipid. Phosphatidylcholine species synthesized *de novo* from diacylglycerol by the enzyme cholinephosphotransferase are subsequently modified by acyl remodeling mechanisms involving sequential actions of phospholipase and acyltransferase activities. The rate of PC synthesis is thought to be dependent on the activity of CTP:choline phosphate cytidylyltransferase (CCT), which is subject to complex regulatory mechanisms involving phosphorylation and reversible enzyme

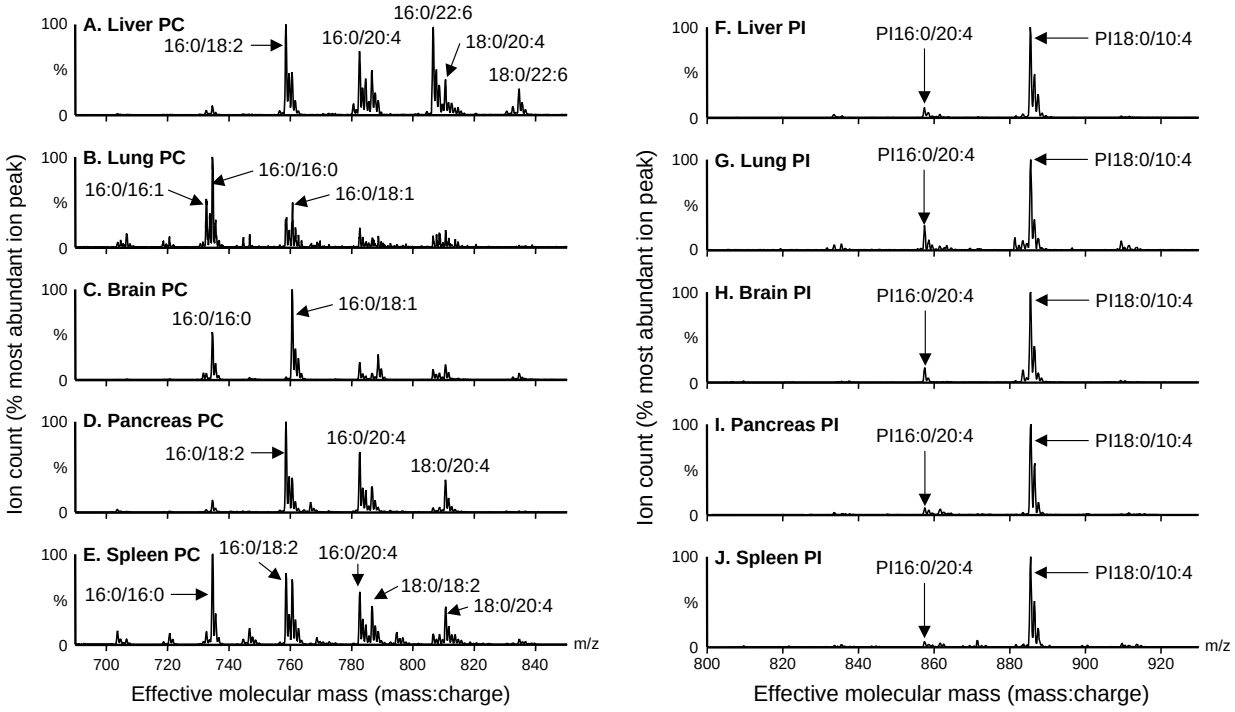

Figure 3 Electrospray ionization mass spectrometry analysis of phospholipid compositions of selected mouse tissue. Total lipids were extracted from liver, lungs, pancreas, and spleen using chloroform:methanol and then analyzed for PC (A–E) and PI (F–J) using diagnostic mass spectrometry scans. The distribution of the phospholipid molecular species in these illustrative spectra is given by the response of the individual ions, presented relative to the predominant ion on display. The identities of the major PC and PI species identified were confirmed by diagnostic fragmentation analysis by tandem MS/MS. (Dombrowsky H, Bernhard W, Rau G, Clark G and Postle A, unpublished results.)

translocation between cytosol and membrane fractions of the cell. In this context, CCT acts as a sensor for the physical structure of the endoplasmic reticulum membrane. Hydrolysis of PC alters the inherent curvature of the membrane and decreases its stored elastic energy, enabling CCT to bind and thus replenish membrane PC.

The spatial pathway of phospholipid synthesis is illustrated schematically in **Figure 4** for the type 2 epithelial cell of the lung alveolus, which synthesizes and secretes lung surfactant. Initial synthesis of phospholipids on the endoplasmic reticulum is followed by a complex series of events that include modification of esterified fatty acid groups by a process of acyl remodeling, selective transport between different intracellular membranes, and uptake of selected phospholipids into lamellar bodies. These lamellar bodies are intracellular stores of surfactant that, when secreted in response to cell stretch, are actively secreted into the alveolar space where they adsorb to the air–liquid interface, oppose surface tension forces within the lungs, and prevent alveolar collapse. In addition, inactive surfactant is recycled by type 2 cells into endosomes that fuse into multivesicular bodies and subsequently into lamellar bodies. Although the phospholipid metabolism of the type 2 cell is complex compared to that of most cell types, it demonstrates very well the various stages in phospholipid synthesis, transport, and metabolism with potential for modification of molecular compositions.

A limited number of conditions are known in which alterations to the processes of phospholipid synthesis and metabolism have profound effects on health and survival. In human subjects, the inability to synthesise the major phospholipids, such as PC and PE, is incompatible with life, so most genetic abnormalities have been identified in abundances of more minor phospholipids. For instance, Barth's syndrome is an X-linked recessive disorder characterised by childhood onset of cardiomyopathy, neutropenia, and abnormal mitochondrial structure and function. The gene affected is the *tafazzin* gene, responsible for acyl remodeling in cardiolipin synthesis. Cardiolipin is a minor phospholipid enriched within the heart and in mitochondria that contains four fatty acid and two phosphate moieties and is synthesised on the endoplasmic reticulum predominately with four oleoyl ($C_{18:1}$) chains. Patients with Barth's syndrome are unable to convert this tetraoleoyl form into the more functional tetralinoleoyl ($C_{18:2}$) cardiolipin species. This is the only condition

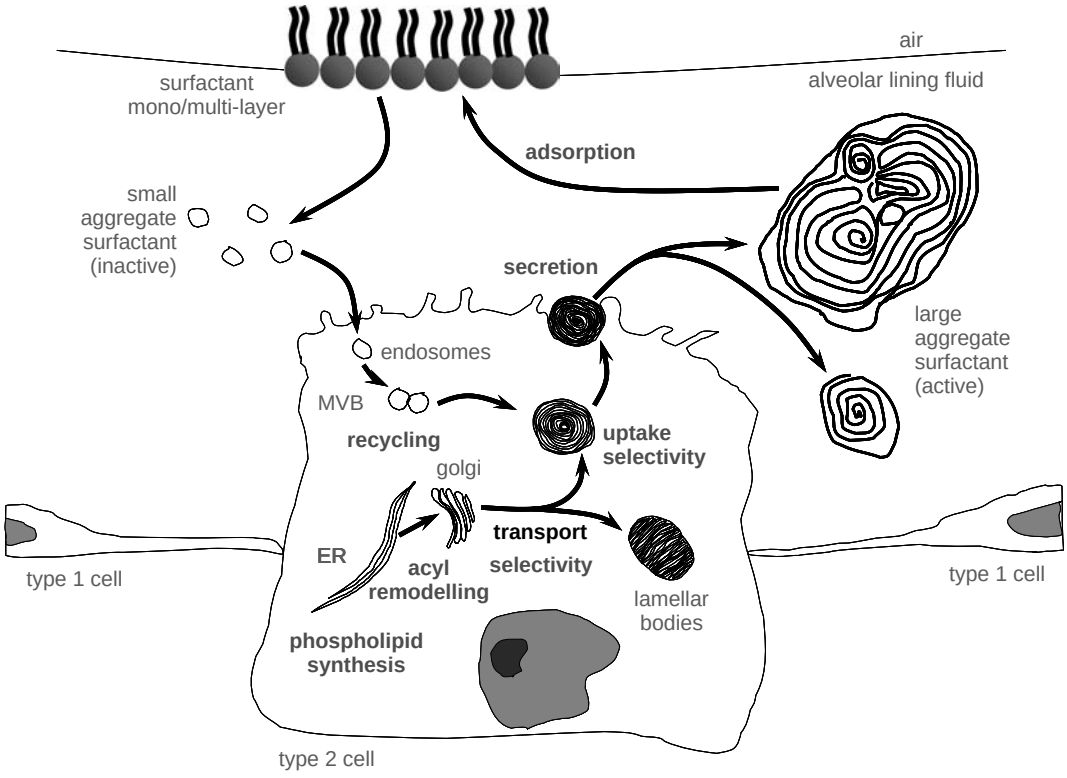

Figure 4 Synthesis and secretion of lung surfactant phospholipid by the type 2 epithelial cell of the lung alveolus. Phospholipid synthesized in the endoplasmic reticulum (ER) is routed through the Golgi apparatus for uptake and packaging into intracellular storage vesicles called lamellar bodies. In response to cell stretch, lamellar bodies fuse with the plasma membrane and secrete their contents into the alveolar space. After processes of adsorption and desorption from the air–liquid interface, inactive surfactant is recycled into lamellar bodies via endosomes and multivesicular bodies (MVB). Metabolically active type 2 cells occupy only approximately 5% of the surface area of the alveolus, with the thin type 1 cells responsible for gas exchange contributing the other 95%.

identified in which the inability to synthesize a precise composition of an individual phospholipid class is apparently responsible for clinical symptoms.

In addition to modification of synthetic mechanisms, alterations to transport and uptake processes can result in severe disease and mortality. ABCA3 is a membrane protein member of the ATP-binding cassette (ABC) family of proteins, which includes the multidrug resistance protein and the ABCA1 protein responsible for reverse cholesterol transport. ABCA3 is though to be involved in the selective uptake and processing of phospholipids destined for lung surfactant assembly within lamellar bodies. Mutations in the *ABCA3* gene cause fatal surfactant deficiency in newborn infants and have been recognized as major contributors to lung disease and respiratory failure in infants delivered full term.

Phospholipid Breakdown

There is also a considerable diversity of specificity of phospholipase enzymes responsible for phospholipid hydrolysis, in terms of both positional and molecular species selectivity. Phospholipase A activity in rat liver will act selectively to remove *sn*-1 16:0 from PC species containing *sn*-2 18:2, whereas cytosolic phospholipase A_2 (PLA_2) is specific for species containing *sn*-2 20:4n-6. In contrast, secretory PLA_2 must be bound to negatively charged phospholipids for activation, but it is not acyl specific. Mammalian phospholipase Cs (PLCs) act preferentially on phosphatidylinositol-4,5-bisphosphate rather than on PI or PC, whereas agonist-stimulated phospholipase Ds (PLDs) are selective for PC species. However, although the distribution of phospholipases is tissue specific, the contribution of their activities to the regulation of phospholipid compositions in most tissues has not been well defined.

Phospholipid Composition in Development

The most extensive changes to phospholipid composition occur during fetal and neonatal development and have been best characterized for PC in liver,

lung, and brain. These changes illustrate clearly the limitations of dietary manipulation on phospholipid composition. During human pregnancy, the polyunsaturated fatty acids (PUFAs) 20:4n-6 and 22:6n-3 are supplied across the placenta from maternal to fetal circulations in increasing quantities toward term. At birth, the onset of milk feeding is characterized by increased intake of the PUFA precursor 18:2n-6. This sequence of nutritional supply is reflected in fetal and neonatal liver PC composition. Immature fetal human liver contains a high proportion of monounsaturated PC species, particularly PC16:0/18:1, and tends to become enriched with species containing 20:4n-6 and 22:6n-3 toward term (**Table 1**).

Postnatally, the content of 18:2n-6 species increases, and fetal and neonatal plasma PC composition directly mirrors this changing pattern. However, these alterations in development are regulated primarily by metabolic and hormonal rather than by nutritional considerations. The increased supply of PUFA from mother to fetus in later gestation is independent of any change in maternal dietary lipid intake and instead is a consequence of hormonal effects on the specificity of PC synthesis and lipoprotein export by the maternal liver. Similarly, although switching from placental to enteral feeding is the major factor causing the dramatic changes to plasma PC at birth, this composition is still dependent on the metabolic regulation of the specificity of hepatic PC synthesis. The programmed nature of this regulation is shown clearly by food restriction in newborn guinea pig pups, which still display equivalent postnatal alterations to plasma and liver PC composition as their fed litter mates, even in the total absence of enteral nutrition.

Table 1 Phosphatidylcholine molecular species composition of human liver during fetal and postnatal development[a]

Molecular species	*Liver phosphatidylcholine concentration (nmol/pg wet weight)*		
	Fetal (15 weeks of gestation, n = 4)	*Stillborn (term, n = 4)*	*Infant (43–64 weeks old, n = 6)*
16:0/16:0	992 ± 156	1004 ± 81	538 ± 121
16:0/18:1	2007 ± 250	2240 ± 173	2353 ± 496
16:0/18:2	466 ± 52	1259 ± 139	2202 ± 273
16:0/20:4	1402 ± 98	1784 ± 38	1062 ± 219
16:0/22:6	431 ± 110	953 ± 82	614 ± 512
18:0/18:2	308 ± 56	443 ± 68	1239 ± 252
18:0/20:4	1298 ± 288	953 ± 89	448 ± 403
18:0/22:6	115 ± 31	210 ± 50	221 ± 267

[a]Molecular species were analyzed by reverse-phase HPLC and quantified by postcolumn fluorescence detection with 1,6-diphenyl-1,3,5-hexatriene. Concentrations expressed as mean ± SD.

In contrast, immature fetal lung PC also contains a high concentration of PC16:0/18:1 but becomes more, rather than less, saturated with progression of gestation due to increased synthesis of the disaturated species PC16:0/16:0 and PC16:0/14:0. PC16:0/16:0 is a major component of pulmonary surfactant that acts to oppose surface tension forces in the lungs and prevent alveolar collapse. Infants who are born preterm with immature surfactant are at high risk of death and disability caused by neonatal respiratory distress syndrome. In contrast to fetal liver, the phospholipid composition of fetal lung is only marginally affected by the changes to lipid nutrition in utero. Nevertheless, some nutritional influence is evident, even though PUFA-containing species are minor components of lung PC. Comparison of PC compositions in prenatal human lung shows a postnatal increase in the content of PC16:0/18:2, which reflects the increased dietary supply of 18:2n-6. The situation in developing lung reflects that of most other tissues in the body, in which dietary lipid modulation causes relatively modest changes to the specificity of phospholipid compositions. Such subtle alterations to membrane composition, however, can exert profound effects on cellular function.

Finally, adult brain PE contains approximately 50% of 22:6n-3 species, enriched in neuronal synapses and possibly involved in synaptic transmission. Failure to acquire sufficient 22:6n-3 in brain PE during neuronal differentiation in early development can lead to permanent suboptimal neurological function. Many of the changes to maternal lipid metabolism in pregnancy represent adaptations to ensure adequate supply of PUFA to the developing fetal brain. Increased synthesis and secretion of PC16:0/22:6 in livers of pregnant rats and guinea pigs correlates with the period in fetal brain growth of maximal accumulation rate of 22:6n-3 into brain PE. Once incorporated into brain or retinal PE, 22:6n-3 is retained throughout life, even in periods of prolonged nutritional deprivation. Infants who are born preterm and with inadequate reserves of 22:6n-3 are recognized to be in danger of nutritional deficiency if fed milk formula lacking preformed long-chain PUFA. For instance, 22:6n-3 content of brain PE was decreased in infants fed such formula and who had died suddenly from sudden infant death syndrome. For this reason, supplementation of preterm infant milk formula with preformed PUFA has been recommended by the European Society for Pediatric Gastroenterology and Nutrition.

Phospholipid Composition in Adult Tissues

Information about the detailed molecular species compositions of phospholipids from adult human tissues is surprisingly haphazard. There have been many isolated reports of extensive characterizations of selected phospholipid classes in individual tissues, but such studies have generally measured compositions of bulk preparations from relatively large tissue samples. Very few clinical or nutritional studies have characterized phospholipid compositions in molecular terms. In reality, each cell type contains in excess of 1000 glycerophospholipid species, with differential compositions between different membranes in the same cell and even between different regions in the same membrane. Such regions of microheterogeneity may occur either because of the physical properties of the lipids themselves (e.g., forming hexagonal rather than bilayer structures) or because of sequestration by membrane proteins. Phase transitions within the membrane can also exert significant effects, and interactions of cytoskeletal components of the cell have been described with relative solid gel-phase phospholipids in the plasma membrane. One additional important factor is the transmembrane phospholipid distribution between the two leaflets of the cell bilayer. For practically all cell types, PC is relatively more concentrated in the outer leaflet, whereas PE is located primarily in the inner (cytoplasmic) leaflet. Importantly, PS is almost totally restricted to the side of the plasma membrane facing the cytoplasm, where it acts as an activator of protein kinase C. Redistribution of PS to the outer leaflet of the plasma membrane is a signal of cell senescence and is a potent activator of the clotting cascade. Finally, there has been considerable interest in the concept of lipid rafts, subfractions of membranes that are resistant to extraction with detergent and have been extensively implicated in transmembrane signaling particularly in immune cells. The compositional aspects of many such studies must be interpreted with caution; recent analyses have indicated that detergent solubility is more an intrinsic property of individual lipids than a property dependent on membrane organization.

Examples of recent ESI-MS analyses of phospholipid molecular species compositions of a variety of human tissues are summarized in **Figure 5**, which compares ESI-MS spectra of PC from human blood lymphocytes, monocytes, and neutrophils. As for most hematopoeic cell types and in contrast to the mouse compositions shown in **Figure 2**, the PC composition of these cells is dominated by monounsaturated PC

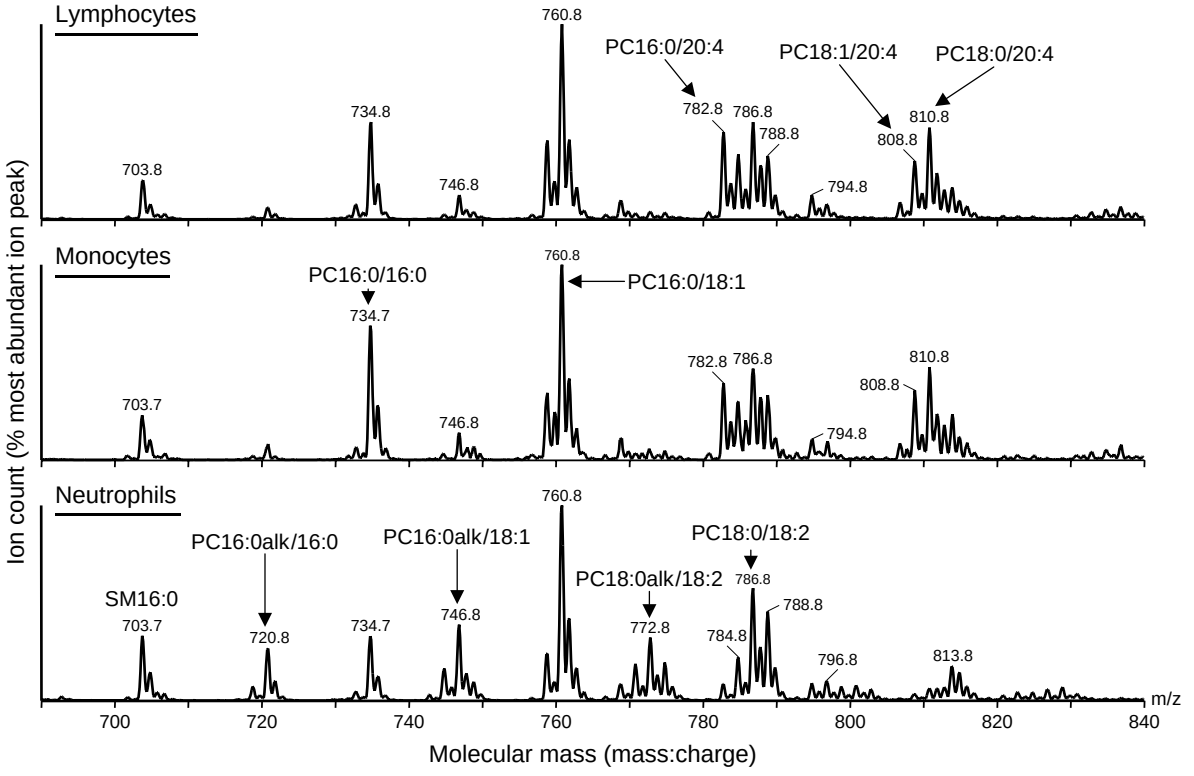

Figure 5 Electrospray ionization mass spectrometry analysis of PC compositions of human blood leukocytes. Total lipids were extracted from lymphocytes, monocytes, and neutrophils and analyzed as described in the legend for **Figure 2**. (Madden J, Wright S, Clark G and Postle A, unpublished observations.)

species, especially PC16:0/18:1 (m/z = 760), but the distribution of polyunsaturated species is considerably variable between cell types. Both lymphocytes and monocytes are relatively enriched in species containing 20:4n-6 (PC16:0/20:4 m/z = 782; PC18:0/20:4 m/z = 810), with an increased content of PC16:0/16:0 (m/z = 734). In contrast, neutrophils are relatively depleted in both PC16:0/16:0 and arachidonoyl species, but they contain considerably higher proportions of *sn*-1-alkyl-*sn*-2-acyl species (PC16:01alk/16:0 m/z = 720; PC16:0alk/18:1 m/z = 746; PC18:0alk/18:2 m/z = 772). This comparison illustrates an important role for phenotypic expression as one contributor toward the specificity of cell PC composition.

Different phospholipid classes from the same tissue generally exhibit considerable variation in composition, shown in **Figure 2** for mouse tissues and also in the analysis of the white matter of human brain. Although brain PC was highly enriched in monounsaturated species, diacyl PE was enriched in species containing PUFA. The distribution of such species, however, was highly asymmetric, with 22:6n3 and 20:4n-6 species containing 16:0 at the *sn*-1 position being present in much lower abundance than the same species containing *sn*-1 18:0. In contrast, both alkenylacyl PE and PS were characterized by a predominance of monounsaturated species. However, whereas PC was enriched in PC16:0/18:1, alkenylacyl PE was enriched in PE18:1alk/18:1 and PS was enriched in PS18:0/18:1. This comparison illustrates the tight regulation of the composition of individual phospholipid classes and emphasizes potentially important differences in molecular compositions that could not be predicted from total fatty acid analysis.

Nutritional Effects on Phospholipid Molecular Species

Practically all nutritional studies of dietary lipid effects on cellular phospholipid compositions have reported fatty acid compositions, with no molecular information. Due to significant differences in the detailed regulation of their phospholipid composition and metabolism, nutritional data obtained from laboratory animals generally have only a restricted application to human nutrition. The data in **Figure 6** are from one study in which human volunteers were fed fish oil supplements for 4 weeks and the change in their erythrocyte PE molecular species composition was measured. Of interest, the extent of increase in species containing

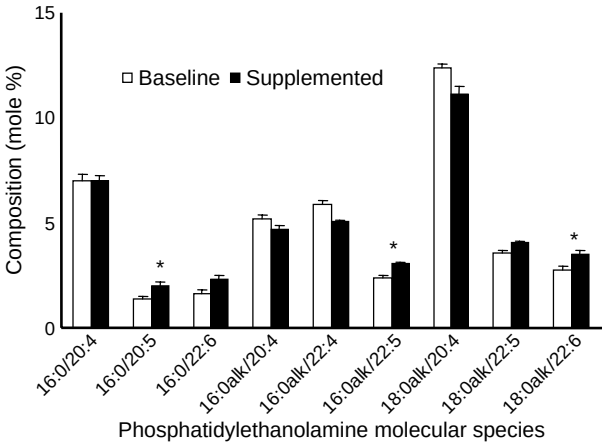

Figure 6 Dietary lipid and the composition of human erythrocyte phosphatidylethanolamine. Erythrocyte PE species were analyzed from six volunteers before and after consumption of fish oil containing 9 g eicosapentaenoic acid (22:5n-3) and 6 g docosahaexenoic acid (22:6n-3) per day for 4 weeks. Results are expressed as mean ± SEM; $*p < 0.05$. (From Knapp HR, Hullin F and Salem N Jr (1994) Asymmetric incorporation of dietary n-3 fatty acids into membrane aminophospholipids of human erythrocytes. *Journal of Lipid Research* **35**: 1283–1291.)

n-3 fatty acids was variable, and the extent of such changes was modest. This comparison illustrates a general observation that although manipulation of cultured cell phospholipid compositions by medium lipid supplementation is relatively easy, phospholipid compositions of similar cell types in vivo are considerably more resistant to dietary manipulation.

Functions of Phospholipids

Phospholipid composition is a significant factor in most cellular processes. This section, however, is restricted to selected examples of the role of molecular species composition with regard to physiological functions.

Membrane Structure

One frequently addressed role of phospholipids is to maintain an appropriate membrane structure for optimal cell function. The term 'membrane fluidity' is often used but is imprecise. It generally describes the combined effects of lateral and rotational movement of lipids within the plane of the membrane. Other concepts are perhaps more useful, such as the stress, termed 'stored elastic energy,' when phospholipids are prevented by their location within the membrane from assuming their lowest energy configuration. Typically, phospholipids such as PC prefer to adopt a convex membrane curvature, whereas molecules such as PE and PA will spontaneously adopt a concave configuration. In these paradigms, alterations to dietary lipid intake

may exert their modulatory effect on cell function by changing phospholipid molecular composition and hence altering these physiochemical properties. Although such effects are evident in model systems, extensive measurement by fluorescence polarization suggests that processes of homeoviscous adaptation restrict the extent of adaptations observed *in vivo*. For instance, increased incorporation of PUFA into membrane phospholipid, which would be expected to have a fluidizing effect, is invariably balanced by compensatory increases in the membrane content of cholesterol and more rigid phospholipid molecules.

Lung Surfactant

Maintenance of the essential composition of lung surfactant phospholipid is critical for the survival of all mammalian species. Lung surfactant is secreted from specialized type 2 epithelial cells in the lung alveolus and forms a continuous lining layer at the air–liquid interface throughout the lungs. To provide adequate gas exchange surface area in the lungs to support respiration, alveolar diameters must be very small, giving a large surface area:volume ratio. One consequence of the small dimensions of the alveolus is that surface tension forces contribute significantly to the dynamics of lung function. Surfactant opposes surface tension in the lungs. It is the absence of adequate surfactant that leads directly to lung collapse and the high incidence of morbidity and mortality associated with neonatal respiratory distress syndrome.

Lung surfactant has a unique phospholipid composition, containing PC16:0/16:0 as 40–60% of total PC and monounsaturated phosphatidylglycerol (PG) species as 10–15% of total phospholipid. Phosphatidylglycerol is not found at such high concentration in any other membrane of the body. PC16:0/16:0 is the principal surface-active component of lung surfactant, has a gel:liquid crystalline transition temperature of 41 °C, and consequently is, in effect, solid at a body temperature of 37 °C. It has been suggested that the compressed PC16:0/16:0 monolayer at the air–liquid interface survives the high surface pressures within the lungs by forming a solid monomolecular sheet, and it thus prevents any surface tension effects. At the same time, PC16:0/16:0 is metabolically inert, and one proposed specialized role for PG is to fluidise PC16:0/16:0 and facilitate its metabolic processing, secretion, and adsorption to the air–liquid interface.

This composition of lung surfactant is restricted to air-breathing animals. Comparative studies with reptiles, amphibia, and lower vertebrates have shown that concentration of PC16:0116:0 in surfactant correlates with the ratio of lung:body surface area as a measure of an animal's reliance on lung-mediated respiration. Lung surfactant from amphibia, by comparison, also contains phospholipid, but this is largely cholesterol and unsaturated PC, which is thought to serve an antiglue function. By analogy with lung surfactant, phospholipid-rich surfactants have been described for other epithelial surfaces, including the stomach, eustachian tube, and synovial surfaces, where they are thought to create a protective hydrophobic lining layer. The comparison with lung surfactant is somewhat misleading, however, because the PC fraction of these other epithelial secretions contains minimal PC16:0/16:0 and high contents of mono- and diunsaturated species.

Signal Transduction

Phospholipids are substrate molecules for a wide range of lipid-derived signaling molecules, including diacylglycerol (DAG), phosphatidic acid (PA), 20:4n6, eicosanoid products, PAF, and lysophosphatidic acid, generated by the action of PLA_2, PLC, and PLD. The activation of these enzymes is complex, partly because of the large number of isoforms present within a cell and also because of the interdependence and coordination of their regulation. For instance, the bacterial peptide formyl-methionyl-leucyl phenylalanine (FMLP) binds to its receptor on neutrophils and activates the G-protein-regulated PLCβ. PLCβ hydrolyses PI-4,5-P_2 to form DAG, an activator of traditional Ca^{2+}-dependent PKC isoforms, and inositol trisphosphate, which stimulates intracellular Ca^{2+} mobilisation. In addition, FMLP activates PC-specific PLD and cytoplasmic PLA_2. PLD generates PA, which also has signaling responses, including stimulation of NADPH oxidase activity, but which is also readily interconverted with DAG. Alkenyl species of PE are probably the major substrates for cytoplasmic PLA_2, which is specific for molecular species containing 20:4n-6. This multitude of responses to a single agonist is highly coordinated and is typical of lipid signaling mechanisms in general. The activation of the various phospholipase enzymes is tightly regulated by a variety of protein kinases, phosphatases, and regulatory proteins, such that their responses are sequential rather than simultaneous.

Evidence suggests that phospholipid structure contributes to the coordinated regulation of phospholipase activation. PI-4,5-P_2, the substrate for PLC, is an obligate activator of ADP ribosylation factor-dependent PLD; consequently PI-4,5-P_2 must be regenerated after the transient activation of PLC,

before maximal activation of PLD can be achieved. In addition, individual phospholipids can act as binding sites for a wide range of signaling proteins and enzymes, enabling their coordinated regulation at the membrane. Perhaps the best characterised of these systems is the generation of trace amounts of 3-phosphorylated PI, typically PI-3,4,5-P_3, when PI-3-kinase is activated by insulin and growth factors. Signaling proteins containing appropriate binding motifs (plecstrin homology or PH domains) then bind to PI-3,4,5-P_3 and initiate signaling cascades. The prototype of such protein is protein kinase B (PKB) also know as Akt. PKB undergoes a conformational change when bound to PI-3,4,5-P_3, becomes phosphorylated, and then is active in the regulation of cell proliferation.

The mechanisms of action of dietary lipid modulation on these signaling pathways are largely unknown. There is good evidence that eating a diet rich in fish oil (containing 22:6n-3 and 22:5n-3) attenuates neutrophil-mediated inflammatory reactions. Part of this antiinflammatory nutritional effect may be to reduce the content of phospholipid species containing 20:4n-6, thus decreasing available substrate for synthesis of eicosanoid and leukotriene products derived from 20:4n-6. Alternatively, it may also result in part from the modulation of the spectrum of molecular species of DAG and PA generated by the various PLC and PLD enzymes. In this paradigm, altering the composition of substrate phospholipid will result in the formation of different DAG or PA species, which then have differential actions on target kinase enzymes. Because inositol phospholipids are generally composed of the 18:0120:4 species, activation of PLC1 will form DAG18:0/20:4, whereas hydrolysis of PC will generate predominately monounsaturated DAG species. It has been suggested, for instance, that individual isoforms of protein kinase C can be differentially regulated in response to different molecular species of DAG, thus providing a molecular basis for many nutritional effects on a wide range of cellular functions.

Despite extensive studies since the 1960s, remarkably little is understood about the fundamental reasons why cells expend considerable energy maintaining lineage-specific molecular species compositions of membrane phospholipids. Even for cell lines in culture, which can be grown successfully over many generations with grossly nonphysiological membrane phospholipid compositions, a degree of lineage specificity is maintained. The detailed metabolic processes that control membrane phospholipid composition are slowly being defined, and studies of the specificities and activities in intact cells of acyltransferase and phospholipid synthetic enzymes using gene transfection and sensitive analytical techniques such as ESI-MS will increase understanding of the fundamental mechanisms involved.

LIPOPROTEINS

J M Ordovas, Tufts University, Boston, MA, USA

Cholesterol and triacylglycerol are transported in blood as lipoproteins. Lipoproteins are generally spherical particles, with a surface layer composed of phospholipid with the fatty acids oriented toward the core of the particle. Included in this phospholipid layer are specific proteins known as apolipoproteins and free cholesterol. The core of the lipoprotein particles is made up of cholesteryl ester and triacylglycerol molecules.

The classification of serum lipoproteins has evolved historically through several phases corresponding with the development of different laboratory methodologies, including electrophoretic, ultra-centrifugal, and immunological techniques. By using these techniques, lipoproteins can be classified based on their electrophoretic mobility, hydrated density, and protein content.

Classification of Lipoproteins

Classification of Serum Lipoproteins According to Their Electrophoretic Mobilities

With the development of techniques to separate proteins according to their electrophoretic behavior, it could be demonstrated that most of the lipid present in serum was associated with proteins migrating with α_1- and β-globulin mobilities. This resulted in the first classification of lipoproteins as α_1- and β-lipoproteins. The ratio of lipid to protein on the α_1-lipoproteins was approximately 1:1, whereas the β-lipoproteins had a greater relative content of lipids. Application of more advanced electrophoretic techniques resulted in further discrimination among the lipoprotein classes and for many years lipoproteins were classified as β-, pre-β-, and α-lipoproteins. Careful observation of the electrophoretic lipoprotein profiles in normals and subjects with familial lipoprotein disorders gave rise to the first classification of lipoprotein disorders by Fredrickson and colleagues. The equivalence between electrophoretic and ultracentrifugal separation is presented in **Table 1**.

Several electrophoretic supports have been used to separate plasma lipoproteins. These include paper, cellulose acetate, agarose, and polyacrylamide. Agarose gel electrophoresis remains the most commonly used for easy and rapid assessment of lipoprotein patterns in the clinical laboratory. This technique is especially useful for identifying the presence of a broad β band in the diagnosis of type III hyperlipidemia. Gradient agarose-polyacrylamide gel electrophoresis under nondenaturing conditions has been an essential tool to analyze low-density lipoprotein (LDL) and high-density lipoprotein (HDL) subclasses, providing a greater resolution than ultracentrifugation. LDL subfractions have been resolved by nondenaturing polyacrylamide gradient gel electrophoresis (2–16%) in up to seven LDL subclasses with densities ranging from 1.020 to 1.063 g ml^{-1} and diameters ranging from 22.0 to 28.5 nm. Usually a major subpopulation and several (one to four) minor LDL subpopulations are found in most subjects examined. A predominance of smaller, more dense LDL, versus larger, more buoyant LDL particles in plasma has been associated with increased coronary heart disease (CHD) risk. There is evidence supporting the genetic origin of the

Table 1 Classification of plasma lipoproteins

Lipoprotein	*Diameter (nm)*	*Density (g ml^{-1})*	*Electrophoretic mobility*	*Major lipids*	*Major apolipoproteins*
Chylomicrons	80–500	<0.95	Origin	Dietary triacylglycerols, cholesteryl esters	A-I, A-II, A-IV, B-48, C-I, C-II, C-III, E
Remnants	>30	<1.006	Origin	Dietary cholesteryl esters	B-48, E
VLDL	30–80	<1.006	pre-β	Endogenous triacylglycerols	B-100, C-I, C-II, C-III, E
IDL	25–35	1.006–1.019	pre-β and β	Cholesteryl esters, triacylglycerols	B-100, E
LDL	18–28	1.019–1.063	β	Cholesteryl esters	B-100
HDL_2	9–12	1.063–1.125	α	Cholesteryl esters, phospholipids	A-I, A-II
HDL_3	5–9	1.125–1.210	α	Cholesteryl esters, phospholipids	A-I, A-II

distribution of LDL subfractions; however, age, gender, and environmental factors strongly influence the penetrance. HDL subfractions have been resolved using a similar technique, with a polyacrylamide gradient ranging from 4 to 30%, into five subclasses (HDL_{3c}, HDL_{3b}, HDL_{3a}, HDL_{2a}, and HDL_{2b}). More recently 11–14 subclasses have been described, including β-migrating particles, using an improved electrophoresis technique. The clinical importance of these subfractions is still under investigation.

Classification of Serum Lipoproteins According to Their Ultracentrifugal Characteristics

The presence of lipids within the lipoprotein particles confers these macromolecular complexes with a lower density compared with other serum proteins. With the arrival of the analytical ultracentrifugation in the 1940s, this characteristic allowed its initial separation as a discrete peak using this technique. During the following years, it was demonstrated that this fraction was made up of a wide spectrum of particle sizes and densities (d) ranging from 0.92 to 1.21 g ml^{-1}.

Lipoproteins were classically separated into four major classes designated as chylomicrons (exogenous triacylglycerol-rich particles of $d < 0.94$ g ml^{-1}), very low-density lipoproteins (VLDL, endogenous triacylglycerol-rich particles of $d = 0.94$–1.006 g ml^{-1}), LDL (cholesteryl ester-rich particles of $d = 1.006$–1.063 g ml^{-1}), and HDL (particles containing approximately 50% protein of $d = 1.063$–1.21 g ml^{-1}). With subsequent improvements to the ultracentrifugation techniques, further heterogeneity was detected within each of those major lipoprotein classes; this resulted in the need for further subdivision into several density subclasses such as HDL_{2a} ($d = 1.10$–1.125 g ml^{-1}), HDL_{2b} ($d = 1.063$–1.10 g ml^{-1}), and HDL_3 ($d = 1.125$–1.21 g ml^{-1}).

There is no doubt that the separation of lipoproteins by ultracentrifugation has been esential for the advances in this field; however, this technique is very labor intensive and the isolated lipoproteins are usually modified due to the high g force and salt concentrations used in this process. The development of new vertical and near vertical rotors has shortened considerably the runs and thus diminished some of these negative effects.

Classification of Serum Lipoproteins According to Their Apolipoprotein Composition

Recent interest on the study of lipoprotein subfractions has resulted in an increased use of methods of separation based on affinity chromatography, specially those using immunoaffinity. By using columns containing antibodies against specific apolipoproteins (**Table 2**), a large number of HDL subpopulations have been resolved. Similarly, this technique

Table 2 Classification and properties of apolipoproteins

Apolipoprotein	*Amino acids*	*Tissue expression*	*Chromosomal localization*	*Functions*
apo A-I	243	Liver Intestine	11	Major structural component of HDL Ligand for HDL binding Activator of LCAT Reverse cholesterol transport
apo A-II	77	Liver	1	Structural component of HDL Activator of hepatic lipase
apo A-IV	377	Intestine Liver	11	Regulator of LPL activity Activator of LCAT Intestinal lipid absorption
apo B-48	2152	Intestine	2	Structural component of TRL Secretion of chylomicrons
apo B-100	4536	Liver	2	Structural
apo C-I	57	Liver Intestine	19	Activator of LCAT Inhibitor of the LRP

apo(a)	Variable	Liver	6	?

allows the separation of several triacylglycerol-rich lipoproteins subfractions.

Lipoproteins containing apo A-I can be separated into two major species: those containing both apo A-I and apo A-II, known as LpAI:AII, and those containing apo A-I but not apo A-II (LpAI). Small numbers of particles containing apo A-II, but not apo A-I, have been detected in normal subjects; however, these particles could become predominant in the presence of rare genetic disorders associated with HDL deficiency. Another HDL species containing apo A-I and apo E is important in reverse cholesterol transport by transporting cholesterol from the cell membranes to the liver for elimination from the body.

Lipoproteins containing apo B consist of four lipoprotein families. Lipoproteins containing apo B only (Lp(B)) are cholesteryl ester-rich and are found primarily within the LDL density range, but they have also been detected within the VLDL range. Particles containing both apo B and apo C (LpB:C), apo B and apo E (LpB:E), and all three apolipoprotein groups (LpB:E:C), are triacylglycerol-rich and are found within the VLDL and IDL density range. The apo C and apo E content decreases as density increases.

More recently, the affinity for lectins of Lp(a), a lipoprotein containing apo B-100 as well as an antigenically unique apolipoprotein [apo(a)], has been used to develop a new technique to measure the levels of this lipoprotein in plasma.

Synthesis and Catabolism of Lipoproteins

Metabolism of Lipoproteins Carrying Exogenous Lipids

Dietary fats absorbed in the intestine are packaged into large, triacylglycerol-rich chylomicrons for delivery through the bloodstream to sites of lipid metabolism or storage. These lipoproteins interact with lipoprotein lipase (LPL) and undergo lipolysis, forming chylomicron remnants. The major sites of LPL activity are adipose tissue, skeletal muscle, the mammary gland, and the myocardium. In these sites, the fatty acids from the trcacylglycerols are used for storage, oxidation, or secretion back to the circulation. The triacylglycerol-depleted particles resulting from the lipolysis, known as chylomicron remnants, pick up apo E and cholesteryl ester from HDL and are rapidly taken up by the liver via a process mediated by the apo E receptor. This is a fast process and chylomicron particles are not usually present in the blood after a prolonged fasting period. The occurrence of chylomicronemia can be easily detected by the presence of a creamy supernatant floating on top of the plasma or serum kept several hours at 4 °C.

Transport of Endogenous Lipids

The liver cell secretes triacylglycerol-rich VLDL, which can be converted first to intermediate-density lipoprotein (IDL) and then to LDL through lipolysis by a mechanism similar to that described for chylomicrons. The excess surface components are usually transferred to HDL, and the triacylglycerol-depleted VLDL becomes an IDL. Some of these particles may be taken up by the liver via an apo E receptor, whereas others are further depleted of triacylglycerols, becoming cholesteryl ester-enriched particles known as LDL, which contain apo B as their only apolipoprotein. Consumption of fat-rich meals or glucose enhances VLDL production.

Some primary causes of elevated VLDL or IDL levels are familial endogenous hypertriglyceridemia (type IV according to Fredrickson's classification) and familial dysbetalipoproteinemia (type III hyperlipidemia). Genetic mutations at the apo E gene locus are responsible for the type III phenotype. Some secondary causes for elevated VLDL levels are obesity, diabetes mellitus, alcohol consumption, as well as the use of high doses of certain drugs (e.g., thiazide diuretics and estrogens). The presence of elevated levels of IDL has been associated with an increased atherosclerotic risk.

LDL particles are major carriers of cholesteryl ester in the blood. An LDL receptor that recognizes apo B-100 and apo E, but not apo B-48, allows the liver and other tissues to catabolize LDL. High-fat and high-cholesterol diets can decrease the activity of the LDL receptor, leading to increased levels of circulating LDL. These particles supply cholesterol to cells in the periphery for synthesis of cell membranes and steroid hormones. Modified or oxidized LDL can also be taken up by the scavenger receptor on macrophages in various tissues, including the arterial wall. This process is a potential initiator of foam cell formation and atherosclerosis.

Several LDL subclasses have been identified using gradient gel electrophoresis. Large, less dense LDL particles are commonly found in premenopausal women and men at low risk for CHD, whereas the small, more dense particles have been associated with a significant increased risk for myocardial infarction. The distribution of these particles appears to have a significant genetic component modulated by age and environmental factors.

Reverse Cholesterol Transport

HDL is synthesized by both the liver and the intestine. Its precursor form is discoidal in shape and matures in circulation as it picks up unesterified cholesterol from cell membranes and other lipids (phospholipid and triacylglycerol) and proteins (A-I, E, and C apolipoproteins) from triacylglycerol-rich lipoproteins (chylomicron and VLDL) as these particles undergo lipolysis. The cholesterol is esterified by the action of the lecithin–cholesterol acyltransferase (LCAT) and the small HDL_3 particle becomes a larger HDL_2 particle. The esterified cholesterol is either delivered to the liver or transferred by the action of cholesteryl ester transfer protein (CETP) to other lipoproteins (such as chylomicron, VLDL remnants, or LDL) in exchange for triacylglycerols. This cholesterol may then be taken up by the liver via receptors specific for these lipoproteins, or it can be delivered again to the peripheral tissues. The triacylglycerol received by HDL_2 is hydrolyzed by hepatic lipase and the particle is converted back to HDL_3, completing the HDL cycle in plasma. In the liver, cholesterol can be excreted directly into bile, converted to bile acids, or reutilized in lipoprotein production.

Several genetic disorders have been identified associated with low levels or total deficiency of HDL.

Effects of Dietary Fats and Cholesterol on Lipoprotein Metabolism

The cholesterolemic effects of dietary fatty acids have been extensively studied. The saturated fatty acids $C_{12:0}$, $C_{14:0}$, and $C_{16:0}$ have a hypercholesterolemic effect, whereas $C_{18:0}$ has been shown to have a neutral effect. Monounsaturated and polyunsaturated fatty acids in their most common *cis* configuration are hypocholesterolemic in comparison with saturated fatty acids. The effects of *trans* fatty acids on lipid levels are under active investigation. Our current knowledge shows that their effect is intermediate between saturated and unsaturated fats. The effect of dietary cholesterol on lipoprotein levels is highly controversial. This may be due in part to the dramatic interindividual variation in response to this dietary component. Specific effects of dietary fats and cholesterol on each lipoprotein fraction are the focus of other articles and they are only briefly summarized below and in **Table 3**.

Effects of Diet on Chylomicron Metabolism

Diets very high in saturated fat have been associated with increased postprandial chylomicrons and chylomicron remnants compared with diets rich in n-6 polyunsaturated fats; however, human experiments carried out using moderate to high fat intake have not shown significant effects of different types of dietary fat or dietary cholesterol on postprandial lipoproteins.

The effects of dietary carbohydrates on postprandial lipoproteins have also been studied. Most protocols have used diets very high in simple carbohydrates. In general, high carbohydrate intake has been associated with increased levels of fasting triacylglycerols and increased postprandial levels of chylomicrons and chylomicron remnants.

Effects of Diet on VLDL Metabolism

It is well-known that diets high in simple carbohydrate increase hepatic secretion of VLDL. This carbohydrate induction of hypertriglyceridemia is the source of the current controversy regarding the optimal diet for subjects at high risk for cardiovascular disease. Some authors have demonstrated that the increased hepatic triacylglycerol secretion induced by high-carbohydrate diets was not accompanied by parallel increases in apo B-100 secretion. In other words, the consumption of low-fat, high-carbohydrate diets did not affect the number of particles but resulted in larger, more triacylglycerol-enriched VLDL particles.

Intake of saturated fat results in an increased secretion of the number of VLDL particles by the liver, whereas the opposite effect is observed with polyunsaturated fat. Of special note are the dramatic effects on VLDL production found following high intakes of n-3 fatty acids. These diets are associated with marked decreases in triacylglycerol secretion by mechanisms not fully understood. It

Table 3 Effects induced on the major lipoprotein fractions by different dietary components following isoenergetic replacement of saturated fatty acids

	MUFA	*PUFA n-6*	*PUFA n-3*	*trans FA*	*Simple carbohydrate*	*Carbohydrate plus fiber*

≈ equivalent effect; ↓ concentration reduced; ↑ concentration increased.

has been speculated that n-3 fatty acids may stimulate intracellular degradation of apo B in hepatocytes. Dietary cholesterol, within the physiological range, appears to play a minor role in hepatic VLDL production.

Effects of Diet on LDL Metabolism

The effects of dietary fat and cholesterol on LDL metabolism have been extensively studied. However, the effects of dietary cholesterol are still highly controversial. Whereas some studies have demonstrated increased LDL production and decreased catabolism associated with high cholesterol intakes, others have failed to find such associations.

Replacement of saturated by polyunsaturated fats has been associated with decreased LDL apo B production in some studies, whereas in other studies, increased ratios of polyunsaturated to saturated fats resulted in increased LDL apo B catabolism. Unlike the effects described for VLDL metabolism, intake of n-3 fatty acids appears to play a minor role on LDL metabolism.

Effects of Diet on HDL Metabolism

Diets high in simple carbohydrates reduce HDL cholesterol levels. This effect appears to be mediated by increases in the catabolism of apo A-I; however, one study has also demonstrated an additional decrease in apo A-I production.

Disorders of Lipoprotein Metabolism

For historical reasons the classification of disorders of lipoprotein metabolism will be presented according to the classical Fredrickson's classification (**Table 4**).

Type I or Familial Chylomicronemia

This disorder is characterized by greatly elevated levels of exogenous triacylglycerols and it is the result of impaired lipolysis of chylomicrons due to a deficiency of LPL or its activator, the apo C-II. Several genetic mutations at the structural genes for both LPL and apo C-II have been reported. These are autosomal recessive traits. In the heterozygous state, subjects have normal to slightly elevated plasma triglycerides, whereas homozygotes have triacylglycerol levels that may exceed $1000\,mg\,dl^{-1}$ in the fasting state. The diagnosis of the homozygous state takes place during the first years of life from the presence of recurrent abdominal pain and pancreatitis. Eruptive xanthomas and lipemia retinalis may also occur.

The recommended treatment includes a diet low in simple carbohydrates and with a fat content below 20% of total energy. The use of medium-chain triglycerides (MCT) has also been reported to be efficacious. Body weight should be maintained within the normal limits and alcohol consumption should be avoided.

Other secondary causes leading to the presence of chylomicrons in the fasting state include uncontrolled diabetes mellitus, alcoholism, estrogen use, and hypothyroidism.

Fasting chylomicronemia has not been clearly associated with increased risk for atherosclerosis; however, there is considerable evidence supporting the atherogenic properties of chylomicron remnants.

Type II or Familial Hypercholesterolemia

Familial hypercholesterolemia (FH) is an autosomal dominant disorder characterized by elevation of plasma LDL cholesterol levels. Mutations at the LDL receptor gene locus on chromosome 19 are

Table 4 Classification of hyperlipidemias according to Fredrickson

Type	*Plasma cholesterol*	*Plasma triacylglycerol*	*Lipoprotein fraction(s) affected*	*Atherosclerosis risk*	*Genetic disorder*
I	Normal to elevated	Very elevated	Chylomicrons	No	Familial LPL deficiency Apo C-II deficiency
IIa	Elevated	Normal	LDL	High	Familial hypercholesterolemia Familial combined hyperlipidemia Polygenic hypercholesterolemia
IIb	Elevated	Elevated	LDL and VLDL	High	Familial hypercholesterolemia Familial combined hyperlipidemia
III	Elevated	Very elevated	IDL	High	Familial dysbetalipoproteinemia
IV	Normal or elevated	Elevated	VLDL	Moderate	Familial hypertriglyceridemia Familial combined hyperlipidemia
V	Normal or elevated	Very elevated	VLDL and chylomicrons	Moderate	Familial hypertriglyceridemia

responsible for this disorder. Multiple different mutations have been described at this locus resulting in the FH phenotype. In the heterozygous state, subjects develop tendinous xanthomas, corneal arcus, and CHD. Elevations of LDL can result from well-characterized genetic disorders such as FH or familial defective apo B-100.

The ranges of LDL cholesterol levels in plasma of FH subjects are 200–400 mg dl^{-1} in heterozygotes and above 450 mg dl^{-1} in homozygotes. The frequency of defects at the LDL receptor locus is about 1 in 500 for the heterozygous state and 1 in a million in the homozygous state.

Inhibitors of 3-hydroxy-3-methylglutaryl (HMG) coenzyme A are useful in the treatment of hypercholesterolemia. Most pharmacological therapies are ineffective in the homozygous state. FH homozygotes may be treated with LDL apheresis, liver transplantation, and portacaval shunt. More recently, encouraging results have been obtained using *ex vivo* gene therapy.

The genetic defect(s) associated with a common form of hypercholesterolemia present in most subjects with cholesterol levels between 250 and 300 mg dl^{-1} has not been elucidated. This disorder may be due to a combination of minor gene defects (i.e., presence of apo E-4 allele) that in combination with the environment (i.e., diet, lack of exercise) predispose individuals to moderately elevated LDL cholesterol levels. This disorder has been also named polygenic hypercholesterolemia.

Familial Defective apo B-100

Familial defective apo B-100 is an autosomal dominant genetic disorder that presents with a phenotype similar to FH. The frequency of this disorder may be similar to FH; however, it varies considerably depending on the ethnicity of the population studied. The specific mutation responsible for this disorder is a point mutation at amino acid 3500 of the mature apo B. The diagnosis of this disorder requires molecular biology techniques.

Type III or Familial Dysbetalipoproteinemia

In this disorder both plasma triacylglycerol and cholesterol are increased. Several mutations within the apo E gene locus have been found to be responsible for this disease; however, in most patients the complete expression of the clinical genotype needs additional interactions such as age, obesity, and diabetes. In addition to the accumulation in plasma of VLDL remnants and chylomicrons, other characteristics of this disorder are tuboeruptive xanthomas and in some cases also planar xanthomas. Therapies include diet and hypolipidemic agents such as fibrates, statin, or nicotinic acid. In most cases, diagnosis can be carried out first by agarose gel electrophoresis, followed by molecular biology techniques to detect the presence of the apo E-2 allele.

Familial Type IV and Type V Hypertriglyceridemias

These two disorders may have overlapping phenotypes. In type IV or familial endogenous hypertriglyceridemia, triacylglycerol levels are increased and HDL is usually decreased. This disorder appears to be autosomal dominant and relatively frequent in populations consuming high-fat diets. The precise molecular defect has not been defined; however, the increase in triacylglycerol is associated with overproduction of triacylglycerol by the liver and often with consequent reduced clearance. Diet should be the first step in therapy, followed if necessary by pharmacotherapy using fibrates or nicotinic acid. Premature CHD has been seen in some but not all cases presenting with this phenotype.

Type V hyperlipidemia is a much more rare disorder. Usually the first signs of this abnormality are abdominal pain or pancreatitis. VLDL levels are high and chylomicrons are present in the fasting state. This abnormality has not been linked to any specific molecular defect. Besides the primary genetic defect, other secondary causes of type V hyperlipidemia are poorly controlled diabetes mellitus, nephrotic syndrome, hypothyroidism, glycogen storage disease, and pregnancy. Recent data indicate increased susceptibility to atherosclerosis.

Familial Dyslipidemia

Familial dyslipidemia may be a variant of the familial hypertriglyceridemias described previously. It is characterized by hypertriglyceridemia in combination with low HDL cholesterol. Patients are generally overweight, with male pattern obesity, insulin resistance, diabetes, and hypertension. These subjects have both increased hepatic triacylglycerol secretion and increased HDL apo A-I catabolism.

