The normal human diet is rich in both DNA and RNA since food is derived from once-living organisms. The metabolism of these exogenous nucleic acids follows a similar pattern to the intracellular process described previously, but the bacterial flora of the intestine are the first point of attack. This digestion is rapid. Studies in pigs (confirmed by later studies in humans) demonstrated that up to 50% of radiolabeled dietary purine was degraded and lost as carbon dioxide gas within 30 min, with the remaining 43% being recovered in the urine and 5% in the feces (**Figure 3**). It has been shown that dietary pyrimidine nucleotides, but not purines, are incorporated into RNA.

Humans thus have no apparent requirement for purines from the diet, and the intestinal mucosa provides an effective barrier to their uptake through a battery of enzymes that rapidly degrade purine nucleotides, nucleosides, and bases to the metabolic waste product, uric acid. This phenomenon may represent an important evolutionary development to protect the integrity of the cellular DNA or to ensure that levels of ATP do not fluctuate in concert with the dietary intake of purines.

The potential toxicity of dietary nucleic acids to humans usually arises not from the nucleic acids but

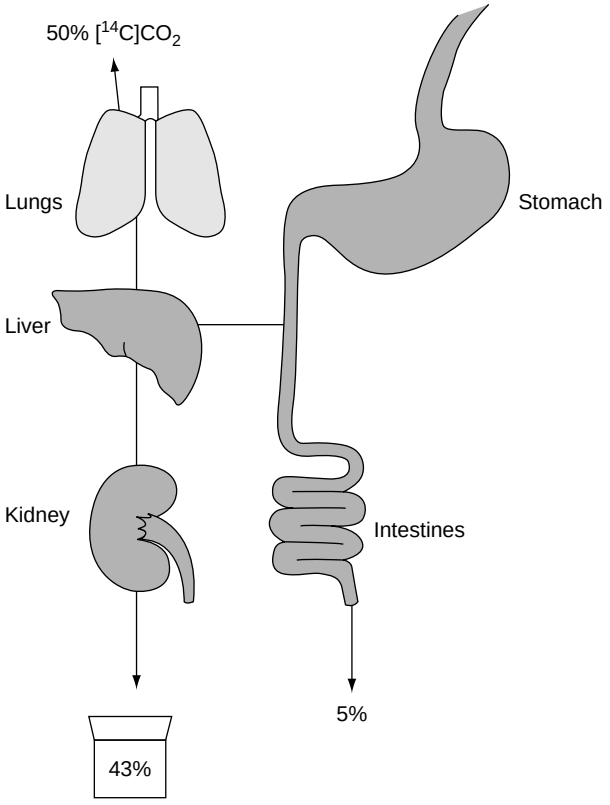

Figure 3 Diagram showing the fate of ^{14}C-labeled exogenous purine (guanine) in an animal model (pig). Radiolabel was recovered only in carbon dioxide gas, urine, or feces. No incorporation into any tissues was found.

from their metabolic end products (principally uric acid). Many investigators have shown that the fate of the dietary purine moiety depends on whether it is administered in the form of DNA, RNA, mononucleotides, nucleosides, or bases, with some being catabolised more readily than others. When normal subjects are fed RNA, the increase in the excretion of uric acid is dramatic alongside a modest increase in plasma urate concentrations. The effect of RNA is also twice that of DNA when the increase in purines in the plasma is measured.

On the other hand, pyrimidine mononucleotides and uridine, but not the base uracil, are absorbed readily from the intestine and utilised for nucleic acid synthesis. This has been demonstrated by studies of humans with hereditary oroticaciduria, a rare defect in *de novo* pyrimidine synthesis at the fourth step involving conversion of orotic acid to UMP. Such patients have a severe megaloblastic anemia that does not respond to the usual forms of treatment. They have been sustained for more than 40 years on oral uridine, indicating that the dietary pyrimidine is absorbed intact and can compensate totally for lack of *de novo* synthesis in humans. Studies using radiolabelled purines and pyrimidines in mice have provided further evidence for the incorporation of dietary pyrimidine nucleosides, but not purine nucleosides, into hepatic RNA.

Nucleosides and Nucleotides in the Diet

In healthy adults, the normal diet is a good source of nucleic acids, nucleotides, and nucleosides, and no supplementation is necessary.

Pharmacological uses for nucleosides and nucleotides Oral uridine, as described earlier, can be used where *de novo* biosynthesis of pyrimidines is defective, and it may be useful in reversing some effects of mitochondrial dysfunction and to minimize the toxic effect of the antitumor drug 5-fluorouracil. Uridine is also a precursor for UDP-glucose, essential for the deposition of glycogen in the liver. Enzymes in the liver, however, rapidly degrade much of each oral dose of uridine. Oral administration of a new prodrug, PN401, inhibits the degradative processes and delivers more uridine into circulation than oral uridine.

Oral CDP–choline is rapidly converted to its components, CDP (which can be recycled to uridine) and choline, an essential component of lipid membranes. Each molecule can then cross the blood–brain barrier, where CDP–choline is used in regeneration of membranes within and around nerve cells. Research in rats and early studies in humans suggest that its pharmacological effects may extend to protection against dementia, memory loss, visual degeneration, and recovery from ischemic strokes.

Beneficial effects of dietary nucleosides and nucleotides There is substantial evidence (principally from research in animal models) that the presence of nucleotides or nucleosides in the diet helps cellular proliferation in the gut, in postoperative trauma, and in the development of the immune response. Although dietary purines are not taken into circulation from the gut, purine nucleotides influence the transcription of several genes in intestinal cells. Nucleotides based on both adenosine and uridine can activate the purinergic receptors on a wide range of cell types. In lymphocytes and other cells, synthesis of nucleotides *de novo* is expanded dramatically when a signal for proliferation is received; the rate of pyrimidine biosynthesis increases more than that of purine biosynthesis. Thus, nucleotides are considered to be 'conditionally essential' since their provision in the diet will provide help through the salvage system where cells are dividing rapidly or where other nutrients, used as precursors, are scarce.

Human milk contains maternal cells, providing nucleic acids, and also nucleosides (particularly cytidine and uridine), and nucleotides equivalent to 10–20 mg/day. Cow's milk contains the *de novo* intermediate orotic acid, which can be taken up by erythrocytes and converted to UMP. Dietary nucleotides have been shown to promote the incorporation of essential fatty acids into membrane lipids in healthy newborn infants and to enhance the integrity and maturation of the intestine and of the immune system. Thus, these components may contribute to the improved immunity seen in breast-fed infants. Many infant formulas are now supplemented with nucleotides/nucleosides, but usually in lower concentrations than in human milk.

Purine ribonucleotides as flavor-enhancing additives The purine 5′-nucleotide monophosphates IMP and GMP, derived from degradation of RNA, have received much attention as the taste-active components in a variety of seafoods and meat. Both IMP and GMP enhance the *umami* flavor generated by monosodium glutamate (MSG). This flavor was generated only by the purine 5′-nucleotides, and not by the pyrimidine nucleotides CMP and UMP, by interaction with receptors on the specific *umami* tastebuds in the mouth. Since ATP is the major free nucleotide in muscle cells, its breakdown into the flavor-enhancing IMP provides a scientific rationale for the improved palatability of meat or game birds that have been hung for several days

after slaughter. Similarly, the distinctive flavors of several cheeses are related to the metabolism, by bacteria, of the characteristic range of nucleotides present in the original milk.

Toxicology

Pathophysiology of Genetic Metabolic Disorders in Nucleotide Metabolism

The important physiological roles played by the nucleic acid precursor rNTP and dNTP molecules in humans has become apparent since the 1970s by the recognition of 28 different inborn errors of purine and pyrimidine metabolism. The spectrum of clinical manifestations ranges from fatal immunodeficiency syndromes to muscle weakness, severe neurological deficits, anemia, renal failure, gout, and urolithiasis (uric acid kidney stones).

Patients in whom the gene encoding a crucial enzyme is absent or defective harbor an 'experiment of nature,' equivalent to the artificial 'knockout' of individual genes in animals. The metabolic consequences of the disorders have highlighted the importance of individual steps in the nucleotide pathways to a particular cell or tissue, particularly the need for intact pathways for nucleic acid synthesis as well as for metabolism, degradation, and recycling of nucleotides.

It is evident from two genetic disorders associated with immunodeficiency that rapid turnover of DNA from cells of the immune system normally produces significant amounts of free deoxyribonucleotides in the bone marrow, which must be degraded to the corresponding base or nucleoside for recycling. The absence of either of two enzymes critical to this pathway, adenosine deaminase and purine nucleoside phosphorylase, results in the accumulation of dATP or dGTP, respectively. Each of these nucleotides inhibits ribonucleotide reductase and may also lead to misincorporation during DNA synthesis. The lymphocytes are particularly sensitive, resulting in a potentially fatal immunodeficiency syndrome with a clinical course similar to that in AIDS. Other rapidly dividing cells, such as those of the skin or the gut, are also affected. These disorders highlight the sensitivity of lymphocytes to the efficient removal of waste from DNA catabolism and, in fact, have provided the basis for development of novel immunosuppressant drugs based on inhibitors of these enzyme activities.

Role of Nucleotide Analogs as Cytotoxic and Antiviral Drugs

DNA in the chromosomes is normally protected by active repair systems against damage by a variety of chemical and physical agents, including ionizing radiation and ultraviolet light. Proofreading activities guard against the incorporation of mismatched nucleotides during DNA replication or transcription. In contrast, the use of certain nucleotide analogs as drugs depends on their incorporation into DNA—the chemical must be recognized and used by the replication enzymes but must prohibit further elongation of the nucleic acid chain. Analogs used in HIV therapy are incorporated by the reverse transcriptase of the virus and bring the reaction to a halt. Toxicity associated with several analogs is known to arise from erroneous incorporation into the patient's mitochondrial DNA because of less stringent proofreading by the mitochondrial DNA polymerase enzyme. Azidothymidine remains one of the most effective and least toxic drugs for AIDS, albeit it is now usually taken in triple therapy.

Nucleotide analogs have been used to inhibit the *de novo* pathways for the synthesis of the precursor nucleosides and nucleotides, leading to depletion of metabolites and imbalance of dNTPs, and hence to misincorporation of nucleotides in RNA or DNA, respectively. Malaria and other parasites rely exclusively on *de novo* pyrimidine biosynthesis; thus, they may be susceptible at drug doses that do not affect the host because the human body can obtain nucleotides from the salvage pathway. Similarly, because of the increased requirement for nucleotides in rapidly proliferating cells, almost all the enzyme reactions (**Figure 2**) have been investigated as potential targets for treatment of cancer, inflammation, or to prevent rejection of transplanted organs. Again, combinations of drugs with different modes of action have often proved most effective.

Toxicity of Exogenous Nucleic Acids to Humans

Dietary nucleic acids are digested fully to their component nucleosides and bases, so nucleic acids are not absorbed *per se* into the body. The potential toxicity to humans of dietary purine bases arises principally because primates lack expression of the gene for the hepatic enzyme uricase. Excess purines are therefore converted to uric acid rather than to the extremely soluble allantoin, as in most other mammalian species. In reptiles, snakes, spiders, and birds, uric acid is the end product of the metabolism of all nitrogenous compounds, analogous to urea in mammals. The main advantage to using this insoluble end product is that there is no obligatory water loss for its excretion, as there is for urea. Consequently, uric acid can be excreted as a slurry by these animals—an evolutionary adaptation enabling survival in arid environments. In contrast, in

humans, excess uric acid may accumulate in the tubules of the kidney as uric acid stones or as crystals in the interstitium, resulting in renal disease. Likewise, crystals can accumulate in the joints or subcutaneously, giving rise to gout symptoms. The most common and effective treatment for gout is the well-known drug allopurinol, which prevents conversion of xanthine to uric acid. The uricase enzyme may be prescribed as short-term therapy to avoid tumor lysis syndrome (the release of massive amounts of nucleic acids when cancerous cells are destroyed by chemotherapy or radiotherapy).

Although the uricase gene appears to be present in human cells, the promoter is not activated, so no enzyme activity is detected in the liver. The biological value of the normal circulating concentration of urate has been debated, but urate ions may provide more than half the antioxidant activity in the plasma of primates.

Not only is uric acid a relatively insoluble form of metabolic waste but also plasma concentrations are kept high because the renal proximal tubule reabsorbs approximately 90% of the filtered uric acid (**Figure 4**) before it can be excreted in the urine. Net reabsorption is higher in healthy males (92%) than in females (88%) and is lower in children of either sex (80–85%). This difference explains the higher plasma uric acid in adult males and means that uric acid is circulating in their plasma at concentrations close to its solubility limit. Reabsorption is much higher (95%) in middleaged males with 'primary gout'—and increasingly in men and elderly women who are treated with thiazide diuretics for high blood pressure. Poor excretion of uric acid is also seen in a familial renal disease associated with gout symptoms in children and young adults of both sexes. Without treatment to lower the uric acid accumulation, the kidney function may be seriously diminished.

Origin of the Body Uric Acid Pool in Humans

The body pool of urate, and hence the plasma urate concentration, is the result of a balance between production, ingestion, and excretion. The main causes of high plasma uric acid concentrations are high intake of exogenous nucleic acid in the diet and overproduction of endogenous purine. Eating less meat, seafood, and other high-purine foods (**Tables 1** and **2**) leads to a lower dietary intake of nucleic acids. In contrast, subjects with genetic defects that remove the usual controls on purine biosynthesis may have overwhelmingly high endogenous levels of the waste product, uric acid.

The contribution of the two sources can be assessed by placing the subject on a purine-free diet for 1 week and measuring the urinary uric acid. In this way, fewer than 5% of patients with gout have been found to excrete abnormally large amounts of urate (>3 mmol/day) derived from endogenous

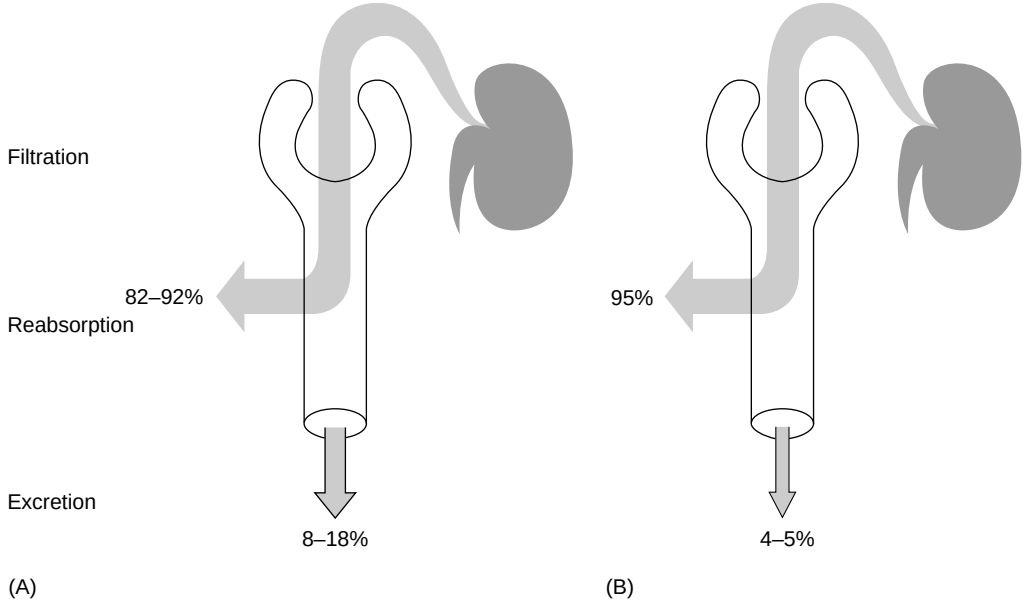

Figure 4 Schematic diagram showing the role of the kidney in influencing plasma uric acid concentration. In the brush border membrane of the proximal tubule, reabsorption by the urate anion exchanger and secretion via a voltage-sensitive pathway both occur. This results in a mean fractional urinary excretion of only 8–18% of the filtered load in healthy subjects and 5% or less in 'primary' gout. The net uric acid reabsorption is (A) higher in healthy men (92%) than in women (88%) and lower in children of either sex (82%), and (B) much higher in middle-aged males with primary gout (95%).

Table 1 Reference guide to the purine content of foods

Foods and beverages rich in nucleic acids/purines

Offal: sweetbreads, liver, kidney, heart, and paté

Wild or farmed game meats (venison, pheasant, rabbit, hare)

Seafoods: sardines, sprats, herring, bloaters, anchovies, fish roe, caviar, taramasalata, trout or salmon, lobster, crab, prawns

Vegetables: asparagus, avocado pears, peas, spinach, mushrooms, broad beans, cauliflower

Pulses and grains: legumes, pulses and soya products such as bean curd, tofu, Quorn

Cereals: all bran, oat, rye, or wheat cereals and products; whole meal, rye, and brown breads

Other: beer and yeast extracts/tablets (Barmene, Tastex); meat or vegetable extracts (Marmite, Vegemite, Bovril, Oxo)

Foods that are moderate or low sources of purine

Beef, lamb, pork (steak or chops), bacon, ham, sausages, some poultry, tongue (all should be eaten in moderation)

Carrots, parsnip, potatoes, lettuce, leeks, cabbage, sprouts, marrow, courgettes

Peanuts, cashew nuts

White bread or flour, cakes, scones, biscuits, cereals

Some fish (see **Table 2**)

Foods and beverages that are purine-free

Milk, cheese, eggs, butter, margarine, cream, ice cream

Sugar, jam, marmalade, honey, sweets

Cucumber, tomato, onions, pumpkin

Fresh, cooked or tinned fruits, nuts

Puddings, custards, yogurt

Fruit juices, soft drinks

Table 2 Concentrations of purines in some common foods and beverages[a]

Food	*Purine (mg/100 g)*	*Protein (mg/100 g)*
Meat		
Beef liver	333	19.7
Beef kidney	285	15.4
Beef heart	285	16.8
Beef tongue	167	16.4
Beef steak	151	19.5
Calf liver	348	19
Sweetbreads	1212	19.6
Veal cutlet	152	19.2
Sheep kidney	312	16.8
Lamb chop	196	14.9
Pork liver	289	22
Pork cutlet	164	16.4
Bacon	85	9.1
Ham	136	19.5
Sausage (beef)	79	13.8
Sausage (pork)	66	11.5
Rabbit	118	20.4
Venison	156	20
Vegetables		
Asparagus	32	2.1
Cauliflower	32	2.1
Celery	20	1.1

Mackerel	246	26
Oysters	116	6
Salmon	88	26
Sardines	399	24
Shrimp	231	22
Tuna	142	29

[a]Results are recorded relative to 100 g of food for purine and for protein, although serving size for each ingredient may be larger or smaller than 100 g.

purines. In these cases, overproduction of purine nucleotides leading to excess uric acid can be traced to a genetic defect. Two such sex-linked disorders are hypoxanthine–guanine phosphoribosyltransferase (HPRT) deficiency and phosphoribosyltransferase superactivity (PRPS). Boys presenting in infancy usually have severe and eventually fatal neurological deficits. Neurological problems are milder or absent,

and only gout may be evident, in those presenting as adolescents. It is important for clinicians to be aware of these disorders, especially when encountering a young patient with gout or an older male with a history dating back to adolescence. In some families, siblings are also affected, and although the gout symptoms can be alleviated, other aspects are less amenable to treatment and genetic counselling should be given.

Gout

Gout is a painful, acute form of arthritis caused by the accumulation of crystals of uric acid in the joints (typically the great toe is the first site to be affected). The pain may be relieved by antiinflammatory drugs or by colchicine, and the accumulation of urate is halted by the drug allopurinol, which inhibits xanthine dehydrogenase. Nevertheless, adopting a low-purine diet has an important role in alleviating the effects of gout.

Historically, 'primary' gout—affecting predominantly middle-aged males—has long been associated with excessive consumption of 'rich' food and drink (**Tables 1** and **2**). Until World War I, affluent European gentlemen habitually consumed vast nucleic acid-rich meals including many different courses and meats. Alcoholic drinks also played their part, with beer being particularly rich in purines derived from yeast RNA and port a potential cause of lead poisoning from glass bottles and decanters.

Both hyperuricemia and gout are relatively common in Polynesians due to a genetic defect in excretion of urate and in Australasians, traditionally high consumers of nucleic acid-rich seafood, meat, and beer. In such countries, the prevalence of gout is as high as 10% compared with 1–4% in Europe. In Europe, the prevalence is higher in countries such as France where the consumption of seafoods and paté is high. The role of diet in the etiology of primary gout is confirmed by the fact that during and immediately after the two world wars this type of gout was virtually unknown. Gout, a hitherto little known disease, is now more common worldwide where affluence or the consumption of meat have increased.

Urolithiasis (Kidney Stones)

Although modest overindulgence in purine-rich food by normal subjects does not precipitate gout, it can predispose to uric acid lithiasis. Uric acid stones are relatively common in countries where the consumption of nucleic acid-rich beverages and food is high and in hot climates if insufficient fluids are consumed. Health foods such as yeast tablets, Spirulina, or supplements containing nucleotides also contribute to uric acid lithiasis.

A number of compounds, such as vitamin C, increase uric acid clearance and thus can precipitate urolithiasis. Perhaps not so well recognized is the uricosuric effect of a high-protein diet and the fact that purine-rich foods also predispose to renal calcium stones. This may be because many purine-rich foods, such as spinach, are equally rich in calcium oxalate. Approximately 25% of vitamin C intake is also excreted as oxalate, which can compound the problem.

The solubility of uric acid is very sensitive to the pH of the urine, which in turn may be altered by components of the diet. The solubility of uric acid in urine at pH 5.0 is low (approximately 1 mmol l^{-1}), but it can be increased 12-fold at pH 8.0 by alkalinising regimens, such as sodium bicarbonate or potassium citrate.

Exacerbation of kidney stone formation by dietary nucleic acids in inherited purine disorders Excess uric acid from dietary purines can also precipitate symptoms that may draw attention to milder forms in adults of HPRT deficiency or PRPS superactivity. A third genetic defect raises levels of adenine, which is converted by XDH to the even more insoluble uric acid analog, 2,8-dihydroxyadenine (2,8-DHA). Undiagnosed, such subjects have progressed to renal failure and even death. One child presenting in coma had a diet of pulses and grains, which have a particularly high adenine content. Since the accumulation of 2,8-DHA is treatable with allopurinol, such nephropathy can be avoided if the defect is recognized and the consumption of nucleic acid-rich foods reduced to a minimum.

Dietary Sources

Nucleic Acid Content of Foods

The nucleic acid content of different foods is expressed generally in terms of purine equivalents, with the data derived from the hydrolysis of nucleic acids and free nucleotides to the constituent bases. Careful analysis by Robert McCance, Elsie Widdowson, and colleagues since the 1930s forms the basis of tables of the composition of foodstuffs.

Foods may be classified into three groups: high, low, or essentially purine free (**Table 1**). As a general rule, growing organisms such as yeast, or rapidly metabolizing tissues such as liver, will be rich in both DNA and RNA. Seeds, grain, and fish eggs are good sources of the genetic material, DNA. Muscle tissue is an excellent source of nucleotides,

such as the energy source ATP. Extracts of meat and yeast have very high purine contents but are usually eaten in small quantities. Some vegetables may provoke gout attacks by virtue of their oxalic acid content rather than that of purines, but legumes, fast-growing parts of brassicas, and asparagus tips may also have significant nucleic acid content. Fats, white flour, sugar, and fruit juices have been separated from the 'living' part of the food and so they are poor sources of nucleic acids.

Table 2 provides data for specific foodstuffs, obtained from the Documenta Geigy Chemical Composition of Foodstuffs tables. The ideal diet for subjects at risk of gout or of uric acid lithiasis is no more than one meat meal per day, using only the low-purine meat and vegetables indicated.

NUTRIENT–GENE INTERACTIONS

Contents

Molecular Aspects

C D Berdanier, University of Georgia, Athens, GA, USA
H C Freake, University of Connecticut, Storrs, CT, USA

The completion of the sequencing of the human genome has resulted in a broadening of focus to include the investigation of the complex environment in which these genes operate. Although the term 'gene' refers to a specific sequence of DNA, the biological effects of that gene are manifest through its expression as a protein or peptide product. Nutrients affect the expression of genes in a variety of ways. Nutrients are required for the synthesis and packaging of DNA. Some have specific effects on the synthesis of messenger RNA (i.e., either suppress or enhance transcription). Others affect the synthesis of the pyrimidine and purine bases used for DNA and RNA synthesis. Some nutrients have an overall effect on protein synthesis, whereas others influence the translation of the messenger RNA into protein or the post-translational modification of the newly synthesized protein. Still others can affect the outcome of gene expression by influencing the environment in which the gene product functions. This article outlines the process of gene expression, focusing on the ways in which it is influenced and regulated by particular nutrients.

DNA Characteristics

The characteristics of every living creature are dictated by the genetic material, DNA. Nuclear DNA is organized into units called chromosomes, of which there are 46 in the human. The chromosomes are found in pairs and contain the individual units called genes. DNA is a double-stranded helix composed of four bases, two pyrimidines (cytosine and thymine) and two purines (adenine and guanine), that are joined together by ribose and phosphate groups (**Figure 1**). DNA is formed when the bases are joined through phosphodiester bonds using ribose as the common linkage. The phosphodiester linkage is between the 5′ phosphate group of one nucleotide and the 3′ OH group of the adjacent nucleotide. This provides a direction (5′ to 3′) to the chain. The bases are hydrophobic and contain charged polar groups. These features are responsible for the helical shape of the nuclear DNA chain. A double helix forms when the bases of each chain interact through hydrogen bonding.

The DNA base sequence is unique for every protein and peptide that synthesized in the body. The sequence of these bases determines the genotype of the individual for each gene product. Although only four different bases are used for the DNA, it is the sequence of these bases that determines the product being produced. Each gene product is uniquely derived from a specific gene. Although all cells contain the same DNA, not all genes are expressed in every cell; some are particular to specific cell types. Thus, the function of DNA is to determine not only the particular characteristics of the individual but also the properties of each cell through the provision of a multitude of genes, each coding for a particular protein found in that cell. Therefore, it functions to transmit genetic information from one generation to the next in a given species and ensures the identity of specific cell types.

The Human Genome Project has detailed the specific base sequence of nuclear and mitochondrial DNA in the human cell. The identification of each gene and its corresponding controls of expression have not been completely elucidated. Although the nuclear genome has been sequenced, it has not been completely mapped; that is, the location, within the DNA, of each gene (and its promoter region) and the identification of the protein or peptide it encodes

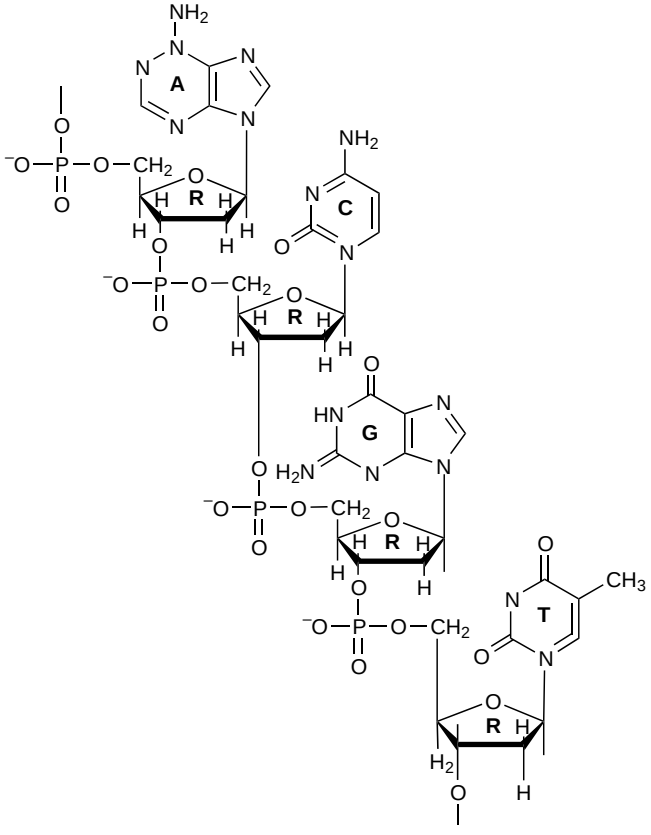

Figure 1 Representation of a segment of DNA showing the phosphodiester bond that uses ribose as the common link between the bases. A, adenine; C, cytosine; G, guanine; T, thymine; R, ribose.

have not been fully determined. In addition, we do not know all the details of the regulation of gene expression. Some genes have been intensely studied, whereas others have yet to be identified. In contrast, the genome in the mitochondria has been completely sequenced and mapped. It is a very small genome encoding only 13 gene products (components of the mitochondrial respiratory chain) under the control of a single promoter sequence, the D-loop. Despite its small size and apparent simplicity, however, we know even less about the regulation of its expression than we know about some of the nuclear-encoded genes.

DNA Synthesis

In the adult, some cell types are extremely long-lived (e.g., neuronal cells), whereas others last only a few days and therefore need constant replacement (epithelial cells, e.g., intestine and skin). This synthesis requires a number of micronutrients, protein, and energy. Should any of these be in short supply, symptoms of malnutrition will be observed, especially in those cell types that have very short half-lives. Typical of niacin deficiency (pellagra), for example, are skin lesions. As epithelial cells die and must be replaced, niacin is needed for this replacement. All the components of the new cells including DNA must be synthesized. The purines and pyrimidines that comprise DNA must be synthesized and this requires energy as well as micronutrients (niacin, riboflavin, pyridoxine, folic acid, vitamin B_{12}, copper, iron, sulfur, zinc, magnesium, and phosphorus). Anemia is another characteristic of malnutrition. Not only must new blood cells be made but also the essential ingredient of these cells, hemoglobin, must be synthesized. Among the nutrients needed for red blood cell synthesis are iron, copper, magnesium, folic acid, vitamin B_{12}, vitamin B_6, and, of course, energy and protein sufficient to support this synthesis.

The nutritional requirements for new cell synthesis are much greater in growing individuals than in adults because growth and cell division are much greater. Thus, energy and protein deficiency can be particularly detrimental. In addition, an adequate supply of specific micronutrients is crucial. For example, zinc deficiency was first described in teenage boys who were stunted and also sexually undeveloped. This report showed that zinc was required for both growth in general and the development of specific organ systems. Folic acid is required for DNA synthesis. Meeting this requirement is crucial during embryonic development. Inadequate folate intake by prepregnant and pregnant women can result in neural tube defects due to insufficient cell division during this time period. Not all women are so affected; there may be genetic differences in the need for folate that in turn determine whether the embryo is affected.

Transcription

Messenger RNA (mRNA) synthesis using DNA as the template is called transcription. The mRNA carries genetic information from the DNA of the chromosomes in the nucleus to the surface of the ribosomes in the cytosol. It is synthesized as a single strand. Chemically, RNA is similar to DNA. It is an unbranched linear polymer in which the monomeric subunits are the ribonucleoside 5′ monophosphates. The bases are the purines (adenine and guanine) and the pyrimidines (uracil and cytosine). Thymine is not used in mRNA. Instead, uracil is used. This base is not present in DNA. Messenger RNA is much smaller than DNA and is far less stable. It has a very short half-life (from seconds to minutes or hours) compared to that of nuclear DNA (years). Because it has a short half-life, the purine and pyrimidine bases that are used to make mRNA must be continually resynthesized. This requires the same array of nutrients noted previously for DNA synthesis.

The synthesis of mRNA from DNA occurs in several stages: initiation, elongation, editing (processing), and termination. Initiation of transcription (the synthesis of mRNA) occurs when factors that serve to stabilize nuclear DNA are perturbed. Perturbation signals pass in to the nucleus and stimulate transcription. A small portion of the DNA (~17,000 bases) is exposed and used as the template for mRNA synthesis. The exposed portion also contains one or more sequences that have control properties with respect to the initiation of transcription. This region is called the promoter region and represents a key site for nutrient interaction. The promoter region precedes the start site of the structural gene and is said to be upstream of the structural gene. Those bases following the start site are downstream. The exposed DNA contains groups of bases called exons and introns. The introns are noncoding and are removed by editing prior to the movement of the mRNA from the nucleus to the cytosol.

Transcription is highly regulated. The DNA in all cell types is identical. However, not all of this DNA is transcribed in all cells all the time. Only certain genes are activated and transcribed into mRNA and subsequently translated into protein or peptides. As mentioned previously, these gene products give

the individual cell type its identity. Central to this regulation are protein:DNA interactions and protein:nutrient interactions. At initiation, basal transcription factors recognize and bind to the start site of the structural gene. They form a complex with RNA polymerase II, an enzyme that catalyzes the formation of mRNA. Transcription factors bind to particular base sequences, called response elements, in the promoter region of the DNA that are upstream of the transcription start site (**Figure 2**). Each gene promoter contains a characteristic array of response elements, and these will determine to which signals the particular gene responds. Transcription factors also bind nutrients, and it is here that some nutrients have their effects on gene expression.

The regulation of transcription often occurs through the regulation of transcription factors. These factors can be regulated by the rates of their synthesis or degradation, by phosphorylation or dephosphorylation, by ligand binding, by cleavage of a pro-transcription factor, or by release of an inhibitor. One class of transcription factors important for nutrition is the nuclear hormone receptor superfamily that is regulated by ligand binding. Ligands for these transcription factors include retinoic acid (the gene active form of vitamin A), fatty acids, vitamin D, thyroid hormone, and steroid hormones. These receptors are proteins with a series of domains. The retinoic acid receptor can serve as an example. Its ligand-binding domain recognizes and binds with high affinity the nutrient signal, retinoic acid. The DNA-binding domain gives gene specificity. It binds to a segment of the gene promoter that contains its corresponding response element, the retinoic acid response element (RARE). A transactivation domain then signals the effective occupation of this response element to the gene as a whole, including RNA polymerase II and its associated proteins. There are additional factors responsible for mediating this interaction between nutrient receptor and the transcription process. They include coactivating proteins, which stimulate transcription, and corepressor proteins, which can cause inhibition of transcription from a particular protein. In general, nutrients can signal the activation of transcription of some genes while at the same time turning off the transcription of others.

An interesting additional feature of this superfamily of nuclear hormone receptors is that they contain two zinc atoms in their DNA-binding domains. Each zinc is bound by four cysteine residues and causes the folding of the protein in a finger-like shape that binds DNA. The zinc ion plays an important role in gene expression because of its central use in the zinc finger of a wide variety of DNA binding proteins. In the case of the receptor superfamily, although zinc is required for receptor function, there is no evidence that it plays a regulatory role. However, there are other transcription factors in which it does play a role. MTF-1 (metal response element (MRE)-binding transcription factor-1) responds to increasing zinc concentrations within the cell by translocating to the nucleus and activating the transcription of genes containing MREs in their promoter region. These genes include

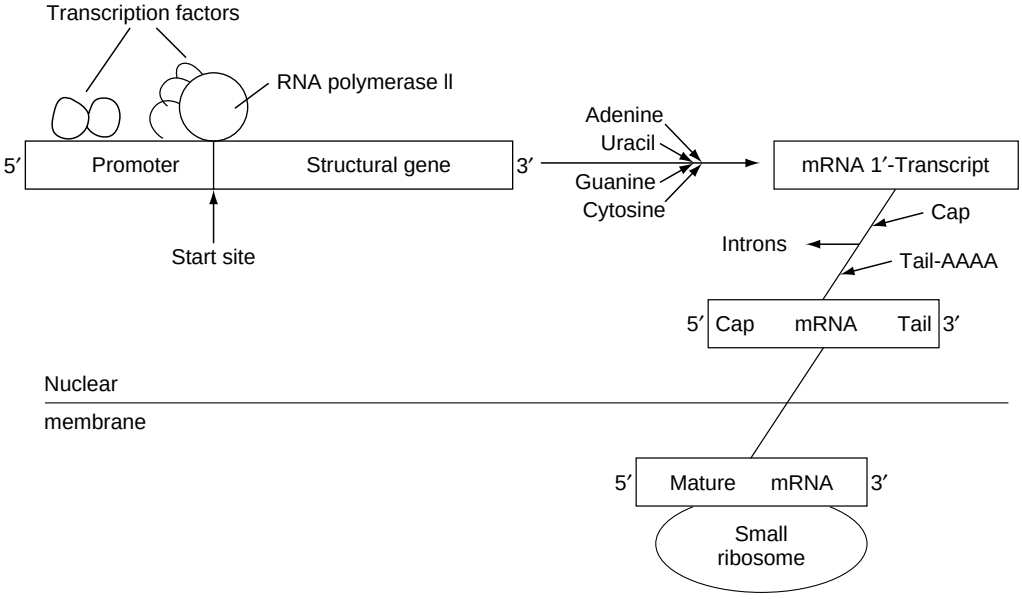

Figure 2 Schematic view of transcription.

metallothionein, which binds zinc and may play a key role in zinc homeostasis.

The direct binding of a nutrient signal to a transcription factor is perhaps one of the simpler ways in which nutrients impact gene transcription. There are other less direct but equally important mechanisms. Genes involved in cholesterol homeostasis are characterized by a sterol response element (SRE) in their promoter regions, which interacts with a sterol response element binding protein (SREBP). This protein is synthesized as a large precursor, incorporated into endoplasmic reticulum membranes, and is unavailable to function in gene regulation until it is cleaved and released. Limited cholesterol availability results in the cleavage and release of SREBP from the membrane compartment and its translocation to the nucleus. There it can perform its gene regulatory function by activating the transcription of genes for cholesterol synthesis as well as the LDL receptor gene. The LDL receptor facilitates cholesterol uptake by the liver. When it is abnormal due to a mutation in its gene, hypercholesterolemia results. The liver is unable to remove cholesterol from the blood and continues to synthesize it since SREBP remains active.

The metabolism and availability of macronutrients also influence gene transcription. Promoter elements have been described that allow a response to glucose (the carbohydrate response element (CHORE)). Although the specifics are unclear, the activity of the protein that binds this element responds to the metabolism of glucose and then stimulates the transcription of relevant genes—for example, those required for glucose metabolism (pyruvate kinase) and fatty acid synthesis (acetyl-coA carboxylase and fatty acid synthase). Fatty acids also influence gene expression. They can affect transcription by binding directly to their own transcription factor (the peroxisome proliferator activated receptor) and also indirectly by reducing the availability of SREBP within the nucleus. The latter mechanism provides a means for linking cholesterol and fatty acid metabolism with the cell.

Nutrients can also affect gene expression indirectly by regulating the release of hormones into the blood. Thus, glucose, in addition to having its own effects on gene expression through the CHORE, also stimulates insulin secretion from the pancreas. Insulin has its own transcriptional effects, often on the same genes that are regulated by glucose. In the postabsorptive state, insulin drops and glucagon is released. This hormone activates an intracellular signaling pathway that results in inhibition of genes involved in glucose metabolism and fatty acid synthesis and stimulation of genes involved in gluconeogenesis (e.g., phosphenolpyruvate carboxykinase). Taken as a whole, macronutrient availability regulates the expression of the complex set of genes responsible for macronutrient metabolism by an aggregate of direct and endocrine-mediated pathways.

Nuclear Processing of mRNA

Once the bases are joined together in the nucleus to form mRNA, it is edited with a reduction in size. Through editing and processing, less than 10% of the original mRNA actually leaves the nucleus. Editing and processing are needed because immature RNA contains all those bases corresponding to the DNA introns. The removal of these introns is a cut-and-splice process whereby the intron is cut at its 5′ end, pulled out of the way, and cut again at its 3′ end. After this group of bases is excised, the bases corresponding to the DNA exons are joined. This cut-and-splice routine is continued until all the introns are removed and the exons joined. Some genes can give rise to multiple protein products since not all exons are necessarily retained in the mature mRNA. Some editing of the RNA also occurs with base substitutions made as appropriate. The mRNA is capped at the 5′ end in a process that adds a guanine base and some methyl groups. Finally, a 3′-terminal poly A tail is added and the mature mRNA is ready to leave the nucleus and move to the cytoplasm for translation. The nucleotides that have been removed during editing and processing are either reused or degraded. Some mRNA is totally degraded, never leaving the nuclear compartment. This serves to control the amount of mRNA. Regulation of the amount of mRNA that leaves the nucleus is a key step in metabolic control.

mRNA Stability

The stability of mRNA can also be regulated within the cytoplasm. Some mRNA have very short half-life (seconds to minutes), whereas others have longer half-lives (hours). This is important because some gene products (i.e., hormones and cell signals) must be short-lived and the body needs to control/counterbalance their synthesis and action. A nutritionally important example of regulation of mRNA stability involves iron and the transferrin receptor. The transferrin receptor is the protein responsible for the uptake of iron into cells. The expression of the transferrin receptor is downregulated by iron in order to limit uptake and potential toxicity of the

mineral at times of high availability. This regulation is achieved through an iron regulatory protein. When iron is limited, this protein is bound to the 3′ untranslated region of the transferrin receptor mRNA. This serves to protect the mRNA from degradative attack and permits its continued translation into active protein. As iron concentrations rise, the binding protein becomes occupied with iron, which results in its dissociation from the transferrin receptor mRNA. The mRNA is then degraded more quickly, concentrations fall, and protein production is limited.