Familial Combined Hyperlipidemia

Familial combined hyperlipidemia (FCH) was initially described as the combination of hypercholesterolemia and hypertriglyceridemia within the same kindred, and with kindred members having one of these abnormalities or both. Moreover, most subjects with FCH have HDL cholesterol levels below the 10th percentile. Affected subjects have elevation in VLDL, LDL, or both. This disorder has a frequency of approximately 10% in survivors of

premature myocardial infarction (less than 60 years of age) and about 14% in kindred with CHD.

It has been reported that affected subjects have overproduction of apo B-100. The precise molecular defect has not been elucidated, although there are already several candidate gene loci, including the LPL. The expression of this disorder may be triggered by other factors, such as overweight, hypertension, diabetes, and gout. The treatment should include diet and exercise and, if necessary, niacin, HMC CoA reductase inhibitors, or fibrates, depending on the major lipid present in excess.

Familial Hyperapobetalipoproteinemia

Familial hyperapobetalipoproteinemia is characterized by apo B values above the 90th percentile in the absence of other lipid abnormalities; it has been suggested to be a variant of FCH. This disorder is relatively common (~5%) in kindreds with premature CHD. The molecular defect is not known, but metabolic studies suggest overproduction of apo B-100.

Familial Hypoalphalipoproteinemia

Severe HDL deficiency, characterized by HDL cholesterol levels $<10\,mg\,dl^{-1}$ is rare and may be due to Tangier disease, apo A-I deficiencies, LCAT deficiency, or fish-eye disease. The apo A-1 deficiency states are due to rare deletions, rearrangements, or point mutations within the apo A-I/C-III/A-IV gene complex. Familial hypoalphalipoproteinemia is relatively common and is characterized by HDL cholesterol levels below the 10th percentile of normal. These subjects have been reported to have either decreased HDL production or increased HDL apo A-I catabolism. This phenotype is present in about 4% of kindred with premature CHD.

The genetic defect or defects are not known; however, it has been suggested that familial combined hyperlipidemia, familial hyperapobetalipoproteinemia, familial dysbetalipoproteinemia, and familial hypoalphalipoproteinemia may be variants of a single disorder. This disorder is characterized by a genetic predisposition in subjects consuming high-fat, high-cholesterol diets to an increased secretion of apo B-containing lipoproteins and an increased catabolism of apo A-I-containing lipoproteins. The expression of the phenotype is usually enhanced by the presence of male pattern obesity.

Familial Lipoprotein (a) Excess

Lipoprotein (a) (Lp(a)) is an LDL particle with one molecule of apolipoprotein (a) attached to it. Elevated levels of Lp(a) (>35–$40\,mg\,dl^{-1}$ or 90th percentile) have been associated with premature CHD. This increased risk appears to result from two different mechanisms: cholesterol deposition in the arterial wall and inhibition of fibrinolysis.

Lp(a) concentrations are highly variable among individuals; however, they tend to remain constant during a person's lifetime. Between 80 and 90% of the variability appears to be of genetic origin, owing, for the most part, to variations at the structural apo(a) gene locus. Lp(a) concentrations are inversely associated with a size polymorphism of apo(a). This polymorphism is due to differences in the number of a multiple repeat of a protein domain highly homologous to the kringle 4 domain of plasminogen. Diets and medications used to lower LDL cholesterol levels do not appear to have a significant effect on Lp(a) concentrations; however, niacin has been reported to decrease Lp(a) levels. There have been reports suggesting that diets high in *trans* fatty acids have some raising effects on Lp(a) levels, whereas estrogen replacement lowers Lp(a) in postmenopausal women.

General Guidelines for the Treatment of Lipoprotein Abnormalities for CHD Prevention

There is a clear benefit from lowering LDL cholesterol with diet or drug therapy in patients with hyperlipidemia or CHD or both. Dietary therapy includes using diets that are restricted in total fat (<30% of calories), saturated fat (<7% of calories), and cholesterol ($<200\,mg\,day^{-1}$). Pharmacological therapies include anion exchange resins, niacin, and HMG CoA reductase inhibitors. The latter agents have been demonstrated to also lower CHD mortality. It should be noted that dramatic interindividual variations have been demonstrated in response to diet and drug therapies. Consequently the efficacy of hypolipidemic therapies will vary from individual to individual. More information is needed about the benefits of HDL cholesterol raising in patients with low HDL cholesterol levels as well as the benefits of lowering triacylglycerol plasma concentrations, and more specifically the triacylglycerol carried in lipoprotein remnants. This is also true regarding the benefits of Lp(a) lowering using niacin in patients with elevated Lp(a) levels.

LIVER DISORDERS

J Hampsey and K B Schwarz, Johns Hopkins School of Medicine, Baltimore, MD, USA

This article covers the role of the liver in normal nutrition, including the important functions of bile salt production, macronutrient metabolism, and fat-soluble vitamin absorption, metabolism, and storage. Next, the pathogenesis of malnutrition in liver disease is discussed, starting with the mechanisms of malnutrition in both acute and chronic liver failure. Specific nutritional issues in liver failure are addressed, including metabolic disturbances of carbohydrates, protein, and fats. Nutritional disturbances in the major types of specific liver diseases are reviewed: hepatocellular, metabolic liver disease, and biliary tract disorders. Nutritional assessment and management of patients with acute, chronic liver disease and end stage liver disease are discussed.

Liver in Normal Nutrition

Bile Salts

A normal functioning liver will secrete 600–1200 ml of bile to the gall bladder on a daily basis. Bile is made up of bile salts, lecithin, conjugated bilirubin, phospholipids, cholesterol, electrolytes, and water. Bile salts, which are the predominant component of bile, are synthesized from cholesterol in the hepatocyte. The primary function of bile salts lies in their interaction with lipid digestion. Bile salts bind with large fat particles, which alone are insoluble in water, and act on them as an emulsifier, breaking down into smaller particles called micelles. Micelles, the product of the fat particle and bile salt structure, aid in the transport of fat to the mucosal membrane for absorption. Fat-soluble vitamins and cholesterol are also incorporated into mixed micelles for proper absorption.

Micellar solubilization is only required for long-chain fatty acids. Short-chain fatty acids (10 carbons

or less) do not require micelle formation for absorption; instead, they enter the portal circulation directly, bound to albumin, and are transferred to the liver for oxidation. Approximately 94% of the micelle forming bile acids are reabsorbed in the ileum and shuttled via the portal hepatic vein bound to albumin back to the liver. Only 6% of bile acids are lost in excretion.

Macronutrient Metabolism

Carbohydrates The liver is responsible for maintaining normal blood glucose concentrations under various metabolic conditions. Among the several metabolic processes that allow this fine regulation are glycogenesis, gluconeogenesis, and glycolysis. The end product of carbohydrate digestion is 80% glucose, with the remaining 20% being fructose and galactose; the latter two are quickly converted into glucose in the liver. Once transported into the hepatocyte, the glucose molecule is phosphorylated (via glucokinase) and cannot leave the cell unless dephosphorylated with glucose phosphatase. Glucose is either used for immediate energy release or stored as glycogen.

Proteins The liver plays a major role in protein metabolism in the deamination of amino acids, urea formation for removal of ammonia, plasma protein synthesis, and in the interconversions among amino acids. Ingested protein is the sole source of the 10 essential amino acids and the primary source of nitrogen necessary for the synthesis of other amino acids. Protein is digested and broken down to amino acids that are absorbed into the circulation and taken to cells throughout the body, primarily the liver, and quickly become combined by peptide linkages. The plasma level of amino acids is tightly controlled and maintained near a constant level. Once the cellular limit of protein storage is met, excess amino acids are degraded and used for energy or stored as fat or glycogen. The liver is the primary site of all amino acid catabolism with the exception of branch-chained amino acid catabolism, which occurs in the muscle cells. The urea cycle, in which the toxic compound ammonia is converted to urea, occurs solely in the liver. The synthesis of the plasma proteins albumin, fibrinogen, and globulin also occurs in the liver.

Lipids The liver plays a role in fat metabolism in four key processes: fatty acid oxidation for energy, lipoprotein syntheses, the synthesis of cholesterol and phospholipids, and the conversion of carbohydrate to fat for storage. Digested fat is a major source of energy in which after splitting into fatty acids and glycerol, the fatty acid components further split via beta oxidation into acetyl-CoA. Two molecules of acetyl-CoA become paired together to form acetoacetic acid and are transported to other cells to provide energy in the citric acid cycle.

Fat-soluble vitamins The liver plays a key role in the absorption of the fat-soluble vitamins—A, D, E, and K—as they are only successfully absorbed in association with fat and sufficient quantities of bile salts. The liver is also the primary storage site for several vitamins, including A, E, K, and B^{12}. Vitamin A is stored in the largest quantity in a sufficient amount to prevent deficiency for 5–10 months. Vitamin D is stored in amounts sufficient for 2–4 months. Vitamin B_{12} is stored in amounts sufficient for at least 1 year. The liver is responsible for the hydroxylation of vitamin D to its storage form, 25-hydroxy vitamin D. It is released into circulation and thence delivered to the kidney where it is converted to its active form, 1, 25-dihydroxy vitamin D.

Specific Nutritional Issues

Carbohydrates As discussed earlier, the liver plays a major role in the maintenance of normal blood sugar levels and overall glucose metabolism. Not surprisingly, in the patient with liver disease, glucose intolerance and insulin resistance are common. Cirrhotic patients are prone to developing diabetes. Energy from carbohydrates plays an important role in protein sparing mechanisms, preventing the use of protein as energy.

Lipids In cholestatic liver disease there is malabsorption of dietary lipid and consequent malnutrition. There are experimental data from primates showing that chronic ethanol consumption results in a decrease of liver phospholipids and of phosphatidylcholine (PC). Consequently, the total phospholipid content of the mitochondrial membranes is decreased; mitochondria are altered both structurally and functionally. There is diminished mitochondrial oxidation because of decreased cytochrome oxidase activity, which can be restored by administration of PC. The extent to which chronic liver disease of etiologies other than chronic ethanol consumption results in similar perturbations is unknown.

Protein Plasma proteins such as albumin and coagulation factors constitute approximately 50% of the proteins synthesized in the liver. In liver disease, decreased synthesis of these proteins has important clinical consequences, including ascites from

hypoalbuminemia and coagulopathy from decreased synthesis of coagulation factors. In end stage liver disease, hypoglycemia can result from decreased hepatic gluconeogenesis from amino acids. Decreased activity of the urea cycle enzymes results in hyperammonemia and hepatic encephalopathy, the ultimate expression of which can be cerebral edema.

Fat-soluble vitamins Deficiencies of fat-soluble vitamins are common in liver disease associated with steatorrhea due to the concomitant malabsorption of fat. Vitamin A deficiency can result in anorexia, growth failure, decreased resistance to infections, and night blindness. Vitamin D deficiency results in osteopenia or osteoporosis as well as rickets. The prevalence of fractures is increased in women being treated for alcohol abuse and also following sobriety; deficiencies of vitamin D as well as calcium, phosphorus, and fluoride may play a role. The deficiency of vitamin E results in neuraxonal dystrophy, clinically manifesting as peripheral neuropathy and cerebellar disturbances. Vitamin K deficiency results in hemorrhage because of reduced synthesis of clotting factors.

Trace elements Zinc deficiency in cirrhotics may contribute to hypoalbuminemia and dermatitis as well as anorexia from hypogeusia. Deficiency of selenium can lead to decreased synthesis of important antioxidant selenoproteins such as glutathione peroxidase. Little is known about the effect of acute or chronic liver disease on other trace elements.

Liver in Specific Hepatobiliary Disorders

Hepatocellular Diseases

Alcoholic liver disease The term 'alcoholic liver disease' refers to a spectrum of types of hepatic injury associated with continuous alcohol ingestion, ranging from alcoholic fatty liver to alcoholic steatohepatitis, fibrosis, and cirrhosis. Nutritional disturbances in alcoholics are an important cause of morbidity and mortality; all classes of nutrients are affected. Anorexia leads to decreased food intake and subsequent protein-calorie malnutrition. Maldigestion and malabsorption can occur secondary to chronic alcohol injury to small intestinal mucosa. Alcohol consumption is often associated with chronic pancreatic insufficiency, which results in steatorrhea and decreased absorption of dietary protein, fat, and fat-soluble vitamins. Chronic alcohol ingestion also results in impaired hepatic amino acid uptake and protein synthesis.

In alcoholics, utilization of lipids and carbohydrates is markedly compromised due to an excess of reductive equivalents and impaired oxidation of triglycerides. Alcoholics are often resistant to insulin and exhibit impaired uptake of glucose into muscle cells. Insulin-dependent diabetes is common. Heavy alcohol consumption is frequently associated with deficiencies of a wide variety of micronutrients, including the fat- and water-soluble vitamins, particularly folate, pyridoxal-5′-phosphate, thiamine, and vitamin A.

Table 1 summarizes the five published controlled trials of the effect of oral or enteral nutritional supplements on patients with alcoholic hepatitis. In most, nitrogen balance and/or protein synthesis improved, although no effect on mortality was shown, perhaps because of the small number of patients studied and/or the duration of follow-up. In the largest study, at 1-year follow-up, the experimental group had a significantly better survival: 2/24 (8%) died compared to 10/27 (37%) of the controls. In general, the effects of parenteral nutrition in alcoholic liver disease are similar to those noted the studies of enteral nutritional supplements.

Many studies have examined the effect of oral or enteral nutritional supplementation in patients with alcoholic cirrhosis. Results are summarized in **Table 2**. Many studies are small and of short duration, so it is not surprising that results are inconclusive. Most studies demonstrated an improvement in nitrogen balance and protein synthesis; only one showed increased survival in the treated group. Taken together, these studies suggest that there are benefits to nutritional supplementation in this population.

A variety of international associations have made nutritional recommendations for patients with various types of alcoholic liver disease. The primary recommendation is of course abstinence, which may be all that is needed in patients with fatty liver. Patients with alcoholic hepatitis should take 40 kcal/kg, 1.5–2.0 g protein/kg, 4–5 g/kg of carbohydrates, and 1–2 g/kg of lipids per day. Those with cirrhosis without malnutrition should take 35 kcal/kg, 1.3–1.5 g protein/kg, and carbohydrates and lipids as recommended for patents with alcoholic hepatitis. Those with cirrhosis and malnutrition should take higher amounts of protein (1.5–2.0 g/kg) and lipids (2.0–2.5 g/kg) and lower amounts of carbohydrates (3–4 g/kg). Fluid should be restricted to 2–2.5 l/day and all eight B vitamins, including folate and thiamine, as well as vitamins C and K should be routinely supplemented. In addition, patients with cholestasis should take 50% of their dietary lipids as medium-chain triglycerides

and should be supplemented with the fat-soluble vitamins—A, D, E, and K. The major strategy in the management of alcoholic cirrhotics with ascites and edema is to restrict fluids to 1–1.5 l/day and to restrict sodium as well.

Autoimmune liver disease The two major categories of autoimmune liver disease are primary biliary cirrhosis (PBC), a disease generally presenting in young female adults, and autoimmune hepatitis, which also most frequently presents in adults but can affect both sexes and present at any time from young childhood to mid-adulthood. PBC results in steatorrhea and malabsorption of the fat-soluble vitamins. Osteoporosis and osteopenia are common.

The nutritional consequences of autoimmune hepatitis, which can evolve into cirrhosis, are similar to those of alcoholic hepatitis and cirrhosis secondary to alcoholic liver disease, and thus the management is similar as well. Occasionally, autoimmune hepatitis can be accompanied by intestinal diseases such as inflammatory bowel disease or celiac disease, and the nutritional management should take both organ systems into account. Although mild liver function abnormalities are common in celiac disease, there are reports of celiac disease in patients with severe liver disease, all of whom demonstrated an improvement in their liver disease with introduction of a gluten-free diet.

Neonatal cholestasis The major differential diagnosis of conjugated hyperbilirubinemia in the first 30 days of life is extrahepatic biliary atresia and the neonatal hepatitis syndrome, for which a large number of specific genetic disorders have been identified. These include α-1 antitrypsin deficiency, inborn errors of bile salt synthesis or transport, cystic fibrosis/liver disease, Alagille syndrome, hypothyroidism, and panhypopituitarism. The nutritional consequences are similar for all: steatorrhea and malabsorption of the fat-soluble vitamins and failure to thrive. Nutritional management is also similar for all: use of an elemental formula rich in medium-chain triglycerides (MCTs) and supplementation with vitamins A, D, E, and K. Water-miscible vitamin E is poorly absorbed; administration of vitamin E solubilized in polyethylene glycol succinate is a more effective way to administer vitamin E to cholestatic infants.

Nonalcoholic fatty liver disease and nonalcoholic steatohepatitis Nonalcoholic fatty liver disease (NAFLD) and nonalcoholic steatohepatitis (NASH) have become very important causes of liver disease in both children and adults, particularly because obesity is being diagnosed in epidemic proportions in both age groups and both liver disorders are most commonly associated with obesity. Children with NAFLD may present before their fifth birthday. The disorder is more common in males. Hepatic fibrosis is common and may even evolve into cirrhosis during childhood. Treatment consists of weight reduction and aerobic exercise. Vitamin E may be beneficial.

In adults, NASH and NAFLD have been recognized for at least 25 years as chronic liver diseases associated with obesity (with or without non-insulin-dependent diabetes mellitus and with or without hyperlipidemia). NAFLD may account for as much as 80% of cases of elevated liver enzymes in the United States. Most adults with the disorders are 110–130% above ideal body weight. The prognosis of NAFLD is good if weight reduction is achieved. NASH is usually slowly progressive but can lead to cirrhosis and the need for liver transplantation in the minority of individuals affected.

In many patients, NAFLD is a component of the insulin-resistance syndrome known as the 'metabolic syndrome,' which is characterized by central obesity, hypertension, hypertriglyceridemia, low levels of high-density lipoprotein-cholesterol, and hyperglycemia. In patients with this syndrome, it is hypothesized that there is greater insulin resistance in muscles and adipose tissue than in liver. As shown in **Figure 1**, in adult patients with NAFLD, the body mass index class $>30\,kg/m^2$ is associated with an increased prevalence of each of the five components of the metabolic syndrome.

As shown in **Table 3**, compared to controls, patients with NASH exhibited a higher intake of

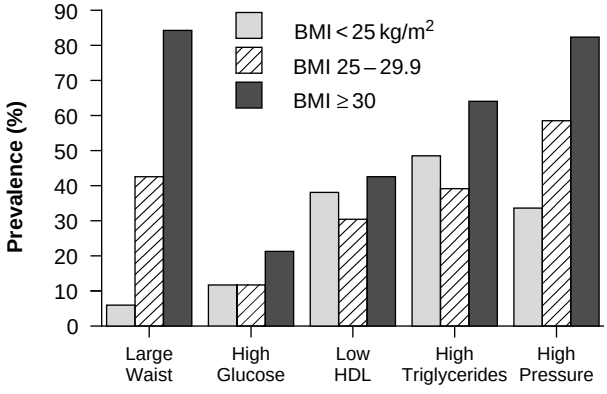

Figure 1 Prevalence of metabolic alterations fitting the criteria of the metabolic syndrome in patients with NAFLD according to classes of body mass index. (Reproduced with permission from Marchesini G, Buigianesi E, Forlani G *et al.* (2003) Nonalcoholic fatty liver, steatohepatitis, and the metabolic syndrome. *Hepatology* **37:** 917–923.)

Table 3 Daily intake of main dietary constituents in NASH patients and controls[a]

	NASH patients (n = 25)	*Controls (n = 25)*	*p value*
Total energy intake (kcal)	2638 ± 444	2570 ± 739	0.695
kcal/kg body weight	33 ± 5	32 ± 6	0.580
Dietary fat (g)	102.8 ± 31.6	92.1 ± 35.2	0.264
Dietary carbohydrate (g)	295.1 ± 53.7	315.2 ± 101.9	0.387
Dietary protein (g)	121.2 ± 25.2	107.2 ± 32.7	0.096
Alcohol (g)	13.3 ± 7.3	13.5 ± 8.9	0.705
Dietary fat (% kcal)	35.1 ± 7.1	32.3 ± 6.7	0.158

saturated fatty acids, total fat, and cholesterol and a lower intake of polyunsaturated fat, fiber, and the antioxidant vitamins C and E. These findings provide a strong rationale for specific dietary modifications in NASH patients.

Pregnancy and liver disease Liver diseases that predominantly affect females, such as PBC and autoimmune hepatitis, decrease the chances of conception and demand that pregnant women with these disorders should be managed in high-risk obstetric facilities. Liver diseases that can evolve as a consequence of pregnancy include intrahepatic cholestasis of pregnancy, acute fatty liver of pregnancy, and HELLP (hemolysis, elevated liver enzymes, and low platelets syndrome). The latter has been associated with disorders of fatty acid oxidation in offspring. Successful pregnancies are the rule for women who have undergone liver transplantation, but preterm delivery and low-birth-weight infants are common. Careful attention to the nutritional management of the pregnant female with liver disease is necessary to ensure the best outcome for the fetus.

Total parenteral nutrition-associated liver disease Premature infants and children with short gut syndrome are particularly prone to develop this disorder, and in the pediatric age group total parenteral nutrition (TPN) liver disease is usually cholestatic. The cholestasis can be solely intrahepatic or can be associated with cholelithiasis. TPN liver disease can be seen at any age and with any disease etiology resulting in long-term dependence on parenteral nutrition; in older children and adults, steatosis is more common as an initial presentation rather than cholestasis. Potential pathogenetic mechanisms include the gastrointestinal dysfunction associated with the lack of enteral nutrients as well as components of the parenteral nutrition solutions as potential hepatotoxins, including amino acids, glucose, lipids (particularly peroxidizable lipids), and photoexposed multivitamins. The most effective management is aggressive administration of enteral

nutrients and a decrease and/or discontinuation of parenteral nutrition as early as possible.

Viral hepatitis Hepatitis A virus infection never results in chronic liver disease, so there are no specific nutritional recommendations for patients with this disorder. Hepatitis B virus infection evolves to chronic hepatitis in ~95% of neonates who acquire the infection perinatally but only ~5% of adults. Hepatitis C virus (HCV) infection has a much higher rate of chronicity in adults—up to 80% of those infected will develop chronic infection. Approximately 20–30% of those will progress to cirrhosis over 10–20 years and a smaller proportion of those will develop hepatocellular carcinoma. There is much less information about nutritional disturbances and nutritional management of patients with chronic viral hepatitis than there is for patients with alcoholic liver disease.

In general, the nutritional recommendations for management of alcoholic hepatitis, cirrhosis, or cholestasis detailed previously can be applied to patients with these various manifestations of chronic viral hepatitis. For example, it has been shown that thiamine deficiency is common in patients with cirrhosis secondary to either chronic alcohol consumption or chronic HCV and thiamine supplementation is indicated for patients with either type of liver disease.

Metabolic Disorders

Galactosemia Galactosemia is secondary to the deficiency of galactose-1-phosphate uridyl transferase. Galactose-1-phosphate is toxic and accumulates in liver and other organs, causing liver failure in early infancy. The usual presentation is hypoglycemia and encephalopathy in the first few days of life. Vomiting, diarrhea, jaundice, and failure to thrive are common. Treatment is by elimination of galactose (and, consequently, lactose) from the diet for life. Liver function improves by this maneuver, but long-term complications such as mental disability, speech defects, ovarian failure, and neurologic syndromes are common despite dietary restriction.

Glycogen storage disease Glycogen storage disease (GSD) I, II, and III are the most common glycogen storage diseases to present with hepatomegaly. Type IV (amylopectinosis) is the only one of these disorders to present with cirrhosis; however, most of the disorders originate from deficiency of a key hepatic enzyme of glycogenolysis. The main nutritional management strategy, most important for types I and III, is the prevention of hypoglycemia; night time administration of cornstarch is often effective. Since restricted diets are key to the management of most inborn errors of metabolism, patients with these disorders are at high risk for nutrient deficiencies.

Hemochromatosis This disorder is among the most common autosomal recessive diseases in the world, occurring as frequently as 1/300. Two mutant alleles of the HFE gene are responsible for essentially all cases. Hepatomegaly and hepatic dysfunction as manifested by elevation of serum aminotransferases are common. Pancreatic dysfunction and darkening of the skin may occur. Transferrin saturation, serum iron concentration, and ferritin levels are the usual tests for iron overload, but molecular testing is rapidly becoming the diagnostic modality of the future. Liver biopsy may still be necessary to determine the degree of hepatic iron overload; management is by dietary iron restriction and phlebotomy.

Hepatorenal tyrosinemia I This disorder, which is secondary to deficiency of fumarylacetoacetate hydrolase, is the most common and severe of the genetic defects of tyrosine metabolism. Initial management is with a phylalanine- and tyrosine-restricted diet. The current intervention with 2-(2-nitro-4-trifluoro-methylbenzoyl)-1,3 cyclohexenedione (NTBC) has improved the quality of life of patients suffering from this disorder because it decreases the frequency of episodes of acute liver failure and coagulopathy.

Hereditary fructose intolerance This disorder results from a deficiency of the enzyme fructose-1-phosphate aldolase, which results in the accumulation of fructose-1-phosphate in the liver. This substance is a competitive inhibitor of phosphorylase, which regulates the conversion of glycogen to glucose. With inhibition of this enzyme, hypoglycemia and lactic acidosis result. The clinical presentation is with vomiting, diarrhea, choelestasis, and hepatomegaly, usually in early infancy. Renal injury and growth retardation are common. Standard treatment is restriction of fructose (and sucrose) from the diet and early treatment results in an excellent clinical outcome.

Urea cycle disorders There are six of these disorders, all of which present with varying degrees of hyperammonemia. In the neonatal period, these disorders present dramatically with somnolence, poor feeding, vomiting, lethargy, seizures, and even hyperammonemic coma. In older children and adults, the presentation may be more subtle and

begin with chronic vomiting, developmental delay, seizures, psychiatric illness, postpartum decompensation, and hyperammonemia associated with valproate therapy. Nutritional management includes restriction of upstream essential nutrients to prevent intoxication and supplementation of downstream nutrients to prevent secondary deficiency. In addition, alternative routes of disposal of precursor metabolites can be stimulated. For the severe deficiencies, including severe neonatal ornithine transcarbamylase deficiency and carbamyl phosphate synthetase deficiency, more aggressive strategies, such as liver transplantation and gene therapy, are being investigated.

Wilson's disease Wilson's disease is an autosomal recessive disorder of copper accumulation secondary to mutations in ATP7B, a copper-binding ATPase primarily expressed in the liver. The clinical expression in children and adolescents is often dramatic subacute hepatic necrosis or fulminant liver failure accompanied by hemolysis. In adults, the hepatic presentation is more subtle—manifestations of portal hypertension and cirrhosis, such as fatigue and ascites, and neuropsychiatric manifestations are common. The management of severe liver disease is liver transplantation. However, in the absence of severe liver disease, treatment is with a copper-restricted diet and copper chelating agents.

Hepatobiliary Disorders

Biliary atresia This disorder is the prototypic biliary tract disorder in infancy, accounting for ~50% of all liver transplants in the pediatric age group and ~10% of all liver transplants. It presents with cholestasis in early infancy; there is a palliative surgical procedure called the Kasai hepatic portoenterostomy that, if performed before 60 days of age, may at least delay disease progression. In ~20–25% of infants in whom the procedure is done in a timely fashion, liver transplantation may never be necessary. Severe steatorrhea and malnutrition are common and malabsorption of the fat-soluble vitamins is profound, sometimes requiring parenteral administration (particularly of vitamin K) to achieve sufficiency. Nutritional deficiency disorders such as osteoporosis are common.

Primary sclerosing cholangitis This disorder most commonly presents in association with ulcerative colitis and less commonly with Crohn's disease or as an isolated entity. The nutritional management of the disorder is essentially like that of other cholestatic disorders; in patients with Crohn's disease of the small bowel, aggressive administration of an elemental diet rich in medium-chain triglycerides may be beneficial. It is accepted, however, that endoscopic interventions should be used as needed in the case of significant biliary obstruction. For prevention of severe osteoporosis, supplementation with vitamin D and calcium is needed. Vitamin K and alendronate may be beneficial in increasing bone mineral density. Serum levels of the fat-soluble vitamins should be monitored in high-risk patients and vitamins replaced as appropriate.

Nutritional Management

Acute Liver Failure

The nutritional status of someone with acute liver failure versus chronic liver failure can differ greatly. The primary goal of the nutritional management in acute liver failure is supportive. An increase in nausea, vomiting, and anorexia may be associated with acute liver disease, which may result in decreased oral intake. If normal nutritional status prior to the insult is assumed, the patient will have a much higher nutritional reserve than that of a patient in chronic liver failure. Energy needs can be met by providing the Dietary Reference Intakes for infants and children and approximately 30 kcal/kg for adults. The provision of adequate protein is crucial in fulminant hepatic failure and encephalopathy. Adequate protein must be provided to minimize catabolism, which may exacerbate any hyperammonemia present. Excessive protein intake should be avoided because it may increase ammonia levels.

Protein recommendations for adults and teenagers are 0.5–1.0 g/kg/day and for infants and children 1.2–1.5 g/kg/day. Additional protein restrictions or an increase in the intake of branched-chain amino acids intake may be beneficial. In health, the ratio of branched-chain amino acids/aromatic amino acids (leucine + isoleucine + valine/phenylalanine + tyrosine) = ~3:1, and in liver failure the ratio may decline to ~1, often in association with some degree of hepatic encephalopathy. There are data indicating that normalization of this ratio by administration of branched-chain amino acid formulae can improve hepatic encephalopathy.

Chronic Liver Disease

Chronic liver disease is often accompanied by nutritional deficiencies. The goals of nutritional management are to provide adequate energy and protein to prevent energy deficits and protein catabolism and to

Table 4 Management of chronic liver failure in children

Nutritional support
Energy intake, 120–150% (recommended daily amount)
Carbohydrate, 15–20 g/kg/day
Protein, 3–4 g/kg/day
Fat, 8 g/kg/day (50% medium-chain triglyceride)
Fat-soluble vitamins
Fluid balance
Avoid excess sodium (<2 mmol/kg)
Ascites: spironolactone (3 mg/kg), furoseimide (0.5–2 mg/kg), albumin infusion, paracentesis
Encephalopathy
Low protein (2 g/kg)
Lactulose (5–20 ml/day)
Coagulopathy
Vitamin K (2–10 mg/day)
Fresh frozen plasma, cryoprecipitate, platelets

From Kelly DA (2002) Managing liver failure. *Postgraduate Medical Journal* **78**: 660–667.

promote hepatic cell growth. Recommendations for nutritional management of children with chronic liver disease are presented in **Table 4**. The energy need for adults with chronic liver disease is 30–35 kcal/kg/day. Energy requirements are increased to compensate for the weight loss that often occurs in cirrhosis. Protein should be provided as 0.8–1 g/kg for adults; unnecessary protein restriction should be avoided because it may only worsen total body protein losses. Energy from fat is best delivered as MCTs due to malabsorption of long-chain fatty acids. Several infant, pediatric, and adult formulas are available with a large percentage of fat in the form of MCTs.

Supplementation with fat-soluble vitamins (A, D, E, and K) in water-miscible solutions is necessary due to the potential for deficiencies associated with fat malabsorption. Serum levels should be monitored regularly to ensure appropriate levels and prevent toxicity. Supplementation with zinc, selenium, iron, and calcium should be given as needed. Copper and manganese should not be supplemented because they are excreted via the bile and may build to toxic levels. Sodium and/or fluid restrictions may be necessary in cirrhosis characterized by ascites and edema. This can impose difficulty because this restriction decreases the palatability of the diet, further decreasing oral intake.

End Stage Liver Disease Pre- and Post-Liver Transplantation

Maintaining optimal nutritional status is important in the patient with end stage liver disease both pre- and post-transplant. However, nutritional assessment in end stage liver disease is particularly problematic. In the pretransplant setting, fluid retention, ascites, and hepatosplenomegaly make body weight an unreliable nutritional index. True decreases in body weight, due to loss of fat stores and lean body mass, may not be fully appreciated solely following weight trends. In the pediatric population, linear growth is often a better indicator of nutritional status. Chronic malnutrition is often present, as reflected in a decrease in linear growth velocity.

Although anthropometric measurements, 24-h creatinine, bioelectric impedance analysis, and indirect calorimetry have all been used, they are affected by ascites and peripheral edema. *In vivo* neutron activation analysis and isotope dilution techniques are more accurate ways of assessing body composition but are time-consuming and costly. For practical purposes, the indirect assessments of 24-h urinary creatinine excretion to determine body muscle mass and mid-arm muscle area can be used for patients without high volumes of extracellular fluid; in those with ascites, the creatinine–height index is a better way of assessing body muscle mass.

Visceral proteins, including albumin, transferrin, prealbumin, and retinol binding protein, are typically used in monitoring nutritional status due to the decrease seen in inadequate dietary protein intake. However, they should be used with caution in liver disease because the synthesis of these proteins is also decreased in end stage liver disease. Serum levels of fat-soluble vitamins should be monitored closely as well.

Improving nutritional status prior to transplant is imperative because malnutrition affects morbidity and mortality post-transplant. Although it may not be possible to reverse the degree of malnutrition, aggressive nutrition support should be implemented to prevent further worsening of the nutrition state and possibly reduce pre- and post-transplant infection and complications.

Post-transplant nutrition support should not be overlooked because the nutrition deficit is not cured merely by the transplant. Additionally, the surgery poses increased nutritional demand for post-surgery healing and support. Nutrition repletion may occur at a more rapid rate than pretransplant because the patient now has a functional liver in which metabolism and digestion of macro- and micronutrients will be improved.

Causes, Prevalence and Prevention
Nutritional Management

Causes, Prevalence and Prevention

M Merialdi and M de Onis, World Health Organization, Geneva, Switzerland

It is widely accepted that weight at birth is a key indicator of fetal and neonatal health, both for individuals and for populations. The strong association between low birthweight and perinatal mortality and morbidity is now well recognized by health care providers, as are the different determinants and health consequences of low birthweight. These epidemiological associations became progressively evident during the past century. In the United States, the practice of weighing infants at birth was introduced at the end of the nineteenth century when low birthweight infants were categorized as 'premature' and usually left unattended with minimal or no intervention attempted to prevent their deaths. When information on birth weight and gestational age was introduced in the birth certificate in mid-twentieth century, it became apparent that prematurity was the most important cause of infant deaths at the national level.

With progressive awareness of the importance of low birthweight as a predictor of infant mortality, it appeared that being born small could be due either to a restriction of the normal process of fetal growth or to delivery before the term of gestation. Thus, the World Health Organization (WHO) made a distinction between the condition of low birthweight (birth weight less than 2500 g) and prematurity (delivery at less than 37 completed weeks, i.e., 259 days). A further development was the introduction of the concept of small for gestational age (SGA) that better describes infants affected by intrauterine growth restriction (IUGR). According to this classification, infants with birth weight below the 10th percentile of a reference population are considered SGA. Although these distinctions and definitions are commonly applied in developed countries, their use is

more difficult in developing countries where information on gestational age is often nonexistent or unreliable. This is unfortunate because low birthweight conditions due to growth restriction or preterm birth have different determinants and prognosis, as well as different epidemiological distributions that vary by country and socioeconomic status. Thus, before discussing the causes, prevalence, and prevention of low birthweight, it is important to understand how its two components (gestational age and fetal growth) can be correctly identified and quantified for epidemiological purposes and what are the major limitations in doing so.

Assessment of Gestational Age and Fetal Growth: Methods and Limitations

Preterm birth is defined as delivery before 37 completed weeks (259 days). To accurately differentiate between preterm and term delivery it is crucial to have a reliable estimate of gestational age. Sonographic determination is the most accurate method to estimate gestational age. When ultrasonography is not available, gestational age can be determined by patient's recall of the time of last menstrual period, physical examination of the size of the uterus, and examination of the neonate. These methods can be used alone or in combination but are inaccurate.

Early pregnancy sonographic estimation of gestational age is crucial also for estimation of fetal growth *in utero*, which is assessed by evaluating the size of several fetal anatomical parameters and comparing those measurements with the normal ranges at specific gestational ages obtained from reference populations with growth that can be considered unaffected by pathological conditions. Alternatively, fetal growth can be assessed by the anthropometrical evaluation of the neonate. Several classification systems have been proposed for newborn birth weight. The simplest is categorizing newborns <2500 g as having a low birthweight, but this classification does not differentiate between infants born small for their gestational age and infants who are small because they are born preterm. Reference charts of birthweight at different gestational ages classify infants as SGA, a proxy for IUGR; adequate for gestational age; and large for gestational age. WHO defines SGA as a birth weight below the 10th percentile for a given gestational age based on the sex-specific reference by Williams *et al*. Because it is based on percentile distributions, this classification categorizes some normal, constitutionally small, newborns at the lower end of the normal fetal growth distribution as growth restricted. In addition, the interpretation of the reference data is complicated by inaccuracies in the estimation of gestational age at delivery and by the pathological processes that may affect the size of infants born early in gestation.

Causes

Recognizing that low birthweight may be due to either IUGR or preterm delivery, and, in some cases, a combination of the two, the scientific community has progressively started to consider that IUGR and preterm delivery are two conditions likely caused by various and possibly independent etiopathological factors.

Several complications of pregnancy, such as preeclampsia, fetal distress, fetal growth restriction, abruptio placenta, fetal death, placenta previa, and multiple gestations, are associated with preterm delivery, either spontaneous or induced. Importantly, developments in obstetric and neonatal care, and the consequent increase in obstetric interventions, are likely to be associated with the increase in rates of preterm delivery observed in recent years. Although several lifestyle factors and conditions have been implicated as possible causes, a definitive etiology has not been determined, making it difficult to identify women at risk and to implement preventive strategies. Poor nutrition, cigarette smoking, and alcohol and drug abuse have been indicated as possible risk factors, as well as young maternal age, poverty, short stature, occupational factors, and psychological stress. In addition, genetic factors are likely to be involved in the etiopathogenesis of preterm delivery, as suggested by the fact that the condition tends to recur in families and that prevalence varies across races. The possible role of infection in triggering preterm delivery has been suggested by several studies that have shown associations between delivery before term and amniotic fluid and chorioamniotic infection, bacterial vaginosis, genitourinary clamydial infection, and periodontal disease. Despite the biological plausibility of these associations, their causal relationship has not been definitely proved by unequivocal scientific and epidemiological evidence.

Several conditions have been associated with intrauterine growth restriction. However, present knowledge of the process of fetal growth is limited by the difficulty of differentiating between constitutional and environmental determinants of fetal growth. This limitation complicates the investigation of an important determinant of fetal growth such as maternal size. Small women tend to have smaller

babies. There is evidence that intergenerational effects on birth weight are transmitted through the maternal line, thus suggesting a genetic effect. However, poor maternal nutrition and social deprivation have been related to impaired fetal growth and may also be related to small maternal size. Similarly, the relationship between fetal size and race may be mediated by genetic and environmental factors. Specifically designed studies are necessary to determine the contribution of genetic and environmental determinants to the process of fetal growth.

Other factors that have been associated with fetal growth restriction are fetal infections, congenital malformations, chromosomal abnormalities, chemical teratogens, vascular disease such as preeclampsia, chronic renal disease, chronic hypoxia, placental and cord abnormalities, and multiple fetuses.

Health Consequences

Low birthweight, due to either preterm delivery or IUGR, is associated with increased neonatal mortality. Mortality tends to increase with decreasing gestational age at delivery and birth weight (**Figures 1 and 2**). Preterm delivery is the most important obstetric complication in developed

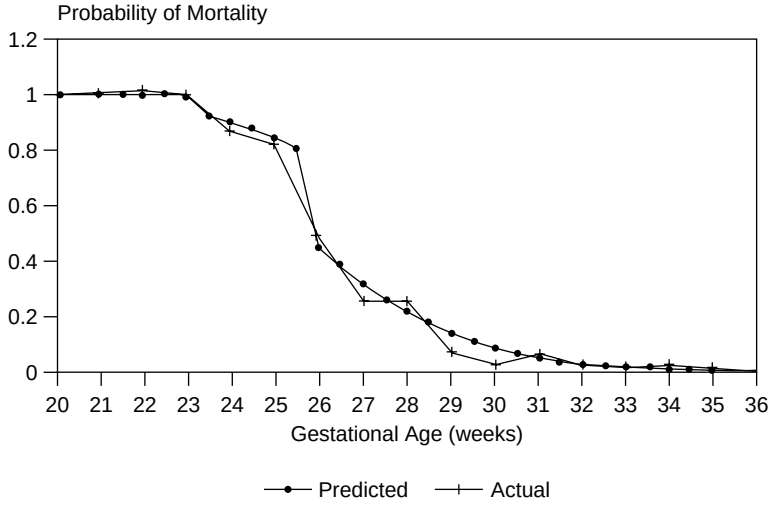

Figure 1 Probability of neonatal mortality as a function of gestational age at delivery in 3386 births between 20 and 37 weeks. The predicted mortality curve is smoothed using statistical methods. Reproduced with permission from Copper RL *et al.* (1993) A multicentre study of preterm birth weight and gestational age-specific neonatal mortality. *American Journal of Obstetrics and Gynecology* **168**: 78–84.

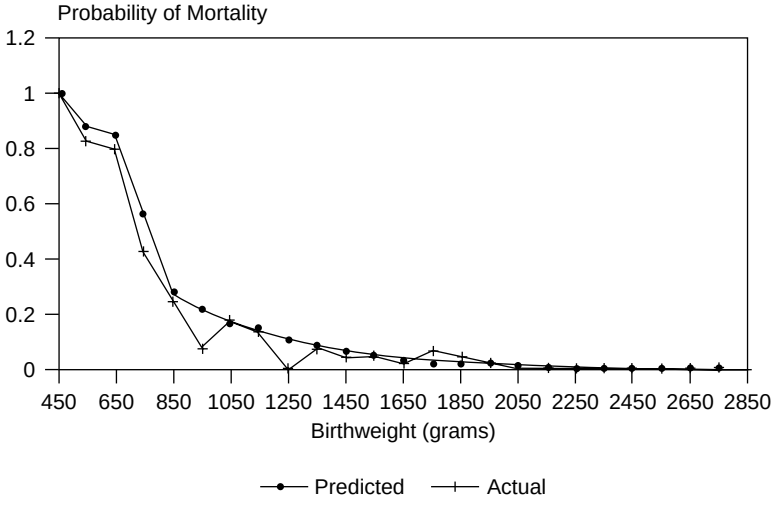

Figure 2 Probability of neonatal mortality as a function of birthweight in 3386 births between 20 and 37 weeks. The predicted mortality curve is smoothed using statistical methods. Reproduced with permission from Copper RL *et al.* (1993) A multicentre study of preterm birth weight and gestational age-specific neonatal mortality. *American Journal of Obstetrics and Gynecology* **168**: 78–84.

countries and, together with IUGR, a major cause of neonatal deaths both in developed and in developing countries. However, the burden of disease of preterm delivery and IUGR in terms of neonatal death is disproportionally heavier for developing countries. Ninety-eight percent of neonatal deaths occur in developing countries, and they account for 33% of all deaths of children younger than 5 years of age. Importantly, 50% of all neonatal deaths are due to being born underweight.

Morbidity is also increased in low birthweight newborns and the negative effects of preterm delivery and/or IUGR tend to persist in infancy as deficits in growth and neurological development. In addition, there is evidence that the negative effects of IUGR may persist long after infancy because low birthweight has been associated with the development of cardiovascular disease, high blood pressure, obstructive lung disease, diabetes, high cholesterol concentrations, and renal damage in adulthood.

Epidemiology

Table 1 shows estimates of prevalence of low birthweight, IUGR, and preterm delivery from three major multicountry studies: the WHO Antenatal Care Trial, the WHO Collaborative Study on Pregnancy Outcomes, and the WHO Misoprostol Trial. The data presented demonstrate that the distribution of low birthweight varies across populations, and the observed differences are due to the varying contribution of preterm delivery and IUGR to the total rates of low birthweight. Rates of low birthweight are higher in developing than in developed countries, as shown by the data presented in **Table 2**. Data from 11 developed areas and 25 developing ones indicate that rates of low birthweight steadily increase as the level of development decreases. The observed differences in low birthweight rates between geographical areas are enormous, with rates ranging from as low as 3.6% in Sweden to as high as 43% in Mumbai, India. Importantly, a global review of the magnitude of the problem demonstrates that many countries currently exceed the internationally recognized cutoff levels for triggering public health action (IUGR >20% and low birthweight (LBW) >15%). Most of low birthweight infants born in developed countries are the result of preterm delivery, whereas in developing countries they are more likely to be IUGR infants. In addition, differences in the distribution of low birthweight are observed at country level, as indicated by the higher prevalence of low birthweight (due mainly to preterm delivery) among African Americans compared to other ethnic groups in the United States.

Prevention

Results from clinical trials provide the most powerful scientific evidence to guide policy and programmatic public health strategies. Interventions aimed at preventing low birthweight either acting toward preterm delivery or IUGR have usually not proven to be effective by randomized clinical trials. The multicausal nature of these conditions is likely responsible for the fact that single interventions do not show an effect of enough magnitude to be detected by medium-sized clinical trials. Thus, appropriate combinations of interventions should be a priority for evaluation in the context of large, methodologically sound trials. Evidence shows that some interventions may be effective and their combined implementation may have a significant public health impact. Interventions likely to be beneficial in preventing IUGR are smoking cessation, antimalarial chemoprophylaxis in primigravide, and balanced protein energy supplementation. Treatment of urinary tract infection, placement of circumferential stitches on a structurally weak uterine cervix (cerclage), and treatment of bacterial vaginosis in high-risk women have been shown to be effective in preventing preterm birth. Unfortunately, these interventions are applicable only to a small number of high-risk women, and their overall effect in the general population is likely to be limited.

In the following sections, nutritional interventions to prevent preterm delivery and IUGR are reviewed with the aim of identifying potentially effective interventions and suggesting possible mechanisms that may link maternal nutritional status to low birthweight. The focus is on the review of randomized clinical trials that provide the most unbiased epidemiological evidence on the effectiveness of interventions. Clinical trials testing the same or similar interventions can be pooled together to estimate an overall effect by means of a systematic review of published and unpublished studies and the meta-analysis of the trials' results.

Nutritional Interventions to Prevent Preterm Delivery

Of the nutritional interventions conducted during pregnancy that have been tested by clinical trials to prevent preterm delivery, only calcium and fish oil supplementation appear promising. In addition, nutritional advice and magnesium supplementation are likely to be effective; however, methodological problems in the analysis of the trials' results prevent from drawing definitive conclusions. Most of the other

interventions that have been hypothesized to have potential to prevent preterm delivery, such as protein and energy supplementation, protein and energy restriction, salt restriction, iron and/or folate supplementation, zinc supplementation, and vitamin A supplementation, have not been proved to be effective.

Nutritional Interventions to Prevent IUGR

Among the interventions that have been tested by randomized clinical trials to prevent IUGR, balanced energy protein supplementation has been shown to reduce the risk of SGA by approximately 30%. On

the basis of these results, it has been proposed that universal balanced energy supplementation should be provided to women in areas with a high prevalence of maternal undernutrition to prevent impaired fetal growth. There is evidence that magnesium supplementation and calcium supplementation may be effective, even though for the latter it is not clear if the observed effect on low birthweight is due to a direct effect on fetal growth or mediated by a prolongation of gestational age at delivery. Other interventions, such as nutritional advice, energy protein restriction, salt restriction, iron and/or folate supplementation, fish oil supplementation, zinc supplementation, and vitamins E, C, and D supplementation, did not show any effect in preventing IUGR. Interestingly, high protein supplementation in women of low socioeconomic status in the United States has been associated with an increase in the rate of SGA infants, suggesting that nutritional supplementation may, in some cases, have potentially harmful effects.

Conclusion

Low birthweight, due to either preterm delivery or IUGR, represents a major public health problem for developing and developed countries. In developed countries, access to adequate obstetrics and neonatal care prevents most of the negative short- and long-term outcomes associated with low birthweight that are observed in developing countries in terms of both mortality and morbidity. Thus, public health efforts should be aimed at improving the level and accessibility of health care in developing countries. This is particularly important because most preventive strategies have been shown by clinical trials to be ineffective. Among nutritional interventions to prevent low birthweight, only balanced energy protein supplementation has been shown to be effective in reducing the risk of SGA and has been proposed to be provided to women in areas with a high prevalence of maternal undernutrition.

Research efforts should focus on the determination of the etiological factors responsible for preterm delivery and IUGR. Despite the considerable burden of disease related to these conditions, very little progress has been made in identifying their causes, thus limiting the possibility to implement effective preventive and primary care therapeutic interventions that would particularly benefit the populations of developing countries with limited access to secondary and tertiary health care.

Nutritional Management

J M Cox, Johns Hopkins Hospital, Baltimore, MD, USA

Introduction

Thanks to advances in modern medicine and technology the outcome of preterm infants has improved dramatically. Many infants are now surviving who are born as young as 23 weeks' gestation and as small as 450 g. These infants enter life with their maternal nutrient supply abruptly disconnected and with only minimal nutrient stores. There is no other time in the life cycle when nutrition is more crucial. Additionally, nutrition in this early neonatal period may have an impact upon health throughout life.

These infants are vulnerable to poor growth and abnormal developmental outcome if not nourished appropriately. Since the preterm infant lacks the ability to voluntarily consume and process nutrients, all of the infant's needs must be provided through enteral and frequently parenteral nutrition. Preterm infants have numerous nutritional risk factors. Nutrient stores are accumulated during the third trimester; therefore, preterm infants have low energy reserves as well as minimal reserves of other nutrients. In fact, infants with birth weights less than 1000 g have energy reserves of less than 200 kcal kg^{-1} (836 kJ kg^{-1}). The metabolic rate of the preterm infant is elevated due to the predominance of metabolically active tissue and minimal fat stores. Protein, fat, and glucose needs are very high to provide adequate energy for metabolism, fat deposition, and growth. The preterm infant has excessive evaporative losses and increased urinary losses, which greatly increase fluid needs. The gastrointestinal tract of the preterm infant is very immature with minimal production of enzymes and growth factors, poor gastric emptying, and discoordinated peristalsis. To further complicate the provision of nutrients, preterm infants have episodes of metabolic instability including hypo- and hyperglycemia, poor lipid clearance, and electrolyte disturbances. The preterm infant also has high rates of stressful events including respiratory distress, hypoxemia, hypercarbia, and sepsis.

Usually, the goal is to provide sufficient nutrients to achieve the fetal growth rate. However, since the fetus and newborn differ in both physiology and metabolism this may not be an appropriate goal and in actuality this goal is rarely achieved both in regards to growth as well as body composition. Most preterm and low-birth-weight infants show significant delays in growth due to the inability to provide adequate nutrients especially in the first few weeks following birth. Over the past several years, improvements in neonatal management and a more aggressive approach to nutrition have accelerated growth but it still lags behind the fetal growth rate. However, the growth potential of preterm infants may actually be greater than even that of the normal infant. Growth velocity in the infant is greatest between 25 and 30 weeks' gestation, greater than at 40 weeks. If the infant is undernourished during this key growth period, adequate catch-up growth may never be achieved. Protein and energy are the key nutrients for growth, but they must be provided in appropriate proportions for the optimal utilization of both. Vitamins, minerals, and electrolytes must also be supplied in adequate amounts and proportions to contribute to growth. During the first few weeks after birth most preterm infants are usually undernourished due to instability so that once stability is achieved an increased supply of nutrients may be necessary to achieve catch-up growth. Nutrients are usually supplied parenterally in the initial period, gradually transitioned to a combination of parenteral and enteral nutrition, and finally when stability has been achieved full enteral nutrition.

Energy Needs

Most estimates of energy expenditure in preterm infants have been done using indirect calorimetry in relatively healthy infants weighing greater than 1200 g. The energy needs of the smaller and more preterm infant may differ somewhat. Basically, energy needs of the preterm infant involve several energy-requiring functions. Resting metabolic rate accounts for the greatest percentage of energy needs. Resting metabolic rate is equivalent to basal metabolic rate plus some of the energy used for growth; estimates have ranged from 45 to 60 kcal kg^{-1} day^{-1}(188–251 kJ kg^{-1} day^{-1}). The energy cost of activity ranges between 2 and 12% of the total energy expenditure. The smaller more premature infants are probably at the lower end of the range while the larger less preterm infant has increased activity and therefore a higher expenditure. Although preterm infants are cared for in a thermoneutral environment, there is, nevertheless, energy lost to thermoregulation during nursing care and medical procedures. There may also be energy lost to thermoregulation in a stable growing infant during bathing, feeding, and when weaned to a bassinette. The energy cost of growth includes that needed for

Table 1 Energy needs of the growing preterm infant

Energy factor	*kcal kg^{-1}day^{-1}*	*kJ kg^{-1}day^{-1}*
Resting metabolic rate	45–60	188–250
Activity	10–15	42–63
Thermoregulation	10	42
Thermic effect of food	8	33
Fecal losses	12	50
Growth	25	105
Total	**110–130**	**460–545**

tissue synthesis as well as the energy stored in tissues. The estimates for growth needs vary widely probably depending on the composition of weight gain in the infant. For the enterally fed infant the thermic effect of food and fecal losses also contribute to total energy need. The total energy needs of the growing preterm infant are summarized in **Table 1**.

Parenteral Nutrition

Since the gastrointestinal tract of the preterm infant is immature, substantive enteral nutrition is not possible in the first 2–3 weeks after birth, especially in those infants whose birth weights are less than 1500 g; therefore, the preterm infant is dependent on intravenous fluid for the bulk of fluid needs. Parenteral nutrition (PN) is basically the infusion of a nutrient solution into the circulation. Its development has allowed for the provision of nutrients during the time that enteral nutrition cannot meet nutrient needs. The use of PN has reduced the catabolism that occurs until full enteral nutrition can be achieved. PN should definitely be considered in infants whose birth weights are $<$1500 g and/or gestational age $<$30 weeks. It may also be needed for the infant whose birth weight is between 1500 and 2000 g and/or gestational age 30–32 weeks especially if the initiation or progression of enteral feeding is likely to be prolonged.

Historically, parenteral nutrition was delayed for several days after birth, probably due to metabolic instability of the infant and concern for tolerance of the components in the solution. More recently, the early use of PN has been recommended within 24 h after birth. This practice minimizes the interruption of nutrient delivery and the catabolism that occurs when only dextrose solutions are infused.

Parenteral nutrition can be administered by two different routes. There are both risks and benefits associated with each route. In the early days of parenteral nutrition it was always infused via an indwelling, surgically placed catheter into a central vein. Since some of the complications with this method were related to the catheter, the use of peripheral veins for infusion became popular and is still employed today. The dextrose concentration of peripheral PN is limited to ~10%; thus, the nutrient intake by this route is somewhat limited without excessive fluid intake. Peripheral parenteral nutrition is usually recommended when its use will be of short duration. While peripheral lines are considered less risky complications can occur. If the intravenous line infiltrates some infants have experienced serious deep sloughing, sometimes requiring skin grafts. These lines require vigilance on the part of nursing to prevent infiltrates and some infants will have multiple intravenous attempts daily because the line needs to be replaced. The advent of the percutaneously inserted central catheter and its liberal use in the last few years has improved and stabilized the delivery of parenteral nutrition to the preterm infant. Central parenteral nutrition is recommended when it is anticipated that it will be used for $>$5–7 days, usually in infants weighing $<$1000–1250 g. If the infant tolerates glucose and clears lipids well it is possible to meet estimated nutrient needs using this route. Complications such as pneumothorax, pleural effusions, and increased risk of sepsis are associated with central lines (**Table 2**).

Components of Parenteral Nutrition

Parenteral nutrition solutions contain dextrose, amino acids, lipids, electrolytes, vitamins, and minerals.

Glucose Glucose, provided as a dextrose solution, is the predominant energy source in PN. It is the main energy substrate for the fetus as well as the

Table 2 Risks and benefits of parenteral nutrion routes

Peripheral	*Central*
Adequate for short-term use	Recommended when PN needed $>$7 days
Dextrose limited to 10–12.5%	Requires placement of central line/PICC line
Can provide 80–85 kcal kg^{-1} day^{-1} if adequate fluid available	Able to meet estimated needs if adequate fluid available
Possible complications	**Possible complications**
Intravenous line can infiltrate and cause deep skin sloughing	Sepsis
Requires nursing vigilance to care for intravenous line	Line complications (pleural effusions, pneumothorax)
Can require multiple intravenous attempts	

neonate after birth. Preterm infants often require more glucose than the term infant secondary to the higher brain to body weight ratio and the need for additional energy for central nervous system energy requirements. Measurements of glucose utilization in the preterm infant range from 6 to 10 $mg\,kg^{-1}\,min^{-1}$(0.033–0.055 $mmol\,kg^{-1}\,min^{-1}$). Glycogen stores are very limited in the preterm infant; therefore, it requires a large and continuous source of glucose. This should be initiated at a rate of ~6 $mg\,kg^{-1}\,min^{-1}$ (0.033 $mmol\,kg^{-1}\,min^{-1}$) and can be advanced 1–2 $mg\,kg^{-1}\,min^{-1}$ (0.0055–0.011 $mmol\,kg^{-1}\,min^{-1}$) each day to an optimum of 12–14 $mg\,kg^{-1}\,min^{-1}$ (0.066–0.78 $mmol\,kg^{-1}\,min^{-1}$) as long as the infant does not become hyperglycemic. Above this rate, glucose is not used for energy but rather fat deposition. This is an inefficient process that can result in increased energy expenditure and carbon dioxide production.

Difficulties with glucose metabolism are a common problem in preterm infants. This may be due to decreased energy stores, increased gluconeogenesis secondary to stress, decreased insulin secretion, or insulin resistance. When hyperglycemia occurs the glucose infusion rate should be decreased, however the rate should not be decreased below 4–6 $mg\,kg^{-1}\,min^{-1}$ (0.022–0.33 $mmol\,kg^{-1}\,min^{-1}$) as this is the minimum supply rate necessary to provide adequate energy to the brain. Usually, the infusion of amino acids improves glucose tolerance by decreasing glucose production, stimulating insulin secretion, and enhancing insulin action. The use of continuous insulin infusions to treat hyperglycemia is controversial. If used, the insulin infusion should be initiated at a rate of 0.05 $U\,kg^{-1}\,h^{-1}$ and titrated to achieve and maintain a plasma glucose concentration between 80 and 120 $mg\,dl^{-1}$ (4.44–6.66 $mmol\,l^{-1}$).

Protein The early administration of protein in the form of crystalline amino acids to the preterm infant is one of the changes to have occurred over the last decade. Early studies of amino acid administration in preterm infants in the 1960s and 1970s raised the concern for protein toxicity because these infusions were associated with acidosis, azotemia, and hyperammonemia; this caused a delay in the routine administraton of protein. However, the above conditions were probably the result of the preparations being casein or fibrin hydrolysates and of suboptimal quality. Since the 1980s crystalline amino acid solutions have been used. In the late 1980s amino acid solutions specifically for use in infants were designed to produce a plasma amino acid level comparable to that of a postprandial breast-fed infant.

The early administration of amino acids is crucial because studies have shown that the preterm infant suffers protein losses of between 0.8 and 1.2 $g\,kg^{-1}\,day^{-1}$. A number of studies have demonstrated that the infusion of amino acids along with glucose decreased protein catabolism. As little as 1–1.5 $g\,kg^{-1}\,day^{-1}$ of amino acids have been shown to prevent negative nitrogen balance. Studies have also shown that the infusion of 3 $g\,kg^{-1}\,day^{-1}$ within the first 2 days of life resulted in increased protein synthesis, suppressed protein breakdown, and produced plasma aminograms similar to the breast-fed infant.

The provision of adequate energy is needed for protein metabolism and deposition. Most infants can achieve positive nitrogen balance at 2 $g\,kg^{-1}\,day^{-1}$ of protein intake when given 50–60 $kcal\,kg^{-1}\,day^{-1}$ (209–251 $kJ\,kg^{-1}\,day^{-1}$) of energy. Additionally, approximately 22 kcal (92 kJ) per g protein (15–20% of kcal) results in reasonable amino acid utilization.

Therefore, protein should be started if possible on the first day of life at 1.5–2 $g\,kg^{-1}\,day^{-1}$ and advanced to 3.5–4 $g\,kg^{-1}\,day^{-1}$ to achieve *in utero* accretion rates.

Cysteine The amino acid cysteine is a conditionally essential nutrient in the preterm infant because they have low cystathionase activity. Cystathionase, an enzyme, is necessary to convert methionine to cysteine. However, this amino acid is unstable in liquid solutions so commercially available crystalline amino acid solutions do not contain cysteine. Plasma levels of cysteine are low in infants receiving cysteine-free PN. Cysteine hydrochloride however is soluble and is stable in aqueous solutions for a short period of time so 40 $mg\,g\,protein^{-1}$ is often added to PN solutions when prepared. The addition of cysteine may result in acidosis necessitating an increase in acetate. However, an additional advantage is that the addition of cysteine decreases the pH of the PN solution, which allows the addition of more calcium and phosphorous.

Lipids Lipids are the most concentrated source of calories in the PN solution. They are available as lipid emulsions of soy bean and safflower oil; 20% emulsions are recommended for use because they contain less phospholipid than the 10% emulsion. Lipids are critical for central nervous system development. Additionally, when infused with the PN solution they may also prevent phlebitis. Lipids are usually infused to prevent essential fatty acid deficiency and as an

energy source. Maximum lipid clearance occurs when lipids are infused over 24 h. Starting recommendations vary; but it is generally accepted to start with 0.5–1 g kg^{-1} day^{-1} between 1–3 days of life. Lipids should be advanced to an optimum of 3 g kg^{-1} day^{-1}. Studies have shown that preterm infants have optimal protein retention when approximately 30–40% of calories are provided as lipids. Plasma triglycerides can be used to monitor lipid clearance. It is generally accepted that levels below 150–200 mg dl^{-1} indicate adequate clearance. Lipoprotein lipase and hepatic lipase are the major enzymes for clearance of intravenous lipid. These activities are inducible by low-dose heparin, which is usually present in central PN solutions. Administration of heparin should be considered in those infants receiving peripheral PN showing poor lipid clearance. In infants with hypertriglyceridemia the provision of 0.5–1 g kg^{-1} day^{-1} of lipid is adequate to prevent essential fatty acid deficiency and is a dose likely to be tolerated by most infants.

Carnitine Carnitine is necessary for the transport of free fatty acids into the inner mitochondrial membrane, the site of oxidation. Since the preterm infant has decreased carnitine synthesis capability and low plasma and tissue concentrations, carnitine may be an essential nutrient. Studies are conflicting as to whether there is benefit to adding it to parenteral nutrition. Its use should be considered in infants with birth weights <1000 g, those receiving long-term parenteral nutrition without enteral feedings, and those with hypertriglyceridemia.

Electrolytes The electrolyte content of parenteral nutrition solutions is usually similar to that found in normal intravenous solutions: usually 3–4 mmol kg^{-1} day^{-1} of sodium and 2–3 mmol kg^{-1} day^{-1} of potassium. Very immature infants and those on diuretics may require additional amounts to maintain normal plasma concentrations. Chloride and acetate need to be dosed based on electrolyte levels. The very young preterm infant may need a higher proportion of acetate secondary to urinary bicarbonate losses. Later, when chronic diuretics are used a greater proportion of chloride may be needed.

Calcium, phosphorous, and magnesium Calcium and phosphorous are relatively insoluble in solution together. This makes it difficult to provide adequate levels of these minerals to meet the needs of the preterm infant. When parenteral nutrition solutions are advanced to 10% dextrose and 2 g protein per 100 ml usually 60–80 mg (1.5–2 mmol) calcium and 40–60 mg (1.3–1.9 mmol) phosphorous can be added to the solution. Since the accretion rate of calcium in the fetus is normally 100 mg kg^{-1} day^{-1} (2.5 mmol kg^{-1} day^{-1}), infants on prolonged parenteral nutrition may develop osteopenia and fractures. The usual dose of magnesium is 0.3–0.5 mEq kg^{-1} day^{-1} (0.3–0.5 mmol kg^{-1} day^{-1}).

Trace minerals Zinc and copper deficiencies occurred in some preterm infants before these trace elements were routinely added to parenteral nutrition solutions. There is very little research that defines the parenteral requirements of trace minerals in preterm infants. The current recommendations for trace minerals are summarized in **Table 3**.

Vitamins Like trace minerals, the recommendations for intake of vitamins are not based on randomized trials but are based on the best information available. Infants receiving these parenteral intakes do not develop deficiencies or evidence of excessive intake (**Table 4**).

Table 3 Suggested parenteral intakes of trace minerals

Trace mineral	*μg kg^{-1} day^{-1}*
Zinc	400
Iron	200
Copper	15–20
Selenium	1.5–2
Manganese	1
Iodide	1
Molybdenum	0.25
Chromium	0.2

Table 4 Suggested parenteral intake of vitamins

Vitamin	*Amount/per kg per day*
Vitamin A (μg)	280–500
Vitamin E (mg)	2.8
Vitamin K (μg)	100
Vitamin D (μg)	4
Vitamin (IU)	160
Ascorbic acid (mg)	25
Thiamin (μg)	350
Riboflavin (μg)	150
Pyridoxine (μg)	180
Niacin (mg)	6.8
Pantothenate (mg)	2
Biotin (μg)	6
Folate (μg)	56
Vitamin B_{12}	0.3

Total dose should not exceed the amounts provided by 5 ml of reconstituted MVI Pediatric (Armor Pharmaceutical Co., Chicago, IL, USA): 700 μg vitamin A, 7 μg vitamin E, 200 μg vitamin K, 10 μg vitamin D, 80 mg ascorbic acid, 1.2 mg thiamin, 1.4 mg riboflavin, 1.0 mg pyridoxine, 17 mg niacin, 5 mg pantothenic acid, 20 μg biotin, 140 μg folic acid, 1 μg vitamin B_{12}.

Table 5 Suggested initiation and advancement of parenteral nutrition for the preterm infant

Component	*Initial*	*Advancement/day*	*Goal*
Dextrose	6–8 m kg^{-1} min^{-1} (0.033–0.044 mmol kg^{-1} min^{-1})	1–2 mg kg^{-1} min^{-1} (0.0055–0.011 mmol kg^{-1} min^{-1})	12–14 mg kg^{-1} min^{-1} (0.066–0.077 mmol kg^{-1} min^{-1})
Protein	1.5–2 g kg^{-1}	1 g kg^{-1}	3.5
Lipids	0.5–1 g kg^{-1}	0.5–1 g kg^{-1}	3

Suggested initiation and advancement of parenteral nutrition in the preterm infant is shown in **Table 5**.

Enteral Nutrition

The provision of adequate enteral nutrition is the goal of those caring for the preterm infant. However, a fear of the development of necrotizing enterocolitis, a serious intestinal disease of preterm infants associated with enteral feedings, has influenced feeding practices. Necrotizing enterocolitis (NEC) is a major cause of morbidity and mortality in preterm infants. The incidence of this disease is estimated to be between 8 and 10% of preterm infants. The cause of NEC is considered multifactorial including enteral feeds, hypoxia, ischemia, patent ductus arteriosus, and infection. Approximately 90% of infants who develop NEC have been enterally fed and several studies have shown that the rapid advancement of enteral feedings is associated with NEC. With the advent of parenteral nutrition, the tendency was to delay enteral feeding for prolonged periods of time in order to prevent this disease and to use parenteral nutrition as the sole source of nutrition. However, it is known that delayed enteral feeding has a negative effect on gastrointestinal structure and function. Lack of enteral nutrition induces gastrointestinal atrophy, depresses gut hormone secretion, and delays the maturation of gastrointestinal motility. There are now numerous studies that demonstrate the benefits of early enteral feeding including the promotion of endocrine adaptation, the accelerated maturation of gut motility patterns, the provision of luminal nutrients, and possible benefits to the immune system. In fact, early enteral nutrition may enhance feeding tolerance and may actually decrease the incidence of NEC.

Trophic Feedings

Even though it is recognized that early enteral feeding is beneficial, there is still hesitation to begin feedings in the early days following birth. One of the strategies that has been extensively studied since the late 1980s is trophic feeding, also referred to as minimal enteral nutrition or gut priming. This method involves giving the infant small volumes of feedings, approximately 10–20 ml kg^{-1} day^{-1}, for a period of 10–14 days before advancing to full enteral feedings. The benefits found are greater energy intake, earlier attainment of full enteral feedings, improved growth, less PN-related complications, reduced risk of infection, and earlier hospital discharge. Furthermore, infants who received trophic feedings had no increased incidence of NEC. Many clinicians have adapted variations of this practice, some with a shortened period of trophic feeds, others reserving this practice for the smallest, most preterm infants while employing advancement of feeds in larger, more stable infants. Once minimal enteral nutrition has been established and the infant is stable enough to advance feedings, it is generally considered a safe practice to increase feedings by 20 ml kg^{-1} day^{-1} while using PN for the balance of intake until an adequate enteral intake has been established and tolerated. Although fast feeding advancement has been associated with NEC, one study has shown no increase in the incidence of NEC amongst preterm infants whose feeds were advanced by 35 ml kg^{-1} day^{-1}.

Feeding Route

Because preterm infants lack the ability to coordinate sucking, swallowing, and breathing, tube feedings must be used. Jejunal feeding was a popular method for feeding infants during the 1970s to early 1980s. It was felt that this method would minimize the risk of reflux and aspiration. This method is now generally reserved for infants in whom reflux and aspiration is complicating chronic lung disease or those who have poor gastric emptying. Now, most infants are fed using an orogastric or nasogastric tube; the former usually selected for the tiniest babies as the feeding tube may occlude one naris and impair nasal breathing.

Feeding Selection

Breast milk expressed by the infant's mother is the preferred type of feeding for most preterm infants. It is nutritionally superior to artificial formula in many respects. There is improved gastric emptying, more

stool frequency, and improved fat absorption when breast milk is used. There are many trophic factors found in human milk that enhance the development of the gastrointestinal tract. Human milk contributes to host defense and reduces the risk of NEC. Preterm infants who have been fed expressed human milk also show a neurodevelopmental advantage but it is difficult to isolate this from the social variables also associated with mothers willing to express their milk. The use of expressed breast milk also enhances mother-infant bonding as this is one task that only the baby's mother is able to perform. However, there are also nutritional concerns related to the use of breast milk in infants born less than 33 weeks' gestation. Protein supplementation is necessary for optimal growth and maintenance of optimal protein status. Supplementation of calcium and phosphorous is also needed for adequate bone mineralization. There are multinutrient fortifiers available that can be added to breast milk to improve nutrient intake. The use of these fortifiers has been associated with improved intake of protein and minerals and growth and bone mineralization, and balance studies show improved nutrient retention.

If breast milk is not available, the feeding of choice becomes preterm infant formulas. These formulas have greater protein content and are cow's milk whey predominant. The carbohydrate is a mixture of lactose and glucose polymers, and the fat a mixture of both long-chain and medium-chain triglycerides for improved nutrient absorption. The concentration of minerals, electrolytes, and vitamins is increased to meet the estimated nutrient needs of the preterm infant when fed in an amount to provide 120 kcal kg^{-1} day^{-1}. Studies have shown that infants fed preterm infant formulas have improved growth over those fed term formula or even fortified breast milk.

Feeding Rate

The decision regarding how to feed must also be made: continuous versus bolus feeding. The preferred method is controversial. Some clinicians feel that continuous feedings are better tolerated while others feel that bolus feedings are more physiologic. In studies, bolus feedings have been associated with improved gastric emptying, and more mature intestinal motility patterns. It is difficult to compare feeding tolerance between continuous and bolus feeds due to differences in the criteria used. Comparison feeding studies have found fewer gastric residuals in those infants given bolus feedings than those fed continuously. A more recent study has found that feeds given as a slow bolus, over 2 h, resulted in a normal duodenal motility pattern, suggesting that some infants may benefit from slow intermittent feedings. Regardless of the method chosen, if an infant does not tolerate one method it may be beneficial to try a different one.

Monitoring Feeding Tolerance

Feeding tolerance among preterm infants must be closely monitored since NEC is associated with enteral feedings. The presence of gastric residuals is one factor that is frequently used, but because preterm infants have poor gastric emptying amounts less than 50% of a previous feed should not be considered significant. Other indicators that should be used in conjunction with gastric residuals include the increase in abdominal girth, the absence of active bowel sounds, the presence of blood in the stool, a change in the number or quality of stools, and the presence of emesis. A careful exam is warranted if these symptoms are present.

Estimated calorie and protein intakes to achieve fetal weight gain are shown in **Table 6**.

Monitoring Nutritional Status

The nutritional status and growth of the preterm infant should be monitored throughout the hospitalization. The daily fluid and caloric intake should be monitored daily, body weight should be recorded daily, length and head circumference should be measured weekly, and all three measurements plotted on standardized growth charts. If growth is inadequate the volume or caloric density of feeds and or the protein content should be increased. Biochemical measurements should also be assessed periodically.

Preparation for Discharge

Approximately 1 week prior to discharge, preterm infants should be converted to the feeding regimen that will be used at home. Infants who have been fed expressed breast milk should demonstrate the ability to directly breast-feed and/or to feed supplemented breast milk or formula from the bottle as needed to gain adequate weight. The infant who weighs less than 2500 g at discharge, especially those infants born at less than 30 weeks' gestation, may require the supplementation of some breast-milk feedings with post discharge formula powder or the feeding of a concentrated post discharge formula for some of the daily feedings.

Table 6 Estimated calorie and protein intakes to achieve fetal weight gain

	Body weight (g)				
	500–700	*700–900*	*900–1200*	*1200–1500*	*1500–1800*
Protein (g)					
Parenteral	3.5	3.5	3.5	3.4	3.2

For those infants who were fed preterm formula, conversion to a nutrient-enriched post discharge formula is recommended. These formulas contain additional protein, vitamins, and minerals compared to term formulas. Studies have shown that infants fed these formulas for the first 9–12 months of life have improved gains in weight, length, and head circumference.

If growth is inadequate with either feeding regimen then alteration in caloric density may be needed. Arrangements should be made for the nutritional status of these infants to be monitored after discharge.

Conclusions

Preterm infants have specialized nutritional needs and each infant must be carefully and continuously assessed to ensure that the best possible nutritional support is provided to promote optimal growth without causing additional morbidity and mortality.

Table 7 Periodic monitoring of nutritional status

Indicator	*Frequency*
Weight	Daily
Length	Weekly
Head circumference	Weekly
Electrolytes (PN)	Daily until stable then 2 times weekly
Electrolytes (enteral)	Weekly

LUNG DISEASES

A MacDonald, The Children's Hospital, Birmingham, UK

Respiratory disease covers a wide range of disorders and interest has grown in the provision of its nutritional support. Epidemiological studies suggest that dietary habits influence lung function and the tendency to common lung diseases, such as asthma, chronic obstructive pulmonary disease (COPD), and lung cancer. Malnutrition and weight loss are commonly reported in patients with COPD, and intensive, specialist nutritional support is required. For cystic fibrosis (CF), nutritional therapy has been shown to improve the prognosis. Novel diet therapies, including exclusion of food allergens and reduction of salt intake, have been tried as possible treatments for asthma. This article outlines the rationale for and describes methods of nutritional support and therapy in the treatment of lung disease.

Chronic Obstructive Pulmonary Disease

COPD is a term used to describe a spectrum of disorders characterized by reduced maximal expiratory flow and slow forced emptying of the lungs (**Table 1**). It is associated with symptoms of obstructive lung diseases, such as cough, mucus production, breathlessness, airflow limitation, and wheezing. COPD can be present with or without substantial physical impairment or symptoms. The World Health Organisation states that it is the fourth leading cause of global mortality. In the United Kingdom, it is estimated that 18% of males and 14% of females aged 40–68 years may have developed features of COPD. Severe exacerbations remain the largest single cause of emergency admissions for respiratory disease, with a mean hospital stay of 10 days.

Table 1 Consequences of disease-related malnutrition in COPD

Reduced lung function and dyspnea
Reduced maximal O_2 consumption
Decreased peripheral muscle function
Decreased exercise performance
Decreased quality of life
Increased need for hospitalization
Increased postoperative complications during lung volume reduction surgery
Increased mortality

Adapted from Stratton *et al.* (2002).

The prevalence of COPD is greatest in socioeconomically deprived people. It is probably underdiagnosed partly because many people do not consult their general practitioners or do not reveal all their symptoms. In general, the major cause of COPD is smoking. Other causes include α_1-antitrypsin deficiency, cystic fibrosis, air pollution, occupational exposure, and bronchietasis.

Chronic bronchitis and emphysema are two of the major diseases grouped under COPD. Patients with COPD have features of both conditions, although one may be more prominent than the other.

Chronic Bronchitis

Definition and etiology Chronic bronchitis is defined by the presence of chronic bronchial secretions sufficient to cause expectoration occurring on most days for a minimum of 3 months for 2 consecutive years. It became recognized as a distinct disease in the late 1950s associated with the great British Smog. It develops in response to long-term irritants on the bronchial mucosa. Important irritants include cigarette smoke, dust, smoke, and fumes; other causes include respiratory infection, particularly in infancy, and exposure to dampness, sudden changes in temperature, and fog. In the United Kingdom, it affects 10% of older people, and it is more common in industrial countries. Chronic bronchitis is a slowly progressive disorder unless the precipitating factors are avoided and it is treated.

Clinical features Symptoms include productive cough and frequent and recurrent chest infections. The disease progresses over many years from a troublesome cough producing a little clear sputum to marked wheezing, severe breathlessness leading to poor exercise tolerance, and copious and purulent sputum. It may cause right heart failure (i.e., cor pulmonale), such as oedema and cyanosis.

Pathology There is hypertrophy of the mucus-secreting glands. The structural changes described in the airways include atrophy, focal squamous metaplasia, ciliary abnormalities, variable amounts of airway smooth muscle hyperplasia, inflammation, and bronchial wall thickening. The respiratory bronchioles display a mononuclear inflammatory process, lumen occlusion by mucus plugging, goblet cell metaplasia, smooth muscle hyperplasia, and distortion due to fibrosis. These changes combined

with loss of supporting alveolar attachments cause airflow limitation by allowing airway walls to deform and narrow the airway lumen.

Emphysema

Diagnosis and etiology Emphysema means 'inflation' in the sense of abnormal distension with air. It is a condition in which there is permanent destructive enlargement of the airspace distal to the terminal bronchioles without obvious fibrosis. In the general population, emphysema usually develops in older individuals with a long smoking history. However, other causes include exposure to heavy metals such as cadmium, and 5% of early presenting cases are caused by the autosomal recessive disorder α_1-antitrypsin deficiency. It affects almost 5% of older people, and it is more common in industrialised countries. The prognosis is variable. Progression is slow, provided it is treated.

Clinical features Patients may be very thin with a barrel chest and have little or no cough expectoration. Symptoms include intense dyspnea with purse-lip breathing and overinflation of the chest. Breathing may be assisted by pursed lips and use of accessory respiratory muscles. The chest may be hyperresonant, and wheezing may be heard. Heart sounds are very distant and overall appearance is more like classic COPD exacerbation.

Chemical Pathology There are three types of emphysema:

Panacinar emphysema: A generalized destruction of the alveolar walls. As a consequence, the elastic network of the normal lung is badly disorganized and the lung becomes floppy, leading to a severe degree of airways obstruction, particularly during expansion. It generally develops in patients with α_1-antitrypsin deficiency.

Centriacinar emphysema: Distension and damage affect the respiratory bronchioles; the more distal alveolar ducts and alveoli tend to be well preserved. This is very common and not necessarily associated with disability.

Paraseptal emphysema: The least common form, involving distal airway structures and alveolar ducts and sacs.

Nutritional Management in COPD

Malnutrition is an important clinical problem in a subpopulation of patients with COPD. Emaciation with emphysema was reported as early as 1898. Studies suggest malnutrition occurs in between 27 and 71% of all patients, increasing with the severity of airways obstruction. In one of the larger studies examining patients with stable COPD, one-fourth of 779 men were less than 90% of their ideal body weight. However, in patients who need hospital admission, malnutrition approaches or exceeds 50%. When acute respiratory failure complicates the clinical course, severe malnutrition is observed in 60% of cases.

Malnutrition has a considerable impact on both morbidity and mortality. Reduced respiratory muscle mass and function as well as increased susceptibility to infection are recognised as deleterious consequences of malnutrition in patients with or without lung disease. In a necropsy study, diaphragm muscle mass was reduced by 43% in malnourished patients whose weights were 71% of ideal body weight. Decreases in body weight, creatinine–height index, total lymphocyte count, serum transferrin, and retinol binding protein have been documented.

Nutritional depletion is an independent risk factor for mortality and hospitalization in patients with COPD. Studies have indicated a hospital stay of approximately 30 days for patients with a body mass index (BMI) of less than 20 compared with 18 days for those with a BMI of less than 30. If a patient with COPD begins to lose weight progressively, the average reported life expectancy is only 2.9 years, and it is considerably less in malnourished patients who have survived an episode of acute respiratory failure during an acute exacerbation of their disease. However, it is not certain whether this implies a casual relationship or whether low weight is a marker for more severely impaired lung function.

Reasons for Malnutrition

The cause of progressive weight loss in patients with COPD is not well understood but two factors have been implicated.

Increased resting energy expenditure The relationship between resting energy expenditure (REE), lung function, oxygen cost of breathing, and malnutrition in COPD has been the focus of much attention in recent years. Results of studies on REE are conflicting. In two early studies on malnourished patients with COPD, Goldstein and coworkers described 10 patients whose REE was 113% of predicted, and Wilson and colleagues described 7 patients with a REE 115% of predicted. In contrast, two later studies found REE to be only 94 and 104% of predicted in stable fasted COPD patients, respectively. It has therefore been hypothesized that if patients

with COPD are not hypermetabolic, malnutrition is related more to impaired gas exchange (as evidenced by a low diffusing capacity of carbon monoxide) than to airflow obstruction. The impaired gas exchange results from loss of the pulmonary capillary bed and may result in an inability to augment cardiac output in response to the stress of even minimal effort, leading to lack of oxygen delivery to the tissues and nutritional depletion. An alternative hypothesis is that malnutrition is precipitated by acute illnesses, leading to a combination of anorexia and hypercatabolism causing significant weight loss.

Reduced energy intake Many studies have examined the energy intake of malnourished COPD patients and have shown it to be either similar to that of well-nourished patients with COPD or higher than the respective dietary recommendations. Most of these studies were conducted on stable patients, but several factors may adversely affect energy and nutrient intake:

Hypoxia-related appetite suppression or anorexia due to acute exacerbation
Chronic sputum production and frequent coughing, which may alter desire for and taste of food
Fatigue, which can interfere with the ability to shop for food and prepare and eat meals
Depression
Side effects of medications, including nausea, vomiting, diarrhea, dry mouth, and gastric irritation, which may limit dietary intake
Raised plasma tumor necrosis factor-α levels
Arterial oxygen desaturation due to altered breathing pattern during chewing and swallowing

Nutritional Support

Several controlled studies have evaluated the effect of nutritional support in COPD in either outpatients or inpatients, and their outcome was related to the overall energy intake achieved. Weight gain was only achieved by substantially increasing energy intake by more than 30% above the usual intake, amounting to more than 45 kcal/kg per day. Moreover, improvement in muscle function or exercise tolerance occurred only with concomitant weight gain. In one of these controlled studies, oral supplementation was given for 3 months to ambulatory malnourished patients with chronic obstructive lung disease. Daily energy intake increased by 48% above the usual intake and corresponded to 47 kcal/kg on average. The authors reported a mean weight gain of 4.2 kg, an increase in maximal respiratory pressures and in handgrip and stemomastoid strength, and a decrease in stemomastoid muscle fatigability; similar improvements were not observed in a control group. However, these improvements were not maintained when oral supplementation was discontinued. In another study, six malnourished patients received an additional 1000 kcal via a nasogastric tube for 16 days, whereas a control group of four received only an additional 100 kcal. A weight gain of 2.4 kg, and improvements in respiratory muscle strength and endurance were seen in the fed patients but not in the control group. Other studies have not demonstrated improvements in weight gain or muscle performance and have been less successful in increasing energy intake.

Type of Nutritional Support

If the patient with COPD is less than 90% ideal body weight for height, nutritional support should be considered. This can be difficult in COPD, but it can be provided on three levels.

Normal high-energy, high-protein diet For many patients with COPD, advising small, frequent nutrient-dense meals, regular snacks, and food fortification using high-energy and -protein foods, such as milk, yoghurt, butter, and cream, may provide adequate nutritional support. Foods of low nutritional value, such as tea, squash, and clear soup, should be discouraged. For some patients who lack vitality, use of readily prepared microwave dinners with a rest prior to mealtime is helpful. A daily multivitamin and minerals supplement may be indicated.

Use of high-energy, high-protein supplements These products can be used to augment a patient's dietary intake. They are available in the form of milk, sweet and savoury drinks, fortified fruit juices, milkshake powder, glucose polymer powders and liquids, and puddings. Patients and caregivers need to be given complete instructions regarding their use to optimise this form of nutritional supplementation. Unfortunately, many studies found that in COPD the use of these supplements led to a reduction in usual energy intake and caused symptoms such as bloating, nausea, and early satiety. Oral supplements are probably less effective in older patients with a systematic inflammatory response.

Tube feeding Overnight tube feeding should be considered in patients with COPD when oral methods of maintaining nutritional status have failed, although few studies have investigated this method. The composition of tube feeds for patients with COPD has received attention. Carbon dioxide

production ($V\dot{C}O_2$) is higher when carbohydrates are the main energy sources and lower when fat is mainly oxidised. However, patients with COPD who are in a stable clinical state usually appear to tolerate carbohydrates without difficulty. Respiratory failure has not been reported in studies of patients with COPD receiving nutritional support with enteral feeds and nutritional supplements containing up to 54% carbohydrate, but further work is needed to determine the optimal and safest feeding regimens for these patients.

Feeding Patients on Artificial Ventilation

The artificial ventilator may be used to control the breathing patterns of patients who have acute breathing problems (e.g., respiratory failure with worsening blood gases). If the patient can be enterally fed, the composition of feed has a profound effect on gas exchanges, especially CO_2 production, and therefore respiratory quotient. This is expressed as the ratio of CO_2 produced to oxygen consumed. Because CO_2 production is greater during carbohydrate metabolism, a diet high in carbohydrate requires increased ventilation to eliminate the excess CO_2, whereas high-fat feeds reduce CO_2 production and are therefore potentially beneficial. Overfeeding negates any beneficial response to high-fat feeds because the conversion of energy to fat involves a disproportionately large production of CO_2.

Cystic Fibrosis

Definition and Etiology

In CF, there is widespread dysfunction of exocrine glands that causes chronic pulmonary disease; pancreatic enzyme deficiency; intestinal obstruction in the neonate (distal intestinal obstruction syndrome); liver disease; infertility, especially in males; and abnormally high concentrations of electrolytes in sweat, resulting from the failure of salt reabsorption in the sweat gland ducts. This is the most common inherited disease in Caucasian populations. A gene located on chromosome 7, coding for the protein called cystic fibrosis transmembrane regulator (CFTR), is defective. CFTR acts as a cyclic-AMP-activated chloride channel blocker. More than 800 mutations of the gene have been identified, and they are categorized into five classes on the basis of CTFR alterations. The most predominant mutation, which accounts for approximately 70% of all the CTFR genes worldwide, is $\Delta 508$, but there is geographical variation and it is less common in non-white races.

Although previously this disease was considered lethal in childhood, the median survival for newborns in the 1990s is predicted to be 40 years. Survival is largely dependent on the severity and progression of lung disease, and more than 90% of mortality is due to chronic bronchial infections and their complications. Patients with pancreatic insufficiency have a worse prognosis in terms of growth, pulmonary function, and long-term survival. The mortality of females is generally greater than that of males.

Incidence

CF affects 1 in 2500 births in Caucasian populations, 1 in 20 000 in black populations, and 1 in 1 million in Oriental populations. It is extremely rare in Japan, China, and black Africa.

Clinical Features

Most children with CF present with malabsorption and failure to thrive accompanied by recurrent or persistent chest infections. In the lungs, viscid mucus in the smaller airways predisposes to chronic infection, particularly with *Staphylococcus aureus* and *Haemophilis influenzae*, and subsequently with *Pseudomonas* species. This leads to damage of the bronchial wall, bronchietasis, and abscess formation.

Approximately 90% of CF patients have pancreatic insufficiency, requiring pancreatic enzyme supplements. Untreated patients pass frequent, large, pale, offensive, greasy stools. Ten to 15% of infants present with a meconium ileus resulting from the blockage of the terminal ileum by highly proteinaceous meconium at birth. Distal intestinal obstruction syndrome may occur later in childhood or adult life. In addition to these symptoms, a number of other complications may occur in CF that are identified in **Table 2**.

Chemical Pathology

CTRF regulates the chloride channel in the cell at its luminal surface, and its absence or dysfunction results in an abnormally high concentration of sodium in sweat and in a low water content in the mucus produced by airways, pancreas, and intestine. In the lung, this leads to ciliary dysfunction and repeated infection and colonisation with bacteria, resulting in a vicious cycle of bacterial colonization, 'lung inflammation,' and scarring. These in turn result in severe bronchiectasis, which progressively destroys lung function.

Arthropathy
Salt depletion
Growth failure/weight loss/failure to thrive
Delayed puberty
Osteopenia

Nutritional Management

Nutritional intervention is associated with better growth and improvement or stabilization of pulmonary function and possibly may improve survival in CF. Malnutrition has several adverse effects, including poor growth, impaired muscle function, decreased exercise tolerance, increased susceptibility to infection, and decreased ventilatory drive. Studies indicate that BMI strongly correlates with lung function, but the exact mechanism of this relationship has not been fully determined. Achieving optimum nutrition and growth may minimize the progressive decline in pulmonary function commonly seen in CF. As early as the 1970s, the Toronto CF clinic was able to show that a high-fat diet promoted a normal growth pattern and improved survival.

Reasons for Malnutrition

A variety of complex organic and psychosocial factors contribute to malnutrition in CF.

Malabsorption Pancreatic exocrine secretions contain less enzymes and bicarbonate, have a lower pH, and are of a smaller volume, and the physical properties of proteins and mucus within the lumen are affected. This results in obstruction to the small ducts and secondary damage to pancreatic digestive enzyme secretions causing malabsorption. Other problems, such as gastric hypersecretion, reduced duodenal bicarbonate concentration and pH, disorders of bile salt metabolism, disordered intestinal motility and permeability, liver disease, and short bowel syndrome after intestinal resection in the neonatal period, may contribute to malabsorption. The severity of malabsorption is variable, and there can be significant malabsorption of protein and fat-soluble vitamins despite adequate use of enzyme supplements.

Increased energy expenditure Resting energy expenditure, an estimate of basal metabolic rate, is 10–20% greater than in healthy controls and may contribute to energy imbalance. Increased REE appears to be closely associated with declining pulmonary function and subclinical infection. Bronchial sepsis leads to local release of leukotrienes, free oxygen radicals, and cytokines, including tumour necrosis factor-α. Antibiotics have been shown to reduce energy requirements of moderately ill patients with chronic *Pseudomonas aeruginosa*.

Anorexia and low energy intake Inadequate energy intake is often the main reason for growth failure in CF. Factors associated with a reduced appetite include

- Chronic respiratory infection and other complications of CF, such as distal ileal obstruction syndrome, abdominal pain, GOR resulting in oesophagitis, pain, and vomiting
- Behavior feeding problems in preschool and school-age children
- Media pressure to eat a healthy low-fat, low-sugar diet
- Inappropriate concepts regarding body image
- Depression
- Eating disorders in teenagers
- Poor use of dietary supplements
- Dislike of high-energy foods

Nutritional Support

Nutritional requirements will vary according to the clinical state as well as the age, sex, and activity of the individual. Because of the heterogeneity of CF, it is impossible to give universal recommendations. Crude estimates suggest an energy intake of 120–150% of estimated average requirements; it is better to assess and monitor energy intake and equate this

to the nutritional status of the patient. If weight gain or growth is poor, the usual energy intake is increased by an additional 20–30% of total intake. Likewise, exact protein requirements are unknown; but it is generally accepted that the protein intake should be increased to compensate for excessive loss of nitrogen in the feces and sputum and increased protein turnover in malnourished patients. Protein should provide 15% of the total energy intake.

High-energy/high-protein diet The encouragement of a high-calorie, high-protein diet will produce growth in the majority of children and adults with CF. A good variety of energy-rich foods should be encouraged, such as full cream milk, cheese, meat, full cream yoghurt, milk puddings, cakes, and biscuits. Extra butter or margarine can be added to bread, potatoes, and vegetables. Frying foods or basting in oil will increase energy density. Extra milk or cream can be added to soups, cereal, desserts, or mashed potatoes and used to top canned or fresh fruit. Regular snacks are important. Malnourished children achieve higher energy intake when more frequent meals are offered. Attention should be given to psychological, social, behavioral, and developmental aspects of feeding. A meta-analysis of differing treatment interventions to promote weight gain in CF demonstrated that a behavioural approach was as effective in promoting weight gain as evasive medical procedures.

Dietary supplements Although almost half of adult patients take dietary supplements, there are few published data to demonstrate their efficacy in CF. One study was unable to show any improvement in height and weight z scores when up to 30% of energy requirements were supplied by a supplement for 3 months. As a consequence, dietary supplements should be reserved for weight loss, any decline in height z score, if intake of a range of nutrients does not meet dietary reference values, or during acute chest infections. They should complement normal food intake and not replace food. In order to avoid reducing the intake of normal food, the recommended quantities are age dependent and are given in **Table 3**.

Enteral nutrition Enteral feeding is more commonly used in teenagers and adults, reflecting their deterioration in nutritional status. It is considered if the patient is less than 85% expected weight for height, the patient's weight has declined by two centile positions, the patient has failed to gain weight over a 6-month period, or the patient has a BMI less than 19. Enteral feeding is associated with improvements in body fat, height, lean body mass, muscle mass, increased total body nitrogen, improved strength, and development of secondary sexual characteristics. To produce lasting benefit, numerous studies have demonstrated that enteral feeding should be continued long term. The choice of route used is influenced by the duration of feeding and the preference of the patient and family, but gastrostomies, sited by endoscopic placement, are usually chosen for long-term feeding (**Table 4**).

Table 3 Recommended dosage of dietary supplements in cystic fibrosis

Adapted from MacDonald A (2001). Cystic fibrosis. In: Shaw V and Lawson M (eds.) *Clinical Paediatric Dietetics*, pp. 137–157. Oxford: Blackwell Scientific.

It is common practice to give enteral feeding for 8–10 h overnight, with at least 40–50% of the estimated energy requirement given via the feed. Most patients tolerate an energy-dense polymeric feed providing at least 1.5 kcal/ml with additional pancreatic enzymes. However, there is some support for the use of chemically defined elemental or short-chain peptide feeds. These are generally low in fat and are administered without the use of pancreatic enzymes, although there is little evidence to support this practice and it is disputed by some. Monitoring for glucose intolerance is important. Patients receiving supplemental feeds who demonstrate repeated blood sugar levels higher than 11.1 mmol/l during the feed may benefit from insulin given before the feed.

Vitamin and mineral supplements Malabsorption of fat-soluble vitamins is likely in most pancreatic-insufficient patients with CF, and the United Kingdom recommends vitamin A, D, and E supplements. Low fat-soluble vitamin concentrations are associated with poorer clinical status and reduced lung function. Clinical features of vitamin A deficiency include night blindness, conjunctival and corneal xerosis, dry thickened skin, and abnormalities of bronchial mucosal epithelialisation. Vitamin A status is difficult to assess due to lack of a reliable marker and serum levels of retinol do not adequately mirror the concentration of vitamin A in the liver. Some researchers have found liver stores of vitamin A in CF to be 2.5 times higher than those in control subjects, despite lower serum levels of retinol and retinol binding protein.

Table 4 Advantages and disadvantages of enteral feeding routes

Method	*Advantages*	*Disadvantages*
Nasogastric	Short-term feeding	Tube reinsertion may be Distressing to patient/caregiver/nurse Easily removed Risk of aspiration Discomfort to nasopharynx Psychosocial implications
Nasojejunal	Less risk of aspiration Short-term feeding	Difficulty of insertion Radiographic check of position Easily removed Risk of perforation Abdominal pain and diarrhoea unless continuous infusion of feed Discomfort in nasopharynx Reflux of bile is facilitated
Gastrostomy	Cosmetically more acceptable Long-term feeding	Increase reflux if present Local skin irritation Infection Granulation tissue Leakage Gastric distension Stoma closes within a few hours if accidentally removed
Jejunostomy	Reduced risk of aspiration Long-term feeding	Surgical/radiology procedure Risk of perforation Must be constant infusion of feed Bacterial overgrowth Dumping syndrome can occur

Adapted from MacDonald A, Holden C, and Johnston T (2001) Paediatric enteral nutrition. In Payne-James J, Grimble G, and Silk D (eds.) *Artificial Nutrition Support in Clinical Practice*, pp. 347–366. London: Greenwich Medical Media.

Decreased bone mineral density and osteopenia associated with low 25-hydroxyvitamin D levels have been described in patients with CF but may be related to poor nutritional status and delayed puberty. Rickets is rarely seen. Possible contributory factors include low body mass index, disease severity, inadequate calcium intake, delayed puberty, or widespread use of systemic or inhaled steroids.

Blood levels of vitamin E are nearly always low unless supplements are given. In older patients, undetectable serum concentrations of vitamin E have been noted in association with neurological syndromes. Symptoms and signs include absent deep tendon reflexes, loss of position sense and vibration sense in lower limbs, dysarthria, tremor, ataxia, and decreased visual activity.

Some CF centres recommend routine salt supplements to all CF infants on normal infant formula, which is low in sodium, and CF patients during hot weather. Anorexia and poor growth may result from chronic salt depletion. Significant hyponatremia may be accompanied by vomiting.

Pancreatic Enzymes

Approximately 90% of patients with CF require pancreatic enzymes to reduce steatorrhea. They are based on animal pancreatic extracts; presented in powder; tablet, or capsule form; and contain a combination of lipase, protease, and amylase. In addition to enzyme content, many factors affect bioavailability of pancreatic enzymes, including enzyme source, manufacturing process, stability, enteric coating of acid-resistant tablets, formulation as either microspheres or microtablets, and particle size. The smallest dose of pancreatin to control steatorrhoea and achieve a normal pattern of growth and weight gain should be used. The Committee on Safety for Medicines recommends that patients with CF not exceed a daily dose of enzymes equivalent to 10 000 IU lipase/kg/day.

Asthma

Definition and Etiology

The word ‘asthma’ originates from an ancient Greek word meaning panting. It is a chronic obstructive disease characterized by tracheobronchial hyperreactivity leading to paroxysmal airway narrowing, which may reverse spontaneously or as a result of treatment. The smooth muscle surrounding the bronchi has an abnormally increased reaction to stimuli. Specific bronchial stimuli include inhaled

allergens (e.g., house-dust mite, pollen, and moulds). Nonspecific bronchial stimuli include upper respiratory tract infections, cold air, exercise, cigarette smoke, excitement, emotional stress, and chemical irritants. Aspirin and other nonsteroidal antiinflammatory medications provoke asthma in some patients.

Prevalence

Since the 1980s there has been a worldwide increase in the prevalence of asthma in both children and adults. This escalating prevalence has led to significant increases in morbidity and mortality due to the disease. It is the most common chronic respiratory disorder, affecting 3–5% of adults and 10–15% of schoolchildren. Half of the people with asthma develop it before age 10, and most develop it before age 30. In childhood, it is twice as common in boys as in girls, but by adolescence equal numbers are affected. Asthma symptoms can decrease over time, especially in children. Many people with asthma have an individual and/or family history of allergies, such as hay fever (allergic rhinitis) or eczema. Others have no history of allergies or evidence of allergic problems.

It is responsible for 10–20% of all acute medical admissions in pediatric wards in children aged 1–16 years. There are 15–20 deaths from asthma in children each year in the United Kingdom. However, from 1979 to 1999, mortality rates of asthma have decreased in England and Wales in all age groups up to 65 years.

Clinical Features

Asthma is characterized clinically by wheezing, dyspnea, and cough. Coughing commonly produces small amounts of yellowish sputum or bronchial plugs. Some patients present with breathlessness. Most people with asthma have periodic wheezing attacks separated by symptom-free periods. Other asthmatics may have cough as their predominant symptom. Asthma attacks can last minutes to days.

Chemical Pathology

The development and phenotypic expression of allergic airway disease depend on a complex interaction between genetic and environmental factors. Exposure of the sensitized airway to a number of trigger factors results in bronchoconstriction, mucosal oedema, and excessive mucus production that in turn leads to airway narrowing and the clinical features of asthma. Airway inflammation is due to an immune-mediated process in which inflammatory cells and inflammatory mediators enter airway tissues to cause disease. Many cell-mediated immunologic factors participate in the inflammatory process of asthma. The most important inflammatory cells involved are eosinophils, mast cells, and T lymphocytes. The first months of life seem to be a particularly vulnerable period and there is evidence that sensitization is related to the level of allergen exposure during early life.

Dietary Management

There is an increasing interest in the relationship between nutrition and asthma. Associations have been reported between the intake of fruit and the antioxidant vitamins A, C, and E and selenium. Suboptimal nutrient intake may enhance asthmatic inflammation, consequently contributing to bronchial hyperreactivity. There is some suggestion that people who have a diet rich in fruit and vegetables have a lower risk of poor respiratory health, and this may be due to the antioxidant nutrients that food contains. Several issues need to be addressed before causality of these associations can be established. Nevertheless, it appears reasonable to issue dietary guidelines for the primary and secondary prevention of asthma that are in line with a healthy diet for the prevention of coronary heart disease and cancer.

Epidemiological studies also suggest that a diet high in marine fatty acids (fish oil) may have beneficial effects on asthma. However, a Cochrane review of nine randomized controlled trials conducted between 1986 and 2001 indicated there is little evidence to recommend that people with asthma supplement or modify their dietary intake of marine n-3 fatty acids (fish oil) in order to improve their asthma control. Equally, there is no evidence that they are at risk if they do so.

Food intolerance There is much controversy surrounding the role of food in the development and onset of asthma. Evidence suggests that atopic or asthmatic parents, whose children have a high risk of developing asthma, should be advised to avoid smoking during pregnancy; avoid cigarette smoke exposure after the child is born; undertake house dust mite control strategies; exclusively breast-feed their infants for 6 months; and subsequently provide their child with a nutritious, balanced diet. In contrast, there is little to suggest that a low allergen diet for high-risk women during pregnancy is likely to reduce the risk of having an atopic child.

Generally, the incidence of food intolerance in asthma is thought to be small, although there is evidence that intolerance to foods may act as a trigger for some cases of asthma. Common food allergens identified include milk, eggs, nuts, orange

squash, wheat, and red wine. The additives sulfur dioxide, tartrazine, sodium benzoate, and salicylates have been implicated, although in the case of sulfur dioxide its ability to cause asthma depends on the nature of the food to which it is added, the level of residual sulfur dioxide in the food, and the sensitivity of the patient. Foods such as nuts, cola drinks, ice, and those cooked in oil have been found to cause symptoms more frequently in Asian children. Many of the studies that have identified certain foodstuffs as triggering asthma have had limitations or flaws in their design, leading to difficulties in interpreting and extrapolating their results.

Both immediate and delayed-onset symptoms have been reported in asthma. The use of diagnostic diets is difficult, partly because of the variability of asthma, delayed reactions, effect of other precipitating triggers, and dangers of inducing an asthma attack during food challenges. A simple exclusion diet excluding food(s) implicated on history is perhaps the most useful diagnostic diet. Because of the inherent problems with asthma, strict food diets are rarely used.

High-sodium diets Epidemiological studies have suggested that dietary salt may play a role in airway responsiveness and a high salt intake may act as a trigger for asthma. A correlation between regional mortality from asthma and purchase of table salt per person has been reported in England and Wales. Epidemiological studies have also suggested an association between a higher dietary sodium intake and a higher prevalence of self-reported wheeze in adults and children. However, not all of the evidence supports this hypothesis. At least three epidemiological surveys and two experimental studies found no evidence of an association between sodium intake and asthma.

LYCOPENES AND RELATED COMPOUNDS

C J Bates, MRC Human Nutrition Research, Cambridge, UK

Introduction

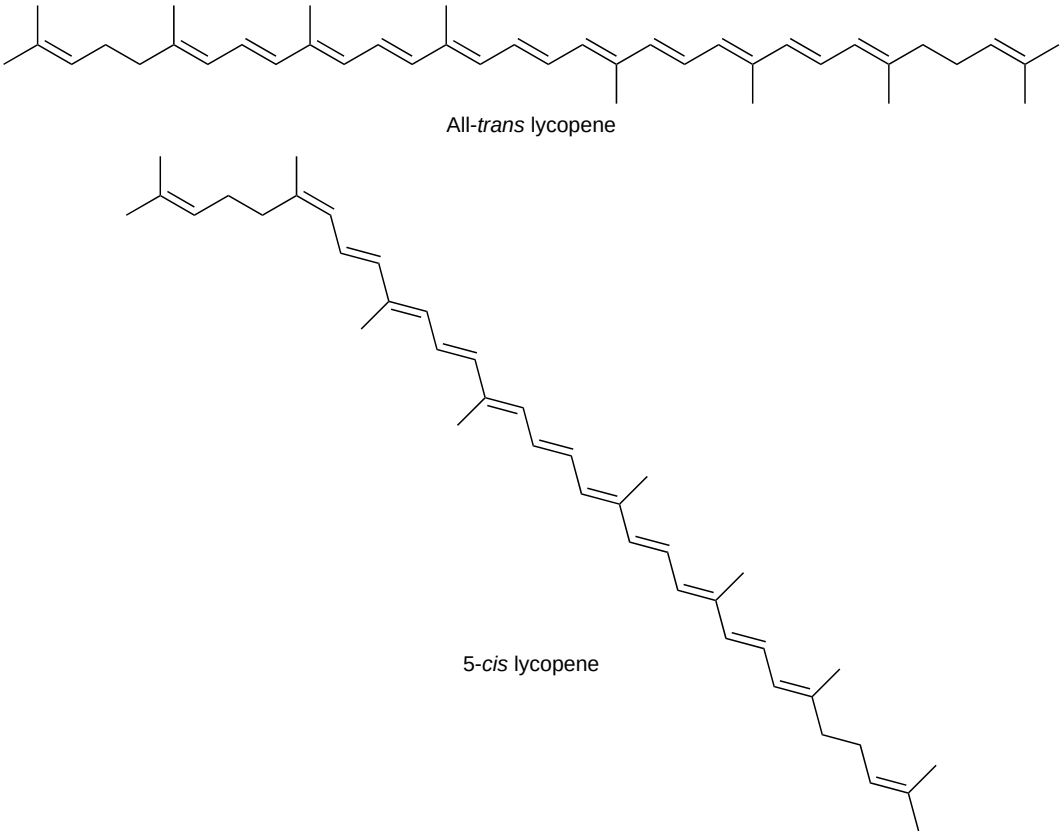
Lycopene, the most abundant pigment in ripe red tomatoes and in a few other fruits, is one of the major carotenoid pigments that is widely present in the diet of the human population in the world today. **Figure 1** illustrates the chemical formula of selected carotenoids that occur widely both in human diets and in the noncellular fraction of human blood in most regions of the world. Carotenoids are yellow-to-red in color, with lycopene being nearer the red end of the carotenoid series. However, unlike the carotenes and cryptoxanthins, it does not possess a beta-ionone ring structure at either end of the molecule, and this precludes it from becoming a precursor of vitamin A in humans and animals. Nevertheless, it is readily transformed from the all-*trans* form that is characteristic of most plants and plant foods for animals and humans, to a range of mono- and di-*cis* forms within the animal's body. In addition, oxidation to epoxides and hydroxylated derivatives occurs, although the control of these oxidation pathways and the nature of their products are not yet well understood or characterized.