Translation

Following transcription is translation. Translation is the synthesis of the protein or peptide, the gene product. Translation occurs on the ribosomes; some ribosomes are located on the membrane of the endoplasmic reticulum and some are free in the cell matrix. Ribosomes consist of RNA and protein. Ribosomal RNA makes up a large fraction of total cellular RNA. Ribosomal RNA is synthesized via RNA polymerase I in the cell nucleus as a large molecule; there, this RNA molecule is split and leaves the nucleus as a large and a small subunit. The large ribosomal unit serves as the 'docking' point for the activated amino acids bound to the transfer RNA (tRNA). The mRNA is bound to the small ribosomal unit. The two ribosomal units reassociate in the cytosol for the translation step. tRNA is used to bring an amino acid to the large ribosome, the site of protein synthesis. Each amino acid has a specific tRNA. Each tRNA molecule is thought to have a cloverleaf arrangement of nucleotides. This arrangement allows the formation of the maximum number of hydrogen bonds between base pairs. Hydrogen bonding stabilizes the tRNA. tRNA also contains a triplet of bases that pair to a corresponding triplet found in the mRNA. This triplet is not identical to the mRNA triplet and is called the anticodon. The bases pair in a preordained manner: adenine to thymine, guanine to uracil, guanine to guanine, uracil to cytosine, inosine to adenine, and so forth. The amino acid carried by tRNA is identified by the codon of mRNA through its anticodon; the amino acid is not involved in this identification.

Translation takes place in four stages, as illustrated in **Figure 3**. Each stage requires specific cofactors and enzymes. The first stage involves the esterification of the amino acids to specific tRNAs. Each of these esterification reactions requires a molecule of ATP. Here again is an explanation of why the provision of energy is crucial to protein synthesis. If a protein contains several hundred amino acids, this step in translation will require several hundred molecules of ATP. Energy-deficient diets result in a shortfall in ATP and so protein synthesis is compromised.

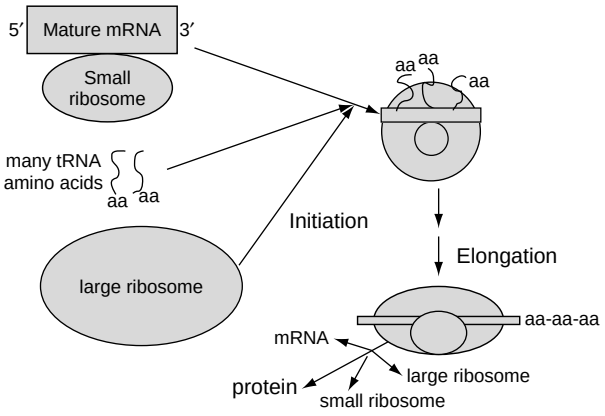

Figure 3 Schematic view of translation.

During the second stage of translation, polypeptide chain synthesis begins. mRNA binds to the small ribosome and an initiation complex is formed. The complex consists of the mRNA cap and the first activated amino acid–tRNA. The ribosome finds the correct reading frame on the mRNA by 'scanning' for an AUG codon. This is the so-called start codon. The large ribosomal unit then attaches and forms a functional ribosome. A number of specific protein initiation factors are involved in this step.

In the third stage of translation, the peptide chain is elongated by the sequential addition of amino acids from the amino acid–tRNA complexes. The amino acid is recognized by base pairing of the codon of mRNA to the bases found in the anticodon of tRNA, and a peptide bond is formed between the peptide chain and the newly arrived amino acid. The ribosome then moves along the mRNA; this brings the next codon into the proper position for attachment to the anticodon of the next activated amino acid–tRNA complex. The mRNA and nascent polypeptide appear to 'track' through a groove between the two ribosomal subunits. This protects the protein being synthesized from attack by enzymes in the surrounding environment.

The final stage of translation is the termination and release of the amino acid chain. The mRNA contains a stop codon that signals termination at the carboxy terminus. The carboxy-terminal amino acid, although attached to the peptide chain, is also esterified to its cognate tRNA–ribosome. A protein release factor promotes the hydrolysis of the ester link between the tRNA and the amino acid. Now the polypeptide is released from the ribosome and is

free to assume its characteristic three-dimensional structure.

Translation is influenced by nutritional status as well as by specific nutrients. Protein synthesis is dependent on the simultaneous presence of all the amino acids necessary for the protein being synthesized and on the provision of energy. If there is an insufficient supply of either, protein biosynthesis will not proceed at its normal pace. This is an example of the consequences of malnutrition with respect to gene expression. Malnourished individuals will not be able to support the full range of *de novo* synthesis of body proteins because their diets are energy poor and/or contain proteins of poor quality. This condition is known as protein-energy malnutrition. It is commonly found in children but may also be observed in adults under severe food deprivation.

An example of an effect of a nutrient on translation of a specific mRNA is that of iron in the synthesis of ferritin. Iron storage in cells occurs through chelation to a protein called ferritin. Ferritin synthesis is highly regulated by iron intake. In iron deficiency, the mRNA start site for ferritin translation is obstructed by an iron regulatory protein. This protein binds to the 5′ untranslated region and inhibits the movement of the 40s ribosome from the cap to the translation start site. When the diet contains sufficient iron and iron status is improved, the iron regulatory protein dissociates from the ferritin mRNA and translation proceeds. When iron availability is limited, the same iron regulatory protein binds to ferritin mRNA (to inhibit its translation) and to the transferrin receptor mRNA, as described previously (to prevent its degradation and ensure its translation). These exquisite mechanisms serve to maintain iron homeostasis.

Post-translational Protein Modification

After translation, the primary amino acid sequence is complete. The secondary and tertiary structure of the protein evolves via numerous interactions between amino acids via hydrogen bonding, disulfide bridges, and ionic bonds. The newly synthesized proteins can be further modified via post-translation reactions. Post-translational protein modification includes the association of various subunits of an enzyme or a carrier or a cell component. For example, the association of the four subunits that make up hemoglobin occurs after the initial synthesis of each of the subunits has occurred. Again, specific nutrients can influence the process. Another example is the post-translational carboxylation of the proteins osteocalcin and prothrombin. Osteocalcin and prothrombin each have glutamic acid-rich regions that, when carboxylated, allow the protein to bind significant amounts of calcium. Calcium binding is an essential feature of the functions of each of these proteins. The post-translational carboxylation of osteocalcin and prothrombin requires vitamin K. Should vitamin K be in short supply, this carboxylation will not occur (or will occur in only a limited way) and these proteins will not be able to bind calcium. Both must bind calcium in order to function. Hence, vitamin K deficiency is characterized by prolonged blood clotting times (inadequate calcium binding by prothrombin) and poorly mineralized bone (inadequate calcium binding by osteocalcin).

Some protein modifications occur in a nutritionally dependent reversible manner. The means whereby macronutrients influence their own metabolism at the level of transcription was outlined previously. In addition, the nutritionally regulated hormones insulin and glucagon influence enzyme activity by phosphorylation/dephosphorylation

Table 1 Examples of nutrient effects on gene expression

Nutrient	*Intermediary protein*	*Gene/gene product*	*Effect*
Cholesterol	Sterol response element binding protein	LDL receptor	Suppresses transcription
Fatty acids	Sterol response element binding protein	Fatty acid synthase	Suppresses transcription in liver
	Peroxisome proliferator activated receptor	Fatty acid binding protein	Increases transcription
Glucose	Carbohydrate responsive factor	Pyruvate kinase, acetyl-coA carboxylase	Increases transcription in liver
Iron	Iron regulatory protein	Ferritin	Increases translation
		Transferrin receptor	Destabilizes mRNA
Vitamin A	Retinoic acid receptor	Retinoic acid receptor	Increases transcription
		Collagenase	Decreases transcription
Vitamin D	Vitamin D receptor	Calcium binding proteins	Increases transcription
Vitamin K		Prothrombin, osteocalcin	Serves as cosubstrate for the post-translational carboxylation of glutamic acid-rich regions of these proteins
Zinc	MTF-1	Metallothionein	Increases transcription

mechanisms. This allows metabolic flux to respond to nutrient availability much more rapidly than would be possible with mechanisms dependent on new protein synthesis.

There are numerous examples of specific nutrients' effects on gene expression. Some of these effects concern the transcription of genes that encode enzymes or receptors or carriers that are important to the use of that nutrient. Examples are listed in **Table 1**. Many nutrients serve more than one function with respect to gene expression. Some influence both transcription and translation, whereas others serve to enhance the transcription of one gene while suppressing the transcription of another. Nutrient–gene interactions can result in either an increase or a decrease in specific mRNA, but there may be no increase in gene product or a measurable increase in gene product function. This speaks to the complicated nature of metabolic control. Simply synthesizing more message units or more enzyme protein does not automatically result in an increase in enzyme activity, an increase in a metabolic pathway, or an increase in a metabolic product. The processes of gene expression and metabolic regulation comprise a complex web of interactions in which nutrients are major and diverse players.

Health Implications

C D Berdanier, University of Georgia, Athens GA, USA
H C Freake, University of Connecticut, Storrs, CT, USA

Food, and the nutrients it contains, has long been known to influence the health and well-being of humans. Included in the list of nutrition-related diseases that afflict humankind are the specific nutrient deficiency diseases and several of the chronic diseases, including some of the most common ones. Each of these conditions has both a nutrition component and a genetic component. With respect to the nutrient deficiency diseases, there is considerable variation in nutrient requirements since the genetics of the consumer dictates how much of each essential nutrient is needed. If the individual's requirement is met, the deficiency disease is prevented. **Table 1** lists the essential nutrients and the symptoms of the deficient state caused by inadequate intake of the nutrients. Some symptoms (i.e., anemia) characterize several different nutrient deficiency states.

In addition to the diseases that are clearly nutritionally related, many of the chronic diseases have a nutritional component. They are also influenced by genetics, and often these two factors interact so that when certain dietary behaviors are found with a susceptible genotype, the disease results. A third kind of nutrient gene interaction relevant to health occurs when dietary constituents either promote or protect against changes in DNA that result in aging or disease. Nutrients that affect the redox balance within the cell are important in this case.

Some disease states result from alterations in a single gene. Function of the gene product is compromised and the specific pathology develops. Acrodermatitis enteropathica is an example of this, in which the affected individual has impaired zinc absorption due to a mutation in the gene encoding a zinc transporter. Menkes' disease is another example; copper absorption is impaired due to an X-linked mutation in the protein needed to release absorbed copper from the enterocyte into the circulation. People with this disorder develop symptoms of copper deficiency. Single gene mutations have been identified that affect the use of a single nutrient. However, in many genetically determined instances of nutrient malabsorption or abnormal use, the situation is more complex and the disease state may develop as a result of small changes in several genes. These situations may be more common than individual

Table 1 Nutrient deficiency disorders[a]

Nutrient	*Disease: signs of inadequate intake*
Ascorbic acid	**Scurvy**: hyperkeratosis, congestion of the hair follicles, skin hemorrhages, conjunctival lesions, gum swelling and bleeding, peripheral neuropathy with hemorrhages into the nerve sheaths, painful joints, deformed chests in children
Thiamin	**Beriberi**: muscle tenderness and peripheral neuropathy, edema, fast pulse, high blood pressure, decreased urine volume, disorientation, memory loss, ataxia, jerky movements of the eyes
Riboflavin	Ill-defined symptoms that are not necessarily related to inadequate intake: poor growth, poor appetite, cracks in the corners of the mouth, dermatitis of the scrotum
Niacin	**Pellagra**: black, roughened skin especially in areas exposed to sunlight; insomnia; loss of appetite; sores in mouth and tongue; indigestion; diarrhea; mental confusion; nervousness; headache; apprehension; forgetfulness
Vitamin B_6	Ill-defined symptoms: poor growth, muscular weakness, fatty liver, convulsions, anemia, reproductive impairment, edema, neural degeneration, enlarged adrenal glands
Folic acid	**Anemia**; macrocytic anemia. Neural tube defects in infants are associated with inadequate folic acid intakes of the mother during the first trimester of pregnancy
Vitamin B_{12}	**Pernicious anemia**; macrocytic anemia. Also loss of peripheral nerve function
Vitamin A	**Night blindness**, poor growth and reproduction, roughened skin (keratomalacia); **xerophthalmia**, leading to blindness, anemia, reduced immune function
Vitamin D	**Rickets**; inadequate calcification of bones resulting in bone deformities
Vitamin K	Poor blood clotting
Vitamin E	Red cell fragility, increase in blood peroxides
Phosphorus	Anorexia, muscle weakness, rickets, impaired growth, bone pain
Magnesium	Muscle spasms, twitching, tremor, anorexia, nausea
Iron	**Anemia**; microcytic anemia due to low hemoglobin, fatigue, inability to concentrate
Zinc	Growth failure, hypogonadism, impaired immune function, enlarged liver and spleen, mental lethargy
Copper	**Anemia**, poor wound healing
Selenium	**Keshan disease**: fragile red blood cells, enlarged heart, cardiomyopathy, growth retardation, skeletal muscle degeneration, cataract formation
Iodine	**Goiter**: enlarged thyroid gland, poor growth, reduced metabolic rate, mental retardation if deficiency occurs in the perinatal period

[a]Some nutrients have no defined deficiency syndromes.

gene mutations. They are also much more complex and more difficult to identify.

Before discussing the different kinds of nutrient–gene interactions in detail, an outline of the kind of variability found within the human genome is presented.

DNA Variability

The DNA in the nucleus is very stable with respect to the base sequence and content. Humans are more similar than different. Variations in DNA sequence have occurred and continue to occur. DNA replication is not 100% faithful nor is DNA repair 100% accurate. Changes in the sequence of bases that comprise the individual genes and their promoter sequences occur as base substitutions, deletions, or rearrangements. Chemicals that generate free radicals can cause DNA strand breaks and a possible loss of a base. Replacement of that base can occur and the strand can be repaired. However, in some instances, the base used for the repair might not be identical to the one lost, and a base substitution will be made. If any of these changes affect the amino acid sequence of the gene product and this substitution is in a critical area that affects function, then a mutation is said to have occurred. Otherwise, the difference in base sequence is referred to as a polymorphism rather than a mutation.

The significance of a deletion or substitution of bases in the DNA of a particular gene will depend on where it occurs and what change it engenders. It may occur in a noncoding region of the DNA or be a base substitution that does not affect the amino acid sequence of the gene product. Some amino acids have more than one base triplet (codon) that dictate its use in the gene product. If the change results in a substitution of a relatively similar amino acid, the function of the protein may be conserved. Some amino acids can be replaced without affecting the secondary, tertiary, or quaternary structures of the protein (and hence its chemical and physical properties), particularly if the base substitution occurs in an area that encodes a nonactive portion of the gene product. If any of these occur there will be little discernable effect on the gene product. The resultant gene product retains its premutation function but has a slightly different amino acid sequence. Polymorphisms in DNA, particularly mitochondrial DNA, are useful tools because they allow scientists to genetically identify individuals and their relatives and also allow population

geneticists to track mutation and evolutionary events through related family members. Particularly useful in this respect are the polymorphisms in mitochondrial DNA. Anthropologists use this information to track population shifts that have occurred over time.

The amino acid sequence within a given species for a given protein is usually similar. However, some individual variation does occur. Examples of 'acceptable' amino acid substitutions are those that account for the species differences in the amino acid sequence of the hormone insulin. As a hormone, it serves a variety of important functions in the regulation of carbohydrate, lipid, and protein metabolism. However, even though there are species differences in the amino acid sequence of this protein, insulin from one species can be given to another species and be functionally active. Obviously, the species differences in the amino acid sequence of this protein are not at locations in the insulin molecule that determine its biological function in promoting glucose use.

Whether the substitution of one amino acid for another affects the functionality of the protein being generated depends entirely on the amino acid in question. An example of potentially important changes in sequence involves three related proteins important to energy balance regulation—the uncoupling proteins (UCPs) 1, 2, and 3. The UCPs function to uncouple the synthesis of ATP from the synthesis of water in the mitochondrial compartment. If UCPs are present, the cell makes less ATP and releases more energy as heat (thermogenesis), thereby decreasing energetic efficiency. If one or more UCPs are absent or nonfunctional due to a mutation(s) in the codes for these proteins, the reverse occurs. More energy is trapped in the high-energy bond of ATP, and this energy is subsequently transferred to synthetic reactions that produce storage energy products: fats and glycogen. With a decrease in energy wastage by the mitochondria, excess fat accumulates. For whatever reason, the individual is unable to produce or release one or more of the UCPs, and fuel metabolism and energy balance are adversely affected. The individual may not be able to rapidly adjust to changes in the environment, such as a dramatic decrease in environmental temperature. This is an example of a nutrient–gene interaction that is part of a disease process, in this case obesity. However, it is not a single nutrient but all energy-containing nutrients—carbohydrates, fats, and proteins—that play a role in obesity development. If the individual does not have access to a plentiful food supply, the obesity phenotype may not be apparent.

Genetics Affects Nutrient Requirements

There are many examples of nutrient requirements being influenced by genetic background. For example, in the early years of determining the human need for vitamin C, human studies showed that there could be large individual differences in the need for this essential vitamin. In addition to genetic variability, vitamin C need was increased in smokers versus nonsmokers and in people with diabetes compared to people without this disease. Similar observations have been reported for vitamin A. A rare but quite profound example of genetically determined differences in nutrient need is that of vitamin D-resistant rickets. Vitamin D constitutes part of an endocrine system within the body that allows calcium absorption to be adjusted to need. Among other actions, it is responsible for stimulating calcium uptake in the small intestine. It works through a protein, the vitamin D receptor (VDR), that, in association with the activated form of the vitamin, stimulates the transcription of genes associated with calcium transport. The VDR gene is subject to mutation, like all other genes. These can affect function, but since there are two alleles for each gene, one inherited from each parent, even those carrying a mutated gene can usually maintain calcium homeostasis using half the complement of receptors. However, if both parents carry an allele for the mutation, their child may inherit two copies of the mutated VDR genes and vitamin D would not therefore stimulate the transcription of the calcium transport proteins. These children would develop a severe form of rickets that would be vitamin D resistant. This is a rare event. These children can be treated with calcium, but they have a requirement for vitamin D that can never be satisfied.

There is another genetic condition, vitamin D-dependent rickets, in which the affected gene is not the VDR but rather an enzyme required for the activation of vitamin D. The receptor is fully functional, but affected individuals are unable to metabolize vitamin D to its active form. In this case, treatment with vitamin D is possible, giving the active form of the vitamin rather than the precursor form normally found in food. Both kinds of rickets are rare but provide a clear example of the influence of genetic background on nutrient function.

A more common example may be found with folate. Folate deficiency in some prepregnant and pregnant women can result in an infant with a condition known as spina bifida. Hydrocephaly can also result. This is a neural tube defect in which the bony covering of the spinal column is incomplete. The defect occurs early in embryonic development when the cells are differentiating into specific cell types. Folate plays an important role in this

differentiation, and in some women (not all) an insufficient intake of folate just before pregnancy and in the early weeks of pregnancy can result in these neural tube defects. It was estimated that 2500 infants per year were born with this problem. As a prevention measure, foods are now fortified with the vitamin. However, many women with very low intakes of folate give birth to healthy infants. It appears likely that some women have an enhanced requirement for folate, and it is the infants of these women who are at risk. Although the specific gene mutations are not clear, a number of candidate genes involved in folate metabolism and transport have been identified.

Another example is hemochromatosis (HH). This is a disorder resulting from unregulated absorption of iron. Usually, iron absorption is downregulated when stores are adequate, but this does not occur with HH and toxic levels build up. The condition is caused by a mutation in the *HFE* gene. Although mutation of both alleles of the gene is rare, it has been estimated that 10% of some population groups may be heterozygous carriers. This is important because enhanced iron absorption is found in heterozygotes and results in liver disease, diabetes, and other chronic conditions. For many individuals and populations, a lack of dietary iron and its association with a host of iron deficiency disorders are concerns. However, individuals with HH need to limit iron intake; thus, information about genotype is clearly useful.