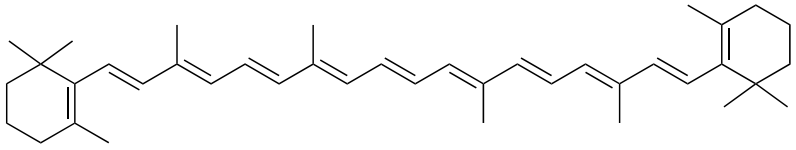
In plant tissues, where it is synthesized, lycopene is thought to help protect vulnerable photosynthetic tissues from light- and oxygen-catalyzed damage. Its role in humans and other animals, which can only obtain the pigment from their diet, is less well understood. Indeed it remains unproven that there is an essential role for lycopene in animal tissues. Nevertheless, considerable research effort is currently being undertaken to test hypotheses that are attempting to link human dietary and tissue lycopene levels to the risk of degenerative diseases, such as vascular diseases, cancers, etc., especially in older people. As discussed in more detail below, this research is being performed in a wide range of tissue culture and animal model systems and human epidemiological studies.

In this article, some key aspects of the chemical and physical properties, the dietary sources, biochemical status indices, and biological significance of lycopene will be described.

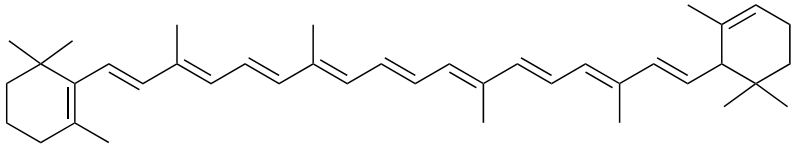
Chemical and Physical Properties of Lycopene; its Food Sources and Enteral Absorption

Lycopene is the most commonly encountered of that subgroup of the naturally occurring carotenoids that have a straight-chain poly-isoprenoid molecule without any terminal β-ionone ring structures (**Figure 1**). The chain length and number of conjugated double bonds determine the absorption spectrum, which peaks at 472 nm with a molar extinction coefficient, $\varepsilon^{1\%}$ of 3450. It is one of the most nonpolar members of the carotenoids, and in organic solution it is also one of the most easily oxidized and thus is easily destroyed, which necessitates the use of rigorous precautions against its oxidative destruction during its extraction and analysis from plants, foods, animal tissues, and body fluids. Currently, such analytical determination is usually based on high-performance liquid chromatography (HPLC), using either its characteristic light absorption property, or its natural fluorescence, or its redox character, for detection and quantitation by absorbance or fluorometric or electrochemical detection. Another characteristic that greatly affects its stability and the problems of its storage and analysis is the phenomenon of *cis-trans* isomerization. Naturally occurring lycopene in tomatoes, the major human food source of this carotenoid, is nearly 100% all-*trans* (**Figure 1**), but during the processing of food, and then during the processes of absorption and accumulation in animal tissues, there is a progressive increase in the proportion of a variety of *cis*-forms. Most of these *cis*-forms contain a single *cis*-bond (mono-*cis*-lycopene), and the 5-, 9-, 13- and 15- mono-*cis*-lycopenes account for more than 50% of the total lycopene in human serum. Smaller quantities of di-*cis*-lycopenes are normally also present. Curiously, another food source of lycopene, red palm oil, has a much higher natural proportion of the *cis*-forms of the pigment. Isomerization is catalyzed by low pH; therefore, stomach acid is believed to be a major factor in the conversion of the all-*trans*-lycopene ingested from tomatoes and their products to a mixture of *cis*-forms in the digestive tract. There is also evidence that further isomerization occurs between the digestive tract and the portal lymphatic lipid micelles. The *cis*-isomers differ from the all-*trans* form in their absorption and intertissue transportation properties, and also in their functional characteristics; for instance, they are more soluble in lipophilic solvents and structures and

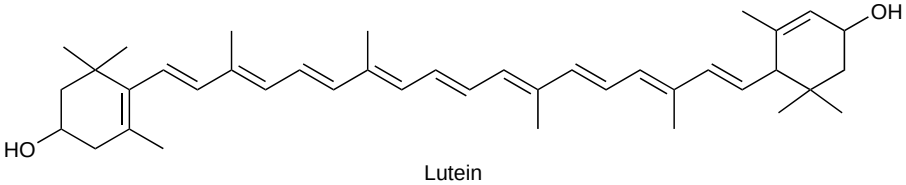




All-*trans* β-carotene



All-*trans* α-carotene



Lutein

Figure 1 Structures of lycopene and certain other carotenoids found in human blood and tissues.

are less likely to aggregate into crystalline forms. However, these physicochemical differences and their biological consequences have yet to be adequately explored and described.

Of all the most common naturally occurring carotenoids, lycopene is by far the most efficient in reacting with and quenching singlet oxygen, $^1O_2$, which is a non-free-radical excited and reactive

Table 1 Lycopene content of selected foods

Food category	*Content as summarized by Clinton (1998) (mg per 100 g wet weight)*
Fresh tomatoes	0.9–4.2
Canned tomatoes	
Tomato sauce	6.2
Tomato paste	5–150
Tomato juice	5–12
Tomato ketchup	10–13
Tomato soup	
Grapefruit	3.4
Guava	5.4
Papaya	2–5.3
Watermelon	2.3–7.2

Source: Clinton SK (1998) Lycopene: Chemistry, biology and implication for human health and disease. *Nutrition Reviews* **56**: 35–51.

form of oxygen. This form of oxygen reacts rapidly with lycopene to yield nonexcited triplet oxygen and excited triplet lycopene. The latter then dissipates its extra energy by solvent interactions, thus regenerating nonexcited lycopene and preserving its original structure by recycling. However, another of its chemical interactions with molecular oxygen appears to result in irreversible oxidation to yield one or more cyclic epoxides, which then probably undergo ring-opening. Nevertheless, there are many unresolved questions about the nature and importance of the many degradation and catabolic pathways that are believed to result in the irreversible destruction of lycopene both *in vitro* and *in vivo*.

Lycopene is an essential intermediate in the pathway for synthesis of the β-ionone ring-containing carotenoids such as β-carotene in plant tissues, and in most plant tissues it is present in only minor amounts. However, in a few, including tomato fruit, watermelon, and red grapefruit, this conversion to the β-ionone ring products by the enzyme lycopene cyclase is hindered, so that the intermediate carotenoid forms, lycopene, phytoene and phytofluene, accumulate instead.

In the US, tomato products provide more than 85% of the total quantity of lycopene consumed by the human population. Mean lycopene intakes in the US are considerably greater than they are in the UK, where the mean daily intake is thought to be less than one-third that in the US, while lycopene intakes in Far Eastern countries such as China and Thailand appear to be much lower still. Wild tomatoes originated in Central America and were introduced into Europe following the opening up of the New World, and were later introduced back into North America from Europe. Because tomatoes are the major source of dietary lycopene in many human populations, some epidemiological studies have been designed on the simplistic assumption that tomato consumption can be used as a general proxy for lycopene consumption, and that any disease associations with tomato consumption can be attributed to the biological effects of lycopene. However, tomatoes also contain significant amounts of other carotenoids, vitamin C, bioflavonoids such as naringenin, and phenolic acids such as chlorogenic acid. Much of the existing epidemiological evidence for possible beneficial effects of lycopene (see below) cannot distinguish unequivocally between the biological effects of lycopene and those of the many other bioactive constituents present in tomatoes.

The bioavailability of lycopene from raw tomatoes is low, but it is greatly increased by cooking or by commercial processing such as conversion to soup, sauce, ketchup, etc., and its availability is also increased by increasing the fat content of the food. Interactions with other carotenoids are complex and have only partly been studied, for instance β-carotene in the same dish seems to increase the absorption of lycopene, but large doses of β-carotene given separately seem to decrease the lycopene content of serum lipoproteins. The contribution of several categories of tomato product to intakes in a recent survey of older people in Britain is shown in **Table 2**. The strength of the correlation between dietary lycopene intake and blood (serum or plasma) lycopene concentration varies greatly among studies

Table 2 Tomato products consumed by people aged 65 years and over in Britain

Categories of tomatoes and tomato products	*Percentage of each category consumed*
Raw tomatoes	36.2
Processed tomatoes	
Soups	8.8
Canned tomatoes	7.0
Grilled	5.4
Fried	3.2
Ketchup	0.4
Tomato-based products	
Canned food	29.5
Pizza	2.3
Other	7.1
Total	99.9

Source: Re R, Mishra GD, Thane CW, and Bates CJ (2003) Tomato consumption and plasma lycopene concentration in people aged 65 years and over in a British National Survey. *European Journal of Clinical Nutrition* **57**: 1545–1554. Reproduced with permission from Nature Publishing Group.

and clearly depends on many factors, one of which is the degree of sophistication of the food table values, since subtle differences in food sources and meal composition affect its bioavailability very considerably.

Tissue Contents and Kinetics of Lycopene Turnover

Once absorbed, passively from lipid micelles by the enterocyte, lycopene enters the portal lymphatics and thence the liver, from which it enters the peripheral bloodstream, mainly in association with the β-lipoproteins, in which it is transported to the peripheral tissues. Its half-life in plasma is of the order of 12–33 days; longer than that of β-carotene, which is less than 12 days. Clearly, many of these factors are interdependent, and there is a need for further clarification of the key independent determinants of lycopene status, and whether plasma levels can provide an adequate picture of tissue and whole body status.

Patients with alcoholic cirrhosis of the liver have greatly reduced hepatic lycopene concentrations; indeed, hepatic lycopene seems to offer a sensitive index of hepatic health. Studies of organ concentrations (**Table 3**), suggest a gradient from circulating levels in plasma to different ones in specific tissues. The different carotenoid ratios between organs (not shown) also indicate selective transport and accumulation. However, the mechanisms involved are poorly understood. No lycopene is detectable in the retina or lens of the eye, where lutein and zeaxanthin are found; however, lycopene is present in the ciliary body.

Table 3 Concentrations of lycopene reported in human tissues

Tissue	*Range of mean or median lycopene concentrations (nmol per g wet weight)*
Adrenal	1.9–21.6
Testis	4.3–21.4
Liver	0.6–5.7
Brain	2.5
Lung	0.2–0.6
Kidney	0.1–0.6
Stomach, colon	0.2–0.3
Breast, cervix	0.2–0.8
Skin	0.4
Adipose tissue	0.2–1.3
Prostate	0.1–0.6
Plasma	0.2–1.1

Values were gathered from 11 publications, all based on HPLC analyses.

Functional Properties and Tissue Health

The capacity for quenching of singlet oxygen has been mentioned above; the exceptionally high rate constant, $K = 3.1 \times 10^{10}\,mol^{-1}\,s^{-1}$, renders it one of the most efficient of known quenchers of this powerful oxidant. In the plant, it probably protects chlorophyll, which produces singlet oxygen as a by-product of photosynthesis. In experiments with lymphoid cells, lycopene provided better protection against singlet oxygen damage than several other carotenoids tested. In skin exposed to UV light, lycopene disappears much more rapidly than β-carotene. Lycopene is also able, in model systems, to inhibit the peroxidation of polyunsaturated lipids and the oxidation of DNA bases to products such as 8-hydroxydeoxyguanosine (8-OHdG). It can react directly with hydrogen peroxide and nitrogen dioxide.

Several studies in cell culture have shown a reduction in the formation of oxidation damage products such as malondialdehyde, and have found less injury to cells exposed to oxidants such as carbon tetrachloride, if lycopene (or other carotenoids) are present.

Another characteristic of lycopene and other carotenoids that may be relevant to inhibition of cancer cell growth is the modulation of gap junction cell–cell communication processes. In particular, carotenoids including lycopene have been shown to enhance the efficacy of the protein, connexin43, which helps to ensure the maintenance of the differentiated state of cells and to reduce the probability of unregulated cell division, and which is deficient in many tumors. They may also interact with and enhance the synthesis of binding proteins that downregulate the receptor for the growth-promoting hormone insulin-like growth factor-1 (IGF-1).

In certain circumstances, lycopene can reduce LDL-cholesterol levels, possibly by inhibiting hydroxymethylglutaryl CoA reductase (HMGCoA reductase), the rate-limiting enzyme for cholesterol synthesis (see below). Lycopene was shown to have modest hypocholesterolemic properties in one small clinical trial.

Health, Research Models and Epidemiological Evidence

Table 4 summarizes the various types of evidence that have been used to test the hypothesis that lycopene may have health-promoting or protective properties in man. The ultimate proof of efficacy, which would be long-term controlled intervention studies with clinical diseases and or mortality as the end points, are extremely difficult,

Table 4 Types of evidence being sought, that a nutrient such as lycopene may protect against oxidation-induced or other disease processes

1. Model *in vitro* systems, e.g., oxygen-derived free-radical trapping in pure chemical mixtures.
2. Tissue (cell and organ) cultures, e.g., reduction of optical opacity development in cultured eye lenses; reduced growth rates or apoptosis in tumor cell cultures.
3. Animal studies demonstrating a reduction of oxidation-induced damage or disease with lycopene supplements or with lycopene-rich foods such as tomatoes or tomato products.
4. Human observation studies using intermediate biochemical markers: e.g., inverse relationships between lycopene intakes or its blood levels and biochemical markers, such as lipid or DNA oxidation products.
5. Studies using pathology-related intermediate markers, e.g., arterial thickening or reduced arterial elasticity; precancerous polyposis, etc.
6. Relationships (without intervention) between tomato intakes or estimated lycopene intakes or lycopene contents of serum, plasma, or tissues (e.g., fat biopsies) and actual disease prevalence or incidence in human cross-sectional, case-control, or prospective epidemiological studies.
7. Intervention studies: lycopene supplements producing a reduction in biochemical markers of oxidation damage or in functional markers, or, eventually, in actual human disease incidence or progression.

expensive, and time-consuming to obtain, and cannot address all possible benefits in a single intervention trial.

The two disease categories that have so far received most attention for possible long-term benefits of lycopene have been the amelioration of cancers and of heart disease. Both benefits are plausible in view of the physicochemical and biological properties of lycopene outlined above, because both categories of disease are characterized by tissue damage, which is thought to be induced or exacerbated by reactive oxygen species in the environment or those generated within the body.

Evidence for Possible Anticancer Protection by Lycopene

Most of the indications with respect to cancer comes from human studies linking tomato intake, total estimated lycopene intake, and serum or plasma lycopene concentrations to the subsequent development of cancers (**Table 5**). There is a small amount of evidence from experimental animal studies, for instance, rat and mouse dimethylbenzanthracene-induced mammary tumor studies have supported the hypothesis, as has a model of spontaneous mammary tumor formation in one strain of mice, but many of the animal models of tumor promotion have been criticized as being too dissimilar from the likely processes of spontaneous tumorigenesis in humans.

Partly for historical reasons, there has been a particular interest in prostate cancer (**Table 5**). A large and early trial in the US (US Health Professionals Follow-up Study) reported an impressive difference between groups with high and low intakes of tomatoes and hence of lycopene for subsequent prostate cancer development, which was not shared with other carotenoids. Plausibility was enhanced by the fact that although human prostate lycopene concentrations are not especially high on an absolute basis (**Table 3**), they are higher than those of other carotenoids in this tissue. Subsequent studies have had variable outcomes. A small pilot study reported that tomato oleoresin supplements given for a short period to prostate cancer sufferers who were due for radical prostatectomy resulted in smaller tumor size and other apparent benefits, but this trial now needs to be repeated on a larger scale.

Table 5 Summary evidence for possible lycopene protection against prostate cancer

No. of studies	*Locations*	*Total no. of participants*	*Types of trial*	*Outcome conclusion*
2	Greece, Canada	937	Case–control (intake of tomato or lycopene, or blood level)	Significant association
7	USA, UK, Canada, New Zealand	3824	As above	No significant association
3	USA	954	Prospective studies based on dietary estimates	Significant association
1	Netherlands		As above	No association
3	USA	723	Prospective studies based on serum or plasma lycopene	Inconclusive; one study found a marginal ($P = 0.05$) benefit vs. aggressive cancer

Table 6 Summary evidence of association of relatively high serum or plasma lycopene with lowered risk of cardiovascular disease (CVD)

Study	*Location*	*Sex (total participants)*	*Types of trial and outcome measures*	*Outcome conclusion*
Euramic	Europe, multicenter	M (1379)	C-C, MI	Significant association with protection[a]
ARIC	USA	M + F (462)	C-C, IMT	NS
Street	USA	M + F (369)	NC-C, MI in smokers	NS
Rotterdam	Netherlands	M + F (216)	C-C, PC	Significant association with protection
Bruneck	Italy	M + F (392)	CS + PFU, PC	NS
Linkoping –Vinus	Sweden and Lithuania	M (210)	CS, mortality from heart disease	NS
Kuopio (KHID)	Finland	M (725)	PFU, acute coronary event or stroke	Significant association with protection
Kuopio (ASP)	Finland	M + F (520)	IMT	Males significant; females not significant.

[a]No association with plasma β-carotene in this study.

C-C, case–control study; NC-C, nested case–control study; CS, cross-sectional study; PFU, prospective follow-up study; MI, myocardial infarct; IMT, intima-media thickness estimate; PC, plaque count. NS, no significant evidence for protection.Significance generally after appropriate adjustment for other known CVD risk factors.

Several studies have provided evidence for protection of certain regions of the digestive tract against tumor occurrence or growth. Two studies, one in Iran and another in Italy, found an inverse relationship between esophageal cancer and tomato consumption. Two Italian and one Japanese study reported evidence for protection against gastric cancer, and two studies claimed a reduction in pancreatic cancer. Results with others cancer have been mixed and inconclusive.

Lycopene and Cardiovascular Disease

Table 6 summarizes the evidence. The European Multicentre Euramic Study, which reported that risk of developing myocardial infarct was inversely related to lycopene intake, after appropriate adjustment for other cardiovascular risk factors. Some Scandinavian studies have subsequently supported this claim; moreover, lycopene is capable of reducing LDL-cholesterol levels, possibly by inhibiting hydroxymethylglutaryl CoA reductase (HMGCoA reductase), the rate-limiting enzyme for cholesterol synthesis.

Other Disease-Related Investigations

In an organ culture model, some evidence for protection of rat lenses against induction of cataractogenesis has been reported. There is good reason to believe that carotenoids in general may play a role in the protection of ocular tissues against the damaging effects of UV light and of reactive oxygen substances, whose exposure to light carries some analogy with the known functions of carotenoids in plant tissues. A possible protective role in the ciliary body and iris has been proposed, but not yet tested.

Conclusions

Clearly lycopene possesses chemical and biological properties, which make it a very attractive candidate for tissue protection and reduction of disease, especially degenerative diseases. Lycopene probably interacts more efficiently with one particular reactive oxygen species, singlet oxygen, than any other commonly occurring nutrient. It appears to share with several other carotenoids the capacity to reduce lipid peroxidation and DNA oxidative damage, and to enhance cell–cell gap junction communication and to protect normal IGF-1 function. It may reduce cholesterol formation and its tissue accumulation in some circumstances. Studies related to cancers and cardiovascular disease are ongoing and are attracting increased research interest.

MAGNESIUM

C Feillet-Coudray and Y Rayssiguier, National Institute for Agricultural Research, Clermont-Ferrand, France

Magnesium (Mg), the second intracellular cation after sodium, is a essential mineral. It is a critical cofactor in more than 300 enzymatic reactions. It may be required for substrate formation (Mg-ATP) and enzyme activation. It is critical for a great number of cellular functions, including oxidative phosphorylation, glycolysis, DNA transcription, and protein synthesis. It is involved in ion currents and membrane stabilization. Mg deficiency may be implicated in various metabolic disorders, including cardiovascular diseases, immune dysfunction and free radical damage.

Magnesium Metabolism

Distribution of Mg within the Body

The normal adult body contains approximately 25 g of Mg, with more than 60% in bone tissue (**Table 1**). Only a fraction of bone Mg (at the surface of the bone crystal) is exchangeable with extracellular Mg. The muscle contains 25% of total body Mg, and extracellular Mg accounts for only 1%. Plasma Mg is approximately 0.8 mmol/l, half of which is ionised and active in physiological reactions half bound to proteins or complexed to anions. In cells, Mg is associated with various structures, such as the nucleus and intracellular organelles, and free Mg accounts for 1–5% of total cellular Mg. Intracellular free Mg is maintained at a relatively constant level, even if extracellular Mg level varies. This phenomenon is due to the limited permeability of the plasma membrane to Mg and the existence of specific Mg transport systems that regulate the rates at which Mg is taken up by cells or extruded from cells. Mechanisms by which Mg is taken up by cells have not been completely elucidated, and Mg efflux particularly requires the antiport Na^{+}/Mg^{2+}. Various hormonal and pharmacological factors influence Mg transport, and it can be assumed that recent developments in molecular genetics will lead to the identification of proteins implicated in Mg transport.

Intestinal Absorption

Net Mg absorption results from dietary Mg absorption and Mg secretion into the intestinal tract via bile and gastric and pancreatic juice. In healthy adults, 30–50% of dietary Mg is absorbed. The secreted Mg is efficiently reabsorbed and endogenous fecal losses are only 20–50 mg/day. Mg absorption occurs along the entire intestinal tract, but the distal small intestine (jejunum and ileum) is the primary site. It is essentially a passive intercellular process by electrochemical gradient and solvent drag. The active transport occurs only for extremely low dietary Mg intake and its regulation is unknown. Mg uptake in the brush border may be mediated by a Mg/anion complex, and Mg efflux across the basolateral membrane may involve Na^{+}/Mg^{2+} antiport systems. A gene implicated in Mg deficit in humans has been identified. It is expressed in intestine and kidney and appears to encode for a protein that combines Ca- and Mg-permeable channel properties with protein kinase activity. This gene may be implicated in Mg absorption. Because of the importance of the passive process, the quantity of Mg in the digestive tract is the major factor controlling the amount of Mg absorbed.

The possibility of an adaptative increase in the fraction of Mg absorbed as Mg intake is lowered is controversial. In fact, experimental studies indicate that fractional intestinal absorption of Mg is directly proportional to dietary Mg intake. Because only soluble Mg is absorbed, all the factors increasing Mg solubility increase its absorption while formation of insoluble complexes in the intestine may decrease Mg absorption. Most well-controlled studies indicate that high calcium intake does not affect intestinal Mg absorption in humans. In contrast, dietary phytate in excess impairs Mg

Table 1 Magnesium in human tissues

	% distribution	*Concentration*
Bone	60–65	0.5% of bone ash
Muscle	27	6–10 mmol/kg wet weight
Other cells	6–7	6–10 mmol/kg wet weight
Extracellular	<1	
Erythrocytes		2.5 mmol/l
Serum		0.7–1.1 mol/l
Free	55	
Complexed	13	
Bound	32	
Mononuclear blood cells		2.3–3.5 fmol/cell
Cerebrospinal fluid		1.25 mmol/l
Free	55	
Complexed	45	
Sweat		0.3 mmol/l (in hot environment)
Secretions		0.3–0.7 mmol/l

From *Molecular Aspects of Medicine*, vol. 24, Vormann J: Magnesium: nutrition and metabolism, pp. 27–37, Copyright 2003, with permission from Elsevier.

absorption by formation of insoluble complexes in the intestinal tract. Negative effects of a high intake of dietary fiber have often been reported, but these actions have certainly been overestimated. In fact, only the impact of purified fiber was considered, but fiber-rich diets are a major source of Mg and roles of the intestinal fermentation and the large bowel in mineral absorption were neglected. It was demonstrated in animal models that fermentable carbohydrates (oligosaccharides and resistant starch) enhance Mg absorption in the large bowel and that a similar effect exists in humans. Other nutrients may influence Mg absorption but these effects are important only at low dietary Mg intake.

Urinary Excretion

Magnesium homeostasis is essentially regulated by a process of filtration–reabsorption in the kidney. Urinary Mg excretion increases when Mg intake is in excess, whereas the kidney conserves Mg in the case of Mg deprivation. Usually, 1000 mmol/24 h of Mg is filtered and only 3 mmol/24 h is excreted in urine.

A total of 10–15% of the filtered Mg is reabsorbed in the proximal tubule by a passive process. The majority of filtered Mg (65%) is reabsorbed in the thick ascending loop of Henle. The reabsorption in this segment is mediated by a paracellular mechanism involving paracellin-1. It is also related to sodium transport by a dependence on the transepithelial potential generated by NaCl absorption. Thus, factors that impair NaCl reabsorption in the thick ascending loop of Henle, such as osmotic diuretics, loop diuretics, and extracellular fluid volume expansion, increase Mg excretion. At least 10–15% of the filtered Mg is reabsorbed in the distal tubule. The reabsorption occurs via an active transcellular mechanism and is under the control of special divalent cation-sensing receptors. Thus, elevated plasma Mg concentrations inhibit reabsorption of Mg from the distal tubule, leading to an increased magnesuria. Other active transport may also exist since some hormones (parathyroid hormone, glucagon, calcitonin, and insulin) may increase Mg reabsorption. Other factors may also influence Mg reabsorption, such as hypercalciuria or hypophosphatemia, which inhibit the tubular reabsorption of Mg. Metabolic alkalosis leads to renal Mg conservation, whereas metabolic acidosis is associated with urinary Mg wasting. Thus, the chronic low-grade metabolic acidosis in humans eating Western diets may contribute to decreased Mg status.

Dietary Sources of Magnesium

Mg is present in all foods, but the Mg content varies substantially (**Table 2**). Cereals and nuts have high Mg content. Vegetables are moderately rich in Mg, and meat, eggs, and milk are poor in Mg. A substantial amount of Mg may be lost during food processing, and refined foods generally have a low Mg content. In addition to Mg content, it is important to consider the Mg density of food (i.e., the quantity of Mg per unit of energy). Vegetables, legumes, and cereals thus contribute efficiently to daily Mg intake, whereas fat- and/or sugar-rich products have a minor contribution. Some water can also be a substantial source of Mg, but it depends on the area from which the water derives.

Table 2 Mg density of foods

Food	*Magnesium density (mg/MJ)*
Vegetables (lettuce, broccoli)	211
Legumes (bean)	113
Whole cereal (wheat)	104
Nuts (almond)	105
Fruits (apple)	30
Fish (cod)	75
Meat (roast beef)	40
Whole milk	38
Cheese (camembert)	15
Eggs	18
Dessert	
Biscuit	10
Chocolate	52

Requirements

Assessment of Mg Status

Several potential markers for estimating daily Mg requirement have been suggested. Plasma Mg concentration is the most commonly used marker to assess Mg status. In healthy populations, the plasma Mg value is 0.86 mmol/l and the reference value is 0.75–0.96 mmol/l. A low plasma Mg value reflects Mg depletion, but a normal plasma Mg level may coexist with low intracellular Mg. Thus, despite its interest, plasma Mg is not a good marker of Mg status.

Ion-specific electrodes have become available for determining ionized Mg in plasma, and this measurement may be a better marker of Mg status than total plasma Mg. However, further investigation is necessary to achieve a standardized procedure and to validate its use as an appropriate marker of Mg status.

Erythrocyte Mg level is also commonly used to assess Mg status, and the normal value is 2.06–2.54 mmol/l. However, erythrocyte Mg level is under genetic control, and numerous studies have shown no correlation between erythrocyte Mg and other tissue Mg.

The total Mg content of white blood cells has been proposed to be an index of Mg status. However, lymphocytes, polymorphonuclear blood cells, and platelets may have protective mechanisms against intracellular Mg deficiency, and the determination of total Mg content in leukocytes and platelets to assess Mg status is of questionable usefulness.

Mg excretion determination is helpful for the diagnosis of Mg deficit when there is an hypomagnesemia. In healthy populations, the urinary Mg value is 4.32 mmol/day and the reference value is 1.3–8.2 mmol/day. In the presence of hypomagnesemia, normal or high urinary Mg excretion is suggestive of renal wasting. On the contrary, Mg urinary excretion lower than normal values is convincing evidence of Mg deficiency.

The parenteral loading test is probably the best available marker for the diagnosis of Mg deficiency. The Mg retention after parenteral administration of Mg seems to reflect the general intracellular Mg content, and a Mg retention more than 20% of the administered Mg suggests Mg deficiency. However, this test is not valid in the case of abnormal urinary Mg excretion and is contraindicated in renal failure.

Determination of exchangeable Mg pools using Mg stable isotopes is an interesting approach to evaluate Mg status. In fact, Mg exchangeable pool sizes vary with dietary Mg in animals. However, more studies are necessary to better appreciate the relationship between Mg status and exchangeable Mg pool size in humans.

Magnesium Deficit

Two types of Mg deficit must be differentiated. Dietary Mg deficiency results from an insufficient intake of Mg. Secondary Mg deficiency is related to dysregulation of the control mechanisms of Mg metabolism.

Dietary Mg Deficiency

Severe Mg deficiency is very rare, whereas marginal Mg deficiency is common in industrialized countries. Low dietary Mg intake may result from a low energy intake (reduction of energy output necessary for physical activity and thermoregulation, and thus of energy input) and/or from low Mg density of the diet (i.e., refined and/or processed foods). Moreover, in industrialized countries, diets are rich in animal source foods and low in vegetable foods. This leads to a dietary net acid load and thus a negative effect on Mg balance. In fact, animal source foods provide predominantly acid precursors (sulphur-containing amino acids), whereas fruits and vegetables have substantial amounts of base precursor (organic acids plus potassium salts). Acidosis increases Mg urinary excretion by decreasing Mg reabsorption in the loop of Henle and the distal tubule, and potassium depletion impairs Mg reabsorption. Mg deficiency treatment simply requires oral nutritional physiological Mg supplementation.

Secondary Mg Deficiency

Failure of the mechanisms that ensure Mg homeostasis, or endogenous or iatrogenic perturbing factors of Mg status, leads to secondary Mg deficit. Secondary Mg deficiency requires a more or less specific correction of its causal dysregulation.

Intestinal Mg absorption decreases in the case of malabsorption syndromes, such as chronic diarrhoea, inflammatory enteropathy, intestinal resection, and biliary and intestinal fistulas.

Hypermagnesuria is encountered in the case of metabolic and iatrogenic disorders, such as primary and secondary hyperaldosteronism (extracellular volume expansion), hypercalcemia (competition Ca/Mg at the thick ascending loop of Henle), hyperparathyroidism, and phosphate or potassium depletion. Hypermagnesuria may also result from tubulopathy, as the selective defect of the Mg tubular reabsorption (chromosome 11q23), Bartter's

syndrome (thick ascending loop of Henle), or Gitelman's syndrome (distal convoluted tubule).

Administration of medications can be a causal factor in the development of secondary Mg deficiency. Administration of diuretics is the main cause of iatrogenic deficit because it decreases NaCl reabsorption in the thick ascending loop of Henle and thus increases the fractional excretion of Mg.

Causes of Mg Deficit

Complex relations exist between Mg and carbohydrate metabolism. Diabetes is frequently associated with Mg deficit and insulin may play an important role in the regulation of intracellular Mg content by stimulating cellular Mg uptake. Hypomagnesemia is the most common ionic abnormality in alcoholism because of poor nutritional status and Mg malabsorption, alcoholic ketoacidosis, hypophosphatemia, and hyperaldosteronism secondary to liver disease.

Stress can contribute to Mg deficit by stimulating the production of hormones and thus increasing urinary Mg excretion and by impairing neurohormonal mechanisms that spare Mg.

Consequences of Mg Deficit and Implications in Various Metabolic Diseases

Mg deficit causes neuromuscular manifestations, including positive Chvostek and Trousseau signs, muscular fasciculations, tremor, tetany, nausea, and vomiting. The pathogenesis of the neuromuscular irritability is complex, and it implicates the central and peripheral nervous system, the neuromuscular junction, and muscle cells.

Mg deficit perturbs Ca homeostasis and hypocalcemia is a common manifestation of severe Mg deficit. Impaired release of parathyroid hormone (PTH) and skeletal end organ resistance to PTH appear to be the major factors implicated, probably by a decrease in adenylcyclase activity.

Perturbations in the action and/or metabolism of vitamin D may also occur in Mg deficit. Because Mg plays a key role in skeletal metabolism, Mg deficit may be a possible risk factor for osteoporosis. However, epidemiologic studies relating Mg intake to bone mass or rate of bone loss have been conflicting, and further investigation is necessary to clarify the role of Mg in bone metabolism and osteoporosis.

Hypokalemia is frequently encountered in Mg deficit. This is due to an inhibition of Na,K-ATPase activity that impairs K and Na transport in and out of the cell and to stimulation of renin and aldosterone secretion that increases K urinary excretion.

There is increasing evidence that Mg deficiency may be involved in the development of various pathologies. Mg deficit is frequent in diabetes and can be a factor in insulin resistance. It can modify insulin sensitivity, probably by influencing intracellular signaling and processing. Mg deficit has also been implicated in the development or progression of micro- and macroangiopathy and neuropathy.

Mg deficit appears to act as a cardiovascular risk factor. Experimental, clinical, and epidemiological evidence points to an important role of Mg in blood pressure regulation. Mg deficit can lead to cardiac arrhythmias and to increased sensitivity to cardiac glucosides. Mg deficit may also play a role in the development of atherosclerosis. In experimental animal models, dietary Mg deficiency results in dyslipidemia, increased sensitivity to oxidative stress, and a marked proinflammatory effect, thus accelerating atherogenosis. Macrophages and polynuclear neutrophils are activated and synthesize a variety of biological substances, some of which are powerful inducers of inflammatory events (cytokines, free radicals, and eicosanoids). The effect of Mg depletion or Mg supplementation may result in the ability of Mg to modulate intracellular calcium. Pharmacological doses of Mg may reduce morbidity and mortality in the period following infarction. The beneficial effect of Mg may result from calcium-antagonist action, decreased platelet aggregation, and decreased free radical damage.

Magnesium Excess

Magnesium overload can occur in individuals with impaired renal function or during massive intravenous administration of Mg. It is most often iatrogenic. Clinical symptoms such as drowsiness and hyporeflexia develop when plasma Mg is 2- or 3-fold higher than the normal value.

Recommended Dietary Allowances

The Estimated Average Requirement (EAR) is the nutrient intake value that is estimated to meet the requirement of 50% of individuals in a life stage and a gender group. Balance studies and data on stable isotopes suggest an EAR of 5 mg/kg/day for males and females. This value is greater during growth in adolescents and is estimated to be 5.3 mg/kg/day. The Mg requirement is also higher during pregnancy because of Mg transfer to the fetus in the last 3 months; therefore, an additional 35 mg/day is recommended.

In infants, the determination of the Adequate Intake (AI) is based on the Mg content of mother's milk and the progressive consumption of solid food.

Table 3 Recommended dietary allowances of Mg

Age	RDA (mg/day)		AI (mg/day)	
	Male	Female	Male	Female
0–6 months			30	30
6–12 months			75	75
1–3 years	80	80		
4–8 years	130	130		
9–13 years	240	240		
14–18 years	410	360		
19–30 years	400	310		
31–50 years	420	320		
51–70 years	420	320		
<70 years	420	320		
Pregnancy		+40		
Lactation		+0		

From the Institute of Medicine (1997).

Thus, the AI is 30 mg/day during the first 6 months of life and 75 mg/day the second 6 months of life.

The Recommended Dietary Allowance (RDA) is the average daily dietary intake that is sufficient to meet the nutrient requirement of 97.5% of individuals and is set at 20% above the EAR +2 CVs where the CV is 10%. During recent years, dietary reference intakes have been revised by the US Institute of Medicine. The recommended intakes of Mg are given in **Table 3**. It is not known whether decreased urinary Mg and increased maternal bone resorption provide sufficient amounts of Mg to meet increased needs during lactation. Thus, the French Society for Nutrition suggests adding 30 mg/day to intake for lactation.

The intake of Mg has been determined in various populations. Evidence suggests that the occidental diet is relatively deficient in Mg, whereas the vegetarian diet is rich in Mg. For instance, the mean Mg intake of the subjects in the French Supplementation with Antioxidant Vitamins and Minerals Study was estimated to be 369 mg/day in men and 280 mg/day in women. Thus, 77% of women and 72% of men had dietary Mg intakes lower than the RDA, and 23% of women and 18% of men consumed less than two-thirds of the RDA.

Conclusion

Based on evidence of low Mg intake in industrialized countries, intervention studies to improve Mg status and to assess its impact on specific health outcomes are required.

MALABSORPTION SYNDROMES

P M Tsai and C Duggan, Harvard Medical School, Boston, MA, USA

The human gastrointestinal tract has an impressive capacity for water, electrolyte, and nutrient absorption. In some disease states, however, this excess capacity is outpaced by either intestinal secretion or inadequate absorption. Malabsorption is defined as the inability of the gastrointestinal tract to adequately absorb nutrients. Although strictly speaking, malabsorption is distinct and contrasted with maldigestion (inadequate breakdown of nutrients in the intestinal lumen), the therapeutic implications of these two conditions are often similar. Multiple causes of malabsorption exist (e.g., inflammatory bowel disease, cystic fibrosis, and short bowel syndrome). We review the pathophysiology, symptoms, and nutritional therapies for common malabsorption syndromes.

Pathophysiology and Symptoms

Malabsorption can occur when any of the several steps in nutrient digestion, absorption, and/or assimilation are interrupted; see **Table 1** for a list of congenital defects in nutrient assimilation. Carbohydrate malabsorption can occur, for instance, when intestinal disaccharidases are reduced in concentration at the enterocyte. The brush border membrane produces four disaccharidases that are important in carbohydrate digestion. These enzymes are sucrase–isomaltase, maltase–glucoamylase, trehalase, and lactase–phlorizin hydrolase. Worldwide, lactase deficiency is the most common type of acquired disaccharidase deficiency since much of the world's population exhibits a noticeable reduction in intestinal lactase concentration after the age of 2 years. In addition, infants and children with diarrheal disease may suffer from acquired lactase deficiency due to intestinal villous damage that is often temporary. With either congenital or acquired lactase deficiency, malabsorbed carbohydrate remains in the intestinal lumen and exerts an osmotic pull on fluids and electrolytes, leading to abdominal cramping and loose stools. Malabsorbed carbohydrate can be metabolized by gastrointestinal tract bacteria, and the fermented gas produced is associated with flatulence and bloating. Bacterial overgrowth of the small intestine, as seen with short bowel syndrome, can also be associated with carbohydrate malabsorption.

Steatorrhea, excessive fat in the stools, results from fat malabsorption and can have several causes, most notably pancreatic insufficiency due to cystic fibrosis, chronic pancreatitis, Shwachman–Diamond syndrome, and Johanson–Blizzard syndrome. Failure of pancreatic secretion of lipase, amylase, and other digestive enzymes leads to persistence of dietary fat in the intestinal lumen, causing bloating, abdominal pain, and bulky, foul-smelling, oily stools. The stools often float due to a high gas content and test positive for fat. Patients also complain of blunted appetite and nausea. Other causes of fat malabsorption include hepatobiliary disease with inadequate bile salt circulation, severe mucosal disease, and short bowel syndrome.

The most common cause of protein malabsorption is so-called protein-losing enteropathy. Etiologies include diffuse mucosal disease such as celiac disease or Crohn's disease, elevated right heart pressure with resultant dilatation of lymphatics and leakage of lymph into the lumen, and colitides such as *Shigella* or *Salmonella* infections. Since protein is a relatively minor component of dietary energy compared with carbohydrate and fat, symptoms of protein malabsorption can sometimes be minimal. However, infectious colitis or exacerbations of inflammatory bowel disease often present with frequent loose stools, which may be bloody. Rare, congenital etiologies of protein malabsorption include enterokinase and trypsinogen deficiencies (**Table 1**).

Finally, the malabsorption of various micronutrients can occur in conjunction with or separate from the macronutrient malabsorption syndromes noted previously. For instance, steatorrhea can be accompanied by excessive fecal losses of the fat-soluble vitamins A, D, E, and K as well as calcium and other minerals. Alternatively, atrophic gastritis or surgical resection of the terminal ileum can lead to vitamin B_{12} malabsorption in the absence of any symptoms of diarrhea. Proximal bowel resection can result in iron, zinc, and calcium malabsorption. A rare cause of micronutrient inadequacy is abetalipoproteinemia, in which fat-soluble nutrients are normally digested and absorbed by the intestine but are not delivered to the circulation due to defective transepithelial transport. Other rare causes of micronutrient malabsorption are noted in **Table 1**.

Table 1 Congenital defects in nutrient assimilation[a]

Disorder	*Enzyme/protein affected*	*Symptoms*
Carbohydrate digestion		
Congenital lactase deficiency	Lactase	Lactose-induced diarrhea
Hypolactasia	Lactase	Lactose-induced diarrhea
Congenital sucrase–isomaltase deficiency	Sucrase–isomaltase	Sucrose-induced diarrhea
Glucoamylase deficiency	Glucoamylase	Starch-induced diarrhea
Trehalase deficiency	Trehalase	Trehalose-induced diarrhea
Carbohydrate absorption		
Glucose–galactose malabsorption	Sodium–glucose cotransport (SGLT1)	Glucose-induced diarrhea
Fructose malabsorption	Facilitative fructose transport (GLUT5)	Fructose-induced diarrhea
Fanconi–Bickel syndrome	Facilitative glucose transport (GLUT2)	Diarrhea and nephropathy
Protein digestion		
Enterokinase deficiency	Enterokinase	Diarrhea and edema
Trypsinogen deficiency	Trypsinogen	Diarrhea and edema
Fat digestion		
Pancreatic lipase deficiency	Pancreatic lipase	Steatorrhea
Fat assimilation		
Abetalipoproteinemia	Microsomal triglyceride transfer protein	Steatorrhea
Hypobetalipoproteinemia	Apolipoprotein B	Steatorrhea
Chylomicron retention disease	Sar1-ADP-ribosylation factor family GTPases	Steatorrhea
Primary bile acid malabsorption	Sodium–bile acid transporter	Steatorrhea, bile acid diarrhea
Tangier disease	ATP binding cassette transporter 1	Hepatosplenomegaly
Sitosterolemia	ATP binding cassette subfamily G, member 8	Atherosclerosis
Ion and metal absorption		
Congenital sodium diarrhea	Defective Na^+/H^+ exchange	Secretory diarrhea
Congenital chloride diarrhea	Defective $Cl^-/HCO3^-$ exchange	Secretory diarrhea
Cystic fibrosis	CFTR	Pancreatic insufficiency, meconium ileus
Acrodermatitis enteropathica	Zinc and iron-regulated transport proteins (ZIP4)	Diarrhea and dermatitis
Menkes disease	Copper transporter	Developmental delay
Wilson's disease	Copper transporter	Cirrhosis
Primary hypomagnesemia	Paracellin	Seizures, deafness and polyuria
Hemachromatosis	Hepcidin, others	Cirrhosis, cardiomyopathy, diabetes
Vitamin absorption		
Folate malabsorption	?	Macrocytic anemia, diarrhea, developmental delay
Congenital pernicious anemia	Intrinsic factor	Macrocytic anemia, developmental delay
Imerslund–Graesbeck syndrome	Cubilin, amnionless	Macrocytic anemia, proteinuria
Congenital deficit of transcobalamin II	transcobalamin II	Macrocytic anemia, diarrhea, developmental delay
Thiamine-responsive megaloblastic anemia	Thiamine transport protein	Anemia, diabetes, cranial nerve defects
Familial retinol binding protein (RBP) deficiency	RBP-4	Vitamin A deficiency
Selective vitamin E deficiency	α-Tocopheral transport protein	Vitamin E deficiency

[a]Included are congenital defects that are associated with gastrointestinal symptoms and/or nutritional deficiencies. Congenital defects not included here include multiple defects in amino acid absorption.
Adapted from Martin M and Wright EM (2004) Congenital intestinal transport defects. In: Walker WA, Goulet O, Kleinman RE *et al.* (eds.) *Pediatric Gastrointestinal Disease: Pathophysiology, Diagnosis, Management*, 4th edn. Hamilton, Ontario: BC Decker.

General Nutritional Management of Malabsorption

As with all nutritional disorders, a thorough nutritional assessment is needed to plan rational therapy of malabsorption. Important historical points to review include duration of symptoms, underlying etiology of malabsorption, ability to meet nutritional needs by mouth, the presence of food allergies, and concurrent medical and surgical problems. The patient's nutritional status (weight, height, body mass index, and their respective percentiles) should

be determined. Tests of body composition such as arm anthropometrics, bioelectrical impedance, or DXA studies should be considered. If the underlying cause of malabsorption is not known, diagnostic gastrointestinal endoscopy, laboratory studies, and/or imaging studies are indicated.

Specific Nutritional Management of Malabsorption

Fluids and Electrolytes

Diarrhea is usually the most distressing problem for patients with malabsorption and may cause dehydration. Care should be taken to correct fluid losses with appropriately designed oral rehydration solutions. Even in the setting of massive secretory diarrhea, such as seen with cholera infections, oral rehydration solutions are effective at treating dehydration. Data support the safety and efficacy of oral rehydration solutions of reduced osmolarity in children with dehydration from acute diarrhea. An oral rehydration solution composed of glucose 75 mmol/L, sodium 75 mmol/L, potassium 20 mmol/L, base 30 mEq/L, and osmolality 245 mOsm/L is well suited for the rehydration and maintenance therapy during dehydration due to diarrhea.

In some cases of severe diarrhea, parenteral hydration is the mainstay of therapy. Examples include glucose–galactose malabsorption, congenital chloride diarrhea, microvillous inclusion disease, and tufting enteropathy. These cases, as well as other severe causes of more common malabsorptive syndromes, also frequently require the use of parenteral nutrition therapy.

Carbohydrate Malabsorption

Lactose intolerance Lactose intolerance is defined by the occurrence of symptoms due to the inability to digest lactose, the main carbohydrate in milk. These symptoms may include abdominal pain, bloating, diarrhea, or flatulence. Lactose malabsorption is attributed to a relative deficiency of the disaccharidase lactase. Primary lactase deficiency is a condition in which lactase activity declines after weaning. Secondary lactose intolerance is usually due to mucosal injury associated with a condition or disease such as infectious diarrhea, Crohn's disease, or short bowel syndrome.

Although people of Northern European ancestry commonly maintain the ability to digest lactose into adulthood, the majority of the world's population produces less lactase after weaning. In addition to the presence or absence of the lactase enzyme, other factors determine whether a person will have symptoms of lactose malabsorption, including the amount of lactose in the diet, the mixture of lactose with other foods, gastric emptying rate, colonic scavenge of malabsorbed carbohydrate, ethnic origin, and age. Primary lactose intolerance is prevalent in African American, Hispanic, Native American, and Asian populations.

Nutritional management of lactose intolerance consists largely of the removal of lactose from the diet. Lactose is a common ingredient in many foods, including breads, crackers, soups, cereals, cookies, and baked goods. Eliminating or reducing lactose-containing ingredients from one's diet is usually adequate to relieve symptoms. Individuals with primary lactose intolerance may require a permanent dietary change. Individuals with secondary lactose intolerance should eliminate all lactose from their diets for a short period of time ranging from 2 to 6 weeks. If symptoms resolve, lactose may be reintroduced slowly as tolerated by the individual. The amount of lactose that an individual can tolerate is highly variable. Many children can tolerate small amounts of lactose, particularly yogurt, hard cheese, or ice cream, without discomfort. Many adults who consider themselves lactose-intolerant can actually tolerate moderate amounts of milk.

For individuals who choose to restrict lactose in their diets, a variety of lactose-free and low-lactose food choices are available. Lactose-reduced products, containing 70–100% less lactose than standard foods, are available commercially. Individuals may also choose to consume dairy products with concomitant administration of lactase enzyme tablets or drops.

Frequent consumption of milk and other dairy foods has been associated with better bone health in some studies, and a strict lactose-free diet may not contain adequate amounts of calcium and vitamin D. **Table 2** provides a list of some commercially available lactose-free calcium supplements.

Table 2 Commercial calcium supplements

Product	*Manufacturer*	*mg Calcium/ tablet*	*IU vitamin D*
Citracal + D	Mission Pharmacal	315	200
OsCal 500 + D	Marion Lab	500	200
Tums	Smith-Kline Beecham	200	0
Calcium Milk Free (2)	Nature's Plus	500	100
Cal-citrate + D	Freeda	250	100

From DiSanto C and Duggan C (2004) Gastrointestinal diseases. In: Hendricks KM and Duggan C (eds.) *Manual of Pediatric Nutrition*, 4th edn. Hamilton, Ontario: BC Decker.

Sucrose Congenital sucrase–isomaltase deficiency (SID) is the most common congenital disaccharidase deficiency. Patients with this disorder lack functional sucrase, although isomaltase deficiency may be normal or absent. Symptoms of SID can include diarrhea, abdominal pain, and poor weight gain. Dietary avoidance of sucrose or table sugar helps relieve symptoms and can sometimes help with the diagnosis. Sucraid, a sacrosidase produced from *Saccharomyces cerevisiae*, is an enzyme that can be given with meals and allows increased tolerance to sucrose.

Fat Malabsorption: Fat and Fat-Soluble Nutrients

Patients with pancreatic insufficiency are unable to produce and secrete enough enzymes to aid with the breakdown of fats in the intestinal lumen. Studies of normal adults and those with pancreatic insufficiency have demonstrated that pancreatic enzyme secretion needs to be less than 15% of normal levels before significant steatorrhea is seen (**Figure 1**). Once clinically significant steatorrhea is determined, recovery of pancreatic function is unlikely.

Historically, patients with pancreatic insufficiency due to cystic fibrosis (CF) were told to minimize symptoms of steatorrhea by limiting dietary fat. However, epidemiologic studies confirmed that this advice led to negative energy balance, undernutrition, and higher mortality rates compared to communities in which CF patients were treated with high-energy, high-fat diets. The introduction of effective pancreatic replacement therapy has been heralded as one of the most significant breakthroughs in the nutritional management of CF, responsible in part for the substantial increase in life span enjoyed by recent generations of CF patients. In fact, the finding of a lower incidence of growth failure in CF patients diagnosed and treated with aggressive nutritional therapy early in infancy has been used as justification for neonatal screening of this condition.

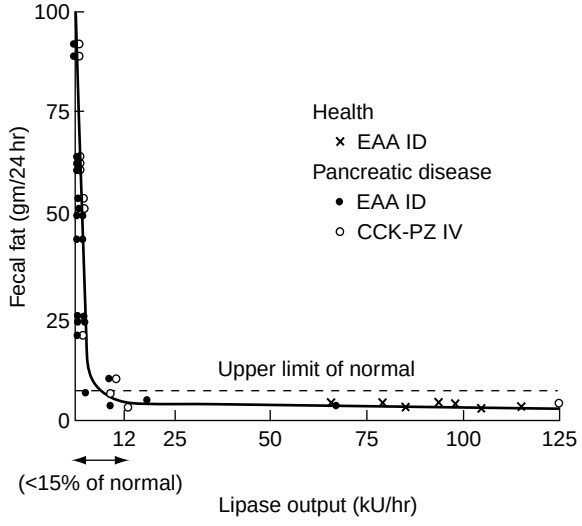

Figure 1 Pancreatic enzyme secretion and steatorrhea. Significant steatorrhea ensues when pancreatic function is less than 15% of normal. (Reproduced with permission from DiMagno EP, Go VLW, and Sumerskill WHJ (1973) Relations between pancreatic enzyme output and malabsorption in severe pancreatic insufficiency. *New England Journal of Medicine* **288**: 814).

Judicious use of pancreatic replacement enzymes is the hallmark of nutritional therapy of CF and other disorders of pancreatic insufficiency. Multiple commercial preparations of porcine pancreatic enzymes are available, most of which contain lipase, amylase, and protease enzymes. The dose is usually titrated to the amount of steatorrhea. If meals take more than 30 min, the dose may be divided, with half given before the meal and half given during the meal. Patients who cannot swallow pills may open the capsules and sprinkle the enzymes into acidic foods.

Another critical aspect of the nutritional management of fat malabsorption is routine supplementation with the fat-soluble vitamins A, D, E, and K. Multiple studies have confirmed that patients with CF, Crohn's disease, and other malabsorptive disorders are prone to micronutrient deficiencies, and some literature suggests that dietary needs for these and other antioxidant nutrients may be increased in settings of infectious and catabolic stress often suffered by these patients. The contribution of fat malabsorption to other important mineral malabsorption, as in the case of calcium or zinc, should also be recognized.

Routine supplementation of fat-soluble vitamins is indicated in patients with fat malabsorption. In addition, serial measurement of fat-soluble vitamin biochemical status is recommended. Since blood nutrient concentrations of these and other nutrients can vary with the concentration of transport proteins, correction for these can aid the interpretation of these lab findings. For instance, vitamin A toxicity should be suspected if the molar ratio of vitamin A:retinol binding protein exceeds 1. Vitamin E concentrations should be corrected for circulating lipids. **Table 3** lists recommendations for therapy of fat-soluble vitamin deficiencies.

Some patients with pancreatic malabsorption may benefit from a diet enriched with medium-chain triglycerides (MCTs). MCTs are absorbed directly into the portal circulation and therefore bypass the steps of intraluminal digestion, reesterification, and enterocyte uptake. Thus, MCTs may be a dietary source of fats more easily absorbed in settings of fat malabsorption due to either pancreatic insufficiency or mucosal disease. However, MCT oils are less energy dense than long-chain fats, more expensive, and do

Table 3 Assessment and treatment of fat-soluble vitamin deficiencies

Vitamin assessment	*Therapy if deficiency*	*Considerations*
A		
Normal: >20 μg/dl	Severe deficiency with xerophthalmia	Serum level is not a good indicator of liver stores.
Marginal stores: 10–19 μg/dl	<6 months old: 50 000 IU PO QD ×2 days, then again at 2 weeks	Low in chronic infection, liver disease, or during an acute phase response.
Deficient: <10 μg/dl	6–12 months: 100 000 IU PO QD ×2 days, then again at 2 weeks	Check retinol binding protein (RBP) circulation in plasma. Assess toxicity by using molar ratio of retinol to RBP:
	>12 months: 200 000 IU PO QD ×2 days, then again at 2 weeks	Retinol(μg/dl) × 0.0349 = μmol/l
	1–8 years: 5000 IU/kg/day ×5 days PO, then 5000–10 000 units/day ×2 months	RBP(mg/dl) × 0.476 = μmol/l
	>8 years and adults: 500 000 IU QD ×3 days, then 50 000 units/day ×14 days, then 10 000–20 000 units/day ×2 months	Molar ratio should be between 0.8 and 1.0. Ratios >1.0 suggest increased levels of free retinol and possible toxicity.
D		
25-OHD:	Vitamin D_2 (Ergocalciferol)	Low in dietary deficiency, decreased absorption, UV light deficiency, prematurity, liver disease, and with certain drugs (anticonvulsants). Higher in summer.
Normal: 9–75 ng/ml	Oral (Drisdol) liquid or capsule	
	Children with malabsorption	
	10 000–25 000 USP units PO/day until normal	Watch for hypercalcemia and hypercalciuria and other signs of toxicity.
	Children with normal absorption	
	1000–5000 units PO ×6–12 weeks	
	IM (Calciferol)—100 000 units/ml	
	10 000–100 000 units IM once. Larger single IM doses may be given.	
	Follow calcium, PTH, 25-OHD concentrations.	
E		
Deficiency if	1 unit/kg/day of water-miscible form plus usual vitamin E supplementation until normal blood levels	Carried exclusively on plasma lipoproteins; thus, vitamin E:total lipid ratio or vitamin E:chol + tryglycerides (TG) is a better indicator of stores than serum levels.
Plasma level <5 mg/L	1 unit = 1 mg dl-α-tocopherol acetate	Conversions
Vitamin E:total lipid ratio <0.6–0.8 mg/g in adults		Total lipids = cholesterol + TG + phospholipids
Vitamin E:chol + TG <1.59 μmol/mmol		Chol (mg/dl) × 0.0259 = chol (mmol/l)
Erythrocyte hemolysis >10%		TG (mg/dl) × 0.0113 = TG (mmol/l)
		Vitamin E (mg/l) × 2.32 = vitamin E (μmol/l)
		Do not give with medications that interfere with vitamin E absorption (vitamin A, cholestyramine, and antacids).
K		
Prothrombin time (PT) deficiency if >13.5 s	Infants and children	Deficiency in malabsorption, long-term antibiotic therapy.
	1–2 mg single IM, SC, or IV dose	
PIVKA-II deficiency if <3.0 ng/ml	Adults	
	10 mg single IM, SC, or IV dose	

From Corrales K (2005) Cystic fibrosis. In: Hendricks KM and Duggan C (eds.) *Manual of Pediatric Nutrition*, 4th edn. Hamilton, ON: BC Decker.

not contain the fatty acids linoleic and linolenic acid, which are essential to humans.

Protein Malabsorption

Protein-losing enteropathy (PLE) can also be treated with a variety of nutritional interventions. PLE due to dilated lymphatics, as with right heart failure, results in leakage of lymphocytes, proteins, and fats into the intestinal lumen. As with fat malabsorption, MCT-supplemented foods and formulas are indicated to allow improved fat absorption in PLE. Fat-soluble vitamin supplementation is indicated. In congenital protein malabsorption syndromes, peptide- or amino acid-based formulas are often helpful.

Mucosal disorders, including inflammatory bowel disease, allergic diseases, and celiac disease, are additional examples of disorders causing protein malabsorption. Once intestinal inflammation is reduced with appropriate medical or nutritional therapy, absorption of protein is usually improved. In Shigella infections, some studies have demonstrated improved nutritional outcomes with a high-protein diet during recovery from the acute symptoms of diarrhea.

Route of Nutrition in Malabsorption

Several factors need to be considered when recommending whether oral, enteral, or parenteral nutrition should be used to provide nutrition to the patient with malabsorption, including etiology of malabsorption, severity of gastrointestinal disease, and underlying nutritional and medical condition. Oral nutrition using modified diets as noted previously is the most customary and desirable by physician and patient alike. In cases of mild lactose malabsorption, modification of a regular, healthy diet to avoid foods high in lactose should be sufficient. In cases in which widespread gastrointestinal disease is leading to severe malabsorption, enteral or 'tube' feeding is helpful for two main reasons: (i) Use of proprietary formulas specially designed for malabsorption is often indicated, and these formulas may be unpalatable, and (ii) enteral feedings, especially slow continuous 'drip' feedings, make efficient use of nutrient transport kinetics, thereby maximizing residual gastrointestinal absorptive function. In severe cases of malabsorption in which tube feedings are unable to achieve adequate nutritional intake, parenteral nutrition may be indicated.

Selection of Enteral Formulas for Malabsorption

A number of commercially available formulas are designed for patients with malabsorption, and these differ with regard to energy density, macronutrient composition, and indicated age. Since infant formulas are often handled in a separate regulatory manner by governments, infant formulas are usually considered separately from formulas designed for older children and adults. In addition, formulas are also conventionally categorized by the extent of the hydrolysis of their protein source. Categories include intact protein formulas, protein hydrolysate formulas, and amino acid-based formulas. Protein hydrolysate formulas are also sometimes referred to as 'semielemental' formulas, and amino acid formulas are sometimes called 'elemental' formulas. However, these terms suffer from vagueness and inaccuracies since not all of their macronutrients are semi- or completely elemental. Marketing strategies often compound the confusion with misleading formula names. These terms should be discouraged, and the terms that refer to the composition and/or biochemical processing should be used instead.

Patients who have carbohydrate malabsorption from lactose intolerance should use lactose-free formula. Fat malabsorption calls for MCT-enriched formula. In cases of protein malabsorption or severe enteropathy, a formula that is a protein hydrolysate or amino acid-based would be most appropriate. Since many malabsorption syndromes overlap in terms of the macronutrient affected, as in cases of severe mucosal disease, some formulas are designed for fat, protein, and carbohydrate malabsorption. For example, all formulas designed for use in adults are lactose-free, and several formulas contain both hydrolyzed proteins and MCT oils.

Clinical Management of Malabsorption

Two of the most clinically challenging scenarios for the management of malabsorption are inflammatory bowel disease (especially Crohn's disease) and short bowel syndrome.

Inflammatory Bowel Disease

Patients with Crohn's disease have widespread and intermittent gastrointestinal inflammation. Some patients with inflammatory bowel disease may require complete bowel rest for several days or even a few weeks to allow time for mucosal healing. In order to provide nutrition during this period, parenteral nutrition may be needed.

Numerous studies have shown that patients with Crohn's disease may safely and effectively achieve clinical remission with primary nutritional therapy. Early literature in the field highlighted the use of protein hydrolysate formulas that, due to unpalatability, often required supplementation with a nasogastric or gastrostomy tube. Recent data have confirmed that intact protein formulas, termed 'polymeric' formulas when describing formulas designed for adults, may work as well as protein hydrolysates, and these formulas can feasibly be given by mouth.

As patients are recovering from an exacerbation and begin advancing their diet, they should temporarily minimize the amount of fiber ingested to decrease trauma to healing mucosa. Patients whose disease affects the small intestine often benefit from temporary avoidance of lactose products as the mucosa heals and brush border membrane enzyme production is restored.

Micronutrients are also needed in the nutritional management of inflammatory bowel disease. Iron supplementation is recommended for anemia that may be secondary to acute or chronic blood loss. Treatment of inflammatory bowel disease frequently requires the use of steroids, which affects bone density. Calcium and vitamin D supplementation is commonly needed to minimize the osteopenic effects of steroid therapy and/or the effects of malabsorption and chronic inflammation.

Short Bowel Syndrome

Patients who have suffered acquired or congenital loss of small intestinal surface area that makes them dependent on specialized enteral or parenteral

support are said to have short bowel syndrome (SBS). Patients with SBS often malabsorb carbohydrates, proteins, fat, as well as numerous micronutrients, depending on the extent and location of bowel resection as well as the presence of mucosal disease in the nonresected bowel.

Special attention should be given to the part of the intestine that remains as well as the length of the intestine. Some patients may have the terminal ileum removed and are unable to absorb vitamin B_{12} and bile acids. Removal of the ileocecal valve increases the risk of bacterial overgrowth. Reduced length also means reduced surface area for the absorption of nutrients and decreased intestinal transit time.

In the immediate postoperative period, parenteral nutrition and gut rest should be used because significant stool output is the norm. Output should be quantified, and electrolytes must be carefully monitored in order to determine appropriate replacement fluids to make up for excess urine, stool, and ostomy losses. Replacement fluids should generally be given separately from standard parenteral nutrition so that they can be adjusted as needed to rapid shifts in fluid and electrolyte status.

As patients recover from surgery, every attempt should be made to feed them enterally as soon as is feasible. Enteral feeds facilitate growth and adaptation of the remaining bowel to allow partial compensation for the missing portion, and several studies have correlated early feeding with better long-term outcome. Attaining independence from parenteral nutrition may take weeks, months, or years. **Table 4** outlines an approach to determining feeding advancement. Whereas some patients are able to grow well or maintain their body weight with enteral feeds, many are dependent on parenteral nutrition. Some patients with SBS also have oral feeding aversion due to prematurity, prolonged mechanical ventilation, and/or prolonged orogastric or nasogastric feeding. Gastrostomy tubes are particularly helpful in this regard.

In infants, breast milk should be used if available. The breast milk may need to be fortified to increase calories, protein, or fat. For older patients or infants who are not receiving breast milk, protein hydrolysates or amino acid-based formulas may be better tolerated since the residual bowel more easily absorbs these nutrients. Lactose-free and MCT-containing formulas are often used as well. Formulas may need to be supplemented with oral rehydration solutions if electrolyte abnormalities persist, particularly with sodium losses through persistent high stool or ostomy output.

Since many patients with SBS are dependent on parenteral nutrition for prolonged periods of time, selenium, carnitine, copper, and zinc blood concentrations should be checked periodically and supplemented if needed. Parenteral nutrition should be cycled off for a few hours each day to help simulate more natural cyclic fluctuations of gastrointestinal hormones. These patients also often have poor absorption of calcium and need calcium supplements to prevent osteopenia, which increases the risk of fractures. Iron may also be needed in patients with anemia from decreased absorption secondary to resection of the duodenum or jejunum. Ultimately, weaning from parenteral and enteral nutrition remains the goal of treatment, although lifelong dietary therapy is often needed.

Table 4 Feeding advancement in short bowel syndrome

Stool output		
If <10 g/kg/day or <10 stools/day	→	Advance rate by 10–20 ml/kg/day
If 10–20 g/kg/day or 10–12 stools/day	→	No change
If >20 g/kg/day or >12 stools/day	→	Reduce rate or hold feeds[a]
Ileostomy output		
If <2 g/kg/h	→	Advance rate by 10–20 ml/kg/day
If 2–3 g/kg/h	→	No change
If >3 g/kg/h	→	Reduce rate or hold feeds[a]
Stool reducing substances		
If <1%	→	Advance feeds per stool or ostomy output
If = 1%	→	No change
If >1%	→	Reduce rate or hold feeds[a]
Signs of dehydration		
If absent	→	Advance feeds per stool or ostomy output
If present	→	Reduce rate or hold feeds[a]
Gastric aspirates		
<Four times previous hour's infusion	→	Advance feeds
>Four times previous hour's infusion	→	Reduce rate or hold feeds[a]

[a]Feeds should generally be held for 8 h and then restarted at three-fourths of the previous rate.

Summary

Malabsorption can involve any of the macronutrients or micronutrients, and these disorders may be congenital or acquired. Determining the type of malabsorption and root cause is essential to providing appropriate nutritional therapy. Multiple formulas, supplements, and dietary regimens exist to target specific defects in the digestion, absorption, and assimilation of nutrients. In addition, many new nutrients are undergoing investigation that may become a standard part of care in the future, including probiotics, prebiotics, and various amino acids.

MALNUTRITION

Contents

Primary, Causes Epidemiology and Prevention

A Briend, Institut de Recherche pour le Développement, Paris, France
P Nestel, International Food Policy Research Institute, Washington, DC, USA

Undernutrition is a condition of poor health resulting from an inadequate intake of energy and/or essential nutrients. It can also be caused by an imbalance between energy and nutrient intakes and requirements due to infection that results in malabsorption, anorexia, or excessive losses.

Causes

The determinants of undernutrition can be categorized as being immediate, underlying, or basic (**Figure 1**). The immediate causes include dependence on a diet that is inadequate in quantity and/or quality. This can be due to low food availability or anorexia from recurrent infections and also poor health status that can result in a vicious cycle of ill health and undernutrition. The underlying determinants are food insecurity, inadequate care for mothers and children, and poor sanitation. The basic determinants influence the underlying determinants and include the environmental, technological, and human resources available to a country or community. Access to and use of resources are influenced by both the political and the economic structures as well as cultural and social factors that affect how resources are used to maintain and improve food security, the provision of care, and sanitation. The following discussion is limited to the immediate causes of undernutrition.

Undernutrition is intergenerational, and a cycle of ill health and growth failure frequently occurs in which undernutrition in childhood leads to small body size in adulthood (**Figure 2**). Genetic and environmental influences also affect both maternal height and prepregnancy weight, both of which are important determinants of birth size and, to a lesser extent, later growth and size.

Food Availability and Diet Quality

Poor access to and an inadequate intake of a good quality diet is the major cause of undernutrition in

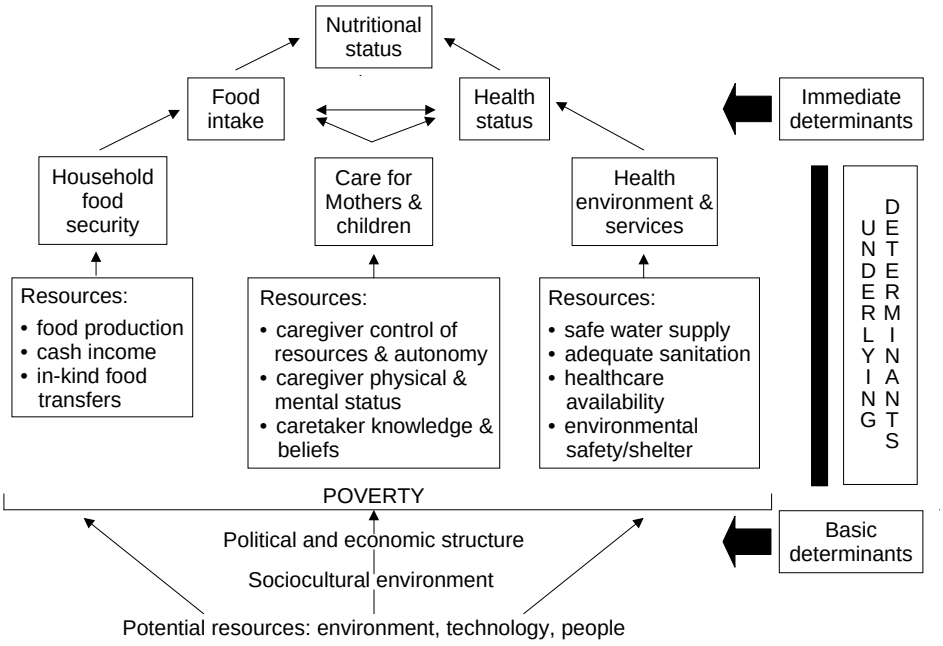

Figure 1 Determinants of undernutrition (Reproduced with permission from Smith LC and Haddad L (2000) *Overcoming Child Malnutrition in Developing Countries: Past Achievements and Future Choices*, Food, Agriculture, and the Environment Discussion Paper No. 30. Washington, DC: International Food Policy Research Institute.)

developing countries. Children are particularly at risk of becoming undernourished due to their high energy and nutrient requirements. Diet diversity, including the intrahousehold distribution of animal source foods, feeding patterns, and child growth are all related to household socioeconomic status.

Low energy intake is associated with growth retardation and often related to a poor quality diet.

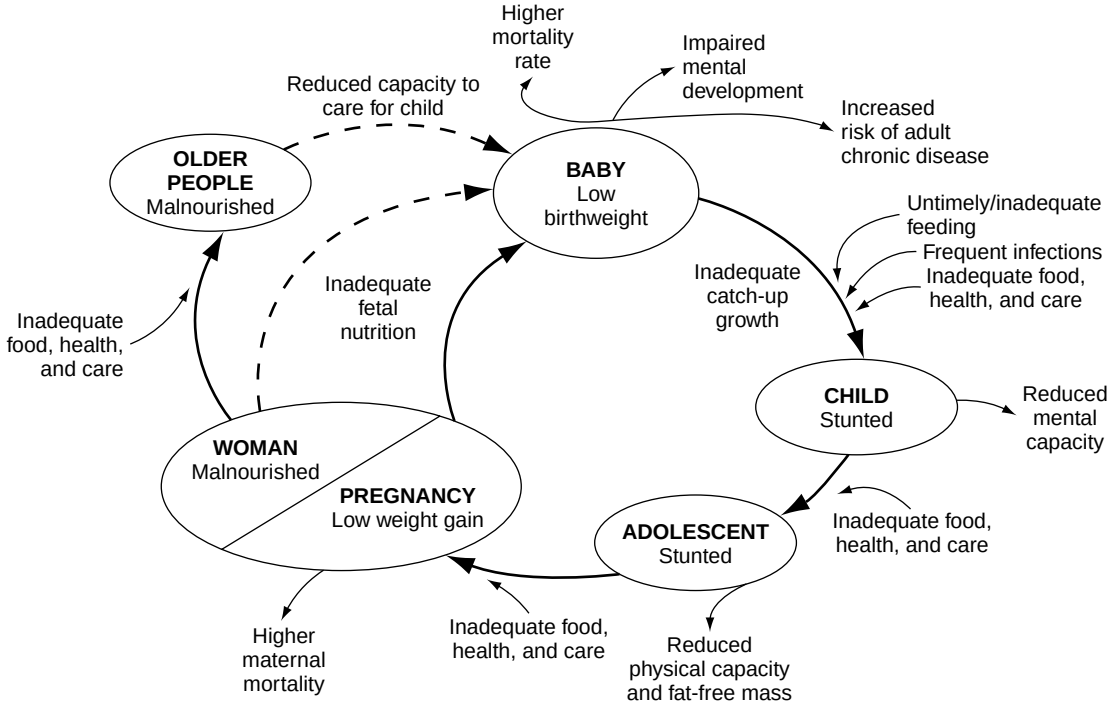

Figure 2 Nutrition throughout the life cycle. (Reproduced with permission from ACC/SCN (2000) *Fourth Report on the World Nutrition Situation*. Geneva: ACC/SCN (in collaboration with the International Food Policy Research Institute).)

Moreover, children can become anorectic when fed monotonous diets, and this can be compounded when superimposed on frequent and repeated bouts of infections. A high-carbohydrate, low-fat diet with a low energy density also precipitates undernutrition in children. Protein deficiency per se is not the major cause of growth retardation, but little is known about the specific effects of essential fatty acid deficiencies on growth. Micronutrient deficiencies, particularly zinc deficiency, cause growth retardation. Zinc supplementation can increase body weight and length/height, but the effect is modest compared with the growth deficit usually observed in growth-faltered children. Children in poor communities are likely to have multiple micronutrient deficiencies, and the combined effect of these coupled with inadequate fat and energy intake will affect growth patterns.

Low income is associated with a low intake of the more expensive animal source foods (meat, fish, dairy, and eggs). The mainly vegetarian diets eaten by children in poor families are frequently associated with growth retardation. Children in developed countries who for cultural reasons eat a diet that lacks any animal products have growth patterns similar to those observed in developing countries.

Women of reproductive age and adolescent girls are also susceptible to micronutrient deficiencies, especially iron, due to their increased physiological requirements for nutrients that can rarely be met from a diet low in animal source foods. In addition, food availability for women is often compounded by sociocultural practices that discriminate against women, and this can start in early childhood and continue throughout the life span.

Infections

Longitudinal studies have shown that infections, especially diarrheal diseases, are associated with growth faltering due to anorexia and/or malabsorption. However, the effect of acute infections on growth is transient, at least in children older than 6 months of age, and no longer apparent after a few weeks. The lack of a long-term effect on growth can be explained by the lower proportion of energy and nutrients needed for growth after 6 months of age, which facilitates catch-up growth after an acute disease. However, chronic infections, even if asymptotic, may lead to anorexia and malabsorption. The frequently observed inverse correlation between markers of chronic infection—such as elevated white blood cell, lymphocyte and platelet counts, C-reactive protein, and gut permeability—and growth supports this hypothesis. A similar mechanism may also explain the delayed growth observed in children infested with worms and the undernutrition observed in adults with chronic diseases, such as HIV infection and tuberculosis.

The edematous form of severe malnutrition, kwashiorkor, has been hypothesized to be due to oxidative stress resulting from insufficient intake of antioxidant nutrients, including selenium, vitamins E, C, and B_2, niacin, and sulfur amino acids. This suggests that infections, leading to an increased production of free radicals, can be one cause of this form of severe undernutrition.

Epidemiology: Assessing the Prevalence of Undernutrition

Food Balance Sheets

The Food and Agriculture Organization (FAO) uses national-level data on the production, export, and import of food in food balance sheets to calculate the average daily per capita energy supply. This value, combined with a measure of the inequality in food distribution, is used to calculate the proportion of undernourished individuals in a population. Globally, 840 million people are undernourished: 11 million in developed countries, 30 million in countries in transition, and 799 million in the developing world. The total number of undernourished people has increased during the past decade, despite the increase in per caput food availability, because of population growth. The proportion of undernourished individuals is highest in Africa, particularly in sub-Saharan Africa, but the greatest number of undernourished people is in Asia (**Figure 3**).

The precision of the FAO estimate for the number of undernourished individuals is dependent on the accuracy and reliability of agricultural statistics in developing countries, many of which include a large sector that produces food for subsistence and not the market economy. FAO is refining its method to adjust for the latter by including data collected at the household level. The food balance method, however, only deals with estimating the deficit in energy but not nutrient intakes. The latter can be obtained from detailed household or individual-level food consumption surveys, although nationally representative dietary intake surveys are rare in developing countries.

Anthropometric Surveys

When energy intake is insufficient to meet requirements, energy is derived by metabolizing fat and lean tissues, mainly muscle. Children first stop gaining height/length and then lose weight, whereas adults lose weight. Weight loss is more rapid in children

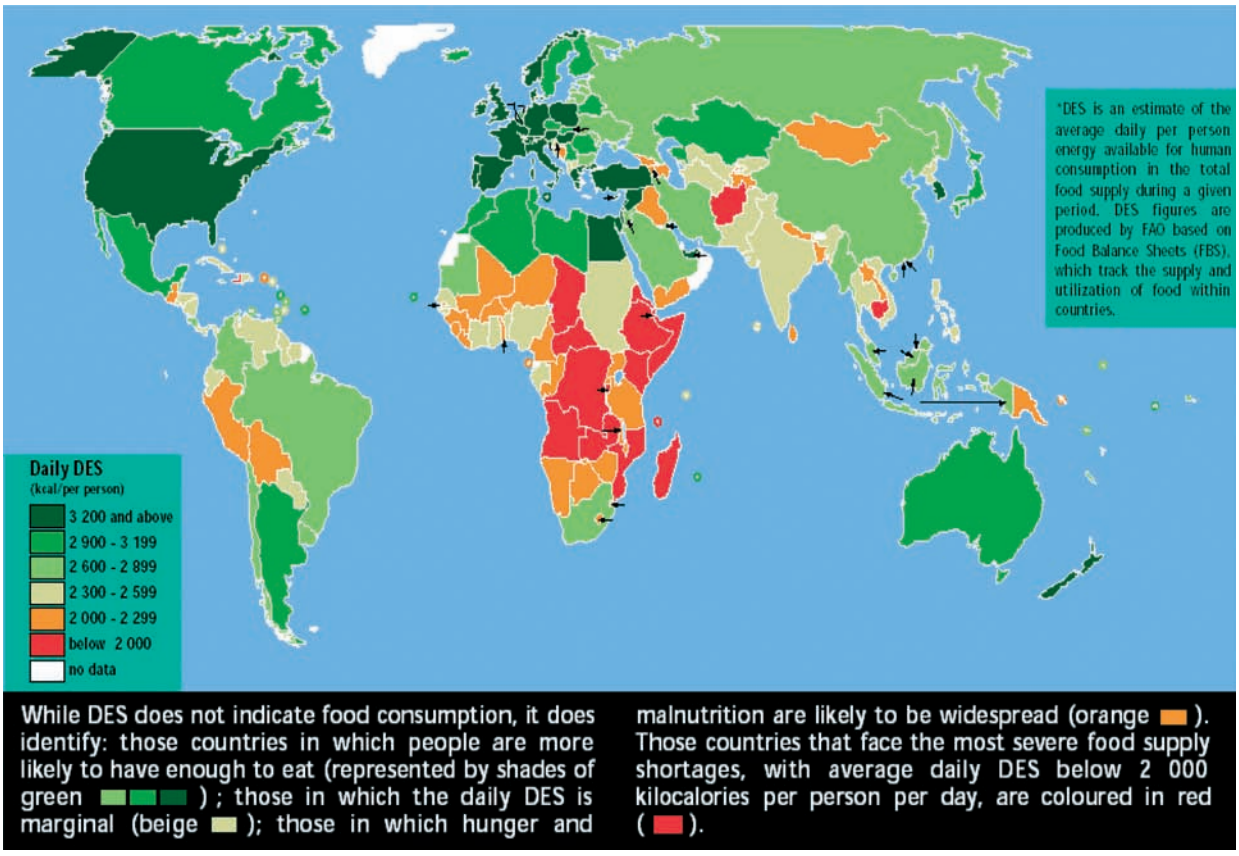

Figure 3 Dietary energy supply (DES), 1994–1996. (Reproduced with permission from the Food and Agriculture Organization (2000) Undernourishment around the world. Counting the hungry: Latest estimates. In: *The State of Food Insecurity in the World*. Rome: FAO.)

than in adults because of their higher energy requirements per kilogram body weight, mainly due to a different body composition. Population-level measurements of body weight and height/length in children indirectly assess the adequacy of food intake on the assumption that a low average body weight and height/length compared with a growth reference reflects an inadequate diet. WHO recommends that the following be used to compare undernutrition in children in different areas of the world:

- Underweight is defined as the proportion of children whose weight in relation to their age is below -2 standard deviations (-2 z scores) of the median of the National Center for Health Statistics (NCHS) reference.
- Wasting is the proportion of children whose weight in relation to their height is below -2 z scores of the median of the NCHS reference.
- Stunting is the proportion of children whose height in relation to their age is below -2 z scores of the median of the NCHS reference.

The previous calculations underestimate the true prevalence of undernutrition because a child can be below his or her optimal weight or height/length yet remain above the -2 z score cutoff point. Wasting is often described as acute malnutrition because it reflects relatively recent weight loss, and stunting is described as chronic malnutrition. Growth retardation is often described as protein–energy malnutrition, which is a misnomer because there is increasing evidence that other nutritional deficiencies besides protein–energy, such as zinc, can lead to growth faltering. Severe undernutrition is defined by a weight in relation to height below -3 z scores of the NCHS reference (marasmus) and/or by the presence of nutritional edema (kwashiorkor or marasmus kwashiorkor), and it is associated with a high risk of dying. WHO and UNICEF maintain a global database on the prevalence of undernutrition among children. Stunting is more prevalent than underweight (**Table 1**) and is often used to monitor long-term trends in undernutrition.

In emergency situations, rapid assessment surveys are often carried out using the mid-upper arm circumference as a proximate indicator of nutritional status in children and, increasingly, adults. This approach is less reliable than methods based on

Table 1 Prevalence of undernutrition by region

UNICEF region	*Under-5 population, 2000*[a]	*Wasting prevalence (%)*		*Underweight prevalence (%)*		*Stunting prevalence (%)*	
		Moderate and severe	*Severe*	*Moderate and severe*	*Severe*	*Moderate and severe*	*Severe*
Sub-Saharan Africa	106 394	10	3	30	9	41	20

weight and height for epidemiological assessment of undernutrition. Measures of mid-upper arm circumference, however, are useful for screening to quickly identify the severely undernourished, especially children, who are at high risk of dying and need urgent case management.

Anthropometry is also used to assess undernutrition in adults, usually as the body mass index (weight/height^2). A body mass index of less than 18.5 defines chronic energy deficiency, and that less than 16.0 defines severe chronic energy deficiency. A global database on maternal nutrition is not available.

Anthropometric surveys do not give information on the causes (dietary, infectious, or other) of the weight and height deficits they measure. Genetic factors are unlikely to determine child growth at a population level because growth is very similar among well-off children from different countries. Breast-feeding patterns, however, may affect growth patterns, and WHO is developing new growth references based on a longitudinal study of infants from diverse geographic sites who are exclusively or predominantly breast fed for at least 4 months with continued breast feeding throughout the first year and on a cross-sectional study of infants and young children age 18–71 months.

Approximately 55% of all child deaths in developing countries are associated with undernutrition (**Figure 4**), of which at least three-fourths are related to moderate or mild undernutrition rather than severe undernutrition. Some nutritional deficiencies, such as vitamin A, can result in higher mortality without a clear effect on growth. Hence, studies examining the association between undernutrition and mortality, using anthropometry as proxy for undernutrition, are likely to underestimate the strength of this relationship.

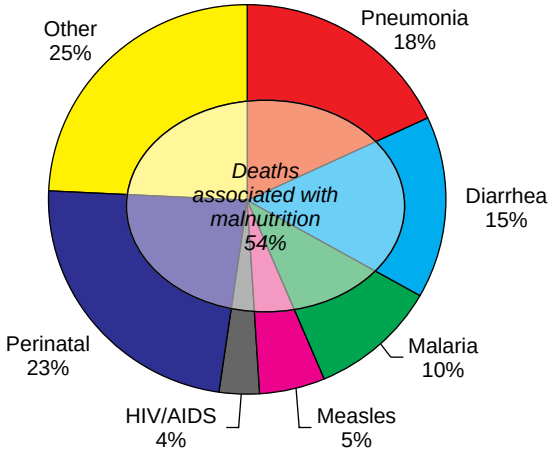

Figure 4 Association between malnutrition assessed by anthropometry and cause-specific mortality in children younger than 5 years of age. Biochemical Surveys

Because of the interest and focus on controlling iodine, vitamin A, and iron deficiencies, national-level surveys for these micronutrients are conducted in developing countries. Urinary iodine level is a good marker of iodine deficiency, which can cause retarded physical development. However, the biochemical markers of vitamin A and iron are acute phase proteins, which are altered during infection, even subclinical infection. Serum retinol declines during infection, overestimating the prevalence of vitamin A deficiency, whereas serum ferritin rises and overestimates adequate iron stores. Hemoglobin, which is often used as a proxy for iron deficiency, is also affected by the prevalence of infection (as is serum zinc). For these reasons, biochemical surveys need to include markers of infection, which adds to their complexity and cost; thus, they are rarely done.

Prevention

Increasing both the purchasing power of poor families and women's access to and control of household resources can prevent undernutrition. Improving the social and economic status of women and households, however, is insufficient to eliminate undernutrition and interventions that affect each stage of the life cycle and are necessary to break the intergenerational cycle of undernutrition (**Table 2**).

Table 2 Intervention points in the life cycle continuum

Nutritional risks	*Interventions to improve nutritional status and growth*
Infancy and early childhood (<6 months)	
Suboptional breast feeding	Feeding colostrum
	Exclusive breast feeding for 6 months
Complementary feeding period (6–24 months)	
Suboptional breast-feeding	Breast feeding
Inadequate and low-quality diet	Nutrition education
Micronutrient deficiencies	Infection control
Frequent infections and parasites	Food supplements
Gender discrimination in food and health care	Micronutrient supplements
Childhood (2–9 years)	
Inadequate and low-quality diet	Nutrition education
Micronutrient deficiencies	Infection control
Frequent infections and parasites	Micronutrient supplements
Gender discrimination in food and health care	School feeding
Adolescence (10–19 years)	
Inadequate and low-quality diet	Iron supplementation (schools)
Rapid growth	Deworming through schools (endemic areas)
Anemia with onset of menstruation	Nutrition and health education (schools)
Infections (including STDs) and parasites	Prevention and management of STDs and other infections
Early pregnancy and lactation	School meals
Gender discrimination in food and health care	Income-earning skill training
Adult women of reproductive age (20–49 years)	
Food insecurity	Income generation
Micronutrient deficiencies	Family planning/birth spacing
Infections and parasites	Prevention and management of STDs
Gender inequities	Agricultural/gardening
STDs and AIDS	Improved technologies
	Adult literacy
Pregnant women	
Inadequate food intake to meet increased demands for fetal growth	Increase intake of bioavailable nutrients and energy
Micronutrient deficiencies	Malaria chemoprophylaxis (endemic areas)
Maternal mortality	Deworming (endemic areas)
Low birth weight	Iron/folic acid supplementation
Birth defects	Postpartum vitamin A
Lactating women	
Decreased quantity of vitamins in breast milk	Increase intake of bioavailable nutrients and energy
Micronutrient deficiencies	Iron/folic acid supplementation
Weight loss	
Post-reproductive age (49+ years)	
Undernutrition	Food security

Early Infancy (<6 Months)

All newborns should be fed colostrum immediately after delivery. Because breast milk is the best food for infants, exclusive breast feeding is the best way to prevent undernutrition in this age group. Exclusive breast feeding also reduces the risk of diarrhea and other infections that can reduce appetite and absorption or increase nutrient losses.

The advantages of breast feeding should be balanced with the risk of HIV transmission if the mother is known to be HIV positive. In early infancy, breast milk may not easily be replaced, and risks should be carefully assessed by program managers before recommending breast milk substitutes.

Beyond exclusive breast feeding, there is a role for micronutrient supplementation for some high-risk children. For example, low birthweight infants can benefit from zinc, iron, and vitamin A supplementation. Where there is a risk of rickets, such as in areas where young infants do not get any exposure to sunlight or calcium intake is very low, vitamin D supplementation is recommended.

Complementary Feeding Period (6–24 Months)

Undernutrition, especially wasting and micronutrient deficiencies, is most prevalent during the complementary feeding period. Linear growth retardation is usually well established during this stage of the life cycle. This age group is particularly vulnerable because of its high nutrient requirements that cannot be supplied through breast milk alone. A variety of nutrition interventions have been proposed to prevent undernutrition, and the use of multiple approaches is likely to be most successful.

Breast feeding promotion Beyond 6 months of age, breast milk alone is not sufficient to sustain optimal growth and its contribution to energy and nutrient intake progressively declines. After the age of 12 months, breast fed children are not better nourished than non-breast fed children. However, prolonged breast feeding is very important and needs to be promoted because it improves child survival. The poor nutritional status of breast fed children older than 6 months of age is due to late introduction of an appropriately balanced diet. Family planning is an important intervention for promoting prolonged breast feeding because a new pregnancy can be a frequent cause of breast feeding cessation.

Nutrition education Undernutrition among children is often ascribed to ignorance, and nutrition education programs are often proposed to resolve this. However, choosing and recommending foods that are appropriate for promoting child growth at low cost is not easy. Moreover, micronutrient requirements in this age group are high, and it is usually not possible to provide a balanced diet without large quantities of animal source foods or fortified foods that are generally not readily available to the poor.

In theory, advising mothers to use nutrient-dense foods when they are available might improve child nutrition. Some nutrition education programs have be shown to be efficacious in pilot studies, but their effectiveness when scaled up has been disappointing.

Infection control Acute infections have a transient effect on the growth of young children. However, controlling chronic infections, including parasitic and other subclinical infections, can have a positive effect on growth. A general improvement in environmental hygiene and sanitation may be more effective in removing this cause of undernutrition than medical interventions per se, with the possible exception of regular deworming.

Food supplements Food supplements are designed to provide nutrients missing from the diet. They are usually made from a cereal flour mixed with a lysine-rich flour, generally soy flour, or milk powder to improve the amino acid balance (e.g., corn–soy blend). The fat content is usually low because fat mixed with flour is rapidly oxidized and cannot be added to food without costly packaging. Nowadays, such food supplements are usually fortified with micronutrients that are likely to be missing in childrens' diet, especially iron, zinc, retinol, and riboflavin.

The efficacy of food supplements has been tested in pilot programs, and most randomized trials that compared the growth of children receiving food supplements with that of children receiving the usual family diet failed to show a major effect on growth, especially height. The reasons for this are not clear. Biological factors may be involved. For example, most trials tested a low-cost supplement that had a high phytate content, which would limit the bioavailability of minerals such as zinc (known to be important for growth) and iron. Moreover, the food supplements were low in fat, which may be a limiting nutrient for children who usually have a very low fat intake. Finally, even in carefully controlled trials the food supplement may be shared within the family, especially if it requires special preparation, which would dilute its effect.

Besides the pilot trials, the use of donated food supplements has been usually limited to food crises,

such as wars and environmental catastrophes. Food supplements are also available in the commercial market, but their price often precludes their use by those most in need of them.

Micronutrient supplements Vitamin A is routinely distributed through immunization programs and is a standard health package delivered in under-5 clinics to improve child survival. In very few countries, prophylactic liquid iron is given to older infants. Routine iron supplementation to children is not without controversy in malarial areas. Most micronutrient supplementation trials have been carried out using syrups, which are expensive to use on a large scale, or tablets/capsules, which are difficult to administer to young children. New formulations, such as multiple micronutrient sprinkles or water-dispersible tablets, are being tested. Highly fortified spreads that can provide fat along with micronutrients are also being tested.

Childhood (2–9 Years)

The nutritional problems of 2- to 5-year-old children are similar to those of younger children. The critical factors being that these children do not eat enough food and they are still susceptible to repeated bouts of infection. Because there is no obvious contact point with these children (e.g., measles immunization), it is difficult to deliver programs that reach them.

Children 6–9 years old can be reached through school feeding programs. School health programs increasingly include deworming, malaria chemoprophylaxis, and iron supplementation to improve student nutrition and health. Where institutional feeding is provided, the potential exists to provide fortified food in a meal or as a snack food. In situations in which institutional feeding is not provided, community mobilization activities in primary education can incorporate messages to support student health and nutrition.

Adolescents (10–19 Years)

Adolescent girls are at special nutritional risk, especially for iron deficiency anemia, with menstruation taking place while growth is still not complete. Few intervention studies have been done on adolescent girls, and those that have focused on anemia prevention. Well-supervised intermittent iron supplementation to adolescent girls in schools or the workplace can reduce their prevalence of anemia. Although iron supplements have been shown to be important for correcting iron deficiency anemia in adolescent girls, there is only a modest improvement in storage iron status in early pregnancy following supplementation in adolescence if the time between the end of supplementation and conception is more than a few months. Iron supplementation in adolescence cannot build sufficient stores to substitute for the need for iron supplements in pregnancy.

Secondary schools are the easiest way to reach adolescents, although in many countries relatively few girls go to school compared to boys. Supplementary food can also be provided through school meals to induce growth and maximize the pubertal growth spurt, increase school attendance, and serve as an excellent opportunity for nutrition and health education relevant to the age group. Such interventions are likely to be effective because of the potential for good supervision. However, any credible intervention program will have to reach the girls who do not attend school. Currently, the few activities targeted to this age group center around HIV/AIDS awareness and education, including the prevention and management of sexually transmitted diseases. These children, especially girls, are particularly vulnerable and often have no voice in the community.

Women of Reproductive Age (20–49 Years)

Many programs designed to improve food security include adult women of reproductive age, who may not be pregnant or lactating. Managers of these programs recognize that the nutritional benefits are not necessarily direct, and it is not easy to measure or attribute any change in nutritional status to the intervention. Such projects, which invariably strive to empower women, include income-generation or credit schemes, home gardening and agriculture, improved technologies, and adult literacy, alone or in combination.

Health-based interventions, such as family planning and longer birth spacing, are assumed to have a more direct effect on women's nutritional status, but the inputs and outcomes rarely, if ever, include issues related to improving the nutritional status of women. However, the potential is there to change this.

The role of iron/folic acid supplements remains equivocal, except where severe deficiency exists. Insufficient data are available to justify the provision of free multiple micronutrient supplements through the public health system, although there is some rationale to improve micronutrient status before these women become pregnant so that they are in

the best nutritional state possible. The demand side issues for supplementation need to be addressed concurrently; otherwise, it is unlikely that these programs can be successful.

In urban areas, adult women of reproductive age may be reached through the workplace, social/community groups, religious centers, etc., where the possibility exists of getting institutional support for health-related activities that include nutrition. Similar groups could be used in rural areas where they exist, and activities that support or strengthen group 'cohesion' should be seen as a component of an add-on nutrition/health activity. As with the other groups of the life cycle framework, it is important to put nutrition in the context of perceived priorities.

Pregnancy

Prenatal programs focus on identifying and counseling pregnant women on appropriate care and nutrition, including breast-feeding, tetanus toxoid immunization, iron/folic acid supplementation, and referral of high-risk pregnancies. Malaria chemoprophylaxis, especially among primigravidae, and deworming need to be encouraged to prevent anemia in areas where these parasites are public health problems. The provision of postpartum vitamin A supplementation is increasing and needs to be further expanded.

Some programs provide and target supplementary food to at-risk and undernourished women. These programs are effective in increasing weight gain during pregnancy, but they have a significant beneficial effect on birth weight only in women who are genuinely at risk of an inadequate diet, such as rural African women who continue to perform difficult manual work during the hungry season. In other settings, the effect is less clear.

Despite the research evidence that iron supplementation is efficacious, this relatively simple program has not been effective in reducing the prevalence of anemia among women. Most iron/folic acid supplement programs suffer from serious operational constraints related to supply and distribution systems, access to health care services, motivation of health care providers, and compliance. Lack of good quality, low-cost, generic iron supplements, suitable compounds and dispensing mechanisms, and potential side effects are unsolved problems that affect compliance.

Although there is little evidence that an iron supplement program works, it remains one of the few options available to improve iron status of the population, and it is the only program that has the potential to meet the high iron requirements of pregnancy. Operation research has shown that intermittent supplementation is less appropriate for pregnant women and daily iron supplementation should be continued as the intervention of choice.

Lactation

Except under extreme famine-like conditions, undernourished women produce sufficient breast milk, but its micronutrient quality can vary depending on the nutritional status of the mother.

Postnatal programs cover the lactation period and include counseling on nutrition (including breast-feeding) and family planning, although these two programs are not usually integrated. Where the prevalence of anemia is higher than 40%, iron/folic acid supplementation should be extended through the first 3 months of lactation. Clinical signs of vitamin A deficiency are known to exist in lactating women, and postpartum supplementation within 6–8 weeks of giving birth has been shown to be beneficial and safe for both the mother and the newborn.

Some programs include provision of a protein and energy supplement during lactation. Controlled trials have failed to show an effect on milk production, but increased weight gain and a sensation of well-being among mothers are potential positive outcomes.

Post-reproductive Age (49+ Years)

There are no reports on nutrition interventions for older people in developing countries, successful or otherwise. At best, they are covered in food security projects targeted at the household level, although the focus is generally on maternal and child nutrition. This age group deserves more attention, especially in areas with a high prevalence of HIV, where older people often play a key role in sustaining the household.

Secondary, Diagnosis and Management

N Solomons, Center for Studies of Sensory Impairment, Aging and Metabolism (CeSSIAM), Guatemala City, Guatemala

Definitional Considerations

In its broadest context, malnutrition is a state of having an inappropriate nutritional status with respect to one or more macronutrient (water, electrolyte, protein, or fat) or micronutrient (vitamin or mineral) constituent of the body. This imbalance can be a deficit, leading to an insufficient supply or content of the nutrient (undernutrition), or an excess, leading to an excessive content or overloading of the organism with a nutrient (overnutrition).

Victor Herbert enumerated six possible causes for all nutrient deficiencies as: decreased intake; impaired absorption; increased wastage; impaired utilization; increased destruction; and elevated requirements. Correspondingly, with the exception of any utilization defect, overnutrition and excesses can result from the reciprocal defects, that is: hyperphagia; hyperabsorption; increased retention; decreased destruction; and decreased requirements.

As discussed in the previous chapter, the term 'primary' malnutrition relates almost exclusively to the first of these mechanisms, that of the ingestion of nutrients from the diet. It is about food consumption and intake. Secondary malnutrition, by contrast, concerns the disturbed and disordered handling of nutrients. When diseases or abnormal physiological conditions interfere with the normal disposition of nutrients ingested from the diet, this is the basis of a situation of 'secondary' malnutrition. A representative, but not exhaustive, list of diseases and conditions producing secondary undernutrition is provided in **Table 1**. The roster of causes of secondary overnutrition is provided in **Table 2**.

The basis for suspecting the presence of secondary undernutrition emerges when there is evidence of malnutrition (deficiency or excess) but food and nutrients are presumably being consumed with in abundance. Once the suspicion emerges, three distinct diagnostic principles need to be addressed: (1) the confirmation of dietary intake, and estimation of its adequacy; (2) the diagnosis and classification of abnormal nutritional status; and (3) the diagnosis of the functional, physiological, or pathological origins of disordered nutrient disposition. To emphasize the

Table 1 Diseases and conditions associated with secondary macronutrient or micronutrient undernutrition

Decreased nutrient absorption
Gastric atrophy
Pernicious anemia
Celiac disease
Inflammatory bowel disease
Intestinal cryptosporidiasis
Pancreatic insufficiency
Biliary obstruction
Cystic fibrosis
Radiation enteritis
Chronic intestinal pseudoobstruction
Increased nutrient excretion
Hepatic cirrhosis
Laxative abuse
Peptic ulcer
Gastrointestinal fistula
Gastric adenoma
Colonic adenoma
Amebiasis
Hookworm
Schistosomiasis
Diabetes mellitus
Fanconi syndrome
Hypoaldosteronism
Hemodialysis; peritoneal dialysis
Increased destruction or internal consumption nutrients
Hyperthyroidism
Cardiac cachexia
HIV/AIDS
Cancer cachexia
Cystic fibrosis
Bone marrow transplants
Pulmonary tuberculosis
Decreased utilization of nutrients
Lead poisoning
Menkes' copper storage disease

point, one must remain attuned to the nutritional status of patients, clients, or populations, and sensitive to the possibility of a nonprimary origin of any under- or overnutrition.

Table 2 Diseases and conditions associated with secondary macronutrient or micronutrient excess (overnutrition)

Increased nutrition absorption
Wilson's disease
Hemochromatosis
Increased nutrition retention
Prader–Willi syndrome
Hypercorticosterism
Hyperpituitarism
Acute tubular necrosis
Chronic renal failure
Decreased destruction of nutrients
Hypothyroidism

Coexistence of Primary and Secondary Malnutrition

It is important to recognize the potential for the simultaneous coexistence of primary and secondary malnutrition in the same individual. Primary malnutrition in the free-living populations can be associated with famine conditions (crop failure, conflict, natural disaster, refugee crisis), in which sufficient food is simply not available. Alternatively, it can arise from the poverty of landlessness or urban margination, where food is not accessible within the household income. A large number of communicable diseases with consequences for nutrient absorption, retention or utilization, such as parasitoses, tuberculosis or HIV/AIDS, are common in these situations of deprivation and misery.

To the extent that a disease process produces anorexia or dysphagia, or even psychic depression, the net effect is to reduce total intake of dietary energy and nutrients. Whatever, malabsorptive or nutrient-wasting components of the underlying disorders will further compromise the nutritional state.

The Reverse Paradigm: Underlying Pathology Revealed by Detection of Abnormal Nutrition

In clinical medicine, a type of 'reversal of roles' often occurs. Rather than primarily recognizing the presentation of the underlying pathology, recognition of an abnormal nutritional status without a suitable dietary cause leads to the diagnosis of the underlying disorder before any specific (pathognomonic) sign or symptom has yet occurred. For instance, the Prader-Willi syndrome of pathological obesity would initially present as common obesity. Similarly, in hypercorticosteroidism (Cushing's syndrome), abnormal fat deposition and weight gain can be the changes that lead to the recognition of the underlying pituitary or adrenal dysfunction.

Classically, in type 2 diabetes, unexplained weight loss is a presenting complaint when polyuria is mild or absent. Moreover, with common forms of childhood gastrointestinal disorders, such as celiac sprue or Crohn's disease, arrested linear growth is often the first clue that something is clinically awry. It provokes the diagnostic inquiry that leads to the recognition of the bowel lesions. In milder presentations of cystic fibrosis, a similar growth failure occurring in infancy, can indicate an underlying pathological disorder.

In fact, the entire roster of conditions listed in **Table 1** and **Table 2**, as well as others of a similar nature, are subject to being diagnosed as the result

Table 3 Three-level diagnostic principles related to secondary malnutrition

Assessment of dietary and nutrient intake: A quantitative and qualitative evaluation of usual dietary intake by a nutritionally trained practitioner or clinical dietician serves to exclude the possibility that the situation is not primary (low intake) in nature and suggests the secondary basis of the nutritional problem. Caveat: In certain situations, a **combination** of reduced intakes **and** nutritional stress at absorption, retention, or utilization may coexist.
Assessment of nutritional status: This includes the measures of anthropometry and body composition, hematological status, biological indices, and functional indicators, as well as clinical (physical) evaluation.
Diagnosis of underlying cause(s) of secondary nutritional imbalance: It is important, where possible, to identify the underlying entitie(s) that are causing the nutritional problem, to enable (where possible) a direct remedial approach to the cause of malnutrition and to orient management based on any pathophysiological knowledge about the underlying disease.

of a secondary change in nutritional status. The practical message is that the nutritional specialist, physician, or nonphysician may be the first person to whom the secondarily malnourished patient is referred and the acumen of recognising a secondary causation will guide the case to an appropriate clinical diagnostic program to uncover (and hopefully address and remedy) the underlying medical or surgical problems. Overarching guideline principles for uncovering secondary malnutrition states are provided in **Table 3**.

Diagnosis of Secondary Malnutrition

In general terms, a common set of principles applies for assessment of nutrient status whether the bases are primary, secondary, or a combination of both. These principles include: body composition measures, hematological and biochemical findings, functional variables, and clinical signs and symptoms. It is more productive to focus here on the nuances, caveats, and distinctions for the detection of altered nutrition due to background conditions beyond spontaneous food intake.

Caveats for the Diagnosis of Secondary Excess Nutriture

The conditions that cause increased retention of energy and hypometabolism are listed in **Table 2**. When it comes to overweight and obesity, the absence of clear-cut overeating combined with other characteristic signs of the different entities should raise suspicion. Excesses of vitamins and minerals may not easily be detected because the homeostatic control of circulating concentrations confounds biochemical diagnosis. Excessive urinary excretion rates of the nutrients or their metabolites often provide better indications than blood levels when micronutrient overload is the issue.

Caveats for the Diagnosis of Secondary Undernutrition

Undernutrition due to disease and dysfunction obviously requires establishment of the following: (1) the existence of deficiencies; and (2) that factors other than underconsumption are influencing the deficiency states. The body composition standard is a body mass index (BMI) of $<18.5\,\mathrm{kg\,m^{-2}}$. With the worldwide pandemic of overweight, recent weight loss of 10% or more of usual body weight may be a more sensitive and reliable indicator of an incipient undernutrition problem. Weight problems diagnosed in this manner would certainly be detectable well before the BMI will have fallen to the aforementioned criterion.

Ill patients with adequate or excessive body mass indices can manifest metabolic substrate metabolism reminiscent of the severe malnutrition syndromes of adult kwashiorkor or marasmus (inanition). Moreover, fluctuations in weight under acute or semiacute situations often reflect changes in fluid balance. This is also the situation in patients with end-stage renal failure undergoing chronic dialysis. Methods such as bioelectrical impedance, dual X-ray absorbance, or isotope dilution in association with indirect calorimetry can assess true lean- and fat-mass status and macronutrient metabolism in patients of apparently normal body mass.

Hematological evaluation is important in nutritional assessment. A low hemoglobin, hematocrit, or red cell count signifies anemia, but in individuals with associated diseases, anemia can have a series of origins (hemolytic, hypoproliferative) that are nonnutritional and will not respond to nutritional therapy.

Biochemical evaluation for nutrient deficiency status in patients with associated disease is fraught with caveats and limitations. Michael Golden has defined two classes of nutritional deficiency: in type 1 deficiencies, nutritional desaturation of tissue stores occurs, and circulating levels of nutrients reflect the total body nutrient status; in type 2 deficiency, there is homeostatic conservation of tissue and circulating concentrations of nutrients, such that blood concentrations remain virtually unaltered in the face of depletion. Deficiencies of zinc and magnesium, among others, fall into this second category. Inflammation and infection are stimuli that directly alter the circulating concentrations of

nutrient indicators. Ferritin and circulating copper are elevated whereas zinc, iron, and vitamin A concentrations are depressed with activation of the acute-phase response to injury. In liver disease, depressed production of binding proteins can alter the usual indicators of nutritional status as a consequence of hepatic pathophysiology itself, rather than preexisting secondary malnutrition. Finally, it almost goes without saying that attempting biochemical nutrient evaluations from blood samples taken during concurrent infusion of micronutrient solutions in parenteral nutrition regimens – and without a period of distribution and equilibration – will not reflect the tissue stores and total body reserves of the respective nutrients of interest.

Functional indicators of nutritional status have been applied to the assessment of secondary malnutrition and have been plagued by pitfalls. This applies to tests of nitrogen status, immune function, and hepatic protein secretion. Tests such as creatinine excretion, white blood cell counts, and cutaneous delayed hypersensitivity anergy, as well as decreased serum albumin, transferrin, transthyronein (prealbumin), and retinal-binding protein concentrations are sensitive to alteration by stress and injury. Failure to recognize distortion from stress underlies an early fallacy in surgical nutrition, in which low values for albumin, lymphocyte counts, and pre-albumin, together with anergy, predicted poor postoperative outcomes. This misconception justified aggressive preoperative parenteral nutrition and albumin infusions, with little impact on predicted outcomes. In these situations, it was the stress and injury of the underlying disease, rather than nutritional status, that was producing the abnormal values for the biomarkers. Recently, insulin-like growth factor has been advanced as a sensitive indicator of protein status in older patients, but whether it is confounded by nonnutritional features of disease remains to be clarified.

Management of Secondary Malnutrition

Secondary malnutrition has many faces and facets. It may have to be addressed both in a public health sense, for communicable diseases, such as parasitoses or HIV/AIDS, and in a medical care context, for disorders that are particular and clinical in nature, such as hereditary or degenerative diseases.

Principles of Management

The first principle is to identify the underlying functional, physiological, or pathological cause of the malnourished state. If the condition is curable, then the management issues are simplified. For instance, if a person is dehydrated because of hyperglycemic diuresis in uncontrolled diabetes mellitus, the short-term management involves administration of exogenous intravenous fluids to restore normal hydration; however, restoring adequate diabetic control to the patient would be the long-term and definitive solution. The undernutrition and growth failure due to undetected celiac disease is easily eliminated by institution of a gluten-free diet. With deficient nutrition in cystic fibrosis, adequate management of pulmonary problems and digestive-enzyme should allow patients to recover and maintain normal nutrition on a balanced oral diet. Thus, medical or surgical address of the underlying disorder, where possible, is the primary tool for management of secondary undernutrition.