It is interesting to note that for some genes involved in nutrient function, no clinical syndromes linked to their mutation or deletion have been described. A possible explanation for this comes from experimental work with mice, in which gene function is typically investigated using gene deletion studies. MTF-1 is a transcription factor that regulates genes in response to zinc availability. Knock-out of the *MTF-1* gene is embryonically lethal (i.e., no offspring develop in the absence of this gene). Thus, mutations or deletions of genes that play a key role in embryonic development will not be seen in adults.

The examples given previously demonstrate a general principle that holds true for all nutrients: There is a variation in requirement that depends on genetic background. This may result from alterations in a single gene, but perhaps more likely it is due to the aggregate effect of differences in many genes that encode products relevant to that nutrient's function. As the human genome becomes better annotated and the significance of sequence differences better understood, it will be possible to make more precise recommendations for nutrient intakes for both individuals and populations.

Nutrient–Gene Interactions in Chronic Disease

A further refinement for recommended nutrient intakes is to include consideration of the relationship of one or more nutrients to the development of chronic disease. Many chronic diseases are the result of an interaction between the genetic heritage or genotype of the individual and the lifestyle choices that individual makes. Conditions such as heart disease, diabetes mellitus, and obesity are in this category. There are also a number of genetic conditions that can be managed by diet. One of the most common of these is lactose intolerance. Approximately 75–80% of the adult population in the world today is lactose intolerant. That is, they cannot consume quantities of milk and some milk products without experiencing gastrointestinal distress. **Table 2** lists some genetic disorders that are amenable to dietary management. There are also some relatively rare genetic diseases that affect genes involved in key nutritionally relevant biological processes. For example, mutations in the gene encoding the low-density lipoprotein receptor can impair the ability of the liver to clear cholesterol from the circulation. If cholesterol in the circulation cannot be removed by the liver, it can accumulate in the blood and perhaps lead to cardiovascular disease.

Many of the major chronic diseases (i.e., heart disease, cancer, stroke, diabetes, and obesity) have identifiable genetic linkages that are nutritionally responsive. That is, if an individual carries one or more gene messages that predispose that individual to one of these diseases, nutrient intake can affect the time course and appearance of the disease. For example, more than 150 mutations have been identified that associate with the development of

Table 2 Genetic disorders amenable to dietary management

Disorder	*Nutrition strategy*
Acrodermatitis enteropathica	Increase zinc intake
Fructosemia	Avoid fructose-containing foods
Galactosemia	Avoid lactose-containing foods
Hereditary hemochromatosis	Limit iron intake
Lactase deficiency	Avoid lactose-containing foods (milk and milk products)
Methylmalonuria	Vitamin B_{12} injections
Obesity (some forms)	Consume only enough energy to meet energy need; increase energy output (exercise)
Phenylketonuria	Control phenylalanine intake such that the need for this amino acid is met but that no surplus is consumed
Sucrase deficiency	Avoid sucrose-containing foods

diabetes. The phenotypic expression (the development of diabetes) of some of these genotypes can be influenced by diet. Numerous mutations, especially in the genes for the lipid-carrying proteins, have been identified as being associated with heart disease. These too may be nutrient responsive, but the details of this responsiveness are not known. Still other mutations have been found that associate with the development of obesity or with one or more of the diseases generically referred to as cancer. Again, the details of nutrient–gene expression in these diseases are lacking.

Although many genetic signatures have been associated with specific diseases, not all people who have these genetic characteristics develop the associated disease. This suggests that not only must one have the genetic characteristic but also one must provide the environment for the disease to flourish. An example of this was reported in the early 1960s. Newly arrived Yemenite Jews and Yemenite Jews who had resided in Israel for at least 20 years were compared with respect to diet, lifestyle, and the prevalence of type 2 diabetes. The newly arrived immigrants had very little diabetes, whereas the established Yemenite Jews had as much diabetes in their population as in the Israeli Jewish populations from other areas of the world. The diets and lifestyles of these population groups were compared to a matched group of Arabs living in the same locations in Israel. The diets were not greatly different among the groups, but the disease was far more prevalent in the Jews than in the Arabs. Studies of the diet consumed by the Jews in Yemen versus that in Israel revealed that there were very few differences with one exception: In Yemen very little refined carbohydrate was consumed. Sugar was not readily available, and what was available was very expensive. Once the Yemenites settled in Israel and adopted the Israeli diet with its abundance of refined carbohydrates, type 2 diabetes began to appear. It was suggested that the change in diabetes prevalence in the Yemenite group was due to an interaction between their genetic heritage and their increased consumption of refined carbohydrate. This report was the first to suggest such an interaction.

As mentioned previously, more than 150 mutations associate with diabetes mellitus, but the presence of one or more of these mutations does not necessarily mean that the person will become a diabetic. Diabetologists have acknowledged that there are far more people with a diabetes genotype than with a diabetes phenotype. That many of the diabetes phenotypes take so many years to develop suggests that given the appropriate lifestyle choices, the phenotype may never develop; however, it may develop very rapidly if poor lifestyle choices are made. In support of this argument, one has only to examine the numbers of new cases of diabetes in times of abundant food supplies and in times of food restriction. During World War II when food was rationed (as was gasoline for automobiles), people ate less and were more active. During this period, the number of new cases of type 2 diabetes declined. The number of new cases of type 1 diabetes (autoimmune diabetes or insulin-dependent diabetes) remained fairly constant. Because food was rationed and activity was increased, fewer people had excess fat stores, and this was probably a contributing factor to the decrease in diabetes development. When food became abundant after the war, food intake again was unrestricted, and over time the prevalence of both diabetes and obesity increased.

Some forms of diabetes and obesity share a genotype that phenotypes as obesity/diabetes, called 'diabesity.' As with the group of diseases called diabetes, obesity has a number of mutations that associate with it. The expression of these genotypes depends largely on whether sufficient food is available and consumed to make possible the phenotypic expression of the obesity genotype. Several of these mutations affect food intake regulation and thus energy balance. If the brain does not receive an appropriate appetite-suppressing signal, then excess energy is consumed, with the result of excess body fat stores. Excess fat stores, particularly in the adipocyte, interfere with the action of insulin in facilitating the entry of glucose into the fat cell. When this occurs, abnormal glucose metabolism (type 2 diabetes) develops. Individuals with excess fat stores can normalize their glucose metabolism if these stores are significantly reduced through food intake restriction and increased physical activity. However, not all instances of diabesity can be resolved in this way.

Technological developments have made it easier to routinely determine the presence of polymorphisms in genes associated with the development of diseases. Given the significance of cardiovascular disease and its association with lipoprotein metabolism, much effort has been focused on this area. Currently, dietary recommendations on fat intake are made for the whole population, but it appears reasonable to suppose that individual responses to a diet designed to lower plasma lipid concentrations will depend on genotype. Evidence for this comes from a G/A polymorphism in the promoter region of the gene encoding the ApoA1 lipoprotein, a major constituent of the high-density lipoprotein (HDL). The A polymorphism is less common and some studies have found an association with the possession of this form of the gene and higher HDL concentrations.

HDL is thought to be protective against heart disease. However, the association between the A polymorphism and elevated HDL is quite inconsistent. This is explained by considering diet. Women with the A polymorphism who consumed >6% of energy as polyunsaturated fatty acids (PUFA) had higher HDL cholesterol concentrations than women consuming <6% dietary PUFA. In women lacking this polymorphism, no such effect of diet was seen. Thus, although women with the A polymorphism would clearly benefit from the standard recommendation for increasing dietary PUFA, those who lack it may not, at least with respect to HDL.

The extent to which individual polymorphisms determine disease risk is likely to be limited. These chronic diseases are complex and outcome is likely to depend on polymorphisms in a number of genes and their interactions with dietary as well as other lifestyle factors. However, as technology improves and more polymorphisms are identified, an aggregate picture of risk will develop that will allow much more refined and specific dietary recommendations to be made. Knowing that these conditions are influenced by lifestyle choices, the identification of susceptible individuals should enable the design of effective strategies to delay disease development. It may not be possible to eliminate the problem, but it may be possible to appreciably delay its onset.

Nutrition Influences Mutation Risk

Although parents largely determine one's genotype, DNA is always subject to mutation. A few or many bases can be destroyed by free radicals, for example, leaving the cell unable to produce a given protein. In turn, this affects the function of the cell. It should be noted that a single affected cell does not represent a lethal event, except for that particular cell. It becomes a problem when many cells have their DNA damaged in the same way and the loss of cell function is significant. In most instances, DNA repair will occur so well that there is little noticeable effect of the initial insult. However, over time, mismatch repair or cumulative assaults on the DNA can have cumulative effects on DNA and cellular function. This cumulative effect of assault has been suggested to explain aging. Aging as a result of cumulative effects of free radical attack on DNA as well as on the vulnerable membranes within and around the cell has been used to explain the gradual loss in cellular function that occurs with age.

Nutrients that protect cells against free radical attack are additional examples of nutrient–gene interactions in health and disease. Such nutrients as vitamin E, ascorbic acid, carotene (vitamin A), selenium, and others serve to suppress free radical formation or to promote the synthesis of enzymes that function in the free radical suppression system. **Table 3** lists nutrients and their roles in free radical protection.

Table 3 Nutrients that have a role in free radical protection

Nutrient	*Role*
Vitamin E	Quenches free radicals as they form via the conversion of tocopherol to tocopheroxyl radical, which is then converted to a quinone
Vitamin K	Serves as a H^+/e^- donor/acceptor
Carotene	Serves as a H^+/e^- donor acceptor (precursor of vitamin A)
Ascorbic acid	Serves as a H^+/e^- donor acceptor; copper is used as well
Selenium	Incorporated as selenocysteine into glutathione peroxidase
Copper, zinc	Essential cofactors for cytosolic superoxide dismutase
Manganese	Essential cofactor for mitochondrial superoxide dismutase

Whereas the nucleus has a very efficient DNA repair process, the mitochondrion does not. However, there is only one nucleus in each cell, whereas there are many mitochondria in that same cell. If one or two are damaged, there are many in the cell to compensate. Disease develops only when damage occurs to a large majority of the mitochondria. A certain threshold of damage must be reached for such damage to have a physiological effect. Again, nutrients that function as free radical suppressants or that enhance the synthesis of enzymes of the free radical suppression system function to protect mitochondria from free radical damage. In the nucleus, the DNA is protected from free radical attack by histone and nonhistone proteins. Histones are highly basic proteins varying in molecular weight from ~11 000 to ~21 000. The histones keep the DNA in a very compact form. In contrast, the mitochondrial DNA does not have this protective histone coat. It is 'naked' and much more vulnerable to damage. In addition, ~90% of oxygen free radicals are generated in the mitochondria, providing the means for such damage should the enzyme superoxide dismutase, a manganese-dependent enzyme found in this compartment, not suppress these radicals. The damage can be quite severe, but because each mitochondrion contains 8–10 copies of its genome and there are many mitochondria in each cell (up to 2000), the effects of this damage may not be apparent. There is another superoxide dismutase found in the cytosol that has a similar function. It is a copper/zinc-dependent enzyme. Again, note the dependence of function on particular nutrients

(manganese, zinc, and copper) that in turn have effects on gene expression in health and disease.

Another way that changing DNA in a single cell can profoundly affect the health of the whole organism involves cancer. In this case, the DNA changes occur in particular genes related to the growth regulatory properties of the cell. Normal homeostatic mechanisms fail and the individual cell multiplies rapidly and therefore has a widespread influence. Nutrition interacts with cancer in a number of ways. It can promote or prevent the initiating mutation. It also will influence the progression of cancer by providing the nutrients required for its growth. The cancer often ultimately influences nutrition by limiting food intake. Another level of complexity is added with chemo- and radiotherapies and their interactions with nutrition.

Throughout this article, examples have been given that illustrate the interactions that occur between nutrients and genes. The ultimate goal of understanding such interactions is to use our knowledge to enhance the expression of genes that sustain good health while suppressing the expression of genes associated with disease. Although it is currently not possible to identify individuals with genetic dispositions to chronic diseases, there is no doubt that such screening tests will be developed and will be used as a basis for recommending nutrient (food) intakes. Optimizing health, after all, is the ultimate goal of good nutrition.

NUTRIENT REQUIREMENTS, INTERNATIONAL PERSPECTIVES

A A Yates, ENVIRON Health Sciences, Arlington, VA, USA

Determining human requirements for nutrients has been a major activity for nutritionists, biochemists, and physiologists for the past 100 years since the advent of methods that have allowed for their isolation, quantification in food, and determination of their function in cell and whole body metabolism. Whereas initial efforts focused on identifying constituents in food required to maintain life and promote growth and thus were considered essential or indispensable, research during the past 60 years has become increasingly focused on elucidating the

specific roles each nutrient plays in health and quantifying, through experimentation and study of healthy populations, the amounts needed on a daily basis to provide for optimal health and prevent disease. This process of estimating requirements for an individual with any level of precision is still in the early stages of development. Nevertheless, many facets of maintaining and improving the health of the public hinge on knowing how much is needed of which nutrients or chemical components of food, and how this differs at different stages of growth and development.

Multiple terms have been adopted to define nutrient requirements, allowances, or standards (**Table 1**). They have been established or adopted by various countries and then used for the major functions of planning food programs or assessing diets for adequacy or excess (**Figure 1**). Major efforts during the past two decades by nutrition scientists throughout the world have resulted in a shift from establishing and periodically revising nutrient allowances or recommendations based on general consensus of adequate levels (e.g., the Recommended Dietary Allowances (RDAs) of the Food and Nutrition Board in the United States, the Recommended Nutrient Intakes (RNIs) of Canada, or the Safe Levels of Intake derived by the expert groups convened by the World Health Organization and Food and Agriculture Organization of the United Nations) to more definitively anchoring the reference values to specific, well-described scientific studies so that when new information becomes available from research, it is clear that new evaluations need to be undertaken. For example, in the past, the RDAs in the United States have been used as the reference values in many situations, from setting the standards for nutrient content in programs that provide single meals, such as in school lunch programs, to the basis for government reimbursement for costs of care in skilled nursing homes (**Table 2**). It is not surprising that one reference value or number, even when adjusted for age or body size and based on scientific studies, is at times not appropriate for the situation in which it is used.

What Is a Nutrient?

The traditional approach to establishing the human essentiality of a nutrient is to show that it can be chemically isolated from foods and can improve or remove a deficiency sign resulting from its lack in the diet. The number of required nutrients defined in this way has increased over the years (**Table 3**).

During the past two decades, as a result of scientific inquiry and experimentation, the line between nutrients that might be considered essential versus nonessential has blurred. There are few new chemicals in foods or food components that, when identified, have been shown to cause severe dysfunction or death when removed from the diet in a similar manner to many of those listed in **Table 3**. However, many chemical constituents of food do contribute to health; current controversy focuses on whether such substances should be considered nutrients. The major difference with the use of modern scientific techniques is the ability now to detect finer gradations of inadequacy so that with some newer constituents the end result is not necessarily death or severe organ dysfunction but decline in health status or ability to function optimally. It could be said that there is merely a longer latency period than with typical nutrient deficiencies or excesses before the effect becomes manifest; such a situation may well characterize the typical diet-related chronic disease. An example of this is the role of vitamin E in decreasing onset of cardiovascular disease: Demonstrated to be effective in animal studies, large-scale studies in humans have so far not documented the expected positive effects on primary prevention of the specific chronic disease.

Groups throughout the world have come to define health as not just the absence of overt disease, such as nutrient deficiency diseases like pellagra (inadequate vitamin B_6) or goiter (inadequate iodine), but also a level of reserve to protect against stress, either environmental or self-induced, and preventive in nature rather than therapeutic. In 1946, the World Health Organization defined health as follows: "Health is a state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity."

Scientific Basis for Establishing Recommended Intakes

Since the initial development of quantitative recommended intakes of nutrients in the 1930s and 1940s, new approaches have provided a stronger science base to the reference values so established. Early development of recommended intakes usually involved convening a group of scientists who considered the available literature and, based on their expert judgment, developed quantitative estimates of requirements for specific subpopulation groups, including by age and gender. Newer statistically supported methods allow for a more science-based approach to such deliberations and consensus.

Table 1 Definitions of reference nutrient values used by selected countries and groups

AI: Adequate Intake

Canada and the United States (1997–present): A value based on experimentally derived intake levels or approximations of observed mean nutrient intakes by a group (or groups) of healthy people. The AI for children and adults is expected to meet or exceed the amount needed to maintain a defined nutrition state or criterion of adequacy in essentially all members of a specific apparently healthy population.

The Netherlands (2000–present): An amount of the nutrient that provides for the needs of almost all those in the group.

DRI: Dietary Reference Intake

United States and Canada: A set of nutrient-based reference values, each of which has special uses.

DRV: Dietary Reference Value

United Kingdom: A term used to cover LRNI, EAR, RNI, and safe intake.

EAR: Estimated Average Requirement

United Kingdom: The required intake of a group of people for energy, protein, a vitamin, or a mineral. About half will usually need more than the EAR and half less.

United States: The daily intake value that is estimated to meet the requirement, as defined by the specified indicator or criterion of adequacy, of half of the apparently healthy individuals in a life stage or gender group.

LRNI: Lower Reference Nutrient Intake

United Kingdom: An amount of the nutrient that is enough for only the few people in a group who have low needs.

RDNI: Recommended Daily Nutrient Intake

Nordic countries: The average nutrient intake that meets the requirement needs of 50% of a group. The remaining 50% of the group will have requirements above the RDNI.

RNI: Recommended Nutrient Intake (formerly in Canada); Reference Nutrient Intake (United Kingdom)

Canada (prior to 1997): The recommended intakes of essential nutrients.

United Kingdom: An amount of the nutrient that is enough, or more than enough, for about 97% of people in a group. If average intake of a group is at the RNI, then the risk of deficiency in the group is small.

PRI: Population Reference Intake

Belgium and European Community: The intake that is enough for virtually all healthy people within a group.

RDA: Recommended Dietary Allowance

United States (prior to 1997): The intake that meets the nutrient needs of 97 to 98% of a group.

Canada and the United States (1997–present): The average daily dietary intake level that is sufficient to meet the nutrient requirements of nearly all (97–98%) healthy individuals in a particular life stage and gender group.

The Netherlands (since 2000): The mean requirement plus twice the standard deviation of the requirement (defined as the smallest intake of a nutrient that both prevents symptoms of deficiency and at which, at the same time, the risk of chronic diseases—to the extent that this is influenced by the nutrient concerned—is minimal, and is thus sufficient for almost all people in a group).

SUL: Safe Upper Level

United Kingdom: An intake level that can be consumed daily over a lifetime without significant risk to health on the basis of available evidence.

UL: Tolerable Upper Intake Level

Canada and the United States (1997–present): Highest level of daily nutrient intake that is likely to pose no risk of adverse health effects for almost all apparently healthy individuals in the specified life stage group. As intake increases above the UL, the potential risk of adverse effects may increase.

European Community (2000–present): The maximum level of total chronic intake of a nutrient (from all sources) judged to be unlikely to pose a risk of adverse health effects to humans.

The Netherlands (2000–present): Intake level above which there is a risk of adverse effects.

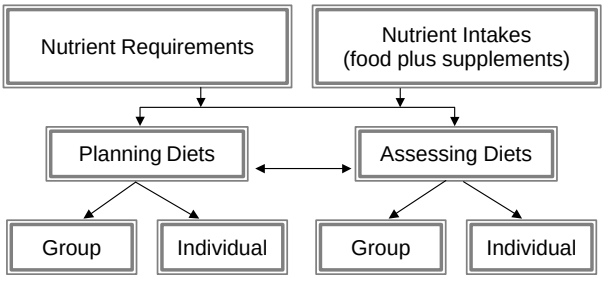

Figure 1 Uses of reference intakes in planning and assessing diets.