Public Health Approaches

The management of the secondary nutritional deficiency attributable to hookworm or schistosomiasis, i.e., iron deficiency, can be achieved both by anthelmintic medications or by supplemental iron to compensate for parasite-induced losses. In countries where HIV/AIDS is rampant efforts for its prevention are fundamental. A food-security crisis grips the whole society in AIDS endemic areas, and this must be relieved with food and economic assistance. The wasting syndromes produced by tuberculosis are best addressed proactively by prevention of transmission and early detection. However, when primary prevention fails, as in the aforementioned infections, efforts to enhance the enteral intake of infected members of the community are particularly essential for their comfort and well being.

Dietary Management of Secondary Overnutrition

The dietary management of secondary overnutrition would logically be to restrict the intake of the nutrients accruing in excess. This is not always facile or feasible, however, due to the intrinsic complexity of foods and beverages, where most are sources of multiple essential micronutrients. Marked reduction in total energy intake can jeopardize the intake of proteins and essential fats. For the metal-storage afflictions such as Wilson's disease and hemochromatosis, removing copper and iron from the diet, respectively, are the fundamental elements of management. Some additional benefits can be gained by blocking the metals' absorption, as with high doses of zinc in Wilson's disease or with strong black tea (tannins) in hemochromatosis. Fundamentally, however, the management of metal-storage diseases requires some interventions to selectively remove the overload by

chelating agents in Wilson's disease and recurrent phlebotomy in hemochromatosis. In a related variant condition, African hemosiderosis, common among Bantu in southern Africa, removing concentrated iron sources from the diet, specifically the iron-loaded native beers, provides effective long-term control.

Dietary and Nutritional Management of Secondary Undernutrition

The syllogism for dietary and nutritional management is to get enough nutrients into the body to restore nutritional adequacy and balance, taking any chronic barriers to uptake and retention into consideration. The blend of nutrients must be tailored to the specific absorptive or utilization problems, e.g., compensatory fat-soluble vitamins in water-miscible forms with severe fat malabsorption, and extra doses of highly available iron with chronic blood loss. These can be delivered within a dietary context with supplements and fortified vehicles in nonacute conditions. Even nondietary routes have been devised as in the treatment of vitamin D deficiency due to Crohn's disease with tanning bed ultraviolet B radiation.

When accumulated undernutrition is dangerously advanced, absorptive barriers are especially severe, or nutrient losses are excessive more concerted nutritional intervention is required. Intensive therapy can be delivered by three routes: orally, with special diets supplemented by liquid formulas; enterally, with liquid formulas perfused by intragastric or intraintestinal feeding tubes; and parenterally, with intravenous formulas infused into peripheral or central veins. Up to 50% of patients on dialysis have protein-energy malnutrition, which may continue undetected. For end-stage renal patients, intradialytic alimentation (adding nutrients to the dialysis fluids) has been used to reduce nutrient loss. Each approach has its distinct costs, special potential, and limitations and risks, and has been explored and refined in the context of age, physiological status, and specific disease states or surgical indications.

Tailoring of nutrient delivery is required with both enteral and parenteral nutrition, depending upon the pathophysiology of the underlying conditions. Both hypo- and hypermetabolic states can occur; indirect calorimetry with metabolic carts is in vogue for prescribing energy delivery in intensive care. When pulmonary compromise is present, the balance among macronutrients is important to minimize carbon dioxide formation in metabolism.

Maintaining abundant amino acid supply promotes protein-sparing and prevents loss of lean tissue in catabolic states. Enrichment of enteral or parenteral regimens with branched-chain amino acids or keto-analog amino acids has been devised to compensate for the metabolic defects of nitrogen handling in hepatic or renal failure states. The objective of nutritional support in patients with liver failure is to provide adequate macronutrients to ensure the specific substrates for energy and protein synthesis and integrity of normal hepatic tissue function, without inducing or accentuating encephalopathy or otherwise aggravating hepatic insufficiency.

In juvenile cholestasis, large amounts of fat-soluble vitamin supplements and medium-chain triglycerides are usually required for optimum growth. With protracted secretory diarrheal diatheses, fluid and electrolyte balance may be the primary concern, followed by macro- and micronutrient nutriture, invoking the institution of parenteral feeding. Cancer cachexia is a major secondary consequence of disseminated neoplasms. It is tempting to prescribe aggressive nutritional support, but a caveat is that certain nutrients acting with certain neoplasms favor the tumor's growth and dissemination. To the extent that various forms of cachexia are partly driven by catabolic responses mediated by proinflammatory cytokines, antagonists directed at counteracting their action hold promise for retarding the nutrient-wasting in various forms of cachexia.

With intensive nutrition, there are risks and adverse consequences intertwined with the benefits. A variation of the refeeding syndrome, that is hyperalimentation complications from excessive energy substrate perfusion or infusion, can produce hypophosphatemic and hypokalemic episodes. Improper formulation of fluids or liquids with micronutrients can cause deficiency or toxicity states in chronic nutritional support. The hazards of indwelling catheters are multiple, from phlebitis of the veins to sudden dislocation or migration. Fluid overload and sepsis are the most troubling complications of intravenous parenteral nutrition.

For tube-feeding enteral alimentation, tube placement is the crucial element. With nasal placement of the tube, there is a finite risk of respiratory tract inflammation and infection from aspiration of formula and secretions. In hospital, enteral nutrition is a risk factor for nosocomial pneumonia. An alternative site for long-term administration of tube-feeds is percutaneous placement of an intragastric feeding tube under endoscopic control.

Aggressive nutritional support, with its attendant expense and potential morbidity, in critically ill patients remains controversial. In terms of cost–benefit analysis, the use of the intensive formats of enteral artificial nutrition seems to be cost effective to reduce post-hip-fracture hospital stay in underweight women and for preoperative

nutritional support, if carried out at home. Preoperative parenteral nutrition has been judged as prohibitively expensive for the small reduction in postoperative morbidity that it produces.

Conclusions

Dietary intake is the most important determinant of over- or undernutrition, but it is not the only influence on an individual's nutritional status. A series of extrinsic environmental factors or intrinsic clinical or physiological disorders can alter the absorption, retention, utilization, and integrity of nutrients. These give origin to secondary malnutrition states. Primary (dietary origin) and secondary (environmental, pathological) factors often combine within the same individuals. From a public health perspective, the goal is to implement broad policies and programs that increase the availability of specific nutrients imperiled by the local environmental problems, e.g., iron in hookworm infested areas, while addressing the primary diseases. In the clinical setting, management requires diagnosing and managing the underlying pathological states interfering with nutritional health while providing compensatory measures to correct secondary nutritional imbalances.

MANGANESE

C L Keen, J L Ensunsa, B Lönnerdal and S Zidenberg-Cherr, University of California at Davis, Davis, CA, USA

The essentiality of manganese was established in 1931, when it was demonstrated that a deficit of it resulted in poor growth and impaired reproduction in rodents. Manganese deficiency can be a practical problem in the swine and poultry industries, and it may be a problem in some human populations. Conversely, manganese toxicity can be a significant human health concern. Here, literature related to manganese nutrition, metabolism, and metabolic function is reviewed.

Chemical and Physical Properties

Manganese is the 12th most abundant element in the Earth's crust and constitutes approximately 0.1% of it. Chemical forms of manganese in their natural deposits include oxides, sulfides, carbonates, and

silicates. Anthropogenic sources of manganese are predominantly from the manufacturing of steel, alloys, and iron products. Manganese is widely used as an oxidizing agent, as a component of fertilizers and fungicides, and in dry cell batteries. Methylcyclopentadienyl manganese tricarbonyl (MMT) improves combustion in boilers and motors and can substitute for lead in gasoline as an antiknock agent. Concentrations of manganese in groundwater normally range between 1 and $100\,\mu g\,l^{-1}$, with most values being below $10\,\mu g\,l^{-1}$. Typical airborne levels of manganese (in the absence of excessive pollution) range from 10 to $70\,ng\,m^{-3}$.

Manganese is a transition element located in group VIIA of the periodic table. It occurs in 11 oxidation states ranging from -3 to $+7$, with the physiologically most important valences being $+2$ and $+3$. The $+2$ valence is the predominant form in biological systems and is the form that is thought to be maximally absorbed. The $+3$ valence is the form in which manganese is primarily transported in biological systems.

The solution chemistry of manganese is relatively simple. The aquo-ion is resistant to oxidation in acidic or neutral solutions. It does not begin to hydrolyze until pH 10, and therefore free Mn^{2+} can be present in neutral solutions at relatively high concentrations. Divalent manganese is a $3d^5$ ion and typically forms high-spin complexes lacking crystal field stabilization energies. The previous properties, as well as a large ionic radius and small charge-to-radius ratio, result in manganese tending to form weak complexes compared with other first-row divalent ions, such as Ni^{2+} and Cu^{2+}. Free Mn^{2+} has a strong isotropic electron paramagnetic resonance (EPR) signal that can be used to determine its concentration in the low micromolar range. Mn^{3+} is also critical in biological systems. For example, Mn^{3+} is the oxidative state of manganese in superoxide dismutase, is the form in which transferrin binds manganese, and is probably the form of manganese that interacts with Fe^{3+}. Given its smaller ionic radius, the chelation of Mn^{3+} in biological systems would be predicted to be more avid than that of Mn^{2+}. Cycling between Mn^{3+} and Mn^{2+} has been suggested to be deleterious to biological systems because it can generate free radicals. However, at low concentrations Mn^{2+} can provide protection against free radicals, and it appears to be associated with their clearance rather than their production.

Dietary Sources

Manganese concentrations in typical food products range from $0.4\,\mu g\,g^{-1}$ (meat, poultry, and fish) to $20\,\mu g\,g^{-1}$ (nuts, cereals, and dried fruit). Breast milk is exceptionally low in manganese, containing only $0.004\,\mu g\,g^{-1}$, whereas infant formula can contain up to $0.4\,\mu g\,g^{-1}$. Teas can be particularly rich in manganese, containing up to $900\,\mu g\,g^{-1}$of the element. An important consideration with respect to food sources of manganese is the extent to which the manganese is available for absorption. For example, although tea contains high amounts of the element, the tannin in tea can bind a significant amount of manganese, reducing its absorption from the gastrointestinal tract. Similarly, the high content of phytates and fiber constituents in cereal grains may limit the absorption of manganese. Conversely, although meat products contain low concentrations of manganese, absorption and retention of manganese from them is relatively high. Based on studies utilizing whole body retention curves after dosing with ^{54}Mn, the estimated percentage absorption of 1 mg of manganese from a test meal was 1.35%, whereas that from green leafy vegetables (lettuce and spinach) was closer to 5%. Absorption from wheat and sunflower seed kernels was somewhat lower than that from the leafy greens at 1 or 2%, presumably due to a higher fiber content or to higher amounts of phytates and similar compounds in the wheat and sunflower seeds. The dephytinization of soy formula increased manganese absorption 2.3-fold from 0.7 to 1.6%.

Analysis

Although manganese is widely distributed in the biosphere, it occurs in only trace amounts in animal tissues. Serum concentrations can be as low as 20 nM and typical tissue concentrations are less than $4\,\mu mol\,g^{-1}$ wet weight; tissue concentrations of 4–$8\,\mu mol\,g^{-1}$ wet weight are considered high. Because of the high environmental levels of manganese relative to its concentration in animal tissues, considerable effort must be made to minimize contamination of samples during their collection and handling.

The most common analytical methods that can sensitively measure manganese include neutron activation analysis, X-ray fluorescence, proton-induced X-ray emission, inductively coupled plasma emission, EPR, and flameless atomic absorption spectrophotometry (AAS). Currently, the most common method employed is flameless AAS. All of these methods, with the exception of EPR, measure the total concentration of manganese in the samples. EPR allows selective measurement of bound versus free manganese.

Physiological Role

Tissue Concentrations

The average human body contains between 200 and 400 μmol of manganese, which is fairly uniform in distribution throughout the body. There is relatively little variation among species with regard to tissue manganese concentrations. Manganese tends to be highest in tissues rich in mitochondria; its concentration in mitochondria is higher than in cytoplasm or other cell organelles. Hair can accumulate high concentrations of manganese, and it has been suggested that hair manganese concentrations may reflect manganese status. High concentrations of manganese are normally found in pigmented structures, such as retina, dark skin, and melanin granules. Bone, liver, pancreas, and kidney tend to have higher concentrations of manganese (20–50 nmol g^{-1}) than do other tissues. Concentrations of manganese in brain, heart, lung, and muscle are typically <20 nmol g^{-1}; blood and serum concentrations are approximately 200 and 20 nmol l^{-1}, respectively. Typical concentrations in cow milk are on the order of 800 nmol l^{-1}, whereas human milk contains 80 nmol l^{-1}. Bone can account for up to 25% of total body manganese because of its mass. Bone manganese concentrations can be raised or lowered by substantially varying dietary manganese intake over long periods of time, but bone manganese is not thought to be a readily mobilizable pool. The fetus does not accumulate liver manganese before birth, and fetal concentrations are significantly less than adult concentrations. This lack of fetal storage can be attributed to the apparent lack of storage proteins and the low prenatal expression of most manganese enzymes.

Absorption, Transport, and Storage

Absorption of manganese is thought to occur throughout the small intestine. Manganese absorption is not thought to be under homeostatic control. For adult humans, manganese absorption has been reported to range from 2 to 15% when ^{54}Mn-labeled test meals are used and to be 25% when balance studies are conducted; given the technical problems associated with balance studies, the ^{54}Mn data are probably more reflective of true absorption values. Data from balance studies indicate that manganese retention is very high during infancy, suggesting that neonates may be particularly susceptible to manganese toxicosis.

The higher retention of manganese in young animals relative to adults in part reflects an immaturity of manganese excretory pathways, particularly that of bile secretion, which is very limited in early life. The avid retention of the small amount of manganese from milk and the postnatal changes in its excretory pattern underscore the considerable changes in manganese metabolism that occur during the neonatal period.

In experimental animals, high amounts of dietary calcium, phosphorus, fiber, and phytate increase the requirements for manganese; such interactions presumably occur via the formation of insoluble manganese complexes in the intestinal tract with a concomitant decrease in the soluble fraction available for absorption. The significance of these dietary factors with regard to human manganese requirements remains to be clarified. Studies in avian species have demonstrated that high dietary phosphorus intakes decrease manganese deposition in bone by approximately 50%. Given that the diet of many individuals may be marginal in manganese ($\leq$2 mg per day intake) while high in phosphorus ($\geq$2000 mg per day intake), this antagonism may have important implications for human health. For example, the low fractional absorption of manganese from soy formula has been related to its relatively high phytate content. The mechanism underlying this effect of soy protein on manganese absorption/retention has not been fully delineated. However, dephytinization of soy formula with microbial phytase can markedly enhance manganese absorption.

An interaction between iron and manganese has been demonstrated in experimental animals and humans. Manganese absorption increases under conditions of iron deficiency, whereas high amounts of dietary iron can accelerate the development of manganese deficiency. The chronic consumption of high levels of iron supplements (>60 mg Fe per day) can have a negative effect on manganese balance in adult women. The mechanisms underlying the interactions between iron and manganese have not been fully elucidated; however, they likely involve competition for either a transport site or a ligand. Both iron and manganese can utilize divalent metal transporter 1 (DMT1); however, the expression of DMT1 is regulated by iron status via the IRE/IRP system. Thus, during iron deficiency, DMT1 is upregulated causing an increase in manganese absorption. Rats fed iron-deficient diets accumulate manganese in several brain regions compared to rats fed control diets; the involvement of DMT1 in this accumulation of manganese is an area of active study. It should be noted that the interaction between manganese and iron can also affect the functions of some enzymes. For example, manganese can replace iron in the iron–sulfur center of cytosolic aconitase (IRP-1), resulting in an inhibition of the enzyme and an increase in iron

regulatory protein (IRP) binding activity. Given the central role of IRPs in cellular iron metabolism, elevated cellular manganese concentration could in theory disrupt numerous translational events dependent on IRPs. That this in fact occurs is illustrated by the observation that following the addition of manganese to cells in culture, there can be sharp reductions in ferritin protein abundance, whereas there are increases in transferrin receptor abundance. This results in changes in intracellular iron metabolism, as reflected by decreases in mitochondrial aconitase (m-aconitase) abundance.

Manganese entering the portal blood from the gastrointestinal tract may remain free or become associated with α_2-macroglobulin, which is subsequently taken up by the liver. A small fraction enters the systemic circulation, where it may become oxidized to Mn^{3+} and bound to transferrin. Studies *in vivo* suggest that the Mn^{3+} complex forms very quickly in blood, in contrast to the slow oxidation of the Mn^{2+}–transferrin complex *in vitro*. Manganese uptake by the liver has been reported to occur by a unidirectional, saturable process with the properties of passive mediated transport. After entering the liver, manganese enters one of at least five metabolic pools. One pool represents manganese taken up by the lysosomes, from which it is transferred subsequently to the bile canaliculus. The regulation of manganese is maintained in part through biliary excretion of the element; up to 50% of manganese injected intravenously can be recovered in the feces within 24 h. A second pool of manganese is associated with the mitochondria. Mitochondria have a large capacity for manganese uptake, and the mitochondrial uptake and release of manganese and calcium are thought to be related. A third pool of manganese is found in the nuclear fraction of the cell; the roles of nuclear manganese have not been fully delineated, but one function may be to contribute to the stability of nucleosome structure. A fourth manganese pool is incorporated into newly synthesized manganese proteins; biological half-lives for these proteins have not been agreed upon. The fifth identified intracellular pool of manganese is free Mn^{2+}. Fluctuations in the free manganese pool may be an important regulator of cellular metabolic control in a manner analogous to those for free Ca^{2+} and Mg^{2+}. Consistent with this concept, in pancreatic islets manganese blocks glucose-induced insulin release by altering cellular calcium fluxes, and manganese directly augments contractions in smooth muscle by a mechanism comparable to that of calcium.

The mechanisms by which manganese is transported to, and taken up by, extrahepatic tissues have not been identified. Transferrin is the major manganese binding protein in plasma; however, it is not known to what extent transferrin facilitates the uptake of manganese by extrahepatic tissue. The concentration of manganese citrate in blood can be fairly high, and this complex may be important for manganese movement across the blood–brain barrier. DMT1 may be involved in manganese transport because it is expressed in discrete areas of the brain. Manganese uptake by extrahepatic tissue does not seem to be increased under conditions of manganese deficiency, suggesting that manganese, in marked contrast to iron, does not play a role in the induction (or suppression) of manganese transport proteins.

There is limited information concerning the hormonal regulation of manganese metabolism. Fluxes in the concentrations of adrenal, pancreatic, and pituitary–gonadal axis hormones affect tissue manganese concentrations; however, it is not clear to what extent hormone-induced changes in tissue manganese concentrations are due to alterations in cellular uptake of manganese-activated enzymes or metalloenzymes.

Metabolic Function and Essentiality

Manganese functions as a constituent of metalloenzymes and as an enzyme activator. Manganese-containing enzymes include arginase (EC 3.5.3.1), pyruvate carboxylase (EC 6.4.1.1), and manganese–superoxide dismutase (MnSOD) (EC 1.15.1.1). Arginase, the cytosolic enzyme responsible for urea formation, contains 4 mol Mn^{2+} per mole of enzyme. Reductions in arginase activity resulting from manganese deficiency result in elevated plasma concentrations of ammonia and lowered plasma concentrations of urea. Reductions in arginase activity due to manganese deficiency may affect flux of arginine through the nitric oxide synthase (NOS) pathway, resulting in alterations in NO production. It has been suggested that arginase plays a regulatory role in NO production by competing with NOS for the same substrate, arginine. Rats fed manganese-deficient diets have shown effects indicative of increased NO production, such as increases in plasma and urinary nitrates plus nitrites and decreased blood pressure; however, neither NOS activity nor NO production have been measured directly. In addition, manganese binding by arginase is critical for the pH-sensing function of this enzyme in the ornithine cycle, suggesting that manganese plays a role in the regulation of body pH. With experimental diabetes, liver and kidney manganese concentrations and arginase activity can be markedly elevated.

This manganese effect on arginase has been suggested to be due to an effect of Mn^{2+} on the conformational properties of the enzyme with a resultant modification of arginase activity. Whether this finding implies an increased manganese requirement for people with diabetes has not been determined.

Pyruvate carboxylase, the enzyme that catalyses the first step of carbohydrate synthesis from pyruvate, also contains 4 mol Mn^{2+} per mole enzyme. Although the activity of this enzyme can be lower in manganese-deficient animals than in controls, gluconeogenesis has not been shown to be markedly inhibited in manganese-deficient animals.

MnSOD catalyzes the disproportionation of $\dot{O}_2^-$ to H_2O_2 and $\dot{O}_2$. The essential role of MnSOD in the normal biological function of tissues has been clearly demonstrated by the homozygous inactivation of the *SOD2* gene for MnSOD in mice. Mice with this phenotype die within the first 10 days of life with a dilated cardiomyopathy, accumulation of lipid in liver and skeletal muscle, and metabolic acidosis. The activity of MnSOD in tissues of manganese-deficient rats can be significantly lower than in controls due to downregulation of MnSOD at the (pre)transcriptional level. That this reduction is functionally significant is suggested by the observation of higher than normal levels of hepatic mitochondrial lipid peroxidation in manganese-deficient rats. Tissue MnSOD activity can be increased by several diverse stressors, including alcohol, ozone, irradiation, interleukin-1, and tumor necrosis factor-α, presumably as a consequence of stressor-associated increases in cellular free radical (or oxidized target(s)) concentrations. Stressor-induced increases in MnSOD activity can be attenuated in manganese-deficient animals, potentially increasing their sensitivity to these insults. Transgenic mice have also been produced that overexpress MnSOD; a decreased severity of reperfusion injury has been noted in these animals, further supporting its physiological significance.

Considerable research is focused on the introduction of the human MnSOD gene into research animals utilizing viral vectors or plasmid/liposome delivery. This gene therapy has been shown to decrease radiation-induced injury, extend pancreatic islet transplant function, and slow the growth of malignant tumors in animal models via overexpression of the MnSOD protein. Another field of research that is rapidly advancing utilizes MnSOD mimetics for treatment of a variety of diseases in which the native SOD enzyme has been found to be effective. These mimetics are small manganese-containing synthetic molecules that have catalytic activity equivalent or superior to the native enzyme. They possess the additional beneficial properties of being nonimmunogenic because they are nonpeptides, able to penetrate cells, selective for superoxide (they do not interact with biologically important molecules), stable *in vivo*, and not deactivated by the destructive free radical peroxynitrite, which is capable of deactivating native MnSOD via nitration of tyrosine. These mimetic compounds have been found to be protective in animal models of acute and chronic inflammation, reperfusion injury, shock, and radiation-induced injury. Both of these therapies, MnSOD gene delivery and MnSOD mimetics, hold promise for future treatments in human chronic and acute conditions.

Finally, further evidence for the biological and research relevance of MnSOD is that experiments have been undertaken on the International Space Station to improve three-dimensional growth of MnSOD crystals in order to develop a better understanding of the role of structure in the reaction mechanism of this enzyme.

In contrast to the relatively few manganese metalloenzymes, there are a large number of manganese-activated enzymes, including hydrolases, kinases, decarboxylases, and transferases. Manganese activation of these enzymes can occur as a direct consequence of the metal binding to the protein, causing a subsequent conformation change, or by binding to the substrate, such as ATP. Many of these metal activations are nonspecific in that other metal ions, particularly Mg^{2+}, can replace Mn^{2+}. An exception is the manganese-specific activation of glycosyltransferases. Several manganese deficiency-induced pathologies have been attributed to a low activity of this enzyme class. A second example of an enzyme that may be specifically activated by manganese is phosphoenolpyruvate carboxykinase (PEPCK; EC 4.1.1.49), the enzyme that catalyzes the conversion of oxaloacetate to phosphoenolpyruvate, GDP, and CO_2. Although low activities of PEPCK can occur in manganese-deficient animals, the functional significance of this reduction is not clear.

A third example of a manganese-activated enzyme is glutamine synthetase (EC 6.3.1.2). This enzyme, found in high concentrations in the brain, catalyzes the reaction $NH_3 + \text{glutamate} + \text{ATP} \rightarrow \text{glutamine} + \text{ADP} + P_i$. Brain glutamine synthetase activity can be normal even in severely manganese-deficient animals, suggesting that the enzyme either has a high priority for this element or magnesium can act as a substitute when manganese is lacking. It should be noted that this enzyme can be inactivated by oxygen radicals; therefore, a manganese deficiency-induced reduction in MnSOD activity theoretically could act to depress further the activity of glutamine synthetase.

Manganese Deficiency

Manganese deficiency has been demonstrated in several species, including rats, mice, pigs, and cattle. Signs of manganese deficiency include impaired growth, skeletal abnormalities, impaired reproductive performance, ataxia, and defects in lipid and carbohydrate metabolism.

The effects of manganese deficiency on bone development have been studied extensively. In most species, manganese deficiency can result in shortened and thickened limbs, curvature of the spine, and swollen and enlarged joints. The basic biochemical defect underlying the development of these bone defects is a reduction in the activities of glycosyltransferases; these enzymes are necessary for the synthesis of the chondroitin sulfate side chains of proteoglycan molecules. In addition, manganese deficiency in adult rats can result in an inhibition of both osteoblast and osteoclast activity. This observation is particularly noteworthy, given the reports that women with osteoporosis tend to have low blood manganese concentrations and that the provision of manganese supplements might be associated with an improvement in bone health in postmenopausal women.

One of the most striking effects of manganese deficiency occurs during pregnancy. When pregnant animals (rats, mice, guinea pigs, and mink) are deficient in manganese, their offspring exhibit a congenital, irreversible ataxia characterized by incoordination, lack of equilibrium, and retraction of the head. This condition is the result of impaired development of the otoliths, the calcified structures in the inner ear responsible for normal body-righting reflexes. The block in otolith development is secondary to depressed proteoglycan synthesis due to low activity of manganese-requiring glycosyltransferases.

Defects in carbohydrate metabolism, in addition to those described previously, have been shown in manganese-deficient rats and guinea pigs. In the guinea pig, perinatal manganese deficiency results in pancreatic pathology, with animals exhibiting aplasia or marked hypoplasia of all cellular components. Manganese-deficient guinea pigs and rats given a glucose challenge often respond with a diabetic-type glucose tolerance curve. In addition to its effect on pancreatic tissue integrity, manganese deficiency can directly impair pancreatic insulin synthesis and secretion as well as enhance intracellular insulin degradation. The mechanism(s) underlying the effects of manganese deficiency on pancreatic insulin metabolism have not been fully delineated, but they are thought to be multifactorial. For example, the flux of islet cell manganese from the cell surface to an intracellular pool may be a critical signal for insulin release. It is also known that insulin mRNA levels are reduced in manganese-deficient animals, which is consistent with their depressed insulin synthesis. In addition, insulin sensitivity of adipose tissue is reduced in manganese-deficient rats, a phenomenon that may be related to fewer insulin receptors per adipose cell. Manganese deficiency may also affect glucose metabolism by means of a reduction in the number of glucose transporters in adipose tissue by an unidentified mechanism. Finally, the effect of manganese deficiency on insulin production may also be due to the destruction of pancreatic J3 cells. It is worth noting that constitutive pancreatic MnSOD activity is lower than in most tissues; this, coupled with the observation that most diabetogenic agents function via the production of free radicals with subsequent tissue damage, suggests that an additional mechanism underlying pancreatic dysfunction in manganese-deficient animals may be free radical mediated.

In addition to its effect on endocrine function, manganese deficiency can affect pancreatic exocrine function. For example, manganese-deficient rats can be characterized by an increase in pancreatic amylase content. The mechanism underlying this effect of manganese deficiency has not been delineated; however, it is thought to involve a shift in amylase synthesis or degradation because secretagogue-stimulated acinar secretion is comparable in control and manganese-deficient rats.

Although the majority of studies concerning the influence of manganese deficiency on carbohydrate metabolism have been conducted with experimental animals, there is one report in the literature of an insulin-resistant diabetic patient who responded to oral doses of manganese (doses ranged from 5 to 10 mg) with decreasing blood glucose concentrations. Although this is an intriguing case report, others have reported a lack of an effect of oral manganese supplements (up to 30 mg) in diabetic subjects, and low blood manganese concentrations have not been found to be a characteristic of diabetics.

Abnormal lipid metabolism is also characteristic of manganese deficiency: Specifically, a lipotrophic effect of manganese has been suggested in the literature. Severely manganese-deficient animals can be characterized by high liver fat, hypocholesterolemia, and low high-density lipoprotein (HDL) concentrations. Deficient animals can also be characterized by a shift to smaller plasma HDL particles, lower HDL apolipoprotein (apoE) concentrations, and higher apoC concentrations. As stated previously, tissue lipid peroxidation rates can be increased in

manganese-deficient animals, possibly as a result of low tissue MnSOD activity.

There is considerable debate as to the extent to which manganese deficiency affects humans under free-living conditions. Manganese deficiency can be induced in humans under highly controlled experimental conditions. In one study, manganese deficiency was induced in adult male subjects by feeding a manganese-deficient diet (0.1 mg Mn per day) for 39 days. The subjects developed temporary dermatitis, as well as increased serum calcium and phosphorus concentrations and increased alkaline phosphatase activity, suggestive of bone resorption. Since the late 1980s, several diseases have been reported to be characterized, in part, by low blood manganese concentrations. These diseases include epilepsy, Mseleni disease, maple syrup urine disease and phenylketonuria, Down's syndrome, osteoporosis, and Perthes' disease. The finding of low blood manganese levels in subsets of individuals with the previously mentioned diseases is significant since blood manganese levels can reflect soft tissue manganese concentrations. The reports of low blood manganese concentrations in individuals with epilepsy are particularly intriguing, given the observations that manganese-deficient animals can show an increased susceptibility to drug and electroshock-induced seizures and a genetic model for epilepsy in rats (the GEPR rat) is characterized by low blood manganese concentrations. It is evident that a deficiency of manganese may contribute to the pathology of epilepsy at multiple points, given that Mn^{2+} is implicated in activation of glutamine synthetase, a Mn^{2+}-specific brain ATPase; production of cyclic AMP; altered synaptosomal uptake of noradrenalin and serotonin; glutamate, GABA, and choline metabolism; and biosynthesis of acetylcholine receptors.

Evidence of widespread manganese deficiency in human populations is lacking. Typically, manganese intakes approximate the 2001 US Institute of Medicine's suggested adequate intakes as follows: 3 μg/day for infants 0–6 months old, 0.6 mg/day for infants 7–12 months old, 1.2–1.9 mg/day for children 1–13 years old, 1.6–2.2 mg/day for older children, and 1.8–2.6 mg/day for adults. The Tolerable Upper Intake Level (UL) is the highest level of a daily nutrient intake that is likely to pose no risk of adverse health effects in almost all individuals. The Institute of Medicine's recommended intakes for manganese set ULs at 2, 3, and 6 mg/day for children 1–3, 4–8, and 9–13 years old, respectively. Values were set at 9 mg/day for adolescents 14–18 years old and at 11 mg/day for adults.

Manganese Toxicity

In domestic animals, the major reported lesion associated with chronic manganese toxicity is iron deficiency, resulting from an inhibitory effect of manganese on iron absorption. Additional signs of manganese toxicity in domestic animals include depressed growth, depressed appetite, and altered brain function.

In humans, manganese toxicity represents a serious health hazard, resulting in severe pathologies of the central nervous system. In its most severe form, the toxicosis is manifested by a permanent crippling neurological disorder of the extrapyramidal system, which is similar to Parkinson's disease. In its milder form, the toxicity is expressed by hyperirritability, violent acts, hallucinations, disturbances of libido, and incoordination. The previous symptoms, once established, can persist even after the manganese body burden returns to normal. Although the majority of reported cases of manganese toxicity occur in individuals exposed to high concentrations of airborne manganese ($>5\,mg\,m^{-3}$), subtle signs of manganese toxicity, including delayed reaction time, impaired motor coordination, and impaired memory, have been observed in workers exposed to airborne manganese concentrations less than $1\,mg\,m^{-3}$. Therefore, an inhalation reference concentration range for manganese has been established by the US Environmental Protection Agency to be between 0.09 and $0.2\,\mu g\,m^{-3}$. Manganese toxicity has been reported in individuals who have consumed water containing high levels ($\geq 10\,mg\,Mn\,l^{-1}$) of manganese for long periods of time. Recently, there has been concern that the risk for manganese toxicity may be increasing in some areas because of the use of MMT in gasoline as an antiknock agent, although there is little evidence that air, water, or food manganese concentrations have increased where this fuel is used.

In addition to neural damage, reproductive and immune system dysfunction, nephritis, testicular damage, pancreatitis, lung disease, and hepatic damage can occur with manganese toxicity, but the frequency of these disorders is unknown. Although there is a limited body of epidemiological data that suggests that high levels of manganese can result in an increased risk for colorectal and digestive tract cancers, most investigators do not consider manganese to be a carcinogen. In contrast, both divalent ($MnCl_2$) and heptavalent forms ($KMnO_4$) of manganese are recognized to be strong clastogens both *in vitro* and *in vivo*; exposure to high concentrations of either form results in chromosomal breaks, fragments, and exchanges. High concentrations of manganese can also induce forward and point mutations

in mammalian cells. High levels of dietary manganese have not been reported to be teratogenic in the absence of overt signs of maternal toxicity. However, there are reports that exposure to high levels of manganese during prenatal development can result in behavioral abnormalities. High levels of brain manganese have been reported in subjects with amyotrophic lateral sclerosis, and it has been suggested that this increase may contribute to the progression of the disease. Similar to the cases in humans, chronic manganese toxicity in rhesus monkeys is characterized by muscular weakness, rigidity of the lower limbs, and neuron damage in the substantia nigra. Findings from a recent study suggest that iron and aluminum, which accumulate in the globus pallidus and the substantia nigra of these animals, induce tissue oxidation that may contribute to the damage associated with manganese toxicity. Neural toxicity is a consistent finding in rats exposed to chronic manganese toxicity. Significant manganese accumulation was accompanied by an increase in cholesterol content in the hippocampal region of manganese-treated rats, which was associated with impaired learning; this impairment was corrected by an inhibitor of cholesterol synthesis. The development of manganese toxicity in individuals with compromised liver function, or compromised biliary pathways, is well documented. Significantly, these individuals can have abnormal magnetic resonance imaging (MRI) patterns, which improve following the alleviation of the manganese toxicity. For example, in some cases improvements in brain function have been achieved after liver transplant. The mechanisms underlying the toxicity of manganese have not been agreed upon but may involve multiple etiologies, including endocrinological dysfunction, excessive tissue oxidative damage, manganese-mediated disruptions in intracellular calcium and iron metabolism, and mitochondrial dysfunction caused by manganese inhibition of some pathways of the mitochondrial respiratory chain.

Severe cases of manganese toxicity in humans have been reported for adults, as well as isolated cases in other groups of individuals who are vulnerable, including children on long-term parenteral nutrition and parenteral nutrition patients who have cholestasis or other hepatic disease. In many cases, the previously mentioned groups of individuals have been reported to be characterized by high brain manganese concentrations based on MRI. Although no known cases have been reported, infants may be at a high risk for manganese toxicity due to a high absorptive capacity for the element and/or an immature excretory pathway for it. If manganese is taken up by extrahepatic tissues via the manganese–transferrin complex, the developing brain may be particularly sensitive to manganese toxicity due to the high number of transferrin receptors elaborated by neuronal cells during development, coupled with the putative need by neural cells for transferrin for their differentiation and proliferation. Newborn rats given daily doses of dietary manganese at a level equivalent to that of soy formula exhibited significant neurodevelopmental delays as assessed by several behavioral tests. It should be noted that the concentration of manganese in soy formula is relatively modest but approximately 60–100 times higher than that of breast milk. Brain manganese concentration was increased and striatal dopamine concentrations were significantly decreased even 45 days after the supplementation ended, suggesting that the impact of manganese on the brain and behavior was irreversible. Thus, dietary exposure to high levels of manganese during infancy can be neurotoxic to rat pups and result in developmental deficits. Further studies on human infants fed diets with different levels of manganese are needed to assess whether there are any long-term consequences of early manganese exposure of newborns.

Another group of neuropathological conditions that has been associated with elevated levels of brain manganese is transmissible spongiform encephalopathies. These diseases found in animals and humans are also referred to as prion diseases. There is strong evidence that in their native state, prions are normal brain glycoproteins that bind copper and have an antioxidant function. However, it has been suggested that in the disease process an abnormal isoform of the protein is generated in which manganese is substituted for copper. This isoform is proteinase resistant, no longer has antioxidant activity, and may play a role in the etiology of these diseases. Indeed, elevated levels of brain manganese, along with lower than normal levels of brain copper, have been measured in patients with the prion disease, Creutzfeld–Jakob disease. Whether the elevated levels of brain manganese observed in these patients as well as in animal models of these diseases play an important role in their pathogenesis or are secondary to other factors remains to be determined.

Assessment of Manganese Status

Reliable biomarkers for the assessment of manganese status have not been identified. Whole blood manganese concentrations are reflective of soft tissue manganese levels in rats; however, it is not known whether a similar relationship holds for humans. Plasma manganese concentrations decrease in individuals fed manganese-deficient diets and are

slightly higher than normal in individuals consuming manganese supplements. Lymphocyte MnSOD activity and blood arginase activity are increased in individuals who consume manganese supplements; however, their value as biomarkers for manganese status may be complicated due to the number of cytokines and disease states that may also increase their expression. Urinary manganese excretion has not been found to be sensitive to dietary manganese intake. With respect to the diagnosis of manganese toxicosis, the use of MRI appears to be promising because the images associated with manganese toxicity are relatively specific. Whole blood manganese concentrations can be correlated with MRI intensity and Ti values in the globus pallidus even in the absence of symptoms of neurological damage. Thus, although it is relatively expensive, MRI may be particularly useful as a means of identifying susceptible individuals in, or around, manganese-emitting factories. In addition, the method may be useful in the evaluation of patients with liver failure.

MEAL SIZE AND FREQUENCY

F E Leahy, University of Auckland, Auckland, New Zealand

Man's eating habits are changing. Terms such as 'super-sizing,' 'portion distortion,' and 'grazing' have appeared in the contemporary vernacular. Therefore, a better understanding of meal size and frequency is particularly important, especially considering the potential role that these new eating patterns may be playing in the dramatic increase in the incidence of illnesses such as obesity, diabetes, and cardiovascular disease in society.

The principal consequences that changes in meal size and frequency have on the body relate to the absorption and metabolism of food. Several factors in addition to meal size and frequency influence absorption and metabolism, such as the physical characteristics of the food, its macronutrient composition, the energy density of the diet, and the physical volume of the meal. However, the particular contribution that changes in meal size and frequency have made to the dramatic change in

society's eating patterns makes them worthy of special attention.

Effect of Meal Size on Absorption

When a meal of mixed macronutrient composition is consumed, the rate at which the carbohydrate, protein, and fat in that meal is absorbed differs. Carbohydrate in the form of glucose and protein in the form of amino acids enter the portal vein within 30 minutes of meal ingestion and later appear in the general circulation. As the glucose concentration in the portal vein increases, there is an increase in the uptake of glucose into the hepatocytes. Pancreatic islet cells react to the increase in blood glucose and secrete insulin, among other hormones, into the circulation. As a result, there is a decline in the release of nonesterified fatty acids from the adipose tissue. Fatty acid oxidation in the skeletal muscle tissue decreases, and as glucose uptake takes place, the muscle cells increase the rate at which glucose is oxidized. Glycogen synthesis in the muscle and liver cells is increased and the uptake of amino acids by muscle tissue may also occur. Up to 4 h after ingestion of the meal, fat in the form of chylomicron triacylglycerol enters the circulation via the lymphatic system. The action of the hormone lipoprotein lipase in the adipose tissue has by now increased, which promotes the storage of fatty acids as triacylglycerol in adipocytes. This synopsis indicates that following the ingestion of a meal, there is a marked increase in glucose oxidation with a corresponding decrease in fat utilization resulting in the storage of fat.

The larger the meal consumed, the more pronounced are the responses described previously. After a large meal is eaten, the plasma glucose concentration will remain elevated for up to 4 h following ingestion. Conversely, the smaller the meal, the more subtle the effect. This indicates that meal size does indeed influence absorption. However, in order for the relationship between meal size and absorption to be fully understood, the role that absorption plays in determining meal size needs to be considered. The following section focuses on the process of absorption and the systems that control the amount of food eaten.

Regulation of Meal Size by Satiety Peptides and Adiposity Signals

Peptides in the gastrointestinal tract and brain are believed to play an important role in the body's decision to commence and conclude meal consumption. When a meal is being consumed, these peptides are secreted by the gut to indicate the level of satiety. Some of this information can be used by the brain to determine the feeling of fullness, in turn influencing the decision to cease consumption. Cholecystokinin (CCK), a polypeptide located in the peripheral and central nervous systems, is one such satiety signal. It is released in proportion to the amount of food being consumed and helps to determine the amount consumed. Following a meal, CCK is secreted from mucosal epithelial cells in the first segment of the duodenum and stimulates the delivery of digestive enzymes from the pancreas, as well as bile from the gallbladder, into the small intestine. In addition, CCK is produced by neurons in the enteric nervous system and is widely distributed in the brain. The exogenous administration of CCK (and CCK-8, its synthetic analogue) has been shown to influence the amount of food consumed in proportion to the dose given. Although CCK (and other satiety signals) acts to limit meal size, it is important to note that it has little effect on body fat stores, meaning that it does not take into consideration the existing adiposity of the individual when signaling the onset of satiety. Therefore, adiposity signals must be considered in parallel because they also play a part in the process of determining meal size.

Adiposity signals such as leptin act in conjunction with satiety signals in the brain during digestion and their concentration is determined in relation to the degree of adiposity. Like CCK, the effect on meal consumption and body weight of their exogenous administration is dose dependent. Leptin is a peptide hormone produced predominantly by adipocytes, and it is also secreted by the epithelial cells of the stomach. The definitive role of leptin in digestive physiology is still being determined, but it is thought to play a part in limiting food intake in conjunction with CCK. It is when the adiposity signals interact with, and influence, the satiety signals originating from the gut that an attempt at controlling energy intake and meal size is made.

Effect of Meal Size on Metabolism

Energy homeostasis, or the state of balance, achieved by matching energy intake with energy expenditure, is partially dependent on the regulation of meal size consumed. In order for meal size to have an effect on energy metabolism, it must affect either or both components involved in the regulation of energy balance, namely energy intake and energy expenditure. Energy balance is the difference between energy ingested and energy expended over a given period of time. Consequently, energy storage is equal to intake minus expenditure. The following sections examine

the effect of meal size on the two components of the energy balance equation.

Effect of Meal Size on Energy Intake

Meal portion sizes have been increasing steadily since the 1970s, in parallel with the increasing prevalence of obesity in society. It is known that portion and meal sizes vary depending on the food source and location of consumption. Not surprisingly, the largest portions consumed are generally those obtained at fast-food restaurants, although the portion sizes of home-cooked meals have been increasing steadily as well. Meal size may thus be contributing to the problem of obesity by leading to a daily total energy intake that is greater than the daily total energy expenditure, resulting in a positive energy balance.

Effect of Meal Size on Energy Expenditure

Total energy expenditure (EE) can generally be divided into three major components: basal metabolic rate (BMR), thermogenesis, and physical activity (**Table 1**). In order for meal size to have an effect on the EE side of the energy balance equation, it must have an effect on one or more of these components. There is no evidence that meal size has an effect on BMR, which refers to the energy expended to maintain the body on a day-to-day basis. Thermogenesis broadly refers to the body's production of heat, which is divided into three categories: dietary, thermoregulatory, and adaptive. It is the dietary category, commonly known as dietary-induced thermogenesis (DIT), that is of greatest relevance to the discussion of the effect of meal size on energy expenditure. It refers to the heat lost by the body as a result of the absorption and metabolism of a recently ingested meal. DIT represents approximately 10% of energy intake, and therefore the energy expended on DIT increases and decreases in relation to the size of the meal and, more important, the energy value of the meal consumed. The larger the meal, the more energy will be expended to absorb, transport, and metabolize the nutrients consumed during that meal. For example, in the case of a meal containing 2000 kJ (478 kcal) of energy, approximately 200 kJ (48 kcal) will be expended on DIT alone. It is in the physical activity component of energy expenditure that the greatest variation between individuals is observed because physical activity levels (and therefore the energy expended on activity) are contingent on lifestyle choices such as employment and leisure time activities. The effect that meal size may have on physical activity is somewhat difficult to quantify. Meal size is perhaps more important to elite athletes, whose energy expenditure is two or three times greater than that of untrained weight-matched athletes with up to 40% of their energy expenditure being the cost of training.

Table 1 Major components of energy expenditure

Component	*Total energy expenditure (%)*	*Represents*
BMR	60–75	Day-to-day running costs of an individual (e.g., circulation)
Thermogenesis	10–20	Heat produced by the body through dietary, adaptive, and thermoregulatory processes
Physical activity	100 − (BMR + thermogenesis)	The sum of work carried out by an individual

BMR, basal metabolic rate.

Effect of Meal Frequency on Absorption

The perceived health advantages of increased meal frequency (as opposed to eating larger, infrequent meals) have been of interest to researchers since the 1930s. In particular, the benefits of this approach were made apparent by the discovery that insulin requirements in diabetics could be decreased in a frequent meal regime. In a series of case reports on patients taking high insulin doses, it was demonstrated that improved glycemic control and decreased insulin requirements can be achieved when glucose is sipped at hourly intervals throughout the day. Similarly, in healthy individuals a diet composed of many small meals compared with an isoenergetic diet composed of larger meals results in decreased insulin and glucose fluctuations.

Meal frequency not only affects insulin and glucose levels but also influences an individual's circulating lipids. An inverse relationship exists between meal frequency and lipid levels, suggesting that infrequent feeding leads to an increased risk of cardiovascular disease due to large fluctuations in circulating lipids. Increased meal frequency, on the other hand, is associated with several benefits, such as decreased serum cholesterol levels, decreased total:high-density lipoprotein cholesterol ratio, decreased esterified fatty acids, and decreased enzyme levels in adipose tissue associated with fatty acid storage. Paradoxically, individuals who report that they eat more frequently not only have lower total and low-density lipoprotein cholesterol (LDL-C) but also have a greater intake of energy, total fat, and saturated fatty acids. Considering that some of these results were found in a free-living

population, it is possible that dietary misreporting, a common occurrence in overweight populations, may be the cause of this inconsistency.

Mechanisms Underlying the Metabolic Effect of Meal Frequency

The mechanisms underlying beneficial responses to frequent feeding as opposed to an infrequent meal pattern are not fully understood. Frequent feeding has been shown to elicit lower plasma glucose fluctuations than does a more infrequent eating pattern. The absolute amount of carbohydrate eaten at each episode of ingestion in a frequent feeding pattern is simply not great enough to elevate glucose to the same extent as more infrequent eating. Small elevations in plasma insulin seen with frequent feeding are most likely in response to minimal fluctuations in glucose. The mechanisms responsible for the effect of an increased frequency of meal eating on lipid metabolism are not as clear-cut. The lower serum cholesterol levels observed during frequent feeding may be related to lower serum insulin levels. Insulin appears to have a key role in enhancing the hepatic synthesis of cholesterol through its ability to stimulate hydroxymethylglutaryl-coenzyme A reductase (HMG-CoA), the rate-limiting enzyme in hepatic cholesterologenesis. Exogenous insulin quickly increases HMG-CoA reductase activity in rats with diabetes and raises levels of the enzyme in animals without the disorder. It is possible that the reduction of serum cholesterol during a diet of habitual frequent feeding in normal healthy individuals may result from a reduction in hepatic cholesterol synthesis, secondary to the maintenance of euglycemia at lower serum insulin levels. A reduction in cholesterol synthesis would result in an increase in LDL receptors, further lowering total and LDL-C levels.

Alternatively, or in addition, the benefits associated with an increased feeding regimen may reflect unintentional or uncontrolled changes in dietary energy and fat intake that may occur when an individual's meal frequency is altered. It is not clear whether a diet of frequent eating results in any adaptational responses of enzymes or hormones that in turn may be providing additional benefit to the individual.

Much of the research that found these benefits is difficult to interpret due to the variety of methods used, the lack of information available regarding the foods consumed, and the exact nature of the dietary intervention. The majority of measurements are made on fasted blood samples, when in fact most individuals are in a postprandial state for the greater part of every 24-h period. The results of such research must be interpreted with caution for a number of reasons, such as the small sample size used and the interactions with other factors that may prolong absorption time (e.g., soluble fiber, low-glycemic index foods, and the administration of α-glycosides).

As discussed previously, frequent feeding has been demonstrated to lower circulating plasma glucose, insulin, and lipids in both healthy and diabetic subjects in the short term. In addition to the lack of clarity on the mechanisms involved, further research is needed to investigate any medium- and long-term benefits of frequent feeding. It is important that, if deemed desirable in terms of metabolic control, increasing the number of periods of feeding encourages the desired dietary pattern and mix of macro- and micronutrients and is not offset by the failure to decrease meal size.

Effect of Meal Frequency on Metabolism

The maxim that was applied earlier to the study of meal size, namely that it can only influence energy metabolism if it affects energy intake and/or energy expenditure, is applicable to meal frequency. The following sections focus on energy intake and energy expenditure, respectively.

Effect of Meal Frequency on Energy Intake

It has long been argued that the frequency of meal intake may have an effect on body weight regulation. It has been suggested that there is an inverse association between meal frequency and body weight. However, there are a number of flaws in the design of many of the studies from which these data have been derived, and caution is required in the interpretation of the results. Design flaws include (i) dietary underreporting, especially of snacking occasions; (ii) reverse causality, which refers to the possibility that people abstain from eating meals when they become overweight in an attempt to lose weight or to prevent further weight gain; (iii) lack of measurement of physical activity or energy expenditure; and (iv) inclusion of people in a diseased state. These important confounding factors may help to resolve the contradictory results of many research trials. Erroneous conclusions have been drawn from the misinterpretation of such results because these studies are extremely vulnerable to methodological errors that may generate spurious relationships that may not actually exist.

There appears to be very little direct empirical evidence in humans to suggest that frequent feeding per se affects appetite and energy intake. Individuals who eat frequently seem to exhibit a greater capacity to compensate for changes in the energy content

of specific meals relative to individuals who derive most of their energy intake from fewer larger meals. Over very short periods, and under highly controlled experimental conditions, frequent feeding can decrease energy intake at a subsequent meal, which may in turn have an effect on appetite regulation. It remains to be seen, however, whether the same would occur in free-living conditions.

Mechanisms by which meal frequency may influence energy intake Although the evidence is inconclusive, feeding frequency may have an impact on appetite and hence affect energy intake. The control of appetite is very complex and is determined by a number of factors. However, the question remains as to whether the frequency of feeding elicits effects on any of these factors, in turn affecting appetite and possibly body weight.

Frequency of feeding may potentially affect the release of neuroendocrine hormones such as neuropeptide Y, galanin, orexin, and melanocortins from the hypothalamus. The release of such hormones may be either stimulated or suppressed during frequent feeding, leading to either higher or lower than normal hormone levels, which may in turn have knock-on effects on energy intake and/or expenditure. Because it is not feasible to investigate such effects in humans, no studies have been carried out to determine this. The release of gut hormones such as CCK, glucagon-like peptide (GLP), and glucose-dependent insulotropic polypeptide (GIP) may be altered in relation to feeding frequency. In rats, the infusion of the sulfated octapeptide of cholecystokinin (CCK-8) causes a significant reduction in meal size as previously mentioned, whereas meal frequency is increased to compensate for the small meals. However, little is known about the effects of meal pattern on CCK in animals or humans. It is possible that frequent feeding may affect CCK release in one of two ways: It may cause the regular release of the hormone in response to each feed, persistently alerting the brain that the individual is satiated, or CCK may be released into the circulation in such small amounts in response to frequent feeding that it is not recognized by the brain and the individual continues to eat. Similar effects may occur with GLP and GIP.

Effect of Meal Frequency on Total Energy Expenditure

As discussed earlier, the three components of energy expenditure are BMR, thermogenesis, and physical activity. For meal frequency to have an influence on energy expenditure, it must affect one or more of these components. BMR (which represents 60–75% of energy expenditure in sedentary individuals) is not known to be influenced by meal frequency. Much the same can be said for thermogenesis, for which extensive research has failed to demonstrate a link between feeding frequency and DIT. It is reasonable and logical to expect that any difference between frequent and infrequent meal-eating patterns would be seen most clearly during the postprandial period when food has just been eaten, where the rate of ingestion of nutrients may alter EE and fuel storage.

Although much research has been carried out on the effects of meal frequency on total energy expenditure, few studies have isolated the physical activity component per se. Greater attention has been paid to the relationship between meal frequency and physical activity with regard to the performance of elite athletes because the manipulation of the meal pattern can potentially be used as a tool to achieve optimal performance. Because carbohydrate requirements in elite athletes are high and endogenous glycogen reserves are limited, athletes undertaking prolonged strenuous exercise seek to maximize carbohydrate availability at all times.

Irrespective of the above, the key determinant of feeding frequency's overall effect on energy balance is whether it has an impact on 24-h energy expenditure, where energy intake is fixed in content and composition and physical activity is kept constant. Numerous studies have been carried out to investigate this, and all have found that no relationship exists. The majority of these studies used either direct or indirect calorimetry or doubly labeled water in their measurements, both of which are highly reliable energy expenditure measurement techniques.

Conclusion

The contemporary terminology referring to the tendency to increase the amount of food eaten at a meal and the greater frequency at which food is eaten demonstrates the importance of a clear understanding of the consequences of meal size and frequency on health. Satiety peptides and adiposity hormones attempt to control the size of a meal eaten, and increased meal frequency, within the constraints of energy balance, has been found to have beneficial effects attenuating circulating substrates. However, to elucidate the influence that meal size and frequency have on absorption and metabolism, and to clarify whether the increase in the volume of food eaten at a meal and the greater frequency at which food is eaten have a direct affect on health, further research on the free-living population is required.