Table 2 Pre-1997 uses of RDAs in the United States

Planning for feeding groups of healthy people (school lunch, elderly feeding programs)
Nutrient goals for healthy individuals
Basics for foods provided in supplemental feeding programs (e.g., WIC)
Procurement of and purchasing food supplies for groups of healthy people
Reference point for evaluating the dietary intake of population subgroups
Nutrient intake targets in intervention programs
Basis of food groups in food and nutrition education programs
Reference point for the nutrition labeling of food and dietary supplements
Basis for fortification of food products
Basis for formulating dietary supplements and special dietary foods
Standards for menu planning for hospitals, correctional facilities, military operations, and other institutional feeding settings

A number of factors must be present before quantitative requirements for nutrients can be made most useful to those who use such estimates for program planning and evaluation:

- There must be some understanding of the chemical. For example, in early work on vitamins, an isolated fraction of cod liver oil was determined to be required for normal eye growth and bone development and was named 'vitamin A.' Subsequent isolation and characterization allowed the isolated mixture to be further separated into what was called the fat-soluble factor for bone growth compared to another required for sight. Thus, vitamin A was differentiated from vitamin D in the lipid-soluble fraction.
- There must be data on how much is present in the diet. In order to obtain these data, the content of the nutrient or food component in multiple typical foods must be analyzed, which thus allows the data to be used to estimate intake or exposure.
- There should be some idea of intake among the population groups of interest. Studies in which known amounts of a nutrient are consumed at varying levels and evidence of inadequacy detected should be conducted. This is typically done first with animal models, followed by human clinical trials or metabolic studies, which include at least one level of intake at which effects of inadequacy are observed and can be linked directly to the nutrient under study. Frequently, it is not possible to remove or add some nutrients to a diet without altering the content of other nutrients; this is particularly true for energy-yielding nutrients, such as omega-3 fatty acids, or substances such as fiber. This makes the interpretation of the resulting data less clear.

Adequate for What?

Usually, once these data are known or have been estimated, it becomes possible to establish an intake recommendation, initially based on observations of

how much appears to prevent the deficiency and how much is in the diet of those not demonstrating the symptoms or signs (indicators) of inadequacy. Many of the earlier recommended intakes were established on this basis, which is why, in many cases, the values may vary greatly across expert groups and countries. As additional data derived from experiments, observations of intake, and consequences of inadequacy of a nutrient in the diet are generated, there is a need for periodic updates of nutrient requirements and recommended intakes (**Table 4**). Changing recommendations may result in the need to make changes in programs and activities, such as food labeling, and thus frequently represent new costs. Of great importance from a scientific perspective is an overt statement of the goal of the derived reference value: Will the reference value provide guidance for minimizing overt deficiencies, usually by providing enough to prevent a known deficiency sign or symptom, or is it set at a dietary level required to maintain a blood concentration or function that might represent storage or a reserve and thus be available in times of stress?

For example, the prevention of scorbutic gums, one of the signs of overt vitamin C deficiency, requires far less vitamin C on a daily basis than the amount needed to maintain 70% saturation of white blood cell ascorbate (vitamin C) levels to counteract potential oxidative stress and damage at the cellular level. Generally, for a nutrient there exists a growing list of possible indicators or outcomes that could be used to estimate requirements (**Table 5**), and for each, a different amount may be needed daily for the specific indicator to meet the body's need and thus demonstrate adequacy.

There is usually a continuum of benefits that occur as the level of intake increases. It becomes very important to define what the criterion(ia) is that has been used to establish the quantitative level of intake recommended. **Figure 2** shows data relating iron intake to three possible criteria or indicators that could be used to determine adequate intakes for women in a national survey in The Netherlands and analyzed by George Beaton. The data show that as the level of iron intake decreases, the number of individuals (or percentage of the population group of women in this age group) who would have their needs met as documented by a given indicator of adequacy decreases. Thus, if prevention of anemia is used as the criterion (in this case, hemoglobin value <110 g/l), an individual whose intake averaged 6 mg/day would have a 40% probability that she would be inadequate (i.e., her hemoglobin value would be below the cutoff). However, if a biochemical marker of function of iron (e.g., total iron binding capacity) were used, the level of intake needed for a 40% probability of being inadequate using that criterion would be approximately 9 mg/day. Finally, if the goal were to maintain a level of storage, such as ferritin concentration, the dietary level would need to approximate 18 or 19 mg/day. Thus, when comparing recommended

intakes, it is critical to know specifically the criterion or criteria used in setting the recommended intake and evaluating adequacy.

Role of Estimates of Average (Median) Requirements

For many of the uses given for reference values, it becomes important statistically to not depend on an allowance that would cover the needs of everyone and thus might include a safety factor added to some adequate level of intake but, rather, to apply estimates of the average requirement for the group of interest. For most nutrients, with iron a notable exception, it can be assumed that nutrient requirements are symmetrically distributed in a population of similar people (**Figure 3**), which means that some will have higher requirements than other similar individuals due to genetics and other factors, and that a median requirement intake level can be determined, such that consumption of a nutrient at that level would be adequate for half of the individuals in the group but inadequate for the other half. If this

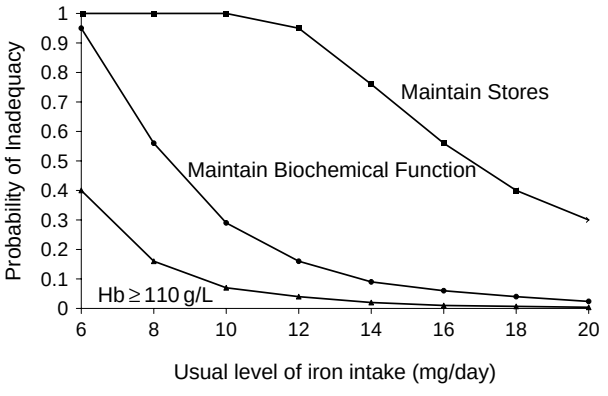

Figure 2 Probability that specified usual iron intake would be inadequate to meet the needs of a randomly selected menstruating woman. (Used with permission, G. Beaton, 1994)

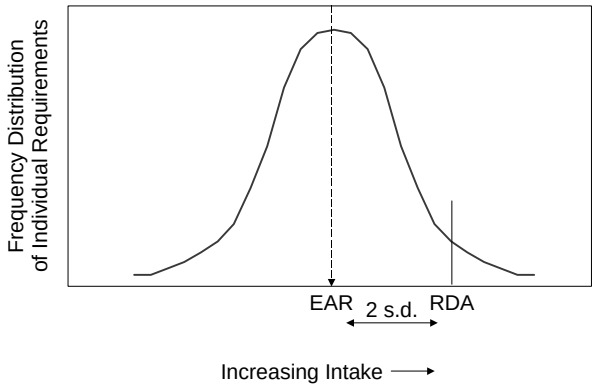

Figure 3 Probability distribution of individual nutrient requirements.

distribution of requirements is symmetrical, then the median and the mean requirement are the same.

Why have an Estimated Average Requirement? There are two main reasons to have an Estimated Average Requirement (EAR): to use as the basis for establishing the recommended intake for an individual and to assess the adequacy of intakes of similar population groups. The concept of establishing an average requirement, and assuming that the requirements of individuals in a population of similar people are symmetrically (or normally) distributed, is not new. Conceptually, it has served as the ideal basis for recommended intakes during the past few decades. However, it was rigorously used on only rare occasions. The RDA has been conceptually defined in the United States during the past few decades as the lowest amount of a nutrient that, in the judgment of the Food and Nutrition Board, meets the known nutritional needs of almost all of the population (subgroup), and it was also more mathematically defined as the mean requirement plus two standard deviations (SD), which would equal an amount required by 97 or 98% of the population to whom it is applied.

The Dietary Reference Intake (DRI) process—a joint effort of the United States and Canada—retained the term RDA, limiting its use to serving as the goal for intake when planning diets for individuals and standardizing the method by which it is established. It is defined as follows: $RDA = EAR + 2SD_{EAR}$. When data on variation in requirements of a specific nutrient are lacking, it is assumed that the standard deviation (variation) in requirements is approximately 10%. This variation in requirements is derived from the variation seen in basal metabolic rate in individuals and the variation seen in protein requirements, with protein being the nutrient whose variability has been most studied.

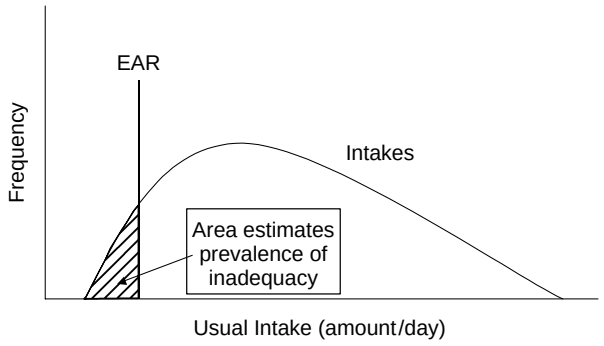

Figure 4 Using the EAR to estimate the prevalence of inadequacy in a population from the distribution of nutrient intakes.

It has been demonstrated statistically that the prevalence of inadequacy in a population whose requirements are symmetrically distributed can be estimated by comparing its intake to the EAR for that nutrient in the same (or a similar) population (**Figure 4**). Thus, in the DRI process, when evaluating vitamin C requirements, experimental data from a clinical study indicated that the average intake for men needed to achieve 70% white blood cell ascorbate saturation (the chosen indicator) was ~75 mg/day, and the EAR was set at 75 mg/day. This is a value that can be applied to the intakes of other similar populations of men who have similar characteristics to determine the percentage of the population who may be inadequate based on this criterion of adequacy (**Figure 5**).

To use this method to assess adequacy of population groups, there are other basic statistical assumptions that should be met. First, an individual's requirement for a nutrient must be statistically independent of the intake for that nutrient (this does not hold for nutrients such as total energy or water—people eat or drink because they know they need energy or water). Second, the amount of variation (the distribution) in the nutrient intake levels in the population group must be greater than the variation in the group of the requirements for the nutrient (this is almost always the case, except when everyone in the group consumes the same food in the same amounts—thus, there is little variability in intake). If these two assumptions are met, along with the symmetry mentioned previously, then the EAR can be used as the cut point for adequacy in other similar populations (as shown in **Figure 4**). This is called the EAR cut point method.

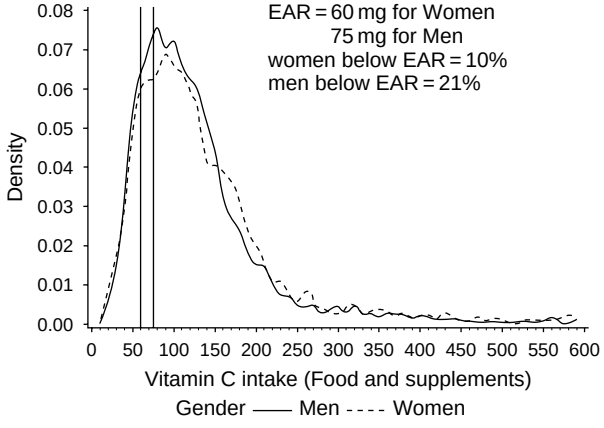

Figure 5 Vitamin C intake data from NHANES III for men and women; using the EAR to determine the expected prevalence of inadequacy.

Because the RDA has been misused as a tool to assess adequacy of intakes of groups in the past by policymakers and scientists alike, it has been argued by some that it is better for scientific panels of experts not to provide, in addition to EARs, any recommended intakes since their only use is to provide guidance to the individual, and health professionals can easily develop recommended intakes from reference values that are average requirements. However, the concept of RDAs in the United States and RNIs in Canada has been accepted in the general population to the extent that to not provide RDAs (and, as an extension, recommended intakes such as Adequate Intakes (AIs) where data are lacking) would result in more misguided actions than would result from providing them along with instructions for their specific and only use: to plan diets for the individual.

Adequate Intake: Used when an EAR cannot be determined Whereas for many nutrients enough data exist to be able to establish levels of nutrient intake at which half of the individuals in a group would be inadequate based on the criterion chosen, for some nutrients the necessary data may be conflicting or lacking. In order to give some guidance to users of nutrient reference values, it is still necessary to provide quantitative numbers. To further differentiate the appropriate uses of the RDA, the DRI framework provides an additional category of a recommended intake for use with individuals to plan diets—termed the AI. This is a level that is considered adequate for all members of the group and thus may overestimate the needs of many, if not all. Statistically, it cannot be used as if it were an EAR to assess adequacy. It does, however, provide guidance for how much an individual should consume. In some cases, it is derived from the average intake of a population in which inadequacy appears to be nonexistent based on review of available indicators or criteria (such as is the case for vitamin K).

Reference Values: Which to Use and When

As mentioned previously, there are two main uses of reference values: to assess diets for adequacy or excess and to plan diets (**Figure 1**). Although these may seem to be the same, in many ways the best reference values to use in these situations may be quite different from each other on a quantitative basis. In addition, each of these major functions is frequently applied in two different situations: to a group's intake (i.e., the intake of a population or subpopulation) or to an individual's intake.

Using DRIs to plan diets If the goal is to plan a diet or menu for a specific group so that the nutrient intake of all but a small number (e.g., 2 or 3%) in the group will have their needs met, it is not necessary for each person to consume at least the RDA; this actually overstates the need of almost all individuals. It is only necessary that the nutrient be consumed such that the intake of only 2 or 3% would be below the EAR. Thus, the goal would be to have a very low percentage of intakes below the EAR (**Figure 4**).

On the other hand, if one is planning a diet for the individual, and there is little knowledge about the individual other than his or her gender and age, then one would want to provide what is thought to be adequate for almost everyone in the group, which is the RDA—by definition set at 2 SD above the median or average requirement (EAR)—or the AI.

Using DRIs to assess diets Frequently, such as when considering whether to fortify the food supply with a specific nutrient or when evaluating the nutritional status of a subgroup in the population, it is necessary to assess the diets of groups through surveys of food intake and from such surveys determine which nutrients may be consumed at inadequate levels. If data on intakes for the group of interest are available, and the group possesses similar characteristics to the individuals studied when deriving the EARs, it is possible to estimate the prevalence of inadequacy in the group of interest from their intake data without information on their requirements or variation in intake.

This is a key reason for establishing EARs for nutrients, and it replaces the questionable past practice of comparing intakes to the RDA. Frequently when this was done, a group might appear to be at low risk of inadequacy because the mean intake of the group as a whole for a nutrient might be at or above the RDA, despite a sizable portion of the group being below their individual requirements, if they had been determined (**Figure 6**).

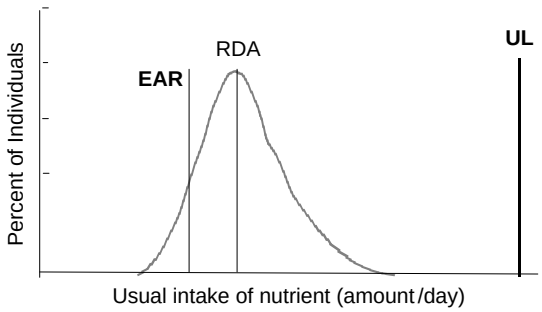

Figure 6 Example of assuming that when the mean intake of a population group is equal to the RDA, there will be a low prevalence of inadequacy. As shown, there may still be a substantial proportion of the population with intakes below the EAR, which would be a better estimate of the prevalence of inadequacy.

Whether this occurred or not would depend on whether the RDA was based on the mean intake of a population in which no one was inadequate or whether the RDA came from data for which some members of the population had inadequate intakes and thus demonstrated one or more possible criteria of inadequacy, which are usually not possible to determine. By using the EAR as the cutoff to determine the prevalence of inadequacy (this applies to those nutrients for which requirements are symmetrically or normally distributed), it is possible to set an acceptable level of inadequacy in situations of scarce resources in which it is not possible to assume that all have an adequate intake.

DRIs for Other Nutrients and Food Constituents

As indicated previously, assumptions regarding variability and independence are involved in using EARs to estimate adequacy and to plan diets. When these cannot be followed, the Food and Nutrition Board's DRI framework included other categories of reference values to provide guidance for program planning and nutrition policy: the AI, including the Estimated Energy Requirement (EER) and the Acceptable Macronutrient Distribution Range (AMDR). In the United Kingdom, population averages along with minima and maxima for some energy-yielding nutrients have been established.

The EERs for use in the United States and Canada are derived from regression equations for adults and for children based on pooled data obtained from a group of international investigators. They represent the first time that energy recommendations have been based on quantitative estimates of energy expenditure (made by the technique of measuring doubly labeled water metabolism) directly in individuals over 2 or 3 weeks for a

large number of people rather than estimating the amount of time spent in various energy-requiring activities over a 24-h period and then multiplying each type of activity by indirect estimates of energy expended.

Reference values for macronutrients such as starch, fiber, and other carbohydrates, various fatty acids, and other lipids such as cholesterol are primarily related to the role that each macronutrient plays in chronic disease development and risk factor reduction. As such, the data that support such reference values are usually less definitive, and definitely more complex, than those for single nutrients that can be easily isolated and manipulated in the diet. This additional set of reference values is given as ranges to provide guidance to federal agencies and others related to nutrient intakes. The ability to identify and quantitate the relationship of accepted risk factors for diseases is also important in reviewing literature to develop macronutrient ranges compatible with low risk of disease and maintenance of health.

Finally, physical activity has been included in the recent DRI series to highlight the very important role it plays in decreasing risk of chronic disease in terms of both maintaining sufficient energy expenditure to allow for maintenance of body weight and maintaining cardiovascular fitness to decrease the risk of heart disease.

Application of Risk Assessment Methodology to Nutrients

One of the many needs for reference values is to provide guidance about when intake of a nutrient may be too much, where the level of intake has the potential for an increased risk through excess consumption. In the past, this was rarely a concern because it was difficult to consume, on a chronic basis, large enough amounts of a specific nutrient from foods to result in serious adverse effects.

Most adverse effects of overconsumption are self-limiting because they usually involve gastrointestinal disturbances (as is the case for dietary fiber) or involve objectionable and readily reversible effects (e.g., turning orange when consuming very high amounts of carotenoids from carotene-rich foods). However, instances of serious adverse effects have been reported in the past few decades due to over-ingestion of isolated nutrients or food constituents, typically in pill form and given in therapeutic doses, or through mistakes in fortification and enrichment of the food supply, but rarely from overconsumption of foods in their natural state.

Recent increases in demand for nutrients as a result of consumer interest in self-management of health, and provocative findings relating specific dietary constituents to possible health benefits, have provided incentives for industry to increase the availability and use of nutrients and food components in dietary supplements and for the voluntary fortification of foods. Thus, the need for science-based reviews of data on the potential for increased risk of serious adverse effects that may result from chronic consumption of individual nutrients in higher amounts than typically encountered with foods has grown in importance. Such reviews have been conducted by Canadian and US scientists through the Food and Nutrition Board, by the United Kingdom's Expert Group on Vitamins and Minerals, and by the Scientific Committee on Food of the European Commission, among others. Each has worked on developing approaches to evaluating reports of adverse effects and establishing, if possible, upper levels of intake for which little concern about risks of serious adverse effects may be expected. Although somewhat differing in the review of specific studies and in defining what might be considered serious, these efforts are all aimed at incorporating the basic components of toxicological risk assessment (**Figure 7**) in the review of nutrients, primarily from a qualitative perspective and on an individual (nutrient-by-nutrient) basis. In all cases, attempts are made to quantitate no-observed-adverse-effect levels as well as lowest-observed-adverse-effect levels of exposure and then divide by an uncertainty factor to obtain the upper reference level or limit (**Figure 8**).

Issues in Establishing Reference Intakes

Extrapolating Data to Other Life-Stage and Gender Groups

Invariably, there is not enough information on studied populations to establish reference values directly for each subgroup. Knowledge of nutritional needs as well as response to higher levels of intake and exposure for such groups, such as during pregnancy or preadolescence, would be very useful. In order to provide adequate guidance when data are lacking, reference intakes are routinely provided by extrapolating the available primary data to these important age or life-stage groups from those subgroups for whom data are available. Consensus on the best methods to use for extrapolation when data are lacking, with modeling and consideration of more sophisticated approaches than just body size or caloric expenditure, is needed to enhance the utility of the derived reference values.

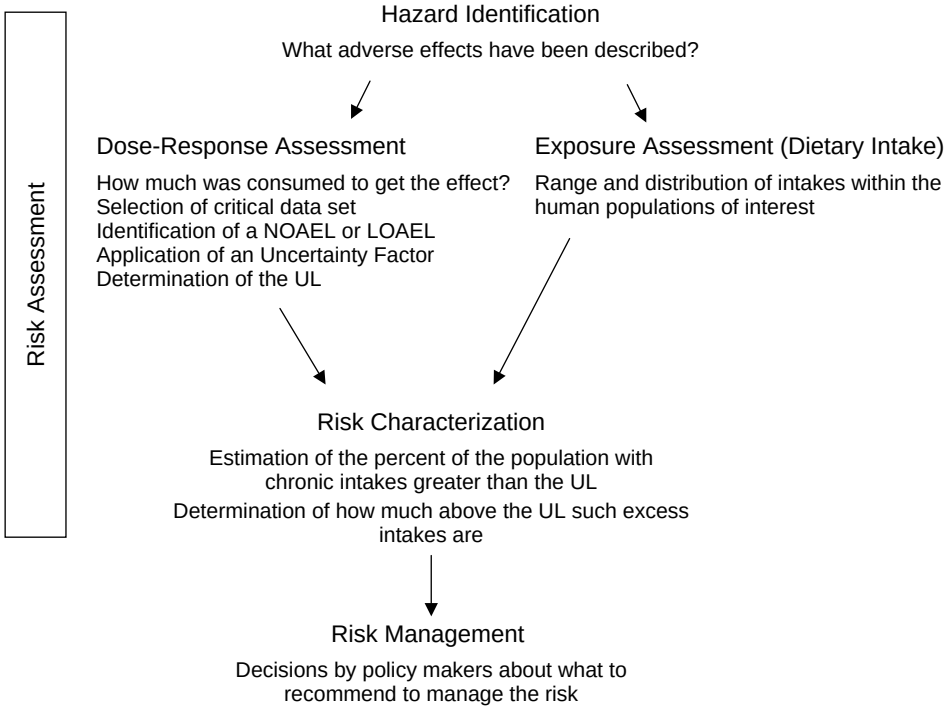

Figure 7 Steps in a model of risk assessment for nutrients.

Role of Nutrient Intake Surveys and Food Composition Databases

Surveys such as the National Health and Nutrition Examination Surveys and the What We Eat in America Survey in the United States, the Dutch National Food Consumption Survey in The Netherlands, and the National Diet and Nutrition Surveys in the United Kingdom serve as the underpinning for tracking changes in consumption and eating behavior of specific vulnerable population groups, such as young children or the elderly, in order to evaluate the potential for targeted intervention programs, either through programs aimed at changing eating behavior (e.g., the 5 A Day Program to enhance fruit and vegetable consumption in the United States) or through fortification of specific foods (e.g., calcium with bread in Canada) or changes in food product formulation (e.g., decreasing *trans* fat in high-fat processed foods). The absence of surveys that link intake with health or quantifiable and validated disease indicators makes it almost impossible to determine risk of inadequacy as well as risk of excess, particularly in vulnerable groups, without very expensive laboratory tests and clinical observation.

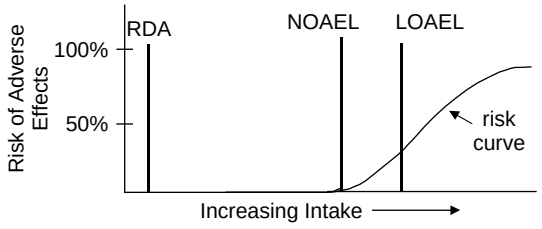

Figure 8 Identifying the hazard: dose–response.

Lack of data or nutrient content in a variety of foodstuffs, as well as lack of valid intake data, decreases the utility of subsequent estimates of inadequacy or exposure. An issue that continues to hamper reliable estimates of intake is selective underreporting and overreporting of intakes of specific foods or portion sizes by responders in surveys, usually related to foods known to be associated with causation of disease in the first case (underreporting) or considered more healthy in the second (overreporting). Although conducting large-scale surveys is costly and highly labor-intensive, poor collection of intake data and lack of replicate food composition information available to estimate intakes continue to hamper attempts to improve accuracy of the estimates. Much work is currently under way to increase the ability for such surveys to estimate intakes.

Approaches to Evaluating Bioactive Food Components

As new technologies, such as metabolomics, develop that allow better understanding of cell

metabolism and interaction among nutrients within cell systems, food constituents that have previously gone unnoticed are gaining recognition for their potential roles in maintaining health and decreasing risk of chronic disease. Some food components appear to work in concert with other nutrients and chemicals and are highly active at nanogram concentration levels in cellular systems involved in decreasing inflammatory responses or cell death. These bioactive substances may be difficult to analyze in food stuffs when they rapidly convert or oxidize into other less active compounds, making traditional methods of determining potential roles in health very difficult to apply. However, such new technologies offer the opportunity to study not pathways but, integrated circuits of multiple systems and bioactive food components simultaneously, modeling from multiple perspectives rather than the typical linear relationships diagrammed in the metabolic pathways identified by the mid-twentieth century. Using these tools, the integrated nature and role of known and unknown chemical constituents of foods will form the basis for evaluating human nutritional requirements in the future.

Steps Toward International Consensus

An issue that is obvious in any consideration of how best to approach estimating human requirements is the need to achieve consensus on the best science-based approaches to determine them. Internationally, the diversity of requirement estimates might mislead one to assume there was significant variability in nutrient needs based on geographic location or genetic makeup. As more information regarding the role that genetic factors play in disease becomes available, the variability seen in actual requirements will diminish. There will continue to be a need to recognize and use information about nutrient bioavailability, which may well be different for diets based on different foods and staples and thus require different reference values for such varied situations, but human physiology is remarkably similar.

Harmonizing approaches to reviewing data and achieving consensus among scientists is an important first step to deriving truly borderless reference values that represent differences that are physiologically and genotypically related rather than culturally related.

Efforts to harmonize are ongoing in a number of settings. Germanic language countries now have joint reference values; Australia and New Zealand are working on joint reference intakes, as are nutritionists in Southeast Asia; countries in the European Union have plans for increasing such joint deliberations beyond the activities involved in developing upper levels; and the United Nations, through the coordinating efforts of the United Nations University, is initiating extragovernmental discussion of basic issues involved in evaluating the human data that serve as the basis for establishing requirements and reference values. All these activities are in the beginning stages. With the enhanced level of communication due to computers and the Internet, such efforts are feasible as well as critical to undertake.

NUTRITION POLICIES IN DEVELOPING AND DEVELOPED COUNTRIES

C Geissler, Kings College London, London, UK

This article reviews the definition of nutrition policy and aspects specific to developing and developed countries; components of typical policies; government structures for their formulation and implementation; the types of programs used to implement policy; historical trends of emphasis; the international promotion of nutrition policies; constraints imposed by major development organisations; the effectiveness and characteristics of successful policies and programs; and emerging issues.

What Is a Nutrition Policy?

Nutrition is the process whereby living organisms use food for maintenance of life, growth, the normal functioning of organs and tissues, and the production of energy. Human nutrition therefore encompasses food composition, food consumption, food habits, the nutritive value of foods, nutritional requirements, the relationship between diet and health, and research in all these fields. Diet in this context means the total solid and liquid foods consumed by an individual or a population group. Nutrition is therefore at the center of a web of a number of disciplines and so policy affecting nutrition involves many government sectors.

In the process of national policy formulation, various ministries and departments of the government (sectors) prepare programs for implementation during a specific plan period. Those aspects of the national policy that are specifically designed to improve the state of nutrition in a country are together defined as 'nutrition policy' or 'food and nutrition policy.'

In developing countries, national policies are published for each sector in periodic national development plans, usually every 5 years. In developed countries, they are formulated at irregular intervals within the term of office of the elected government. Nutrition does not usually constitute a separate sector and so aspects of nutrition policy appear under the policies of specific sectors, such as agricultural, food, health, education, and social welfare. These aspects are by no means comprehensive and during the stage of implementation are generally not coordinated through any official mechanism.

Policy Differences in Developing Countries

Nutrition policy preparation and implementation in developing countries differs from that in developed countries in two main aspects, as discussed in the following sections.

Types of Nutrition Problems Addressed

In developing countries, these are mainly undernutrition, labeled as protein energy malnutrition, and specific deficiency conditions, most commonly vitamin A, anemia, and goiter. Although the so-called 'diseases of affluence' often affect the richer urban sections of the population, they have not been policy priorities, but they have recently become so in some Asian and Latin American and other developing countries. However, countries such as China that are in nutritional transition between the predominance of diseases of poverty and of affluence have to consider how to reduce remaining nutritional deficiencies but avoid the nutrition-related problems afflicting developed countries. In developed countries, chronic diseases related to poor nutrition, such as obesity, coronary heart disease, diabetes, and osteoporosis (sometimes referred to as 'overnutrition'), are the main problems addressed because most micronutrient deficiencies have been contained, although anemia remains prevalent, as does goitre in some areas, and pockets of undernutrition also exist in developed countries.

Influence of External Aid Agencies

In many developing countries, governments are assisted in the formulation of nutrition policies by agencies such as the World Bank, the United Nations Children's Fund (UNICEF), the World Health Organisation (WHO), and the United Nations Food and Agricultural Organisation (FAO), and specific projects are often resourced by external funding, technical assistance, and food aid.

National Nutrition Policies and Government Structures

Since the 1970s, nutrition has been recognized as an important objective of national development and an indicator of such development. In developing countries, this objective determines the goals that form the major ingredients of a national nutrition policy. In both developed and developing countries, a typical policy would aim to ensure a biologically safe and physically clean food supply sufficient to amply meet people's physiological, social, and cultural requirements of a variety of foodstuffs at commonly affordable prices. The specific programs to implement such policies usually include a mixture of analyses of the situation and individual interventions of the types outlined in the following section. Analyses for the purpose of monitoring the nutritional situation and providing public information and recommendations may include the periodic assessment of consumption patterns and energy and nutrient intakes, the identification of populations at risk of deprivation and excessive or imbalanced food consumption through specific studies and surveys, analyzing and composing dietary patterns in terms of food groups and nutrients, and defining minimum and desirable standards of the requirement of food energy and nutrients for various age groups and specific groups of the population with special needs.

Because nutrition is generally not a sector *per se*, it usually does not have a direct budget and in many countries the ministry of health is charged with improving the state of nutrition of the people, whereas aspects of food come under the ministry of agriculture. In most developing countries, implementation of the nutrition policy is carried out by these ministries or a ministry of planning through autonomous or semiautonomous councils, commissions, or committees, which may or may not be intersectoral in their compositions. These may report to the relevant ministry, cabinet, or, rarely, directly to the president. In some countries, nutrition units also exist in the provinces to provide regional planning information and actions. Some nutrition planning bodies receive advice from ad hoc technical committees as needs arise. The weakness or strength of such bodies can be judged from the change in nutritional status of the people since their establishment.

In developed countries, the ministries or departments of health and agriculture also share the main responsibility for nutrition. However, there is often conflict between the interests of producers and consumers within ministries of agriculture. Many of the nutrition and health policies in both types of countries incorporate aspects such as education and modifying activity levels, and so other ministries become involved to provide the facilities for these.

Types of Programs and Interventions

The types of interventions that form part of national nutrition policies in both developing and developed countries tend to be limited to palliative measures such as vitamin supplementation, nutrition education, and child feeding programs because many of the underlying factors that lead to malnutrition, such as unemployment, low wages, and land tenure arrangements, involve fundamental economic and political interests that are much more difficult and contentious to address. In developed countries, which are by definition richer, the governments generally provide economic safety nets for the unemployed, disabled, and other disadvantaged sections of the population. These people have to be cared for by extended family or other means in developing countries. The pattern of programs is therefore different between developed and developing countries because of differences in the nutritional problems and the wealth of the population and government. However, the types of programs are similar. The types of interventions that affect nutrition can be divided into general categories summarized in **Table 1**.

Historical Trends

There have been changes in emphasis in the type of programs advocated throughout the decades to improve nutrition as knowledge of nutrition has grown and as governments and development agencies have experienced success or failure in various approaches.

During World War II and the postwar period of the 1940s, the emphasis in developed countries was on institutional feeding, such as school meals, school milk, and the distribution of concentrated vitamin sources to children and mothers. These approaches were continued in developing countries by international agencies, such as FAO and WHO, after their establishment postwar.

As decolonization progressed, a growing interest in the process of economic development and nutrition led to the recognition that individual interventions had little impact on malnutrition and that a more integrated approach was needed to improve the use of available resources. In the 1950s, the international agencies therefore promoted 'applied nutrition programs,' which are village-based

Table 1 Types of nutrition programs

Explicitly nutritional
Programs directly related to food, including those aiming to improve food availability, accessibility, quality, safety, consumption, and knowledge.
Nutrition-oriented food policies
Agricultural production, kitchen gardens, marketing, storage, processing, safety
Food price and distribution control, food price subsidies, taxation, food stamps, rationing
Feeding programs
Mother and child: nutrition rehabilitation centres; on site, take home
Schools: lunch, breakfast, snack, milk
Workers: canteens, Food for Work
Elderly: community center; Meals on Wheels
Weaning foods
Formulated, fermented, amylase rich
Fortification, supplementation
Iron, B vitamins, iodine, vitamin A, iron, vitamin D, vitamin C, amino acids
Nutrition education
Implicitly nutritional
Programs with indirect nutritional impact through improvement of effective food demand, food utilization, and energy balance
Health
Primary health care: immunization, antiparasites, rehydration, basic medicines, prenatal care, health education, first aid
Sanitation: water supply, water treatment, water storage, waste disposal, drainage and spraying, hygiene education
Economic
Income generation
Income maintenance: welfare benefits, unemployment benefits, child allowances, etc.
Income substitution by subsidized basic needs
Activity moderation
Cereal mills, water storage and transport, child care crèches
Sports facilities, cycle paths, etc.
Integrated
Combining explicit and implicit nutritional interventions; For example, targeted 'applied nutrition programs', and 'community development programs'

programmes with components addressing several of the multiple factors of malnutrition, such as income generation activities, horticulture, health care, and nutrition education.

During the 1960s, attention focused on the world food supply and concern that the population could outstrip production. Thus, food and nutrition programs were centered around the production and dissemination of high-yielding varieties of cereals, wheat, rice, and maize—the 'green revolution' package. In the same decade, the idea developed that a specific 'protein gap' existed between the amount of protein available in national food supplies and population needs. A second focus was therefore on means to increase the production and consumption of protein from a variety of novel sources. During this same period, in the United States awareness increased that pockets of food poverty still existed in this affluent country. The resulting concern about 'Hunger in America' led to new welfare programs, such as the Women, Infants, and Children program.

By the 1970s, after 25 years of experience in nutrition interventions within economic development strategies in developing countries, it was recognized that increased national wealth did not always result in improved welfare and nutrition as predicted by the 'trickle-down' theory of development. Nutrition was therefore proposed as a specific goal for national development because a better nourished population would achieve more effective development. Government nutrition policy should be integrated and coordinated by a nutrition planning unit in an umbrella organization such as a ministry of planning or a prime minister's office so that the underlying causes would be simultaneously addressed by the appropriate government sector. This approach was fostered by development agencies such as FAO and the US Agency for International Development and was adopted by several countries, particularly after it was endorsed at the World Food Conference in 1974.

In developed countries, an increased interest in nutrition policy emerged as it was realized that existing legislation, based on food purity and the prevention of adulteration, and also the control of deficiencies, was not adequate to deal with the changing nature of nutrition problems of chronic nutrition-related diseases. Several government

advisory, professional, and consumer bodies in the United States, United Kingdom, and other countries recommended appropriate dietary goals with the common theme of reducing fat, sugar, and salt intake and increasing the intake of dietary fiber, fruit, and vegetables. The recommendation to reduce the intake of certain nutrients appeared to be a threat to some sectors of the food industry, resulting in considerable opposition to the recommendation and arguments about the validity of the evidence on which the recommendation was based. Other constraints to updating food and nutrition policy included legislation designed to prevent adulteration and maintain quality as previously perceived, such as minimum fat levels in milk and premiums on animals with high fat content. However, the proposals were gradually accepted and incorporated into government policies, while industry recognized new opportunities in the production of high-fiber, low-fat, low-salt and -sugar food products. Norway was the first developed country to have an integrated food and nutrition policy in 1975. Other developed countries subsequently formulated food and nutrition policies within their health and agriculture sectors.

By the 1980s, attempts in developing countries to apply the rational procedures advocated by the national nutrition planning approach for the selection of appropriate interventions had demonstrated the paucity of data on which to decide nutritional priorities and the effectiveness of various interventions, the difficulties of placing a policy priority on nutrition, and the problems of effective intersectoral coordination. This approach was subsequently abandoned by the development agencies. These hurdles, however, led to better evaluation of interventions and to measurements of the functional impact of malnutrition. In the 1980s, the promotion of intersectoral planning gave way to ensuring that existing sectoral interventions such as agricultural development programs included nutrition considerations. The other main theme was the targeting of nutrition interventions to those most in need and the involvement of local communities in self-sustaining development programs. This was brought about by the structural adjustment programs described later.

The 1980s also saw greater recognition of the role that women play in child nutrition through their economic as well as reproductive roles; the income that they control empowers them to make decisions beneficial to their own health and that of their children. There was also a renewed recognition of the role of diet quality in the promotion of nutrition status by the understanding that micronutrients have a function in child survival beyond deficiency diseases. This led to the promotion in developing countries of small-scale home gardening, capsule distribution, and fortification programs. Such programs had been in use for several decades in developed countries, providing land for kitchen garden allotments, the provision of supplements to children and mothers during the world wars, and the fortification of white flour with vitamins and minerals from that period to the present day as well as later compulsory fortification of margarine with vitamins A and D.

The main theme of the 1990s in developing countries was subsequently micronutrient intervention, including particularly vitamin A, iron, iodine, and, to a lesser extent, folic acid. There developed a research interest in population trials with several micronutrients that may lead to changes in nutrition policy and interventions. For example, the importance of vitamin A was investigated not only for eye lesions and blindness but also for resistance to respiratory and diarrheal infections; antioxidants began to be tested for their possible role in protection against cancer, heart disease, and other conditions; and zinc and other micronutrients were explored as a means to address the issue of restricted growth, which is widespread in developing countries.

In the 1990s, more developed countries produced explicit nutrition policies and also integrated measures to increase physical activity. For example, in the United Kingdom explicit nutritional goals were set for the first time in the 1992 government health policy, *The Health of the Nation*, which focused on five key areas for action—coronary heart disease and stroke, cancers, mental illness, HIV/AIDS and sexual health, and accidents—the first two of which are diet related. The diet and nutrition targets were as follows:

Reduce the average percentage food energy from saturated fats by at least 35% (to no more than 11% food energy)

Reduce the average percentage food energy from total fat by at least 12% (to no more than approximately 35% food energy)

Reduce the percentage of men and women aged 16–64 years who are obese by at least 25 and 35%, respectively (to no more than 6% of men and 8% of women)

Reduce the percentage of men drinking more than 21 units of alcohol per week and women drinking more than 14 units per week by 30% (to 18% of men and 7% of women)

By concentrating on these targets, it was expected that the associated dietary changes and reduction in

obesity would have beneficial consequences on such diseases as cancer, osteoarthritis, diabetes, etc. A nutrition task force was set up to oversee implementation and a physical activity task force was also set up to develop physical activity targets and detailed strategies. On a regional basis, the WHO European Region prepared the First Action Plan for Food and Nutrition Policy 2000–2005, which includes a food and nutrition task force. Food-based dietary guidelines were produced in the United States and subsequently in other countries and by FAO/WHO.

Food safety became a major concern in the 1990s, particularly in the developed countries. European consumers in particular lost faith in the science establishment due to initial assurances that BSE (mad cow disease) was no danger to human health, and they became extremely cautious about the safety of the food they purchased. In the United Kingdom, this distrust also led to a revision in government structure via the Food Standards Act 1999 so that agricultural and consumer food interests that had been combined within the Ministry of Agriculture Food and Fisheries were separated into the Food Standards Agency to champion consumer interests and the Department for the Environment, Food and Rural Affairs to oversee agriculture. A similar body was established within the European Union, the European Food Safety Authority, in 2002. In the United States, food and nutrition are regulated by the Food and Drug Administration, whereas other aspects of food and nutrition policy are regulated by the US Department of Agriculture. Due to the increased requirements to adhere to the new food safety expectations, it is more difficult for developing country exporters to gain market share in the developed world, affecting their own food security through constrained export opportunities. Along with these new food safety considerations have been concerns about genetically modified (GM) foods.

Also in the 1990s, there was increased awareness that pockets of food poverty still existed in developed countries, following the increased economic inequality that occurred in the 1980s in both developed and developing countries, partly due to government cutbacks in welfare programs (see International Constraints). This led to actions to relieve the constraints of the poor. This echoed a similar period in the United States in the 1960s involving 'Hunger in America,' which resulted in new welfare programs.