MEAT, POULTRY AND MEAT PRODUCTS

P A Lofgren, Oak Park, IL, USA

Animal source foods are major contributors to the nutrients in the food supply in many countries. Of these foods, animal muscle (or meat) foods and products are excellent examples of nutrient-dense, or naturally nutrient-rich, foods that provide a relatively large amount of many nutrients per the amount of calories provided in a typical serving. For purposes of this article, discussion is limited to the muscle foods: beef, pork, lamb, veal, poultry, and some of the processed products made from these muscle species.

For meat and meat products there are extensive and comprehensive nutrient databases available for reference for particular products of interest. Thus, this article will provide a sampling of the data available for representative meats and meat products.

One of the best and most comprehensive listings of the nutrient values of all meat, poultry, and other meat products is the nutrient database developed and maintained by the US Department of Agriculture. In this database, complete nutrient profiles are listed for more than 700 beef, 200 pork, 195 lamb, 85 veal, 140 poultry, and 130 turkey products. This database can be accessed and searched on-line at the Web site www.nal.usda.gov/fnic/foodcomp. This database is updated as new data become available for various food products. The most recent version of this database is the *USDA National Nutrient Database for Standard Reference*, Release 17, published in 2004.

For another extensive listing of the nutrient values of many meat and meat products, including some by brand name, the reader is referred to the publication *Bowes & Church's Food Values of Portions Commonly Used* (18th edn.). This reference, although not as extensive in terms of products listed, provides data directly in common serving sizes and provides available data on some additional nutrient and nutrient-related components of meat products (e.g., values for ω-3 and *trans* fatty acids, glutathione, vitamin D activity, and other vitamin-like compounds).

Nutritional Value

The nutritional value of foods, including meat and meat products, can be defined in a number of different ways, from simply listing the quantities of various nutrients contained in the foods to consideration of biological factors that affect the utilization of these nutrients by the body. Some foods may contain nutrients in forms that the body cannot readily utilize. Thus, nutrient bioavailability, or availability, becomes important.

The nutritional value of meat and meat products is related to the quantity and utilization of nutrients and the potential for these products to either enhance or restrict nutrient utilization by the body. There are five major classes of nutrients: protein, lipid, carbohydrate, vitamins, and minerals.

The nutrient content of meat (muscle foods) is fairly similar among the various mammals, birds, and fish. However, differences in the levels of the various nutrients may result from differences in the

carcass composition among species and within species as a result of different fat-to-muscle ratios in the edible portion. As fat percentage increases, nutrient concentration of the muscle portion decreases. Also, to a certain extent, the fat profile/composition and other nutrient content levels may be modified or affected by the animal's diet and/or genetic makeup.

In general, cooking or heat processing has only minimal effects on the nutritional value of muscle foods. In most cases, cooking usually decreases moisture content and concentrates other nutrients, including fat content, especially in lower fat products. This is due to moisture loss. However, in some intensely heated meat products, fat content may also be reduced significantly with negligible loss of other nutrients.

Classes of Nutrients and Meat Products

Protein

Proteins comprise the structural unit of all muscle cells and connective tissue. As such, meat and meat products (muscle foods) are major protein sources. Furthermore, muscle foods, as a group, are excellent sources of high-quality protein that supplies all the essential amino acids in desirable proportions for human consumption. Amino acids are the building blocks of protein, and those provided by meat match or exceed the profile required by humans.

The protein content of most muscle foods, on a wet basis, is between 15 and 35%. This percentage will change due to the moisture and lipid content of the specific product. On a raw weight basis as purchased at a store, the protein content is generally less than 20%. However, people do not eat muscle foods raw, and visible fat in red meat products and skin in poultry products are usually trimmed away. Therefore, muscle foods, as consumed, have a much higher protein content, in the range of 30%.

Lipids

The lipid component of meat and meat products includes a diverse group of substances, such as glycerides (glycerol with fatty acids attached), phospholipids, and sterols. The basic component of most meat lipids is the fatty acids, which can be saturated, monounsaturated, or polyunsaturated.

The relative amount of lipid in muscle foods is probably the most variable aspect of the nutritional profile. Within the lipid component, the relative amount of the different forms of fatty acids present is another variable among meat products. Despite the common reference to animal fats (and especially meat and meat products) as 'saturated,' less than half of all the fatty acids of meats are saturated. The largest proportions of fatty acids in meats are monounsaturated, followed by saturated and then polyunsaturated fatty acids. Among meat products, poultry has a higher proportion of polyunsaturated fatty acids and slightly less saturated fatty acids compared to other meat sources.

The fat in meat products provides much of the flavor associated with these foods and also contributes to the palatability and overall acceptability by consumers.

In addition, the fats in meat and meat products also contain several essential fatty acids (linoleic and linolenic acid), and they contain the fat-soluble vitamins A, D, E, and K.

Carbohydrates

Meat and meat products are not significant sources of dietary carbohydrates. Almost all dietary carbohydrates come from plant sources. The only naturally occurring carbohydrate in muscle foods is glycogen. In some processed meat products, such as those that are 'sugar-cured,' there may be additional sucrose or glucose added.

Vitamins

Meat and meat products are especially good sources of most of the water-soluble vitamins. In general, meat is the major dietary source of vitamin B_{12} and is an excellent source of many of the other B vitamins, such as pyridoxine (B_6), biotin, niacin, pantothenic acid, riboflavin, and thiamin. For vitamin B_{12}, red meat products such as beef and lamb are especially good sources. Pork products are one of the very best sources of thiamin. Although present in muscle foods, the fat-soluble vitamins are less abundant than in plant foods. Vitamins E and K are present, but at lower levels.

Vitamin D activity may be present in some meat products, but at extremely low levels. This is reflected in the USDA nutrient database, in which vitamin D activity is not listed for beef, pork, lamb, veal, and chicken/turkey products; however, it is listed for some processed meat products. In recent years, there has been production research on beef, pork, and lamb to determine if added vitamin D_3 or its metabolites, fed to the animal for a brief period of time prior to slaughter, can result in improved meat tenderness. Although the results are inconsistent, and commercial application is premature, there is some indication that tenderness may be improved with relatively low levels of vitamin D supplementation, which seems to leave very little residual vitamin D_3 or its metabolites in the muscle. Research in Denmark notes that the more biologically active 25-OHD is present at low levels in meat; however, there is no consensus on the conversion factor for 25-OHD to calculate vitamin D

activity. Also, there are very few data on the vitamin D and 25-OHD levels in most meat products. This represents a potential future area of research regarding the nutrient composition of meat.

Minerals

Meat and meat products are good to excellent sources of most minerals. Among the macrominerals, calcium is not high in muscle foods, although phosphorus and potassium are prominent. In natural meat products, sodium is present but not a significant contributor to the diet. However, processed meat products may contain significantly higher levels of sodium (added as part of curing, preserving, or flavor-enhancing ingredients). Some of the microminerals (trace elements) are especially abundant in meat and meat products. Iron is of greatest significance from meat sources because it is present in the 'heme' form, which is more bioavailable than the non-heme form. Of meat products, beef is an especially rich source of iron in this bioavailable form.

Muscle tissue is a very rich source of minerals, such as phosphorus, potassium, magnesium, iron, copper, zinc, and selenium. For instance, pork, poultry, and beef are especially good sources of selenium.

Bioavailability of Nutrients

Muscle foods have been shown to contain 'intrinsic' factors that improve the bioavailability of a variety of nutrients. Moreover, the bioavailability of these nutrients from muscle foods is high, often exceeding the availability for the same nutrients in foods derived from plants. Heme iron is one example. Zinc and copper have been shown to be more available from meat sources than from plant sources. Several of the B vitamins may also be more bioavailable from meat sources than from plant sources.

Another interesting aspect of meat products is their ability to promote the bioavailability of nutrients in nonmuscle foods when the two are eaten together. This has been referred to as the 'meat factor.' Perhaps the best example of this is the positive effect of meat in the diet on non-heme iron sources, also in the diet.

Nutrient Density of Meat and Meat Products

The nutrient density of meat is high. Muscle foods have high levels of essential nutrients per unit of weight and per amount of calories provided. Meat and meat products (muscle foods) provide significant amounts of essential nutrients at levels/concentrations higher than those of most other foods relative to the caloric content provided. The US Food and Drug Administration food labeling guidelines allow a food to be designated a 'good' source of a nutrient if it contributes 10% or more of the Daily Value (DV) and an 'excellent' source if it contributes 20% or more of the DV, for that nutrient, per 3-oz. serving. Most meat products are good or excellent sources of many nutrients. It is generally recognized that in diets that lack muscle foods, greater care is required in diet/menu selection to ensure that adequate levels of essential nutrients are present and bioavailable.

Meat Sources and Nutritional Values

Beef

Beef is an excellent source of high-quality protein, and provides significant contributions of many B vitamins and minerals. In macronutrient terms, the lean-to-fat ratio of the particular beef product influences the calorie and nutrient composition. In general, as the fat content decreases, the concentration of other nutrients (especially protein, B vitamins, and minerals) in beef tends to increase. Most beef products available to the consumer are much leaner than they were 20 or 30 years ago. This is a result of changes in feeding and genetics, producing leaner animals, and also due to closer trim levels on the products that consumers see in the meat case. Whereas in the past, beef cuts with 1/4 in. of fat trim were common, now the same products have only 1/8 in. fat trim or, in some cases, even 0 in. fat trim. In the case of ground beef products, 10 or 20 years ago 17% fat ground beef was considered as 'extra lean.' Today, ground beef is commonly available at fat levels as low as 5 or 10%. Other common fat levels for ground beef are 15, 20, and 25%; however, a large proportion of current ground beef sales are in the 5–15% fat level range.

The fat content of beef contains a varied fatty acid profile, with the largest proportion being contributed by monounsaturated fat, followed by saturated fat and polyunsaturated fatty acids. In addition, because it is a ruminant product, beef is an excellent source of the naturally occurring fatty acid conjugated linoleic acid (CLA), which has been demonstrated to provide anticarcinogenic properties among other health benefits.

Table 1 provides the energy, protein, and lipid profile of beef along with other meat sources. For a comparison of the mineral composition of beef products versus that of other common meat sources, see **Table 2**. For a comparison of the vitamin composition of beef products versus that of other common meat sources, see **Table 3**.

Pork

Pork, like beef, is an excellent source of high-quality protein and contributes significant amounts of many B vitamins and minerals. As for other muscle foods, pork's nutrient composition is greatly affected by its fat and water content. As fat percentage decreases, the concentration of other nutrients increases. In addition, as pork is cooked and moisture is removed, the concentration of nutrients also increases. Pork is an excellent source of minerals, such as selenium, iron, zinc, phosphorus, and potassium. Compared to other muscle foods, the contribution of pork to selenium in the food supply is especially significant.

Pork is an excellent source of the B vitamins. Pork is an especially good source of thiamin (vitamin B_1), being the single best source of this vitamin among commonly eaten foods. The fat profile of pork can be influenced by feeding regimes such that it is more or less saturated or firm. However, overall the fatty acid profile of pork is largely monounsaturated, followed by saturated and then polyunsaturated fatty acids.

Lamb

Although it represents a smaller portion of overall muscle food consumption, lamb still provides a nutrient profile with significant benefits for the human diet. In addition to being a source of high-quality protein, lamb is also a good source of many minerals and B vitamins. Vitamin B_{12} is especially abundant in lamb. It is also a good source of the minerals iron and zinc.

In addition, as a ruminant, lamb is another naturally occurring dietary source of CLA, a unique fatty acid with anticarcinogenic and other health benefits (from animal model studies).

Veal

Although representing a smaller proportion of overall meat consumption, veal still provides a nutrient profile that is very beneficial. As with all meat sources, veal provides high-quality protein in a product that may be slightly leaner (in terms of fat) than other red meat sources. Compared to other meat sources, veal has a lower iron content.

Poultry

The nutrient composition of poultry (chicken and turkey) is similar to that of red meat animals with a few exceptions. Poultry is lower in iron content, and thus heme iron, than beef. Turkey is slightly higher in several minerals (Ca, Fe, P, K, Zn, and Cu) than chicken. As in red meats, there are significant amounts of several B vitamins (e.g., niacin, B_6, and pantothenic acid) compared to other meat sources, and these are not significantly reduced during cooking.

The fat content of poultry is predominantly monounsaturated fat, followed by saturated fat and polyunsaturated fat. Poultry fat, like pork fat, is somewhat more unsaturated than beef fat. Poultry is significantly higher in polyunsaturated fat compared to beef, pork, lamb, and veal.

Processed Meats

Processed meats represent a diverse array of products that have undergone additional treatment from the fresh meat form to the point of consumption, including curing with other ingredients added and the addition of salt or other flavor or preservative mixtures. Also, these products often represent combined meat sources.

Summary

Muscle foods provide significant amounts of essential nutrients at levels/concentrations higher than those of most other foods relative to the caloric content provided. Almost all of the essential nutrients are present in muscle foods at some level. Furthermore, muscle foods provide nutrients in a form that enhances the bioavailability of nutrients from both the meat and other dietary sources. It is generally recognized that in diets that lack muscle foods, greater care is required in diet/menu selection to ensure that adequate levels of essential nutrients are present and bioavailable.

MICROBIOTA OF THE INTESTINE

Contents

Prebiotics

J M Saavedra and N Moore, John Hopkins School of Medicine, Baltimore, MD, USA

Introduction

The gastrointestinal (GI) system in humans comprises the largest surface area of any organ in the body. The complexity of this system and its functions provides us with the ability to take in nutrition, selectively process it, assist in maintaining fluid and electrolyte balance, and offers a vehicle for excretion of waste while at the same time offering the first line of defense against toxins, pathogens, and other noxious agents. The indigenous gut microflora make up the complex ecosystem that inhabits the GI lumen, which mediates part of the interaction between the external environment and the host.

The basic development and makeup of the human intestinal microflora, and the metabolic, immune, and functional effects of the host are discussed below. The importance of maintaining a balance in this ecosystem, and the recent use of nutrition for providing beneficial microflora and the clinical effect this offers will be presented.

Normal Microflora

The intestinal microflora of healthy humans is comprised of more than 400 species of bacteria with a population of 10^{12}–10^{14} colony-forming units (CFU) per gram, of which more than 98% are resident in the colon. This bacterial population nearly exceeds the population of cells in the human body. The microflora is composed of both aerobic and

predominantly anaerobic microorganisms that when equilibrium within an individual is maintained confer nutritional and immune benefits. A prime example of the importance of microorganisms in the GI tract was the study of gnotobiotic (germ-free) mice, which suffered persistent enteritis and severe infections with poor survival rate. Through the interaction of the mucosal surface with the GI tract microflora an important system of immune defense is established.

The presence of microorganisms in different segments of the GI tract varies both qualitatively and quantitatively. Bacteria from the mouth are predominantly anaerobes including streptococci, *Bacteroides*, *Lactobacillus*, and some yeasts; these wash down to the stomach with the intake of food and function of swallowing. In the stomach the acid environment destroys most of the oral and food-ingested microorganisms. The microflora of the stomach is comprised of mostly Gram-positive and aerobic microflora at very low levels (10^3 CFU ml^{-1}). *Peptostreptococcus*, *Fusobacterium*, and *Bacteroides* species are present in low numbers while *Clostridium* is uncommon.

The volume of microflora increases exponentially from the small intestine, which is sparsely colonized, to the richly populated colon. The concentrations of bacteria found in the small intestine are between 10^3 and 10^4 CFU ml^{-1}, again both facultative anaerobes and aerobic bacteria with almost complete absence of coliforms and *Bacteriodes*.

The microflora of the colon dramatically increases to a concentration of 10^{11}–10^{12} CFU gm^{-1}. This bacterial load accounts for up to 50% of the volume of colonic content. Although the colonic microflora comprises more than 400 different species it is predominantly anaerobic including *Bacteroides*, *Fusobacterium*, *Bifidobacterium*, *Lactobacillus*, *Enterobacter* and coliforms, and other facultative anaerobes (*Staphlococcus* and *Candida* species).

Development of Microflora

The GI tract is essentially sterile at the time of birth and bacterial colonization begins upon exposure to the environment. Progression of colonization is initially fast, followed by a gradual process of modification over the first few years of life. As the baby passes through the birth canal bifidobacteria and lactobacilli are typically acquired and rapid colonization of mainly enterobacteria occurs. The hospital environment, type of feeding, and type of delivery affect the early colonization of the intestine after birth. Normal vaginal birth permits the transfer of bacteria of the mother as the infant passes through the birth canal. However, with Cesarean delivery this transfer is absent and the hospital or other immediate environment can have a more significant effect on colonization. In these infants, colonization with anaerobic bacteria, especially *Bacteroides*, occurs later than with vaginally delivered infants.

Within the first few days and with introduction of feeding, the newborn intestine (through oxidation–reduction) promotes the establishment of aerobic bacteria, predominantly enterobacteria, *Enterococcus* and staphylococci, and anaerobic bacteria, bifidobacteria, *Bacteroides* and *Clostridia*. As the aerobic bacteria consume oxygen the intestinal milieu becomes more amenable to anaerobic bacteria and aerobic bacteria in turn decline. In breast fed infants bifidobacteria counts increase dramatically and account for 80–90% of the total fecal flora. Lactobacilli and *Bacteroides* also increase but to a lesser extent, while enterobacteria decrease. In formula fed babies *Enterococcus* is the predominant bacteria present with significantly less bifidobacteria and *Bacteroides* than the breast-fed infant. It is the difference in microflora, especially in the greater presence of bifidobacteria, and the presence of oligosaccharide and other bifido-genic factors in breast milk that likely confer a protective effect to the infant against infection, particularly against diarrheal disease.

With the introduction of weaning foods the fecal flora of babies begins to change resembling that of adults by 1 year of age. Concentrations of aerobes decrease and anaerobes (streptococci, *Enterobacter*, *Escherichia coli*, *Bacteroides*, and *Lactobacillus*) increase and predominate by 1–2 years of age. Bifidobacteria concentration also decreases but is generally maintained throughout adulthood (**Figure 1**).

Once well established the microflora is unique to each individual and maintained fairly undisturbed throughout adult life. Changes in general health

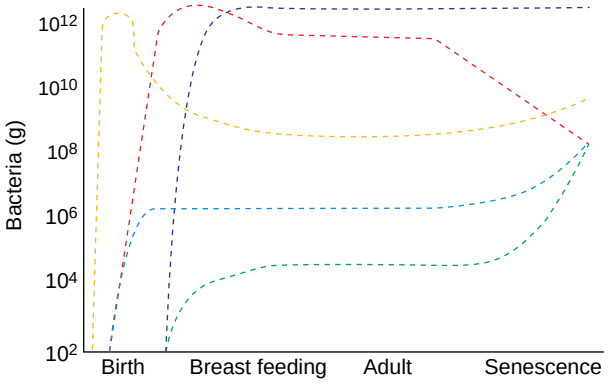

Figure 1 The intestinal flora and its relation to age. (purple), *Bacteroides*, Eubacteriae, Peptococcaceae; (red), Bifidobacteriae; (orange), *E. coli*, streptococci; (blue), lactobacilli; (green), Clostridiae.

and wellbeing, exposure to toxins in the food supply, and utilization of medications, particularly antibiotics, all transiently alter the colonic flora, often profoundly. When the equilibrium of this complex system occurs the host is potentially compromised. However, recovery to the original state of colonization usually occurs upon removal of the altering factors.

Metabolic Activity of Microflora

The structure and function of the gastrointestinal tract is influenced greatly by the presence and make-up of indigenous microflora. In the germ-free murine model, lack of microflora leads to a thinner, less cellular intestinal wall; the villi are thinner, crypts shallower and mucosal surface area is decreased, thus interfering with the gut immune system and nutrient handling processes. The intestinal flora is responsible for production of some micronutrients, particularly vitamins (biotin, folate, and vitamin K), and also fermentation of carbohydrates, which results in the production of short-chain fatty acids (acetate, proprionate, and butyrate). These end products are known to be active in the regeneration and health of the mucosal cellular make up. Glycosylation of complex carbohydrates on the microvillus membrane are specifically related to anaerobic bacteria in the gut lumen. Additionally, the microflora modulates the release of peptides and some proteins from the endocrine cells in the mucosa of the GI tract.

Innate bacteria induce many beneficial responses of the gut immune system. Bacterial interaction with the epithelial cells can enhance local immunity and deter response to antigens. Gram-negative bacteria cause the production of proinflammatory cytokines including interleukin-6 and tumor necrosis factor alpha (TNF-α).

Gut Barrier Effect

Health of intestinal mucosa and the equilibrium of the microflora are essential for the immune response of the GI tract to both ingested and systemic invaders. The colonic microflora plays a key role in maintaining mucosal integrity and the deterrence of pathogenic/toxic bacteria. To maintain the bacterial equilibrium the indigenous bacteria appear to compete with pathogenic bacteria predominantly in the colon for enterocyte receptors, as well as for luminal nutrient. Additionally, the production of short-chain fatty acids from bacterial fermentation of carbohydrates and the transformation of proteins to sterols and bile acids destroy potential mutagens of ingested foods. Dietary antigens are prevented through this system of barrier protection. Alterations will produce an immunoinflammatory response; ultimately entrance of antigens into the body can occur, inducing a systemic allergic response.

Flora-Nutrient Interactions

There is a complex interaction between food and microflora in a feedback-like system. Different types of diets can lead to changes in fecal flora, and its resultant metabolic activity can be altered. When individuals consuming a vegetarian diet were compared to those on a typical Western diet, the latter had microflora that showed greater hydrolyzing ability leading to a more effective metabolism of bile acids and subsequently reduced cholesterol. Similar studies in mice have shown differences with high-fat diets versus low-fat diets.

Disaccharides are broken down in the proximal small intestine by enzymes in the brush border and microvilli of the intestinal epithelium. Glucose, sucrose, lactose, and maltose are the predominant disaccharides hydrolyzed and these rarely reach the colon. When the brush border is unable to produces the enzymes needed for metabolism, the disaccharides are not absorbed in the small bowel and ultimately reach the colon where they interact with the abundant colonic bacteria. Subsequent fermentation causes an osmotic imbalance pulling water into the lumen and causing diarrhea. Significant and rapid production of short-chain fatty acids causes changes in the fecal pH and can irritate the colonic mucosa.

Complex carbohydrates, such as dietary fibers, are predominantly fermented in the colon by colonic bacteria, mostly anaerobic flora. Short-chain fatty acids, acetate, propionate, and butyrate are the predominant by-products and in lesser amounts carbon dioxide, hydrogen, methane, and water. Slow and regular production of short-chain fatty acids provides an energy source that helps the regeneration of colonic mucosa. Fatty acids are also used for hepatic very low density lipoprotein synthesis, which has been reported to have influence in cardiovascular disease.

Dietary protein is only partially digested in the small intestine producing amino acid (NH_2) and carboxyl groups (COOH). These amines enter the colon and are hydrolyzed by enzymes of colonic bacteria. Amines and short-chain fatty acids will enter the systemic system through absorption by the colonic mucosa and portal vein into the bloodstream where they will be appropriately utilized by tissues. These substances then return to the liver through the portal circulation and are excreted as urea in the urine.

Primary bile acids originating from the liver are excreted into the small intestine and conjugate with amino acids, particularly taurine and glycine. Conjugated compounds in general are not well absorbed and cannot re-enter the hepatic circulation without further breakdown. Bacterial action hydrolyzes the conjugated amines, releasing free bile acids 7α- and 7β-dehydroxylation of the bile acid nucleus, and hydroxyl groups C-$_3$, C-$_6$, and C-$_7$. *Bacteroides, Bifidobacterium, Fusobacterium, Clostridium, Lactobacillus,* and *Streptococcus* are the main bacteria that assist in this hydrolysis. These free bile acids can recirculate through the enterohepatic circulation. Bile acids assist in digestion of fats in the intestine. Colonic microflora also transform excess cholesterol found in the large intestine to coprostanol thus reducing available cholesterol and increasing cholesterol to be excreted in stool.

Bacterial microflora of both the small and large bowel synthesizes a number of essential vitamins. Most importantly vitamin K production by the liver is dependent on the metabolic activity of bacteria in the ileum. Prothrombin, a blood-clotting factor, is synthesized in the liver. Glycoprotein arising from the prothrombin complex cannot be synthesized unless the liver contains menaquione. Bacteria in the intestine synthesize menaquione at the terminal ileum where it can be absorbed and reach the liver to promote clotting factors.

Vitamin B_{12} is completely synthesized from microflora in animals. Meats and dairy products from these animals is a primary source of B_{12} for humans, but it is also synthesized in the large bowel. However, the small bowel is the site of optimal absorption of B_{12} so synthesized B_{12} is not well absorbed. Additionally, biotin and other B complex vitamins (folic acid and thiamine) are synthesized by GI microflora.

Microflora and Host Interactions

The immune response within the GI tract is both innate and adaptive. The innate immune system is a pre-existing system that begins to eliminate invading pathogenic microorganisms immediately upon exposure. Natural barriers of the mucosal epithelium begin this immune response. Rapid induction of an immune response occurs with initial inflammation through phagocytosis. Neutrophils and macrophages engulf bacteria in an effort to get rid of them before insult to the epithelium occurs. Phagocytes also release important chemokines and cytokines that increase the inflammatory response activating the adaptive immune mechanisms when necessary.

The adaptive immune mechanisms are able to differentiate indigenous microflora and mount a response to pathogenic microbes. This process involves cells of the gut-associated lymphoid tissue (GALT) resulting in production of IgA. The adaptive branch of the GI immune system is antigen specific allowing a 'memory' of such and responding specifically to re-exposure to offensive bacteria or toxins. It is through this delicate interplay between innate and adaptive immune mechanisms that an adequate immunologic defense response can be maintained while the adaptive immune system is activated in the hope of averting a harmful systemic reaction.

Mucus/Mucin Glycoproteins

Mucus is continuously produced by goblet cells to lubricate and protect the GI epithelium. The primary gene identified that is located in the goblet cell and predominantly responsible for the production and secretion of mucus and its resulting sugar, mucin, is the MUC_2 gene. This is through an elaborate process of encoding a peptide modified by *o*-glycosidic bonds to a variety of carbohydrate residues to amino acids serine or threonine resulting in a glycoprotein with high carbohydrate content that provides the potential to bind sites for both indigenous and pathogenic bacteria. Mucin, the resulting glycoprotein, forms a viscous gel that coats the epithelial surface of the intestine protecting it from chemical and mechanical stress. Coating of the epithelia thus denies pathogenic bacteria the opportunity to adhere preventing an inflammatory response. This is the first line of defense of the intestine against pathogenic microbes. Indigenous bacteria also utilize the carbohydrate component of mucins as fuel, encouraging the growth of health-promoting bacteria (particularly anaerobes).

Colonization Resistance

Varying levels of bacteria throughout the GI tract have inherent benefit to the function of each portion of the GI tract. Thus, selective discouragement of colonization is necessary. For example, the low number of bacteria in the small bowel allows the function of nutrient breakdown and absorption. Intrinsically, the small bowel limits the levels of bacteria through antegrade peristalsis, and bactericidal action of the gastric acid and biliary enzymes of the liver. The ileocecal valve at the terminal end of the small bowel functions as a gate deterring the entrance of colonic bacteria into the small bowel. Presence of higher concentrations of colonic bacteria causes mucosal inflammation and villous atrophy ultimately interfering in its function.

Bacterial overgrowth syndrome is due to anatomical and physiologic alterations of the small bowel

causing proliferation of bacteria in the upper GI tract. Conditions causing hypochlorhydria (decreased secretion of hydrochloric acid) such as gastritis, drug therapy, and dysmotility contribute to bacterial overgrowth. Surgical or anatomical malformations resulting in ineffective peristalsis or absence of the ileocecal valve also contribute to this syndrome. Impaired micelle formation causes fat malabsorption and steatorrhea. Higher levels of free bile acids in the proximal portion of the small bowel bind with vitamin B_{12} thus preventing absorption in the terminal end. Additionally, amino acid and carbohydrate malabsorption occurs leading to increased fecal nitrogen, lower serum proteins, and ultimately protein calorie malnutrition.

The Gut-Associated Lymphoid Tissue (GALT)

The complex function of the gut-associated lymphoid tissue (GALT) is the critical protective immune system in the GI tract. Peyer's patches are cells found in the mucosa and submucosa of the small intestine and contain CD4, CD8 T cells and B cells. M cells that overlay the epithelium transport antigens to the Peyer's patches that initiate the adaptive immune response. Production of secretory IgA occurs and other immune cells then enter systemically through the Peyer's patches and into the mesenteric lymph system. IgA cells prevent pathogens from adhering to the intestinal surface thus preventing gut cell damage.

Altering Gut Flora

The concept of manipulating microflora to enhance the positive aspects of the GI tract has become a more focused endeavor. However, this concept is not new. The early recognition of fermented foods offering health benefits dates back to the early 1900s. Eli Metchnikoff was the first to recognize this benefit when he observed the long lives and good health of Bulgarian peasants and associated this with the large amounts of milk soured with lactic acid bacteria (LAB) they consumed.

Since then much study of the health benefits from introduction of orally supplemented beneficial bacteria has taken place. This concept has been termed probiotics and is defined as the consumption of microbes that confer a positive effect on the host in prevention and treatment of specific pathologic conditions. Bifidobacteria, *Lactobacillus*, and *Streptococcus thermophilus* have been the most recognized and studied probiotics because of their ability to survive the upper GI tract and proliferate, although transiently, in the colon. The purported health benefits of these and other probiotics include prevention and treatment of diarrhea (particularly rotaviral and antibiotic associated), improved lactose digestion, enhanced gut immune function, and, most recently, prevention and treatment of food allergy and its systemic effects (atopic dermatitis and possibly gastrointestinal allergic disease). Use of probiotics to beneficially alter flora composition and its effects will be elaborated on in a separate chapter.

The effects of probiotics on the host are transient and without regular consumption of these products the colon cannot maintain the level of beneficial colonization that connfers the health benefits. Therefore, a key to the probiotic effect and possible enhancement of native colonic flora would be a substrate for gut bacterial growth through fermentation. Certain dietary carbohydrates and fibers that escape digestion in the upper GI tract are ideal for this action. This recent concept involving such carbohydrates is termed prebiotics.

Prebiotics: Definition and Uses

Definition

A prebiotic is generally accepted as a nondigestible food ingredient that selectively stimulates the growth and/or activity of native bacteria in the colon to beneficially affect the host. This generally, but not always, implies:

- a 'natural' food component;
- ability to by-pass the upper GI tract (not digested);
- ability to be selectively fermented by 'beneficial,' nonpathogenic colonic bacteria;
- ability to modify the established microflora; and
- ability to confer an advantageous physiologic activity to the host.

Classifications

Various food components have been recognized to have prebiotic activity, including various fermentable carbohydrates (lactulose, gums, lactilol, soyoligosaccharides, galacto-oligosaccharides Xylo-oligosaccharides. However, the best studied of these have been those classified as dietary fructans. Dietary fructans can either be derived from naturally occurring oligosaccharides or can be artificially synthesized. These carbohydrates contain one or more fructosyl-fructose links that make up the majority of osidic bonds. They are linear or branched fructose (oligo)polymers with either β-2-1 linked inulins or β-2-6 linked levans. These oligosaccharides exist naturally in many plants including onions, garlic, the roots of Jerusalem artichoke,

asparagus root, chicory root, and wheat (**Table 1**). Inulin is extractable from root plants particularly Jerusalem artichoke and chicory, while fructooligosaccharide is hydrolyzed from inulin yielding a shorter chain sugar. It is the degree of polymerization (DP) that distinguishes the fructans. Fructooligosaccharides are β-D-fructans with DP between 2 and 10 while inulin has DP 10–60. Essentially, they are sucrose molecules with 1–3 fructose units linked by a β-(2,1)-glycosidic bond. Most oligosaccharides are synthesized from sucrose and therefore usually have a terminal glucose end. Inulin, derived from chicory, is broken down using an inulase enzyme making a smaller (2–10) chain with lower DP (4). Oligofructose is a form synthesized from sucrose by β-fructofuranosidase linking fructose monomers to sucrose.

Both inulin-derived and synthesized fructooligosaccharides have been shown to resist digestion in the upper GI tract. Ninety per cent of consumed inulin and fructooligosaccharide was excreted at the terminal ileum of adult ileostomy patients. Furthermore, the undigested oligosaccharides are not recovered in the fecal mass indicating they are completely fermented in the colon. In many ways, prebiotics behave as a form of dietary fiber that has specific effects on colonic flora.

Table 1 Fructo-oligosaccharide (FOS) content of common fruits, vegetables, and grains

Food type	*FOS concentration (mg gm^{-1})*
Fruits	
Apples	0.1
Banana	0.1
Banana, ripe	2.0
Blackberry	0.2
Orange, navel	0.3
Peach	0.4
Raspberry, red	0.2

Adapted from Campbell J, Bauer L, Fahey G, Hogarth AJCL, Wolf B, and Hunter D (1997) *Journal of Agricultural and Food Chemistry* **45**: 3076–3082.

The mother's milk is a key factor in the early establishment of the infant's colonic environment. Up to 10% of the carbohydrates in human milk are not lactose, and human milk contains high concentrations of other carbohydrates and glycoconjugates that fall under the general category of prebiotic food substances. The monosaccharides of breast milk include D-glucose, D-glactose, sialic acid, L-fructose, and N-acetylglucosamine. Chain lengths range from three to ten with the majority having a lactose end. Combinations of these monosaccharides result in more than 130 varieties of oligosaccharides in human milk. These galacto-oligosaccharides in breast milk have lactose as their reducing end. Many human milk oligosaccharides elongate by enzymatic attachment of *N*-acetylglucosamine linked to a galactose residue. Several of these carbohydrates, including *N*-acetylglucosamine, are considered 'bifidus factors' or 'bifidogenic,' increasing the growth and establishment of bifidobacteria in the intestine of the breast fed infant. Human milk oligosaccharides also appear to prevent attachment of pathogenic microorganisms by competing with epithelial ligands for bacterial binding sites. Several types of human milk oligosaccharides appear to be bacteria specific. For example, sialyated oligosaccharides inhibit attachment of *Pneumococci* and influenza viruses, while galacto-oligosaccharides and fructosylated oligosaccharides can inhibit *E.coli* attachment. The bifidogenic effects, as well as those of direct interaction with the intestinal mucosa, are considered to be some of the mechanisms by which these agents confer a protective effect on the lactating infant.

Oligosaccharide content of the breast milk varies among individuals and within an individual. Levels are highest in the newborn period peaking after 5 days and slowly declining through the first 3 months. The levels of oligosaccharide in the breast milk also are dependent on time of feeding and generally are higher at the beginning of the feed.

Other, less well-studied oligosaccharides including maltose, soya, and xylose-oligosaccharides have some effect on increasing microbe colonization; however, they are weak prebiotics because of the lack of specificity of their fermentation.

Clinical Effects of Prebiotics

Average consumption of dietary fructans as part of a normal diet has been estimated to be 1–4 g day^{-1} in

the US. Europeans tend to have a higher intake ranging from 3 to 10 g day^{-1}. Many products worldwide are produced with supplemental oligosaccharides. Owing to the nondigestible nature of dietary fructans, the nutritional value in terms of calories and energy is negligible. The actual energy produced by these carbohydrates relates to the by-products of fermentation, specifically short-chain fatty acids (SCFA) and lactate.

Effect in the Upper GI Tract

From the dietary point of view, oligosaccharides meet the criteria to be considered a dietary fiber. Fibers are categorized as soluble, insoluble, or mixed. Definition of dietary fiber has focused on biochemical attributes and physiologic effects. Insoluble fibers (nonfermentable) decrease colonic transit time and increase fecal volume thus acting as a bulking agent.

Oligosaccharides because of their fermentable nature are considered a soluble fiber. Their effect on the upper GI tract is to slow down gastric and small bowel transit time, thereby altering glucose metabolism and increasing sensitivity to insulin. Altered fat metabolism by the binding of bile acids thus decreasing serum cholesterol and triglyceride levels has been reported with oligosaccharide supplementation in hypercholestrolemic patients.

There is a strong link between oligosaccharide consumption and the integrity of the GI mucosa. A trophic effect of the mucosa and hyperplasia of the epithelial cells occurs from a hormonal response to dietary fructans although the mechanism it not clear. Adequate or improved trophism of the intestinal wall may increase the absorption capacity for such minerals as calcium, magnesium, iron, copper, and zinc. Of particular interest is the effect of oligosaccharides on calcium absorption. Recent studies have demonstrated increased calcium absorption in teenage girls consuming a prebiotic mixture. Although there are not enough studies as yet to determine what compounds and at what doses connfer this health benefit, it is proposed that the short-chain fatty acids produced from fermentation lower fecal pH and increase colonic absorption of calcium.

Effects in the Colon

The main effect of inulin and fructooligosaccharide in the colon is directly related to fermentation. The process of fermentation from innate bacteria produces short-chain fatty acids and lactate. Increase in biomass contributes to the bulking effect that oligosaccharides have on stool. Additionally, fecal pH is decreased due to suppression of the production of putrefactive substances.

Carbon dioxide and hydrogen are produced in this process contributing to disagreeable side effects when given in high doses. Abdominal cramping, increased flatulence, and bloating have been shown to occur significantly more in studies where adults received 15 g day^{-1} or more of fructooligosaccharide and inulin as compared to a placebo group. However, in a limited number of controlled pediatric studies these symptoms were not seen at doses of up to 3 g day^{-1}.

The greatest value of inulin and fructooligosaccharide is their role in stimulating the growth of innate microbes in the colon. Inulin and fructooligosaccharide selectively promote proliferation of bifidobacteria and *Bacteriodes*. In adult studies fructooligosaccharide and inulin given in doses of 10 g day^{-1} resulted in increased levels of bifidobacteria and decreased levels of enterobacteria and enterococci without GI side effects. In establishing a predominant microbial environment of bifidobacteria, epithelial adherence of pathogenic bacteria is deterred.

It is generally assumed that the immunologic effects seen with probiotic consumption (bifidobacteria, lactobacilli) would apply with the altered microbial balance with prebiotics. However, there is a lack of well-designed trials to support this. Limited animal studies of prebiotics have shown increased lymphocytes in the GALT and peripheral blood, although any impact on the host has not been addressed.

Conclusion

It is clear that the intestinal ecosystem of organisms in humans play a critical role in the development and health maintenance of the human intestine. The intestinal flora can be modified in a positive way via dietary means. Further studies should help define future dietary recommendations in support of improvement in gastrointestinal and immunologic function.

Probiotics

M Gueimonde and S Salminen, University of Turku, Turku, Finland

Introduction

The human gastrointestinal (GI) tract harbors a complex collection of microorganisms. The individual digestive system contains about 1.5 kg of viable (live) bacteria, made up of more than 500 different identified microbial species. Indeed, the total number of bacteria in the gut amounts for more than 10 times that of eukaryotic cells in the human body, and this bacterial biomass can constitute up to 60% of fecal weight. This complex microbiological community is called the intestinal microflora. While most people are familiar with the side-effects of some members of it (e.g., diarrhea), the beneficial effects in stabilizing gut well-being and general health are less well known. These so-called 'friendly' bacteria are naturally present in the GI tract as part of the normal healthy intestinal microflora and ensure the balance that creates a healthy individual. Such beneficial microbes and a healthy intestinal microflora also constitute the main source of probiotics used to improve intestinal and host health.

Fermented products containing living microorganisms have been used for centuries to restore gut health. Such utilization of live microorganisms to improve host health forms the basis of the probiotic concept.

Usually probiotics are taken in the form of dairy products, drinks, or supplements, but in African countries they have traditionally also been ingested in fermented cereal and in fermented vegetables in Asian countries. The claimed benefits of traditional fermented foods range from treatment of diarrheal diseases to alleviation of the side-effects of antibiotics to the prevention of a number of other health problems. In some countries fermented foods have even been associated with benefits to the skin.

Definition of Probiotics

Probiotics have been defined as 'bacterial preparations that impart clinically verified beneficial effects on the health of the host when consumed orally.' According to this definition the safety and efficacy of probiotics must be scientifically demonstrated. However, as different probiotics may interact with the host in different manners, their properties and characteristics should be well defined. It is understood that probiotic strains, independent of genera and species, are unique and that the properties and human health effects of each strain must be assessed in a case-by-case manner. Most probiotics are currently either lactic acid bacteria or bifidobacteria, but new species and genera are being assessed for future use. The probiotic bacteria in current use have been isolated from the intestinal microflora of healthy human subjects of long-standing good health and thus most of them are also members of the healthy intestinal microflora.

It has been demonstrated that probiotics have specific properties and targets in the human intestinal tract and that they are able to modulate the intestinal microflora.

Intestinal Microflora

Composition of the Intestinal Microflora

The human GI tract hosts a rich and complex microflora that is specific for each person depending on environmental and genetic factors. Different bacterial groups and levels are found throughout the GI tract, as corresponds with the different ecological niches present from mouth to colon. The stomach and the upper bowel are sparsely populated regions (10^3–10^4 CFU per g contents) while the colon is heavily populated (10^{11}–10^{12} CFU g contents). In

the small intestine genera such as *Lactobacillus* and *Bacteriodes* are usually found, whereas those considered predominant in the large bowel include *Bacteriodes*, *Bifidobacterium*, *Eubacterium*, *Clostridium*, *Fusobacterium*, and *Ruminococcus* among others. Several health-promoting properties have been attributed to defined members of the intestinal microflora such as lactobacilli and bifidobacteria. A balanced microflora provides a barrier against harmful food components and pathogenic bacteria and has a direct impact on the morphology of the gut. Hence, the intestinal microflora constitutes an important factor for the health and well-being of the human host and a healthy stable microflora affords a potential source of future probiotics.

Development and Succession of Microflora during Life-Time

The human fetus is sterile and the maternal vaginal microflora comprises the first inoculum of microbes. The indigenous intestinal microflora develops over time, determined by an interplay between genetic factors, mode of delivery, contact with the initial surrounding environment, diet, and disease. As a result, every individual has a unique characteristic microflora. The human intestinal microbiota does not exist as a defined entity; this population comprises a dynamic mixture of microbes in each individual.

The establishment of the gut microflora, a process commencing immediately upon birth, provides an early and massive source of microbial stimuli, and may consequently be a good candidate 'infection.' This step-wise succession begins with facultative anaerobes such as the enterobacteria, coliforms, and lactobacilli first colonizing the intestine, rapidly succeeded by bifidobacteria and lactic acid bacteria. The indigenous gut microflora plays an important role in the generation of an immunophysiological regulation of the gut, providing key signals for the development of the immune system in infancy and also interfering with and actively controlling the gut-associated immunological homeostasis later in life. A healthy microflora can thus be defined as the normal individual microflora of a child that both preserves and promotes well-being and absence of disease, especially in the GI tract, but also beyond it. It provides the first step in long-term well-being for later life and the basis for this development lies in early infancy. Failure in the establishment of a healthy microflora has been linked to the risk of infectious, inflammatory, and allergic diseases later in life. Demonstration of this has stimulated researchers to elucidate the composition and function of the intestinal microflora.

Microflora Research

In spite of the recent development of DNA based methods, microbiota development and characterization in the human host still rests largely on the culture-based assessment pioneered by Japanese researchers. The identification of different microbial species and strains has been dependent on microbial characterization, which is usually based on limited phenotypic properties and the metabolic activity of the microbes, for example, sugar fermentation profiles. There are several bacteria, however, that cannot be cultured and isolated or identified by the traditional methods. The culture technique as used in microbial assessments of feces is also hindered by the fact that microbes in the feces will mainly represent the microflora in the lumen of the sigmoid colon, while the composition of the intestinal microflora differs both along the GI tract and between the lumen and the mucosa. For more accurate information on the population elsewhere in the intestine, samples should be taken by endoscopy or during surgery. Most of our current data on microflora are derived from results obtained from fecal samples and culturing. These data indicate that there are several successive phases in microflora development related to age (**Figure 1**). In early infancy the microflora is scant and simple consisting mainly of bifidobacteria. During breast-feeding it remains so, but following weaning its complexity increases, reaching the state observed in adults where the microflora is specific to each person. Aging is related to further changes and the diversity is again decreased. The microflora becomes more unstable and vulnerable to diseases, for example, diarrheal diseases caused by intestinal pathogens.

Current research efforts focus on revealing genomic data on both probiotic microorganisms and certain important intestinal commensals. This has

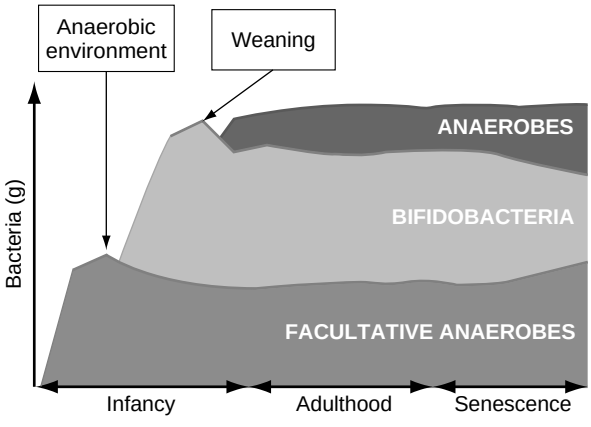

Figure 1 Development of microflora throughout life.

provided information indicating that gut commensals not only derive food and other benefits from the intestinal contents but also have a role in influencing the human host by providing maturational signals for the developing infant and child and providing later signals for alteration to gut barrier mechanisms.

The genomic data on, for instance, *Bifidobacterium longum* and *Bacteroides thetaiotaomicron*, both important members of the human intestinal microflora, give an indication as to how specific bacteria are adapted to the development of the gut by specific genes enabling the use of intestinal mucins and breast milk oligosaccharides as main sources or nutrients.

Genomic information on *B. longum* also gives insight into the adhesive mechanisms that comprise a basis both for populating the infant gut and for communicating developmental signals to specific areas and sites of the gut mucosa. Furthermore, a large part (>8.5%) of the *B. longum* genome is devoted to carbohydrate transport and metabolism, indicating a versatile metabolism well adapted to life in the intestine and making it very different from, for instance, *Lactobacillus johnsonii*.

Bacteroides thetaiotaomicron has also been shown to modulate glycosylation of the intestinal mucus and to induce expression of angiogenins, revealing proposed mechanisms whereby intestinal microbes may influence the gut microecology and shape the immune system. Incorporating such information with host gene expression data from the exposed mucosal sites and beyond them will enable us to understand the role of both microbial transfer and succession and microbe–microbe and host–microbe interactions. Recent information demonstrates that the vast community of indigenous microbes colonizing the human gut also shapes our development and biology.

Role of Microflora in Health and Disease

Major dysfunctions of the GI tract are thought to be related to disturbances or aberrationss of the intestinal microflora. Recent findings confirm that aberrations can be documented and related to disease risk. The microorganisms present in our GI tract thus have a significant influence on our health and well-being.

The development of the intestinal microbiota needs to be characterized to define the composition that helps us to remain healthy. Specific aberrations in the intestinal microflora may predispose to disease. Such aberrations have been identified in allergic disease, including decreased numbers of bifidobacteria and an atypical composition of bifidobacterial microflora. Also, aberrations in *Clostridium* content and composition have been reported to be important. Similar predisposing factors may also exist in the case of microflora and both inflammatory gut diseases and rotavirus diarrhea. Microflora aberrations have also been reported in rheumatoid arthritis, juvenile chronic arthritis, ankylosing spondylitis, and irritable bowel syndrome patients. A thorough knowledge of the intestinal microflora composition will offer a basis for future probiotic development and the search for new strains for human use. Many diseases and their prevention can be linked to the microflora in the gut.

Modulation by Probiotics

In general, probiotic bacteria do not colonize the human intestinal tract permanently, but specific strains are able to transiently colonize or persist for some time in the intestine and may modulate the indigenous microflora. The rationale for modulating the gut microflora by means of probiotics derives from the demonstration that this microflora is important to the health of the host. Specific probiotics have been shown to colonize temporarily the human intestinal tract, thereby modulating the intestinal microflora both locally and at the commensal level. Such modification has not been reported to be permanent; rather it is related to a balancing of aberrant or disturbed microflora to assist it to return to normal metabolic and physiological activities. Such modulation and restoration of the normal state of the microflora activity is a key target for probiotic action. However, the state of the microflora should be well characterized to enable the selection of specific probiotics to counteract the aberration or disturbance in question.

Specific probiotic bacteria can modulate both the intestinal microflora and local and systemic immune responses. Activation of immunological cells and tissues requires close contact of the probiotic with the immune cells and tissue on the intestinal surface. Interestingly, both lactobacilli and bifidobacteria, which colonize mainly the small and large intestine respectively, when given as probiotic supplements were able to modify immunological reactions related to allergic inflammation, whereas lactobacilli were ineffective in protection against cows' milk allergy. In this respect, preferential binding of probiotics on the specific antigen-processing cells (macrophages, dendritic, and epithelial cells) may be even more important than the location of adhesion. It is also known that the cytokine stimulation profiles of

different *Bifidobacterium* strains vary and that strains isolated from healthy infants stimulate mainly noninflammatory cytokines.

Results of an increasing number of clinical and experimental studies demonstrate the importance of constituents within the intestinal lumen, in particular the resident microflora, in regulating inflammatory responses. Probiotic bacteria may counteract inflammatory processes by stabilizing the disturbed gut microbial environment, forming a stable healthy microflora and thus improving the intestine's permeability barrier. Another mode of action comprises enhancing the degradation of enteral antigens and altering their immunogenicity. Yet another mechanism for the gut-stabilizing effect could be improvement of the intestine's immunological barrier, particularly intestinal IgA responses. Probiotic effects may also be mediated via control of the balance between pro- and anti-inflammatory cytokines. Such effects may be mediated through changes in the intestinal microflora, especially by modulation of the bifidobacteria microflora.

Importance of Understanding Intestinal Microflora

It is obvious that an understanding of the cross-talk that occurs between the intestinal microflora and its host promises to expand our conceptions of the relationship between the intestinal microflora and health. There is also an increasing amount of information indicating that specific aberrations in the intestinal microflora may render us more vulnerable to intestinal inflammatory diseases and other diseases beyond the intestinal environment. It is likely that some aberrations may even predispose us to specific diseases. Unfortunately, however, we are still far from knowing the qualitative and quantitative composition of the intestinal microflora and the factors governing its composition in an individual.

Probiotic Effects

Living microorganisms have long been used as supplements to restore gut health at times of dysfunction. It is clear that different strains from a given microbial group may possess different properties. It is thus important to establish which specific microbial strain may have a beneficial effect on the host; even closely related strains can have significantly different or even counteracting effects. Their properties and characteristics should thus be well defined; studies using closely related strains cannot be extrapolated to support each other.

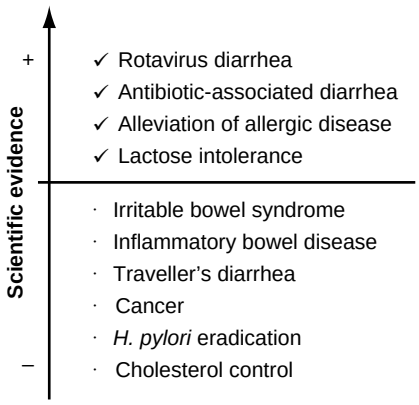

Figure 2 Health benefits of probiotics.

Working hypotheses can be supported by studies carried out *in vitro* using cell culture models or *in vivo* using animal models. However, the studies most important for efficacy assessment are carefully planned and monitored clinical studies in humans.

In summary, well-designed human studies are required to demonstrate health benefits. Using the criteria thus obtained it can be concluded that certain specific probiotics have scientifically proven benefits that can be attributed to specific products (see below). Other reported probiotic health-related effects are only partially established (**Figure 2**), and require more data from larger double-blind placebo controlled studies before firm conclusions can be reached.

Scientifically Documented Effects

Diarrhea The mechanisms by which probiotics prevent or ameliorate diarrhea may involve stimulation of the immune system, competition for binding sites on intestinal epithelial cells (**Figure 3**), or the elaboration of bacteriocins or binding of virus particles in the gut contents. These and other mechanisms are thought to be dependent on the

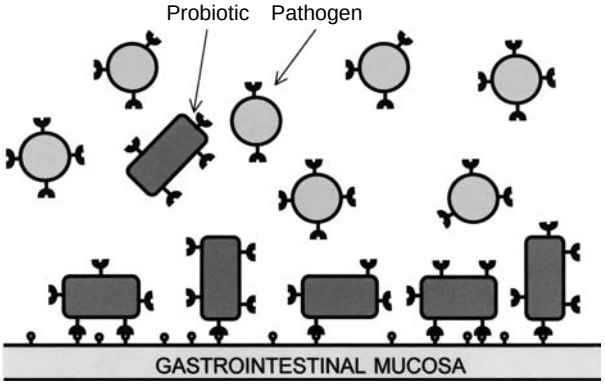

Figure 3 Probiotic adhesion and replacement of pathogenic bacteria.

type of diarrhea being investigated, and may therefore differ between viral diarrhea, antibiotic-associated diarrhea, or traveller's diarrhea.

Viral diarrhea Shortening of the duration of rotavirus diarrhea using *Lactobacillus* GG (LGG) is perhaps the best-documented probiotic effect. A reduction in the duration of diarrhea was first shown in several studies around the world and also in a recent multicenter European study on the use of LGG in acute diarrhea. Other investigators demonstrated that supplementation with a combination of *Bifidobacterium bifidum* and *Streptococcus thermophilus* reduces the incidence of diarrhea and shortens the duration of rotavirus shedding in chronically hospitalized children. On average, the duration of diarrhea was shortened by 1 day in both hospitalized children and those treated at home.

Other investigators have studied the immune modulating effects of probiotics as a means of reducing diarrhea, suggesting that the humoral immune system plays a significant role in the probiotics' effect.

From these numerous studies it is clear that probiotics do indeed play a therapeutic role in viral diarrhea. Even meta-analyses have been conducted in this area, showing that probiotic therapy shortens the duration of acute diarrhea in children. However, the exact mechanism of action involved is not clear and is very likely multifactorial.

Antibiotic-associated diarrhea The incidence of antibiotic-associated diarrhea is between 5 and 30%. The success of probiotics in reducing or preventing this form of diarrhea has been convincing, and includes a number of probiotics as well as various antibiotics.