In the twenty-first century, many of the interventions emphasized in previous decades continue to form the tools of nutrition policy, and community trials continue. The experiences of these efforts in developing countries have been drawn together in a United Nations Administrative Committee on Coordination/Standing Committee on Nutrition review of 'what works.' No such review has been carried out on the effectiveness of various interventions in reducing the chronic nutrition-related diseases, possibly because the history of interventions is shorter. However, some systematic reviews on interventions for specific diseases have been conducted.

The main new emerging intervention is the development of genetic modification to provide crops with higher levels of the micronutrients that are commonly deficient in developing countries, such as iron and vitamin A, and with resistance to poor environmental conditions, such as drought and soil salinity. To date, GM foods have realized benefits largely for producers in developed countries in terms of higher productivity and lower costs. Despite no obvious benefits to consumers other than perhaps lower prices, GM soybean products have been consumed in the United States since the 1990s. However, European consumers and many in the United States are concerned that the food safety and environmental safety issues related to GM foods have not been adequately researched. The mandatory labelling of foods as 'containing GM organisms' is proposed as one solution, allowing consumers to make informed choices, but this has been opposed by GM producers as being too expensive to keep the GM and non-GM crops separate throughout the food distribution chain. The public sector has a role to play, and some new institutional arrangements, including the Global Alliance for Improved Nutrition concerning food fortification, are seeking to create incentives for the private sector to develop fortified foods for the benefit of the poor.

International Context

International Promotion

Hunger and malnutrition were put on the international agenda by the League of Nations in the 1930s, and the first conference of the United Nations in 1943 was devoted to food and agriculture. It remained an important focus of the United Nations technical agencies, FAO, WHO, and UNICEF, which were created immediately after World War II. Other international organizations have since been established, including the World Food Programme, World Food Council, International Fund for Agriculture Development, United Nations Fund for Population Activities, the World Bank, and the Consultative Group on International Agriculture. All these organizations and other international

supporting bodies have explicit objectives to eradicate human suffering due to hunger and malnutrition and to promote well-being and sound standards of health for all peoples of the world. The focus of these groups has been mainly on developing countries, but developed countries have recently been considered. These organizations have played an important role in relation to nutrition policies in developing countries by (i) providing technical assistance in the formulation and implementation of policies, programs, and activities; (ii) providing program and project funding; (iii) collecting and disseminating data, such as the World Food Surveys conducted by FAO every decade since 1946, which have greatly influenced the ideas of nutritionists and development policymakers in estimating the extent and defining the causes of malnutrition and have shaped the technical assistance deemed to be appropriate; (iv) organizing fora for debate on topics relevant to food and nutrition policy, such as the World Food Conference (1974); Alma Ata Conference of Primary Health Care (1978); World Conference on Agrarian Reform and Rural Development (1979); Convention on the Elimination of All Forms of Discrimination Against Women (1979); Fourth UN Development Decade (1990); World Summit for Children (1990); Innocente Declaration on Protection, Promotion and Support of Breast-Feeding (1990); Montreal Policy Conference on Micronutrient Malnutrition (1991); Rio Declaration on Environment and Development (1992); and International Conference on Nutrition (1992). The World Food Summit convened in November 1996, two decades after the influential World Food Conference of 1974, with the objective "to renew the commitment of the world leaders at the highest level to the eradication of hunger and malnutrition and the achievement of lasting food security for all." The UN Millennium Summit in 2000 produced the Millennium Development Goals, espoused by each of the UN agencies. These were to (i) eradicate extreme poverty and hunger; (ii) achieve universal primary education; (iii) promote gender equality and empower women; (iv) reduce child mortality; (v) improve maternal health; (vi) combat HIV/AIDS, malaria, and other diseases; (vii) ensure environmental sustainability; and (viii) develop global partnership for development. The agencies have set specific targets for each of these goals.

Some of the resolutions of these fora are very broad and clearly unachievable, such as the nutrition goals of the Fourth United Nations Development Decade (1990s), which were to (i) eliminate starvation and death caused by famine, (ii) reduce malnutrition and mortality among children substantially, (iii) reduce chronic hunger tangibly, and (iv) eliminate major nutritional diseases.

The more specific targets of the World Summit for Children (1990) to be reached by the year 2000, included (i) reduction in severe as well as moderate malnutrition among children younger than 5 years old by half of 1990 levels, (ii) reduction in the rate of low birth weights (2.5 kg or less) to less than 10%, (iii) reduction of iron deficiency anemia in women by one-third of the 1990 level, (iv) virtual elimination of iodine deficiency disorders, and (v) virtual elimination of vitamin A deficiency and its consequences, including blindness. These have clearly not been reached, and the setting of such unobtainable targets has been criticized on the grounds that they divert the attention of nutrition planners away from local priorities to global issues.

International Constraints

In the early 1980s, many developing countries experienced severe economic crises and had to implement a variety of 'structural adjustment policies,' enforced by the international finance agencies, the International Monetary Fund and the World Bank, to reduce government spending and improve balance of payments. Reduced spending resulted in cutting a variety of welfare programs that had been effective in controlling malnutrition, such as food price subsidies. Structural adjustment conditions have been rigidly imposed by the agencies for countries to obtain new financial loans. These institutions are funded by quotas from members who have voting rights in proportion to their contribution, assessed according to economic status, so that decisions are effectively in the hands of the major industrialized countries, especially the United States. This banking structure means that the policies of borrowing countries are dictated by the richer industrialized nations.

Structural adjustment has frequently resulted in changes of particular concern to the poor, such as increased food prices and decreased expenditure on social programs. The effects of these policies on health care, food consumption, incomes, and prices appear to have led to a serious deterioration in indicators of nutrition, health status, and school achievement in several countries, although it is difficult to distinguish policy effects from those of general economic decline. Efforts were subsequently made by UNICEF and other bodies to buffer vulnerable groups from these effects. During the same period, there were also cutbacks in welfare programs in developed countries, such as the provision of school meals.

International Trends in Malnutrition

To what extent have nutrition policies in developing and developed countries been effective in reducing malnutrition? During the 20 years between the World Food Conference in 1974 and the International Nutrition Conference in 1992, there have been considerable changes in the extent of malnutrition. The percentage of underweight children has declined in all areas of the world except sub-Saharan Africa and South America, but the numbers have declined only in China and have increased markedly in Southeast Asia and sub-Saharan Africa. Most data on nutritional status relate to preschool children because these are considered the most vulnerable, but other age groups are certainly not immune to malnutrition. Since 1992, international assessments of nutritional status have included women, but no information is available on trends. On the other hand, the prevalence of obesity and associated diseases has increased alarmingly in developed countries and also in several developing countries. Since the 1990s, international nutrition reports have moved from an almost exclusive focus on developing countries to include the nutrition concerns of developed countries.

What Is the Secret of Success?

Although undernutrition is clearly related to poverty, some countries are better nourished than others at similar levels of national wealth. Some countries are much better than others with a similar gross national product (GNP) in terms of indicators of nutrition and health, such as food available for consumption and infant mortality. Countries that have done best to improve undernutrition in recent years are those in which there is greater equity or in which policies have concentrated on ensuring the satisfaction of basic needs, including adequate food. Their political ideologies range from communist China to capitalist South Korea and Taiwan. China is the classic example of a country that is still poor but has largely dominated malnutrition and famine through effective organization of food production and distribution. Other examples are Costa Rica, Chile, Cuba, Kerala state in India, Sri Lanka, and Thailand, which have better nutrition conditions than other counties with similar GNPs. In contrast, some countries have extensive chronic malnutrition despite massive aid (e.g., Bangladesh) and rapid economic growth (e.g., Brazil).

These improvements cannot all be ascribed to specific nutrition policies. What are the lessons that can be learned about the effectiveness of the nutrition interventions commonly used to implement nutrition policies? This is not an easy question to answer because the evaluation of effectiveness of specific interventions is theoretically simple but practically difficult since evaluation has to take into account general economic change. An important function of international development and research agencies such as the World Bank, the International Food Policy Research Institute, FAO, UNICEF, and WHO since the 1970s has been to draw together research on the impact of policies and programs on the economic, health, and nutritional status of beneficiaries to distinguish the characteristics of success. Most of these have concentrated on developing countries. Several features of successful large-scale nutrition interventions in relation to undernutrition have been extracted and are summarized next.

The objectives must be based on a careful analysis of the real problem and be achievable in a timescale set within the program design. Community and local nongovernment organization involvement is essential in the design and implementation so that there is a sense of joint ownership for self-sustaining success. The overall effectiveness depends on coverage, and if interventions are targeted at specific groups there has to be a trade-off between the cost-effectiveness of targeting and wider coverage of the population. Charismatic leadership and good management are essential, and the appropriate mix of components must be accompanied by effective administration with a balance between bottom-up and top-down actions. Most successful programs include strong training and supervision. Effective implementation is helped by setting clear targets and by monitoring and evaluating the process, with flexibility to modify the program where necessary. The attitude of the workers is crucial in determining the potential for scaling up from a pilot project with selected staff to a large-scale operational program that has to use existing staff. Awareness of the consequences and causes of malnutrition and a political commitment at all levels are important. These common characteristics are a useful basis for the planning of future programs to maximize their success.

Emerging Issues in the Twenty-First Century

Some of the main emerging and reemerging nutrition issues of the new millennium for developing countries are those that reflect changing economic,

demographic, and disease patterns and include HIV/AIDS, the nutrition transition, refugees, adolescents, and aging.

In developed countries, aging is also one of the main emerging issues, along with the continued increase in obesity in both adults and children, with concomitant increases in related diseases such as diabetes. It has been recognised that this cannot be dealt with only on the nutrition front, and nutrition policies and recommendations are now including measures to increase activity in the population. Research continues to refine the association of various food factors with aspects of health and so determines policy. For example, the United States has already undertaken folic acid fortification of flour and the United Kingdom is considering doing so.

Millions have died of AIDS, especially in sub-Saharan Africa, with devastating effects on people's livelihoods. For the individual, the disease raises nutrient requirements and reduces the immune system, increasing vulnerability to other diseases. A major issue is the transmission of HIV from mother to child during pregnancy, at birth, or with breastfeeding. For the household, HIV/AIDS reduces the capacity to care for young children and infected household members and to work to ensure food security, resulting in deteriorating nutritional status. Women feel the impact most severely. Nutrition policy has to relate to prevention and nutritional care, which can significantly postpone illness and prolong life.

More developing countries will have to modify their nutrition policies to address the shift from problems of nutritional deficiency and infectious diseases to problems of chronic diet-related diseases, including obesity, diabetes, cardiovascular disease, hypertension, and various forms of cancer. These shifts are associated with changes in diet and lifestyle patterns that accompany industrialization, urbanization, economic development, and market globalization and that result in the increased consumption of energy-dense diets and sedentary work and leisure occupations.

National and international conflict has resulted in millions of refugees and internally displaced persons, estimated by the United Nations to be 35 million, of which 80% are women and children, and acute malnutrition is frequently reported. Nutritional support of these displaced populations is a concern for national governments and international agencies.

Most attention in the past has been focused on the nutrition of young children and on pregnant and lactating women, and other groups have been relatively neglected. Recently, the special needs of adolescents have begun to be addressed. Adolescents comprise approximately 20% of the world's population, and adolescence is a period of intense physical, psychosocial, and cognitive development, during which they gain up to 50% of their adult weight, height, and skeletal mass, caloric requirements are maximal, and poor eating habits and pregnancy are additional concerns. More attention will be paid to this group and to ways to avoid the consequences of poor nutrition during this period.

Another neglected group is the elderly. Currently, there are 580 million people older than 60 years (61% in developing countries), and this number is projected to increase to 1 billion by 2020 (71% in developing countries). The majority are women because they live longer than men. Special problems associated with nutrition include osteoporosis and fractures, vulnerability to malnutrition, and degenerative diseases.

Conclusions

A nutrition policy is easy to draw up on paper but is useless unless implemented. Many countries have adopted nutrition policies that were ineffective because they were not or could not be implemented. Some policies could not be implemented even if the political will existed because they were too complex, such as National Nutrition Planning, or could not be scaled up successfully from pilot projects to operational programs because they did not have funding for an equivalent level of training and supervision, such as the Applied Nutrition Program. Successful implementation depends on many economic and technical factors but most important on political will. Success in improving nutrition has been achieved in countries with a wide range of political ideologies but with a common theme of government commitment to promoting equity and to satisfying basic needs. Some types of specific interventions can be successful without such commitment, such as nutrient supplement programmes, but the criteria of success have to be clearly defined in terms of population coverage, sustainability, and to what extent the program addresses the main nutritional problems.

NUTRITION TRANSITION, DIET CHANGE AND ITS IMPLICATIONS

B M Popkin, University of North Carolina, Chapel Hill, NC, USA

The world is experiencing rapid shifts in structures of diet and body composition with resultant important changes in health profiles. In many ways, these shifts are a continuation of large-scale changes that have occurred repeatedly over time; however, the changes facing low- and moderate-income countries appear to be very rapid. Broad shifts continue to occur throughout the world in population size and age composition, disease patterns, and dietary and physical activity patterns. The former two sets of dynamic shifts are termed the demographic and epidemiological transitions. The latter, whose changes are reflected in nutritional outcomes, such as changes in average stature and body composition, is termed the nutrition transition. These three relationships are presented in **Figure 1**.

Human diet and activity patterns, and nutritional status, have undergone a sequence of major shifts, defined as broad patterns of food use and their corresponding nutrition-related diseases. During the past three centuries, the pace of dietary and activity change appears to have accelerated to varying degrees in different regions of the world. Furthermore, dietary and activity changes are paralleled by major changes in health status as well as by major demographic and socioeconomic changes. Obesity emerges early in these shifting conditions, as does the level and age composition of morbidity and mortality. Although there are five broad nutrition patterns dating back to the origins of modern man, the focus of this article is on the three most recent periods (**Figure 2**). For convenience, the patterns are outlined as historical developments; however, 'earlier' patterns are not restricted to the periods in which they first arose but, rather, they continue to characterize certain geographic and socioeconomic subpopulations. The first two patterns relate to earlier periods in the evolution of man—the first pattern of collecting food and the second

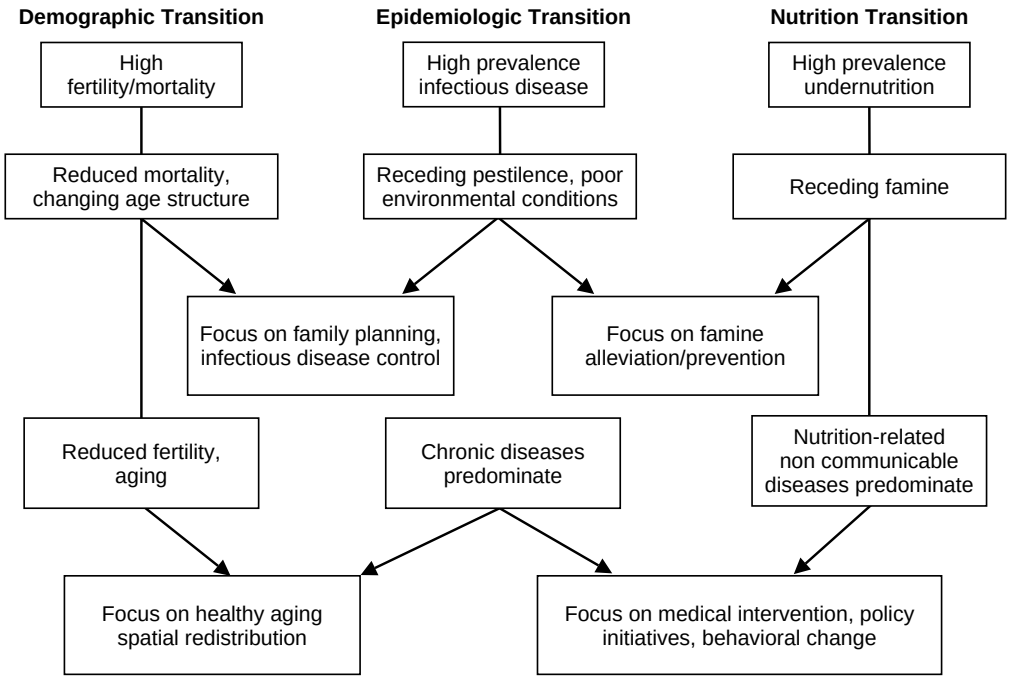

Figure 1 Stages of health, nutritional, and demographic change. (From Popkin BM (2002) The shift in stages of the nutrition transition in the developing world differs from past experiences! *Public Health Nutrition* **5**(1A): 205–214.)

pattern of famine. The following are the three later periods:

Pattern 3: Receding famine: The consumption of starchy staples had predominated and continues to do so, but these items become less important in this low-fat diet as limited amounts of fruits, vegetables, and animal protein are increasingly added to the low-fat and high-fiber diet. Many earlier civilizations made great progress in reducing chronic hunger and famines, but only in the last third of the past millennium have these

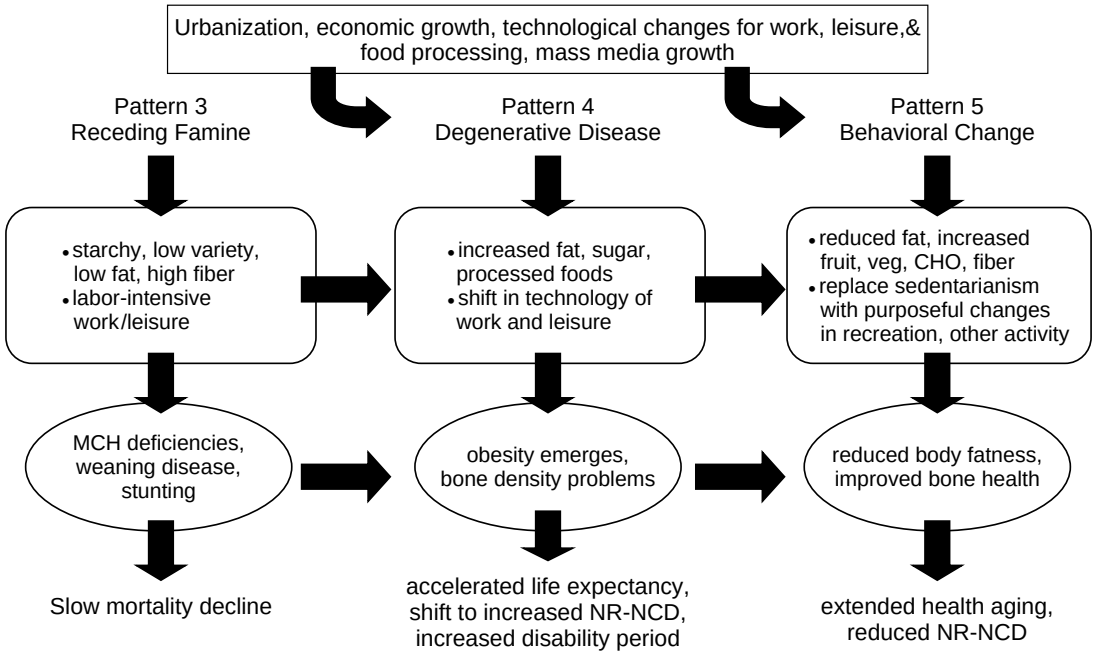

Figure 2 Stages of the nutrition transition. (From Popkin BM (2002) The shift in stages of the nutrition transition in the developing world differs from past experiences! *Public Health Nutrition* **5**(1A): 205–214.)

changes become widespread, leading to marked shifts in diet. However, famines continued well into the eighteenth century in portions of Europe and remain common in some regions of the world. Activity patterns start to shift and inactivity and leisure become a part of the lives of more people.

Pattern 4: Nutrition-related noncommunicable disease (NR-NCD): A diet high in total fat, cholesterol, sugar, and other refined carbohydrates, low in polyunsaturated fatty acids and fiber, and often accompanied by an increasingly sedentary life is characteristic of most high-income societies (and increasing proportions of the population in low-income societies), resulting in increased prevalence of obesity and contributing to the degenerative diseases that characterize the final epidemiologic transition stage.

Pattern 5: Behavioral change: A new dietary pattern appears to be emerging, evidently associated with the desire to prevent or delay degenerative diseases and prolong health. Whether these dietary changes, instituted in some countries by consumers and in others also prodded by government policy, will create a large-scale transition in dietary structure and body composition remains to be seen.

Our focus is increasingly on patterns 3–5, particularly the rapid shift in much of the world's low- and moderate-income countries from the stage of receding famine to NR-NCD. **Figure 2** presents this focus. The concern about this period is so great for many that the term 'nutrition transition' is synonymous with this shift from pattern 3 to 4.