LGG has been shown to prevent antibiotic-associated diarrhea when consumed in both yogurt form or as a freeze-dried product. Also, *Saccharomyces boulardii* has been found to be effective in preventing antibiotic-associated diarrhea. Other microorganisms such as *Enterococcus faecium* or a combination of *L. acidophilus* and *L. bulgaricus* have also been reported to be effective.

Alleviation of symptoms of allergic disease It has been shown that changes in intestinal microflora composition precede the development of some allergic diseases, indicating a potential area for probiotic application. LGG given prenatally to mothers and during the first months to infants with a high risk of atopic disease has reduced the prevalence of atopic eczema to about half in the infants receiving the strain. Furthermore, extensively hydrolyzed whey formula supplemented with LGG or *Bifidobacterium lactis* Bb12 is more effective than unsupplemented formula in eczema alleviation in infants with atopic eczema.

These results indicate a high potential for probiotic application in the treatment and reduction of risk of allergic diseases.

Lactose intolerance Several studies have shown that lactose-intolerant individuals suffer fewer symptoms if milk in the diet is replaced with fermented dairy products. The mechanisms of action of lactic acid bacteria and fermented dairy products include the following: lower lactose concentration in the fermented product due to lactose hydrolysis during fermentation; high lactase activity of bacterial preparations used in production; and increased active lactase enzyme entering the small intestine with the fermented product or within the viable bacteria.

The bacterial enzyme beta-galactosidase, which can be detected in the duodenum and terminal ileum after consumption of viable yogurt, is thought to be the major factor improving digestibility by the hydrolysis of lactose, mainly in the terminal ileum. Another factor suggested to influence lactose digestion is the slower gastric emptying of semisolid milk products such as yogurt.

In conclusion, there is good scientific evidence to demonstrate the alleviation of lactose intolerance symptoms by specific probiotic lactic acid bacteria. However, the strain-specific lactase activities may vary from nil to very high values. Thus, different products may have varying lactose contents and individual strains, when released into the duodenum, vary in their lactase activity.

Potential Effects Requiring Further Clinical Work

Intestinal microecology and cancer A number of studies have focused on the impact of probiotics on intestinal microecology and cancer. *Lactobacillus acidophilus, L. casei* Shirota strain, and LGG have been shown to have inhibitory effects on chemically induced tumors in animals. Some specific strains of probiotic bacteria are able to bind carcinogens and to downregulate some microbial carcinogenic enzymatic activities. This phenomenon may then reduce carcinogen production and exert a beneficial effect in the colon, the urinary tract, and the bladder.

The most interesting documentation is that concerning *L. casei* Shirota. There have been several mechanistic studies on the effects of the strain reporting decreased mutagen excretion, and some human clinical studies have been conducted using this strain. In clinical and multicenter studies carried

out in Japan, prophylactic effects of oral administration of *L. casei* Shirota on the recurrence of superficial bladder cancer have been reported. Recently, a large Japanese case control study has been conducted on the habitual intake of lactic acid bacteria and risk reduction of bladder cancer. Results suggested that the habitual intake of fermented milk with the strain reduces the risk of bladder cancer in the Japanese population. More studies, and especially human studies in other countries, are needed prior to the establishment of firm conclusions.

Irritable bowel syndrome There is a rationale for investigating the effect of probiotics in the treatment of this common disorder where intestinal motility and dysfunctions in the intestinal microflora are important factors to consider. In a recent study using *L. plantarum* 299v, a reduction of symptoms was reported. *Enterococcus faecium* preparations have also been evaluated for the treatment of patients with irritable bowel syndrome, and although patient-recorded symptoms did not show significant differences, the physician's subjective clinical evaluation revealed an improvement.

Inflammatory bowel disease Inflammatory bowel disease (IBD) comprises a heterogeneous group of diseases of unknown etiology (Crohn's, ulcerative colitis, and pouchitis), but here also factors related to the intestinal microflora seem to be involved, providing a rationale for the application of probiotics. From reviewing studies on the use of probiotics in IBD it can be concluded that, although there are some promising preliminary findings, more well-planned long-term studies are needed before any firm conclusions can be drawn.

Traveller's diarrhea There are a few studies on the prevention of traveller's diarrhea using probiotics and these show a positive outcome for LGG and a combination of *L. acidophilus* LA5 with *B. lactis* Bb-12. The results offer some indication of beneficial effects, even though some studies yielded no reported effects, but information from good and extensive human studies using defined strains for traveller's diarrhea is still largely lacking. The current data on traveller's diarrhea show no scientifically proven effects for any of the strains used. More studies are required for efficacy assessment.

***Helicobacter pylori* eradication** Specific strains of lactic acid bacteria have been reported to inhibit a wide range of intestinal pathogens including *Helicobacter pylori*, which is involved in the process of gastric ulcer development. Lactic acid bacteria are often able to survive acidic gastric conditions and it has therefore been proposed that they may have a beneficial influence during the eradication of *H. pylori*. It has been reported that both the inhibitory substances produced and the specific strains may influence the survival of *Helicobacter*, and studies have been conducted, particularly with a *L. johnsonii* strain. It has been shown that there is good *in vitro* inhibition and that fermented milk containing the strain has a positive effect when consumed during *Helicobacter* eradication therapy. However, more controlled human studies in different populations need be conducted to verify this effect.

Cholesterol control The cholesterol-lowering effects of probiotics have been the subject of two recent reviews with contradictory results. The first, which focused on short-term intervention studies with one yogurt type, reported a 4% decrease in total cholesterol and a 5% decrease in LDL. Contrary to this, the second review concluded that no proven effects could be found. In this context, it is clear that long-term studies are required before the establishment of any conclusion.

Safety

Safety assessment is an essential phase in the development of any new food. Although few probiotic strains or prebiotic compounds have been specifically tested for safety, the long history of safe consumption of some probiotic strains could be considered the best proof of their safety. Although some lactobacilli and bifidobacteria have been associated with rare cases of bacteremia, usually in patients with severe underlying diseases, the safety of members of these genera is generally recognized due to their long history of safe use and their lack of toxicity. Furthermore, the low incidence of infections attributable to these microorganisms, together with a recent study showing that there is no increase in the incidence of bacteremia due to lactobacilli in Finland despite the increased consumption of probiotic lactobacilli, supports this hypothesis. With regard to other bacteria such as enterococci, *S. boulardii*, *Clostridium butyricum,* or some members of the genus *Bacillus* the situation is more complicated, even though they have been used as probiotics for some time.

In addition to the possibility of infection there are other risks that must be taken into account (**Table 1**). These include those risks associated with the metabolic properties of the strain (capacity for deconjugation/dehydroxylation of bile salts,

Table 1 Probiotic action: potential benefits and risks

Action mechanisms	*Potential risks*
Improvement of gut barrier (immunologic, nonimmunologic)	Proinflammatory effects
Modulation of aberrant gut microbiota	Adverse effects on innate immunity
Modulation of inflammatory response	Infection
Degradation of antigens	Production of harmful substances
Binding/inhibition of carcinogens	Antibiotic resistance (Specific risks related to host, strain characteristics, or interactions)

production of enzymes favoring the invasion/translocation through the epithelium, etc.), with the presence of active substances in the probiotic or product (immunoactive substances, toxic compounds, etc.), or with antibiotic resistance. It is clear that strains harboring transferable antibiotic resistance genes should not be used. In this context the specific risks related to each probiotic strain must be carefully identified.

Guidelines are needed to test the safety of probiotics. However, taking into account the great diversity of probiotic microorganisms, it is necessary to identify the specific risks associated with the respective strains, as well as the risk factors associated with the host and the possible interactions between probiotic–host–food components in order to assess the safety of these products. Additional epidemiological surveillance and follow-up of novel strains should be conducted. In this context, the specific risks related to each probiotic strain must be carefully identified. With regard to this, knowledge of mechanisms involved is a key factor not only for the assessment of health effects but also for the safety aspects of probiotics.

Future Challenges

Some of the claimed beneficial effects of probiotics are backed by good clinical studies. However, other possible effects call for further investigation in new, well-planned, long-term human clinical studies prior to any firm conclusions being made. Protocols for human studies need to be developed for probiotics. In some cases, even postmarketing surveillance studies on intakes and long-term effects are useful; such studies have in fact already been used for the safety assessment of current probiotics.

The assessment of potential probiotic strains must be based on a valid scientific hypothesis with realistic studies supporting it. In this respect, knowledge of mechanisms of action is a key factor for hypothesis formulation and for the selection of biomarkers appropriate to the specific state of health and well-being or reduction of risk of disease. It is thus important to improve our knowledge of the mechanisms involved and take into account the fact that probiotic mechanisms of action are multifactorial and that each probiotic may have specific functions affecting the host.

It is also of key interest to increase our knowledge of intestinal microflora composition and to understand its role in health and disease, identifying those microorganisms related to the health status of the host, in order to select probiotic strains able to modulate the intestinal microflora in a beneficial manner.

Knowledge accrued regarding the intestinal microflora, nutrition, immunity, mechanisms of action and specific diseases should be carefully combined with genomic data to allow the development of a second generation of probiotics; strains for both site- and disease-specific action.

NIACIN

C J Bates, MRC Human Nutrition Research, Cambridge, UK

This article is reproduced from the previous edition, pp. 1290–1297, © 1999, Elsevier Ltd.

Absorption, Transport, and Storage

Niacin is a B vitamin that is essential for health in humans and also in most other mammals that have been investigated. Niacin is associated with a characteristic deficiency disease in humans known as pellagra. Pellagra has been described and identified in various communities, notably in Spain and North America, in the last century and the early years of this century. It has persisted in Yugoslavia, Egypt, Mexico, and some African countries. Pellagra is characteristically associated with maize-based diets. The skin lesions found in pellagra are most severe during the summer months because of the effects of the exacerbating sun exposure. However, some countries with a maize diet (e.g., Guatemala) avoid pellagra by means of the niacin present in roasted coffee (**Table 1**). Others avoid it by lime treatment, e.g., in the preparation of tortillas.

Preformed niacin occurs in foods either as nicotinamide (niacinamide) or as the pyridine nucleotide coenzymes derived from it, or as nicotinic acid, without the amide nitrogen, which is the form known as 'niacin' in North America. Both nicotinamide and nicotinic acid are equally effective as the vitamin, but in large doses they exert markedly different pharmacological effects, so it is important, at least in that context, to make and maintain the distinction. In addition to the preformed vitamin, an important *in vivo* precursor is the amino acid L-tryptophan, obtained from dietary protein. Because the human total niacin supply, and hence niacin status, depends on the dietary tryptophan supply as well as on the amount of preformed dietary niacin and its bioavailability, it has become the accepted practice to express niacin intakes as 'niacin equivalents,' which is a combination of mg preformed dietary niacin and mg niacin which can become available by conversion from tryptophan within the body. As discussed later, this calculation involves several assumptions, and is therefore only an approximation to the actual supply to the body for any particular individual; however, it is considered adequate for most practical purposes.

It appears likely that the most important ultimate sources of preformed niacin in most foods, particularly those of animal foods, are the pyridine nucleotides: NAD(H_2) and NADP(H_2). Hydrolases and pyrophosphatases present in biological tissues convert these coenzymes to partly degraded products, which are then available as sources of the vitamin. NAD glycohydrolase and pyrophosphatase enzymes are present in the gut mucosa to assist hydrolysis and absorption of the hydrolyzed products, and these are likely to include both nicotinamide and nicotinamide ribonucleotide, the latter being further degraded to the riboside. Absorption of nicotinamide or nicotinic acid by the mammalian intestine has been shown to consist of a saturable transport component, dominant at low intakes, which is dependent on sodium, energy and pH, and a nonsaturable component, which becomes dominant at high doses or intake levels. Absorption is efficient even at such high discrete doses as 3 g or more: as much as 85% of such a dose is subsequently excreted into the urine. Absorption of test niacin doses introduced directly into the human upper ileum is rapid, with peak levels appearing in blood plasma within 5–10 min.

Transport of niacin between the liver and the intestine can occur *in vivo*, as indicated by radioactive probes in animals, and the liver appears to be a major site of conversion of niacin to its ultimate functional products: the nicotinamide nucleotide coenzymes. Nicotinamide can pass readily between the cerebrospinal fluid and the plasma, thus ensuring a supply also to the brain and spinal cord. Liver contains greater niacin coenzyme concentrations than most other tissues, but all metabolically active tissues contain these essential

Table 1 Niacin equivalents in selected foods[a]

	Niacin equivalents from preformed niacin[b] (mg per 100 g, wet)	*Niacin equivalents from tryptophan[c] (mg per 100 g, wet)*	*Total niacin equivalents (mg per 100 g, wet)*
Milk	0.1	0.8	0.9
Raw beef	5.0	4.7	9.7
Raw white fish	2.4	3.4	5.8
Raw eggs	0.1	3.7	3.8
Raw potatoes	0.6	0.5	1.1

[b]Amount available for absorption. In the case of bread, rice, and maize, the total amounts present are 1.7, 1.5, and 1.2 mg per 100 g, but apart from the niacin added in the fortification of white flour, 90% of this is unavailable for utilization by humans.
[c]Assuming that 60 mg tryptophan yields 1 mg niacin equivalent.
[d]Niacin is released from trigonelline in coffee beans by the roasting process.

metabolic components. Both facilitated diffusion (which is sodium- and energy-dependent and saturable), and passive diffusion (which is nonsaturable) contribute to tissue uptake from the bloodstream. With the exception of muscle, brain and testis, within the body nicotinic acid is a better precursor of the coenzyme form than is nicotinamide. The liver appears to be the most important site of conversion of tryptophan to the nicotinamide coenzymes.

Of the two pyridine nucleotide coenzymes, NAD is present mainly as the oxidized form in the tissues, whereas NADP is principally present in the reduced form, $NADPH_2$. There are important homeostatic regulation mechanisms which ensure and maintain an appropriate ratio of these coenzymes in their respective oxidized or reduced forms in healthy tissues. Once converted to coenzymes within the cells, the niacin therein is effectively trapped, and can only diffuse out again after degradation to smaller molecules. This implies, of course, that the synthesis of the essential coenzyme nucleotides must occur within each tissue and cell type, each of which must possess the enzymatic apparatus for their synthesis from the precursor niacin. Loss of nicotinamide and nicotinic acid into the urine is minimized (except when the intake exceeds requirements) by means of an efficient reabsorption from the glomerular filtrate.

Metabolism and Excretion

The conversion of tryptophan to nicotinic acid *in vivo* is depicted in **Figure 1**. The rate of conversion of tryptophan to niacin and the pyridine nucleotides is controlled by the activities of tryptophan dioxygenase (known alternatively as tryptophan pyrrolase), kynurenine hydroxylase, and kynureninase. These enzymes are, in turn, dependent on factors such as other B vitamins, glucagon, glucocorticoid hormones, and estrogen metabolites, and there are various competing pathways which also affect the rate of conversion. For these reasons, a variety of nutrient deficiencies, toxins, genetic and metabolic abnormalities, etc. can influence niacin status and requirements.

For practical purposes, on the basis of studies performed in the 1950s, 60 mg tryptophan is deemed to give rise to 1 mg nicotinic acid; hence 60 mg tryptophan contributes 1 mg niacin equivalent, for dietary intake calculations and food tables (see **Table 1**).

The two pyridine nucleotide coenzymes, formerly known as 'coenzymes I and II,' then for a period as 'DPN and TPN,' and known nowadays as 'NAD' and 'NADP' (nicotinamide adenine dinucleotide and nicotinamide adenine dinucleotide phosphate), are involved in hundreds of enzyme-catalyzed redox reactions *in vivo*. Although a minority of these

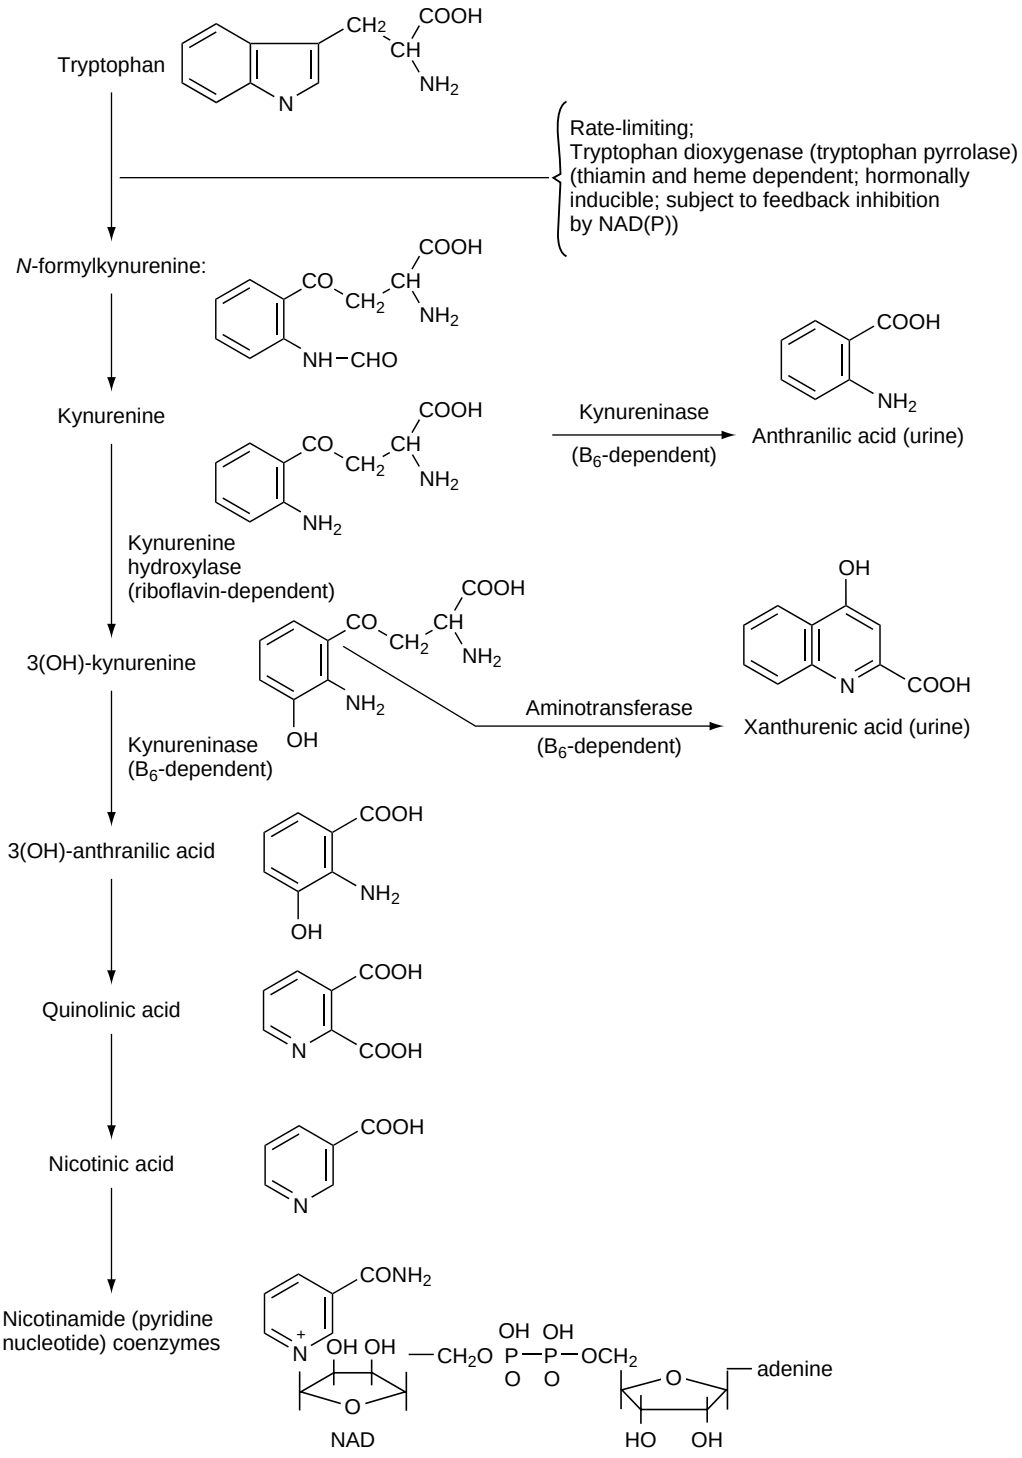

Figure 1 *In vivo* conversion of tryptophan to nicotinic acid and NAD.

diverse reactions can use either of the two niacin-derived cofactors, most are highly specific for one or the other.

Catabolism of the pyridine nucleotide coenzymes *in vivo* is achieved by four classes of enzymes: NAD glycohydrolase, ADP ribosyl transferase, and poly (ADP ribose) synthetase, (all of which liberate nicotinamide), and NAD pyrophosphatase (which liberates nicotinamide mononucleotide which is then further hydrolyzed to nicotinamide). Turnover of nicotinamide then results in the formation of 1-methylnicotinamide (usually described as

N^1-methyl nicotinamide or NMN), an excretory product which is excreted in the kidney and appears in the urine, together with some further oxidation products, typically the 1-methyl-2-pyridone-5-carboxamide and 1-methyl-4-pyridone-3-carboxamide (usually referred to as '2-pyridone' and '4-pyridone', respectively). These excretory turnover products can be used as indicators of whole body niacin status (see below). At high intakes of niacin, as much as 85% of the intake may be excreted unchanged; however the excretion of nicotinamide always predominates over that of nicotinic acid.

Hydrolysis of hepatic NAD to yield nicotinamide allows the release of niacin for utilization by other tissues. Relative protection of the pyridine nucleotide within certain key enzymes such as glyceraldehyde 3-phosphate dehydrogenase confers a protection on certain key metabolic pathways, thus ensuring good homeostatic control. By contrast, there is evidence that the enzymes which catalyze pyridine nucleotide turnover may be hyperactivated within cells that have been damaged by carcinogens, including mycotoxins, thus starving these damaged cells of essential cofactors and causing their death, presumably to protect the rest of the organism. This effect may help to explain the otherwise puzzling observation that moldy grain in the diet can increase the risk of pellagra when niacin and tryptophan intakes are marginal. In normal, healthy cells, the compartmentalization of hydrolytic enzymes prevents unwanted coenzyme turnover, and this compartmentalization seems to become breached in damaged or dying cells.

Other urinary excretion products of niacin include nicotinuric acid (nicotinoyl glycine); nicotinamide *N*-oxide, and trigonelline (N^1-methyl nicotinic acid); the latter may arise from bacterial action in the gut or from the absorption of this substance from foods. The pattern of the different turnover metabolites varies between species, between diets (depending partly on the ratio of nicotinamide to nicotinic acid in the diet), and partly with niacin status; thus there are complex regulatory mechanisms to be considered.

Metabolic Function and Essentiality

The best-known functions of niacin are derived from the functions of its coenzymes: NAD and NADP in the hydrogen/electron transfer redox reactions in living cells. Like most B vitamins, niacin is not extensively stored in forms or in depots that are usually metabolically inactive, but rather those that can become available during dietary deficiency. However, some 'storage' of the coenzymes NAD and NADP in the liver is thought to occur. An inadequate dietary intake leads rapidly to significant tissue depletion within 1–2 months, and then successively to biochemical abnormalities, followed by clinical signs of deficiency, and eventually to death. As with the other B vitamins, rates of turnover and hence the rates of excretion of coenzyme breakdown products decline progressively as dietary deficiency becomes more severe and prolonged, so that the tissue levels are relatively protected and spared. In adult humans a severe deficiency may take many months to develop before it results in the clinical signs of pellagra.

Some of the most important and characteristic functions of NAD manifest in the principal cellular catabolic pathways, responsible for liberation of energy during the oxidation of energy-producing fuels. NADP, however, functions mainly in the reductive reactions of lipid biosynthesis, and the reduced form of this coenzyme is generated via the pentose phosphate cycle. NAD is essential for the synthesis and repair of DNA. NAD has, in addition, a role in supplying ADP ribose moieties to lysine, arginine, and asparagine residues in proteins such as histones, DNA lyase II, and DNA-dependent RNA polymerase, and to polypeptides such as the bacterial diphtheria and cholera toxins. In the nucleus, poly (ADP ribose) synthetase is activated by binding to DNA breakage points and is involved in DNA repair. It is also concerned with condensation and expansion of chromatin during the cell cycle and in DNA replication. Niacin status affects the level of ADP ribolysation of proteins. A high level of poly (ADP ribose) synthetase activity, which is found in some tumors, can result in low levels of NAD. A chromium dinicotinate complex found in yeast extracts may function as a glucose tolerance factor or in detoxification, but this has not yet been proven.

Because the electron transport functions of NAD frequently involve flavin coenzymes, and because both flavin coenzymes and vitamin B_6 coenzymes are involved in the conversion of tryptophan to niacin *in vivo*, there are important metabolic interactions between these B vitamins. A similarity of clinical deficiency signs, making it difficult to distinguish between them, may be encountered in population studies of deficiency.

Because the body's need for niacin can be met completely by dietary tryptophan, it is not, strictly speaking, an essential vitamin. In this respect it resembles carnitine, which can be synthesized entirely from lysine, but for which in some circumstances a dietary requirement exists. Traditionally, however, niacin is classified as an essential vitamin, because some human diets have tended to be lacking

in niacin and its precursor, tryptophan. Some animals such as sheep and cattle appear to be able to synthesize sufficient niacin for their needs from tryptophan, and do not therefore need preformed niacin in their diets.

Assessment of Niacin Status

Whereas the measurement of B vitamin status has, in recent years, tended to focus on blood analysis, perhaps mainly because of the convenience of sample collection, the development of blood-based status analysis for niacin has lagged behind that of the other components of the B complex. Some studies have indeed suggested that the erythrocyte concentration of the niacin-derived coenzyme NAD may provide useful information about the niacin status of human subjects; that a reduction in the ratio of NAD to NADP to below 1.0 in red cells may provide evidence of niacin deficiency; and that a decline in plasma tryptophan levels may indicate a more severe deficiency than a decline in red cell NAD levels. These claims now need to be tested in naturally deficient human populations. The niacin coenzymes can be quantitated either by enzyme-linked reactions or by making use of their natural fluorescence in alkaline solution.

At present, niacin status is most commonly assessed by the assay of some of the breakdown products of niacin coenzymes in the urine. Of these, N^1-methyl nicotinamide (NMN) is the easiest to measure, because of a convenient conversion *in vitro* to a fluorescent product, which can then be quantitated without the need for separation. However, more definitive and reliable information can be obtained by the measurement of urinary NMN in conjunction with one or more of the urinary pyridone turnover products (N^1-methyl-2-pyridone-5-carboxamide and N^1-methyl-4-pyridone-3-carboxamide), which can be detected and quantitated by UV absorption following high-pressure liquid chromatography. The Interdepartmental Committee on Nutrition for National Defense (USA) selected the criterion of niacin deficiency in humans as an NMN excretion rate of $<5.8\,\mu$mol (0.8 mg) NMN per day in 24 h urine samples.

Requirements and Signs of Deficiency

As for most other micronutrients, the requirement of niacin to prevent or reverse the clinical deficiency signs is not known very precisely, and probably depends on ancillary dietary deficiencies or other insults occurring in natural human populations. For the purpose of estimating niacin requirements for dietary reference values, the criterion of restoration of urinary excretion of NMN during controlled human depletion–repletion studies has been selected, and on this basis, the average adult requirement has been estimated as 5.5 mg (45 μmol) of niacin equivalents per 1000 kcal (4200 kJ). Adding a 20% allowance for individual variation this needs to be increased to 6.6 mg (54 μmol) per 1000 kcal, (4200 kJ), which is the current reference nutrient intake (UK). Niacin requirements were, by convention, expressed as a ratio to energy expenditure. For subjects with very low energy intakes, the daily intake of niacin equivalents should not fall below 13 mg, however. If dietary protein levels and quality are high, it is possible for tryptophan alone to provide the daily requirement for niacin equivalents. Dietary niacin deficiency is now rare in most Western countries.

The appearance of severe niacin deficiency as endemic pellagra, especially in North America in the nineteenth and early twentieth centuries, has been ascribed to the very poor availability of bound forms of niacin (in niacytin, a polysaccharide/glycopeptide/polypeptide-bound form, which is 90% indigestible), together with the relatively low content of tryptophan occurring in grains (see **Table 1**). However, the lack of available niacin and tryptophan may not have been the whole story, since coexisting deficiencies or imbalances of other nutrients, including riboflavin, may also have contributed to this endemic disease. It appears also that the choice of cooking methods may have been critical, since the Mexican custom of cooking maize with lime in the preparation of tortillas helps to release the bound niacin from its carbohydrate complex and to increase the bioavailability of tryptophan-containing proteins, and thus to reduce the prevalence of clinical deficiency disease. In parts of India, pellagra has been encountered in communities whose main staple is a form of millet known as 'jowar', which is rich in leucine. It was proposed, and evidence was obtained from animal and *in vitro* studies, that high intakes of leucine can increase the requirements for niacin. However, other evidence is conflicting (this interaction is not fully understood). In parts of South Africa, iron overload has been reported to complicate the metabolic effects of low niacin intakes.

The average content of niacin in human breast milk is 8 mg (65.6 μmol) per 1000 kcal (4200 kJ), and this is the basis for the recommendations (and dietary reference values) for infants up to 6 months. In the UK, the Reference Nutrient Intake niacin increment during pregnancy is nil, and during lactation it is 2 mg per day.

The most characteristic clinical signs of severe niacin deficiency in humans are dermatosis (hyperpigmentation, hyperkeratosis, desquamation – especially where exposed to the sun), anorexia, achlorhydria, diarrhea, angular stomatitis, cheilosis, magenta tongue, anemia, and neuropathy (headache, dizziness, tremor, neurosis, apathy). In addition to the pellagra caused by dietary deficiency or imbalance, there are also reports of disturbed niacin metabolism associated with phenylketonuria, acute intermittent porphyria, diabetes mellitus, some types of cancer (carcinoid syndrome), thyrotoxicosis, fever, stress, tissue repair, renal disease, iron overload, etc. The picture in other species is not radically different; however, deficient dogs and cats typically exhibit 'black tongue' (pustules in the mouth, excessive salivation) and bloody diarrhea, pigs exhibit neurological lesions affecting the ganglion cells, rats exhibit damage to the peripheral nerves (cells and axons), and fowl exhibit inflammation of the upper gastrointestinal tract, dermatitis, diarrhea, and damage to the feathers. All species exhibit reduction of appetite and loss of weight; however, it is of interest that the skin lesions seen in humans are rare in most other species.

Dietary Sources, High Intakes, and Antimetabolites

As can be seen from **Table 1**, different types of foods differ considerably, not only in their total contribution to nicotinic acid equivalents, but also in the ratio of the contribution from preformed niacin and from tryptophan. In a typical Western diet, it has been calculated that if the 60 mg tryptophan = 1 mg niacin formula is applied, then preformed niacin provides about 50% of the niacin supply in the diet. In practice it seems possible for all of the niacin requirement to be provided by dietary tryptophan in Western diets. As is the case for the other B vitamins, meat, poultry, and fish are excellent sources of niacin equivalents, followed by dairy and grain products, but as noted above, certain grains such as maize, and whole highly polished rice, can be very poor sources and may be associated with clinical deficiency if the diets are otherwise poor and monotonous.

In recent years, both nicotinamide and nicotinic acid have been proposed and tested for possibly useful pharmacological properties at high intake levels. This new phase of interest in the vitamin has, in turn, raised concerns about the possible side effects of high intakes, and the definition of maximum safe intakes.

The greatest interest, in pharmacological terms, has been centered around nicotinic acid, which has been shown to have marked antihyperlipidemic properties at daily doses of 2–6 g. Nicotinamide does not share this particular pharmacological activity. Large doses of nicotinic acid reduce the mobilization of fatty acids from adipose tissue by inhibiting the breakdown of triacylglycerols through lipolysis. They also inhibit hepatic triacylglycerol synthesis, thus limiting the assembly and secretion of very low-density lipoproteins from the liver and reducing serum cholesterol levels. Large doses of nicotinic acid ameliorate certain risk factors for cardiovascular disease: for instance they increase circulating high-density lipoprotein levels. The ratio of HDL_2 to HDL_3 is increased by nicotinic acid; there is a reduced rate of synthesis of apolipoprotein A-II and a transfer of some apolipoprotein A-I from HDL_3 to HDL_2. These changes are all considered potentially beneficial in reducing the risk of cardiovascular disease. If given intravenously, large doses of nicotinic acid can, however, produce side effects such as temporary vasodilatation and hypotension. Other side effects can include nausea, vomiting, diarrhea and general gastrointestinal disturbance, headache, fatigue, difficulty in focusing, skin discoloration, dry hair, sore throat, etc. A large trial for secondary prevention of myocardial infarction, with a 15 year period of follow-up, produced convincing evidence for moderate but significant protection against mortality, which was attributed either to the cholesterol-lowering effect or an early effect on nonfatal reinfarction, or both. Nicotinic acid is still the treatment of choice for some classes of high-risk hyperlipidemic patients, although newer drugs may have fewer side effects and therefore be preferred.

The potential benefits of the lipid-lowering effects of nicotinic acid have to be considered in the light of possibly toxic effects, particularly for the liver. These may manifest as jaundice, changes in liver function tests, changes in carbohydrate tolerance, and changes in uric acid metabolism including hyper-uricemia. There may also be accompanying ultrastructural changes. Hyperuricemia may result from effects on intestinal bacteria and enzymes, and from effects on renal tubular function. Such toxic effects are especially severe if sustained release preparations of nicotinic acid are used.

Nicotinamide does not share with nicotinic acid these effects on lipid metabolism or the associated toxicity. However, it has been shown to be an inhibitor of poly (ADP ribose) synthetase in pancreatic β cells in animal studies. A high-risk group of children aged 5–8 years in New Zealand given large doses of nicotinamide daily for up to 4.2 years had

only half the predicted incidence of insulin-dependent diabetes.

Other claims for megadoses of nicotinic acid or nicotinamide, such as the claim that abnormalities associated with schizophrenia, Down's syndrome, hyperactivity in children, etc. can be reduced, have so far failed to win general acceptance. Clearly niacin deficiency or dependency can exacerbate some types of mental illness such as depression or dementia. There have been a number of attempts to treat depression with tryptophan or niacin, or both, on the basis that the correction of depressed brain levels of serotonin would be advantageous. However, these have met with only limited success. Schizophrenics have been treated with nicotinic acid on the basis that their synthesis of NAD is impaired in some parts of the brain, and that the formation of hallucinogenic substances such as methylated indoles may be controlled.

There are various medical conditions and drug interactions that can increase the requirement for niacin. Examples are: Hartnup disease, in which tryptophan transport in the intestine and kidney is impaired; carcinoid syndrome, in which tryptophan turnover is increased; and isoniazid treatment, which causes B_6 depletion and hence interference with niacin formation from tryptophan. Hartnup disease (the name of the first patient being Hartnup) is a rare genetic disease in which the conversion of tryptophan to niacin is reduced, partly as a result of impaired tryptophan absorption. Affected subjects exhibit the classical skin and neurological lesions of pellagra, which can be alleviated by prolonged treatment with niacin. Another genetic disease which may respond to niacin supplements is Fredrikson type I familial hypercholesterolemia; nicotinic acid is effective in reducing the raised blood cholesterol levels associated with this abnormality.

There are several analogs and antimetabolites of niacin that are of potential use or metabolic interest. The closely related isoniazid is commonly used for treatment of tuberculosis; indeed, nicotinamide itself has been used for that purpose. Nicotinic acid diethylamide ('nikethamide') is used as a stimulant in cases of central nervous system depression after poisoning, trauma or collapse. Possible antineoplastic analogs include 6-dimethylaminonicotinamide and 6-aminonicotinamide; however, the latter is also highly teratogenic. These latter compounds inhibit several key enzymes whose substrates are NAD or NADP, by being converted *in vivo* to analogs of these coenzymes. The compound 3-acetyl pyridine, which also forms an analog of NAD, can have either antagonistic or niacin-replacing properties, depending on the dose used. Commonly used drugs such as metronidazole are also niacin antagonists.

NUCLEIC ACIDS

E A Carrey, Institute of Child Health, London, UK
H A Simmonds, Guy's Hospital, London, UK

The nucleic acids are fundamental to genetics and to metabolism. Deoxyribonucleic acid (DNA) is found in the chromosomes within the nucleus and the mitochondria, and it contains the genetic information. Ribonucleic acid (RNA) is found both in the nucleus and in the surrounding cytoplasm, and its various forms fulfill several tasks associated with the transfer of the genetic message and its eventual translation into proteins. Each nucleic acid is a linear polymer of nucleotides (**Figure 1A**). Nucleosides, the related small molecules, consist of a pentose sugar bound to the N-9 atom of a purine or to the N-1 of the

The nucleic acids, vital constituents of all living cells, were discovered by Miescher in 1868 and isolated from the nuclei of pus cells and spermatozoa of Rhine salmon. The major constituents of nucleic acids were shown to be sugars, phosphate groups, and the characteristic purine and pyrimidine bases, now considered to be some of the first chemicals to emerge from the 'primordial soup' before life began on Earth. Emil Fischer and colleagues established the chemical structure of the purine bases, including uric acid—the end (waste) product of purine metabolism in humans—at the end of the nineteenth century.

This article outlines the biosynthesis of nucleic acids and gives a brief overview of the physiological functions of nucleosides, nucleotides, and nucleic acids. It describes the toxicity that may arise from degradation of both endogenous and dietary (exogenous) nucleic acids in humans and provides a summary of the nucleic acid content of foods.

Physiology

Structure

The nucleic acids are fundamental to genetics and to metabolism. Deoxyribonucleic acid (DNA) is found in the chromosomes within the nucleus and the mitochondria, and it contains the genetic information. Ribonucleic acid (RNA) is found both in the nucleus and in the surrounding cytoplasm, and its various forms fulfill several tasks associated with the transfer of the genetic message and its eventual translation into proteins.

Each nucleic acid is a linear polymer of nucleotides (**Figure 1A**). Nucleosides, the related small molecules, consist of a pentose sugar bound to the N-9 atom of a purine or to the N-1 of the

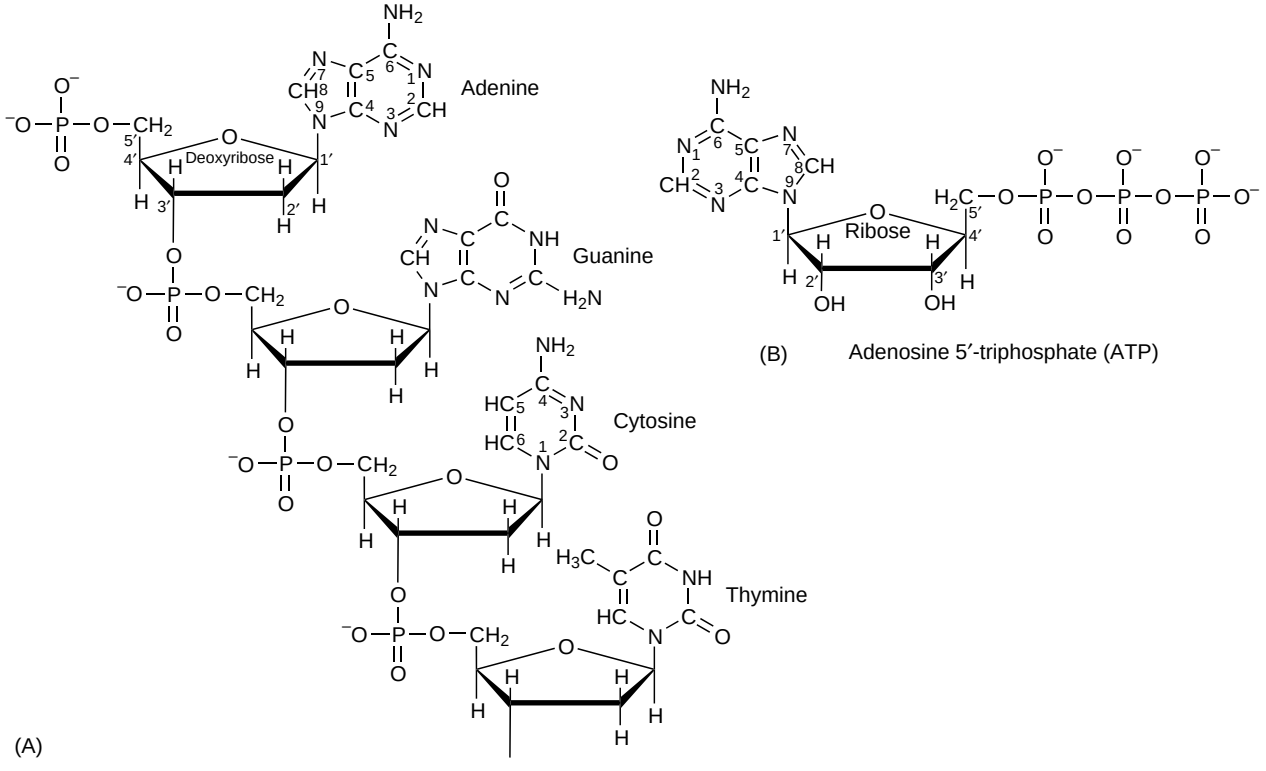

Figure 1 (A) Schematic representation of part of a DNA strand showing the structural formulas of the four constituent bases, adenine, guanine, cytosine, and thymine, linked via the 3′-OH group of the deoxyribose moiety to the 5′-phosphate group of the next nucleotide. Also shown is the numbering of the atoms in the deoxyribose, as well as the pyrimidine and purine rings. The latter consist of a six-membered pyrimidine ring fused to a five-membered imidazole ring. (B) Structural formula of ATP indicating that the ribose, as distinct from deoxyribose, has an OH group at the 2′ position on the pentose ring.

pyrimidine ring: With one or more phosphate groups at the 5′ position of the sugar, the molecule is a nucleotide (**Figure 1B**). When nucleoside triphosphates (NTP) are linked through the 5′ phosphate groups to the 3′ position of the previous residue on the growing chain, the chemical energy for the polymerization is provided by the removal of the second and third phosphate groups.

In DNA the pentose is 2′-deoxyribose (**Figure 1A**) and the bases are adenine (A), guanine (G), cytosine (C), and thymine (T). Two strands are wound in opposing chemical directions in the well-defined double-helix structure of DNA, with each nucleotide of one strand linked by hydrogen bonding to a complementary nucleotide on the other (A-T and G-C). The deoxyribose and phosphate groups form the outer sides of the 'ladder.'

The RNA molecule is chemically single stranded, but double-helical regions arise when stretches of complementary sequences allow hairpin loops to form. In addition, the base uracil (U) is found instead of thymine, and the pentose is ribose.

Nucleic Acid Biosynthesis in Humans

The first step in the synthesis of DNA and RNA in humans involves the formation of the purine and pyrimidine ribonucleotides. They are derived endogenously by two routes: the energetically expensive multistep *de novo* route (**Figure 2**), using small

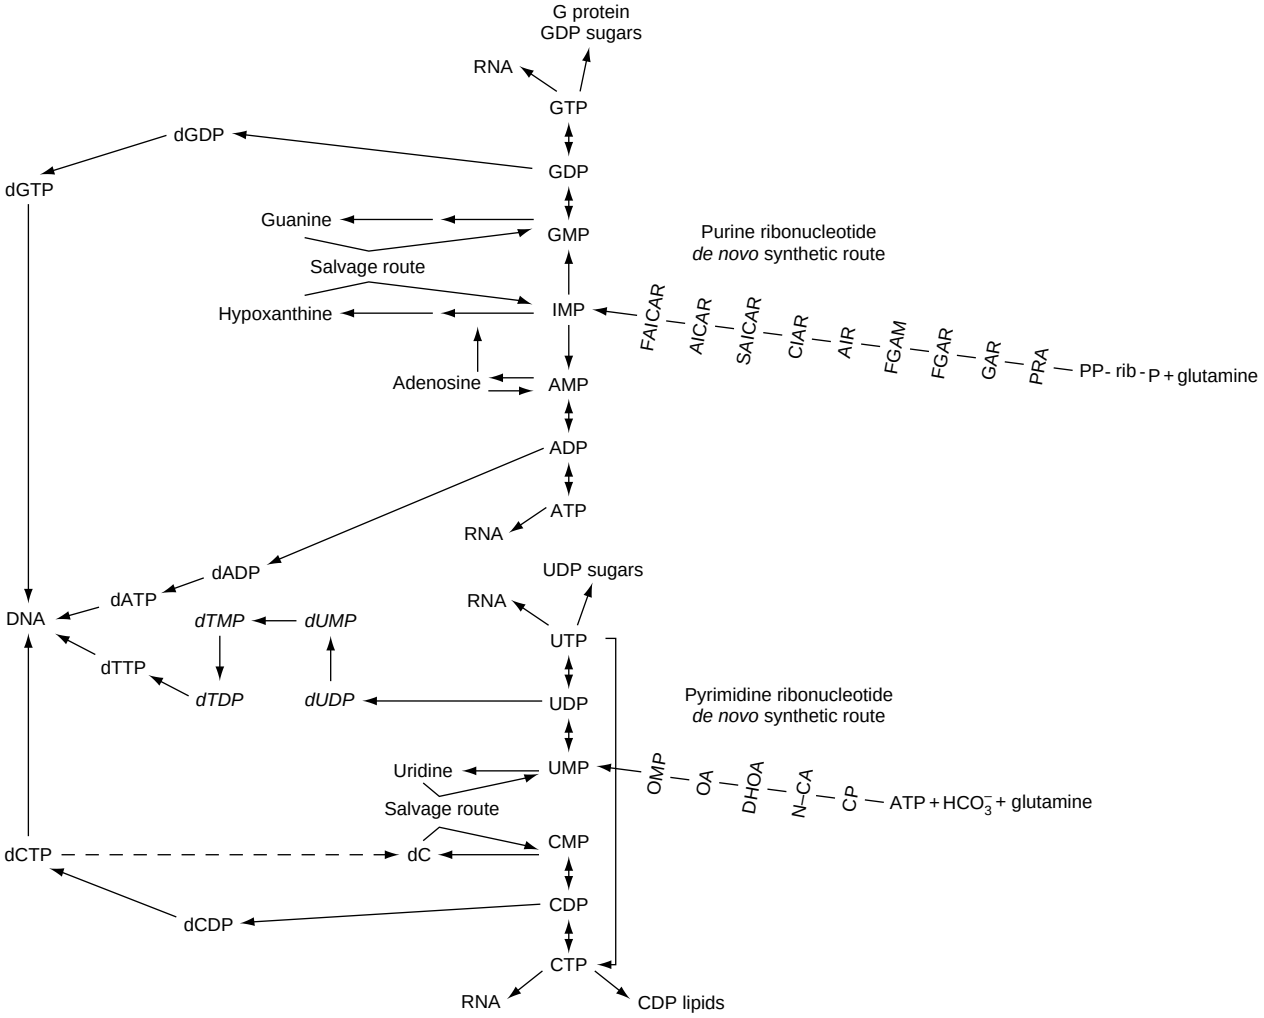

Figure 2 Metabolic pathways for the synthesis of DNA and RNA from their purine and pyrimidine ribo- and deoxyribonucleotide precursors. The dotted line from dCTP indicates the route of breakdown to deoxycytidine (dC), which can be salvaged by dC kinase and incorporated into dCDP lipids or DNA. HCO_3^-, bicarbonate; CP, carbamoyl phosphate; N-CA, carbamoyl aspartate; DHOA, dihydroorotic acid; OA, orotic acid; OMP, orotidylic acid; PP-rib-P, 5-phosphoribosyl-1-pyrophosphate; PRA, 5-phosphoribosylamine; GAR, glycinamide ribotide; FGAR, *N*-formyl glycinamide ribotide; FGAM, *N*-formylglycinamidine ribotide; AIR, 5-aminoimidazole ribotide; CAIR, 5-aminoimidazole-4-carboxy ribotide; SAICAR, *N*-succino-5-aminoimidazole-4-carboxamide ribotide; AICAR, 5-aminoimidazole-4-carboxamide ribotide; FAICAR, 5-formamidoimidazole-4-carboxamide ribotide.

molecules such as carbon dioxide, amino acids, and ribose sugars as precursors; and the energetically less expensive 'salvage' pathway. Purine bases and pyrimidine nucleosides from the breakdown of nucleic acids and nucleotide cofactors are salvaged within the cells, generating nucleotides that can be incorporated into nucleic acids. In most cells in the body, salvage processes are more important than *de novo* synthesis, and the ribonucleotides recycled in this way exert feedback control on the *de novo* routes.

The ribonucleoside 5′-monophosphates generated from either pathway are rapidly phosphorylated within the cell to the triphosphate form for immediate use in the synthesis of RNA or in a variety of cellular processes. The most abundant ribonucleotide in the body is adenosine 5′-triphosphate (ATP), which is the universal energy carrier of all living organisms (**Figure 1B**). In addition, ATP molecules are part of the coenzymes (NAD, NADP, FAD, etc.), which assist in many reactions including the conversion of food into energy. Adenosine and guanosine nucleotides within cells have roles in the transduction of external signals into cellular responses and in the translation and synthesis of proteins. Pyrimidines, present at much lower concentrations in cells, also fulfill diverse functions. UDP-glucose and CDP–lipids are active intermediates in the synthesis of glycogen and membranes, respectively, and sugars linked to UDP or GDP are used in the glycosylation of proteins, many of which are exposed on the outer surface of cells. UDP-glucuronic acid is an essential component of the pathways in liver, gut, and kidney that convert foreign molecules and steroids into soluble forms for disposal from the body.

To make DNA, the ribonucleoside diphosphates (rNDP) are reduced to the corresponding 2′-deoxyribonucleoside diphosphates (dNDP) in a reaction catalyzed by ribonucleotide reductase. This reaction produces dADP, dGDP, and dCDP, which are phosphorylated to the triphosphate form; dUDP is converted via dUMP to dTMP, providing the four substrates essential for DNA synthesis. The DNA polymerase enzymes form double-stranded DNA by sequential addition of monomers complementary to the bases on the opposite strand. Crucially, a 'proofreading' activity in the enzyme ensures the accuracy of the process, and hence double-stranded DNA provides a stable format for genetic information.

Nucleic Acids in the Storage and Transmission of Genetic Information

The role of DNA and RNA in the storage and transmission of genetic information is well established and can be found in standard textbooks. The hereditary material in the nucleus of human cells is packed into 23 chromosomes, and additional DNA is found in the mitochondria. The human genome is known to contain approximately 30 000 coding sequences, or genes, and a substantial proportion of DNA has a regulatory role in transcription of the genes. The sequence of the four bases and the capacity of DNA to be copied into two complementary strands underlie the genetic information of all living organisms. Interactions between DNA and the transcription factors determine the time and place in the body where genes are transcribed, causing development and metabolism to occur.

RNA molecules are synthesized initially on a DNA template by a DNA-dependent RNA polymerase in a process called transcription, in which ribonucleotides complementary to the bases of one strand of DNA are joined by 3′–5′ phosphodiester bonds.

Cells contain three types of RNA, each of which is chemically modified after transcription from the DNA template. The three kinds of RNA together are important in the translation of the genetic message to synthesize proteins in the cell. Most RNA is in the cytoplasm, principally in the form of ribosomal RNA (80% of the total), which performs structural and catalytic roles in ribosomes, the site of the growing polypeptide chain in protein synthesis, whereas messenger RNA (5%) provides the template for protein synthesis. The amino acids are brought to the assembly site covalently bonded to transfer RNA (15%), with their order in the growing protein being specified by the order of the bases in mRNA.

Synthesis of nucleic acids and their precursors in different human cells is related to cellular function

Synthesis of both DNA and RNA is prominent in cells and tissues with a high rate of turnover or metabolism (e.g., liver, gut epithelium, skin, dividing lymphocytes, bone marrow, and hair follicles). In most tissues in the adult, cells differentiate to perform specialized tasks and therefore cell division is used only to replace cells that have been lost. Different complements of enzymes are expressed in each cell type, and therefore tissues have characteristic profiles of internal metabolites, including nucleotides and nucleosides.

For example, in cells that do not continuously divide, such as heart and muscle, nucleotide profiles are relatively simple, relating to the major requirement to sustain levels of cofactors and ATP. In contrast, rapidly dividing cells in liver and intestine show a complex nucleotide pattern, supporting these organs as major sites of nucleic acid

metabolism. The gut is particularly important in this respect. The rate of cell turnover in the luminal villi is high, and it has been calculated in rat that approximately 30 mg of endogenous nucleic acid from dead cells enters the gut lumen daily. This means that the rate of nucleic acid synthesis in liver and intestine is much higher than in tissues such as muscle.

Metabolism of Endogenous Nucleic Acids and Excretion of End Products

There is a considerable turnover of endogenous nucleic acids and ribonucleotides daily during muscle work, wound healing, erythrocyte senescence, mounting an immune response, etc. However, only a small fraction of these vital endogenous compounds are actually degraded and lost from the body. The contents of dead cells are normally used by nearby cells, and degraded RNA or cofactors are recycled within living cells using active 'salvage' routes.

Salvage of the polynucleotides DNA and RNA begins when the molecules are degraded by enzymes—ribonucleases for RNA and deoxyribonucleases for DNA—to liberate nucleotides. The next step, degradation by specific 5′-nucleotidases (removing the phosphate groups) to nucleosides or deoxynucleosides, is essentially irreversible. In turn, removal of amino groups and the sugar residue will give the purine bases hypoxanthine and xanthine or the pyrimidine bases uracil and thymine.

Any pyrimidine nucleosides that are not salvaged are converted first to the bases uracil and thymine, which are further catabolized in a series of steps to β amino acids. All are soluble and readily excreted. There is thus normally no measurable pyrimidine end product and therefore no toxicity from endogenous or dietary pyrimidines.

In contrast, the purine bases are converted to xanthine (an insoluble metabolite) by the enzyme xanthine dehydrogenase (XDH) and then to the equally insoluble end product uric acid. This compound can normally be disposed of in the urine, but high concentrations can lead to the formation of kidney stones or deposits in the joints and under the skin. Some rare genetic disorders of purine biosynthesis can remove feedback regulation, or excessive breakdown of cells may overload the salvage system, resulting in very high endogenous levels of uric acid.

Metabolism of Dietary Nucleic Acids in Humans