Shifts in Dietary and Activity Patterns and Body Composition Seem to Be Occurring More Rapidly

The pace of the rapid nutrition transition shifts in diet and activity patterns from the period termed the receding famine pattern to one dominated by NR-NCDs seems to be accelerating in the lower and middle-income transitional countries. We use the word 'nutrition' rather than 'diet' so that the term NR-NCDs incorporates the effects of diet, physical activity, and body composition rather than solely focusing on dietary patterns and their effects. This is based partially on incomplete information that seems to indicate that the prevalence of obesity and a number of NR-NCDs is increasing more rapidly in the lower and middle-income world than it has in the West. Another element is that the rapid changes in urban populations are much greater than those experienced a century ago or less in the West; yet another is the shift in occupation structure and the rapid introduction of the modern mass media. Underlying such changes is a general concern for rapid globalization as the root cause.

Clearly, there are quantitative and qualitative dimensions to these changes. On the one hand, changes toward a high-density diet, reduced complex carbohydrates, increased added sugar and other caloric sweeteners, and inactivity may be proceeding faster than in the past. The shift from labor-intensive occupations and leisure activities toward more capital-intensive, less strenuous work and leisure is also occurring faster. On the other hand, qualitative dimensions related to multidimensional aspects of the diet, activity, body composition, and disease shifts may exist. The social and economic stresses that people face and feel as these changes occur may also be included.

Scholars often note that the pace and complexity of life, reflected in all aspects of work and play, are increasing exponentially. There are also unanticipated developments, new technologies, and the impact of a very modern, high-powered communications system. It is this sense of rapid change that makes it so important to understand what is happening and anticipate the way in which changes in patterns of diet, activity, and body composition are occurring. Although the penetration and influence of modern communications, technology, and economic systems related to 'globalization' have been a dominant theme of the past few decades, there seem to be some unique issues that have led to a rapid increase in globalization and its impact.

Stating that globalization is the cause results in a focus on broad and vaguely measured sets of forces; this ignores the need to be focused and specific, which would allow us to develop potentially viable policy options. It is difficult to measure each element of this globalization equation and its impact. These processes certainly have been expanded, as indicated by enhanced free trade, a push toward reduction of trade barriers in the developing world, and the increasing penetration of international corporations into the commerce in each country (measured by share of gross national product (GNP) or manufacturing). Similarly, other economic issues related to enhanced value given to market forces and international capital markets are important. Equally, the increasing access to Western media, the removal of communication barriers enhanced by the World Wide Web, cable TV, mobile telephone systems, etc. are important. The accelerated introduction of Western technology into manufacturing and the basic sectors of agriculture, mining, and services is also a key element.

Another way to understand the types of changes the developing world is facing is to consider an urban squatter's life and a rural villager's life in China approximately 20 years ago and today. During the 1970s, food supply concerns still existed; there was no television, limited bus and mass transportation, little food trade, minimal processed food, and most rural and urban occupations were very labor intensive. Today, work and life activities have changed: Small gas-powered tractors are available, modern industrial techniques are multiplying, offices are automated, soft drinks and many processed foods are found everywhere, TVs are in approximately 89% of households (at least one-fifth of which are linked to Hong Kong Star and Western advertizing and programing), younger children do not ride bicycles, and mass transit has become heavily used. Considering that such changes are also occurring in much of Asia, North Africa, the Middle East, Latin America, and many areas (particularly cities) in sub-Saharan Africa, it is evident that the shift from a subsistence economy to a modern, industrialized one occurred in a span of 10–20 years, whereas in Europe and other industrialized high-income societies, this occurred over many decades or centuries.

To truly measure and examine these issues, we would need to compare changes in the 1980–2000 period for countries that are low and middle income to changes that occurred a half century earlier for the developing world. However, data on diet and activity patterns are not available, and there are only minimal data on NR-NCDs and obesity.

The elements of the nutrition transition known to be negatively linked with NR-NCDs are obesity, adverse dietary changes (e.g., shifts in the structure of diet toward a greater role for higher fat and added caloric sweeteners in food, reduced fruit and vegetable intake, reduced fiber intake, greater energy density, and greater saturated fat intake), and reduced physical activity in work and leisure. The causes of these elements of the nutrition transition are not as well understood as the trends in each of them. In fact, few studies have attempted to research the causes of such changes, and there are only a few data sets equipped to allow such crucial policy analyses to be undertaken.

Obesity Trends

The most commonly measured health outcome of the shifts in the structure of diet is obesity. The shifts in adult overweight and obesity in the developing world in the past 10–30 years are far faster than in the higher income countries. We examined the shifts in body composition among Chinese adults aged 20–45 years during an 8-year period. Not only did mean body mass index (BMI) increase but also the shape of the BMI distribution curve changed during the 8-year period. From 1989 to 1997, the proportion of underweight men and women declined considerably and the prevalence of both overweight and obesity increased greatly. In fact, the proportion of overweight or obese men more than doubled from 6.4.0 to 14.5% and the proportion of overweight or obese women increased 50%, from 11.5 to 16.2%.

China is not unique; here, data from a few low- and middle-income countries are presented to compare their increase in the annual prevalence of overweight and obese adults with that of the United States. **Figure 3** presents the annualized increase in the percentage points of prevalence for data from high-income countries with comparable data. **Figure 4** shows how quickly overweight and obesity have emerged in Mexico as a major public health problem. Compared to the United States and European countries, where the annual prevalence increase in overweight and obesity is approximately 0.25 each, the rates of change are very high in Latin America. Cuba's data only represent Havana. Similar shifts in the prevalence of obesity are presented for North Africa and the Middle East and Asia in **Figures 5** and **6**, respectively.

What is important to note is that the increase in the proportion of the adult population that is overweight is far greater in all the lower income countries than in the United States or most European countries. Only Spain, with its large shift in overweight in the past decade, is close to the speed of change of these countries.

Dietary Changes: Shift in the Overall Structure over Time

The diets of the developing world are shifting equally rapidly. There are no good data for most countries on total energy intake, but there are reasonable data to examine shifts in the structure of the diet. Food balance data were used to examine the shift over time in the proportion of energy from fat.

The dramatic changes in the aggregate income–fat relationship from 1962 to 1990 are displayed in **Figure 7** by the estimated regression lines based on cubic polynomial regressions. Most significantly, even the poor nations had access to a relatively high-fat diet by 1990, when a diet deriving 20% of energy (kcal) from fat was associated with countries having a GNP of only $750 *per capita*,

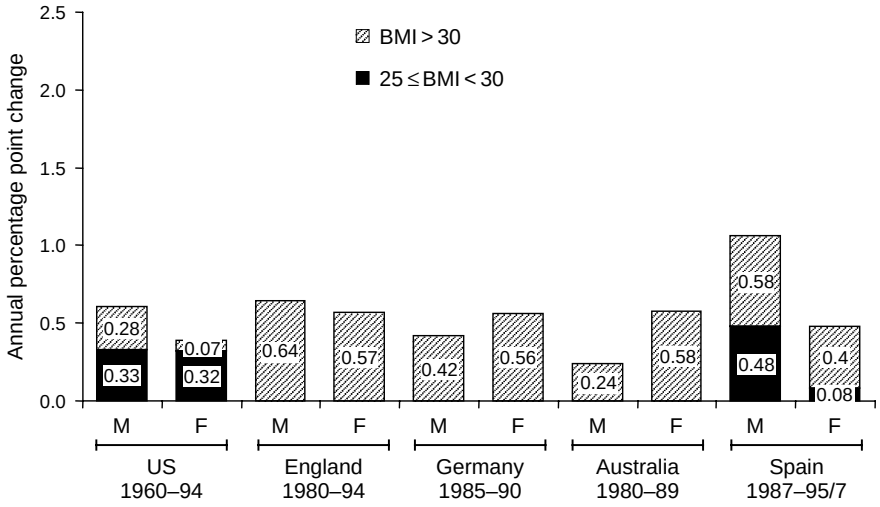

Figure 3 Obesity trends among adults in the United States and Europe (the annual percentage point increase in prevalence). BMI, body mass index; F, female; M, male. (Popkin BM (2002) The shift in stages of the nutrition transition in the developing world differs from past experiences! *Public Health Nutrition* **5**(1A): 205–214.)

whereas in 1962 the same energy diet (20% from fat) was associated with countries having a GNP of $1475 (both GNP values in 1993 dollars). This dramatic change arose from a major increase (10–13%) in the consumption of vegetable fats by poor and rich nations; similar increases (3–6%) also occurred in mid- and high-income nations.

At the same time, there were decreases in the consumption of fat from animal sources for all except the low-income countries. The availability of animal fats continued to be linked to income, though less strongly in 1990 than in 1962. These decreases, combined with the increase in vegetable fat intake for all income countries, resulted in an overall decrease in fat intake for moderate-income countries of approximately 3% but an increase of approximately 4 or 5% for low- and high-income countries. **Figure 7** shows these substantial shifts in the relationships between GNP and the composition of diets over time.

Vegetable fats in 1990 accounted for a greater proportion of dietary energy than animal fats for

countries in the lowest 75% of countries (all of which have incomes less than $5800 per capita) of the per capita income distribution. The absolute level of vegetable fat consumption increased, but there remained at most a weak association between GNP and vegetable fat intake in these aggregate data. The change in edible vegetable fat prices, supply, and consumption is unique because it equally affected rich and poor countries, but the net impact is relatively much greater on low-

income countries. Recent analysis in China shows that the pace of change for increased energy density and animal source foods in the diet has accelerated.

There is also an equally large and important shift in the proportion of energy from added caloric sweeteners in the diets of lower income countries. In fact, an additional 100–200 kcal per day was available for daily consumption from added caloric sweeteners in the diet in 2000 compared to 1962 in the developing world. In the United States, this added caloric sweetener increase derives mainly from soft drinks and fruit drinks, but in many other countries the source of this increase is other foods, even basic processed foods that have sweeteners added to them. Increasingly, high-fructose corn syrup is used as the sweetener of choice. This is unfortunate because there are mechanisms by which glucose may limit intake, but not fructose.

When we specifically examine the combined effect of these various shifts in the structure of rural and urban Chinese diets, we find an upward shift in the energy density of the foods consumed. In this study, the kilocalories of energy intake from foods and alcohol per 100 grams of food in both urban and rural Chinese adult diets increased by more than 10% (to 2.42) between 1989 and 1997. These are very rapid shifts in energy density. It is important to note that the value of 2.42 is not comparable with the normal measure of energy density of the diet. The normal method includes full measures of all beverages, whereas the Chinese Food Composition Table, from which this data was extracted, measures only a few beverages (milk, coconut juice, sugarcane juice, spirits, beer, wine, champagne, and brandy) and excludes many beverages, particularly tea and coffee. A number of clinical investigations have varied the energy density of the diet in ad libitum studies. Each study shows that increases in energy density, often as small as from 1 to 1.3 kcal/g, can increase total energy intake. For these reasons, energy density changes in China, and most likely in other developing countries, are critical components of dietary change to be monitored.

Rapid Social Change Is Important: Urbanization, Rapid Demographic Change, and Other Behavioral Changes Are Occurring Simultaneously

Diets have shifted in urban areas in a far more dramatic fashion than in rural areas. We do not focus on many of the complex issues related to the type of urban change that has occurred. Nevertheless, critical sociodemographic issues include the following:

- Rapid reductions in fertility have enhanced the shift in the age distribution.
- Urbanization continues unabated in Asia and Africa. More poor will reside in urban than rural areas in future decades.
- Economic changes, particularly increased income and income inequality, appear to define changes in many regions of the developing world.
- Globalization of mass media is occurring at an earlier stage of economic development than occurred in higher income countries in the past.

Urbanization

In other published work, we have shown how the structure of diet has shifted markedly as populations have urbanized. This relationship will, by itself, shift the structure of diet significantly at the national level as urbanization continues and as the proportion of the population in urban areas grows.

Structural Shifts in Income–Diet Relationships Are Occurring

Changes in dietary behavior can be caused either by shifts in the composition of society regarding the plurality of the educated, rich, or urban residents or by changes in actual behavior of those with specific characteristics. This latter type can include a change in consumption behavior such that for the same level of education or income, a person would buy different amounts or types of commodities at different points in time. Research conducted in China shows that there have been profound behavioral shifts of this type during the past decade (i.e., for each extra dollar of income, additional high-fat foods are purchased vs. what would have been purchased in previous years for the equivalent extra dollar). Economists speak of this effect as one that shows how the decision-making demand pattern for food has changed, so for the same income level the patterns of demand have changed significantly from earlier periods. The explosion in access and exposure to mass media may very well have created this situation.

Mass Media

There is no doubt that access to modern mass media has increased very rapidly, particularly in the past decade. Elsewhere, we have shown worldwide trends. It is most useful to examine the proportion of households in a country that have TV sets to gain insight into this topic. Again, we use China Health and Nutrition Survey (CHNS) data to demonstrate the types of changes in one setting. Overall, 88.5% of Chinese households in the CHNS sample had TVs in 1997. It is important to note that not only the proportion of people with access to TV was shifting but also the types of programs and access to Western influences were shifting. In the 1980s, cable systems in China did not provide outside programming, but by 1997 approximately one-fourth of Chinese provinces provided access to Phoenix Star TV, a Hong Kong TV system that relies heavily on US and British programming and provides modern TV advertising.

Again, although there are no extensive data on the proportions of Chinese households with access to mass media 30–70 years ago, it is certain that the penetration into Chinese households in 1997 was far greater than it was into US households 50 years ago, when TV was in its infancy.

Health Effects: Is the Biology Different? Rather, Do We Have Different Social Structures and Body Composition Patterns That Affect BMI–Disease Relationships? Are There Genetic Variants That Are Important?

There are a number of different ways these questions could be answered in the affirmative. One is if the body composition and other unmeasured race/ethnic factors affect susceptibility to NR-NCDs. Another might be if previous disease patterns (e.g., the presence of malaria or other tropical diseases) led to disease patterns that predisposed the population to certain problems. One component of this may be the fetal insult syndrome developed and popularized by Barker.

There is a growing body of research that shows the international standards, used to delineate who is overweight and obese, are not appropriate for many large subpopulations in the world. For instance, a BMI of 25 in an Asian adult appears to have a far greater adverse metabolic effect than in a Caucasian adult. In fact, the World Health Organization and the International Obesity Task Force formed a group of scientists and agencies in Asia to review this topic. This group held international meetings and has proposed a lower BMI cutoff for Asians of 23 for overweight and 25 for obesity. In one paper comparing China, the Philippines, and US Hispanics, blacks, and whites, the odds of being hypertensive were higher for Chinese men and women compared to other subpopulation groups at lower BMIs in the 23–25 range. Ethnic differences in the strength of the association between BMI and disease outcomes warrant further consideration.

Zimmet and others who have focused on this issue as it relates to lower income countries believe that the highest genetic susceptibility for adult-onset diabetes is for Pacific Islanders, American Indians, Mexican Americans and other Hispanics, and Asian Indians. Those with modest genetic susceptibility include Africans, Japanese, and Chinese. The age of onset (usually after age 50 years) of non-insulin-dependent diabetes mellitus is much lower for these susceptible populations, and it appears that the prevalence is higher for a given level of obesity and waist:hip ratio. Zimmet

summarizes a large selection of literature that has explored these issues relating to diabetes among susceptible populations.

It is not clear how much of this difference between subpopulations regarding BMI–diabetes or other BMI–morbidity relationships is a function of differences of body composition, metabolic or genetic factors, or social causes. We have shown that part of the apparent race–hypertension relationship may also be explained by socioeconomic status.

Another dimension relates to the issue of inflammatory burden. Evidence that inflammation plays a central role in cardiovascular disease (CVD), particularly at all stages of atherosclerosis, is persuasive. This position is supported by basic science and epidemiology. As reviewed in a meta-analysis, the magnitude of the associations between CVD outcomes and levels of inflammatory factors, such as C-reactive protein, albumin, white blood cell count, and fibrinogen, is surprisingly consistent across studies, despite differing designs, populations, duration of follow-up, and case definitions.

There is another pathway related to the role of previous health problems for which there is less understanding and no real documentation of its impact (e.g., malnutrition that caused a virus to mutate, parasitic infections that affected long-term absorption patterns, or a parasite that is linked to an unknown genotype—comparable to sickle cell anemia and its evolutionary linkage with malaria). We have no basis for speculation about this potential pathway.

However, the final pathway—the effect of fetal and infant insults on subsequent metabolic function—appears to be a critical area. If the rapid shifts toward positive energy imbalance are occurring concurrently with higher levels of low birth weight in a population, then this becomes a much more salient aspect of this argument. For the developing world, where intrauterine malnutrition rates are high and there is a high prevalence of nutrition insults during infancy, the work of Barker and many others portends important potential effects on the prevalence of NR-NCDs in the coming decades. Not only is there an emerging consensus that fetal insults, particularly with regard to thin, low-birth-weight infants who subsequently face a shift in the stage of the transition and become overweight, are linked with increased risk of NR-NCDs but also infancy may equally be a period of high vulnerability. Three studies by Hoffman suggest that fat metabolism of stunted infants is impaired to the extent that this may lead to increased obesity and other metabolic shifts. Other work on the role of stunting on obesity suggested such an effect, but Hoffman's work suggests the mechanism and fits with the correlational work.

The CVD Epidemic Is Beginning

Evidence from many developing countries shows that nutrition-related chronic diseases prematurely disable and kill a large proportion of economically productive people, a preventable loss of precious human capital. This includes countries in which HIV/AIDS is a dominant problem. Four out of five deaths from nutrition-related chronic diseases occur in middle- and low-income countries. Reddy reviewed these data and noted that

> the current high burden of NCDs is highlighted by the estimates for 1998 that indicate these disorders contributed to 58.8% of global mortality and 43% of the global burden of disease, measured as disability adjusted life-years lost. The contribution of low- and middle-income countries to this burden is large; about 77% of the total mortality and 85% of the total burden of disease attributable to NCDs arises from these countries. (page 231)

The burden of cardiovascular disease alone is now far greater in India, and also in China, than in all economically developed countries in the world combined. Low-income communities are especially vulnerable to nutrition-related chronic diseases, which are not just diseases of affluence. CVD, cancer, diabetes, neuropsychiatric ailments, and other chronic diseases are becoming major contributors to the burden of disease, even as infections and nutritional deficiencies are receding as leading contributors to death and disability.

Furthermore, CVD in the developing world emerges at an earlier age. As Reddy notes,

> Thus in 1990, 46.7% of CVD-related deaths in developing countries occurred below the age of 70 years, in contrast to only 22.8% in the high-income industrial countries. The Global Burden of Disease Study projected 6.4 million deaths would occur due to CVD in the developing countries in 2020, in the age group of 30–69 years. (page 233)

A World Health Report updates this analysis and focuses on the important role of obesity and CVD and cancer deaths in the developing world.

There are major differences in the profiles of the CVD epidemic across the developing world. For instance, hypertension and stroke are more likely to emerge in east Asia, whereas diabetes occurs earlier in south Asia.

As would be expected from the dietary and obesity data noted previously, CVD levels are far greater in urban areas of the developing world, but

often the opposite is true in the developed higher income countries.

Social Burden of Changes in Diet, Body Composition, and Health

In higher income countries, increasingly higher income groups follow a more healthful lifestyle, whereas the poor do not. Thus, higher income Americans consume a more healthful diet pattern, exercise more, and smoke less, and similar patterns are found in other high-income countries. In contrast, the prevailing opinion has been that the opposite is found in the developing world, namely that the poor are less likely to have a heavy burden of NR-NCDs compared to the rich. This is changing rapidly. It has been shown that obesity has declined among the better educated and increased among the lower educated in southeastern Brazil. It has also been shown that not only are less healthful dietary patterns consumed by higher income Chinese but also other dimensions of lifestyle (inactivity, smoking, and drinking) are poorer among the higher socioeconomic status (SES) Chinese. In other research, scholars of China have shown a rapid shift in food consumption patterns among different income groups in China that seems to indicate a shift in the burden of poor diets toward the poor in China. It has been shown that for countries with a GNP per capita of more than $2500, the likelihood is very great that there will be more obesity among the lower SES groups compared to higher SES groups.

The Future

Consuming a more tasteful and richer diet is a goal of most of the world's population. As shown here, dietary change is universal. In particular, rapid change is seen in the poorest areas of the world. The challenge is to learn how to continue to improve the palatability and quality of our diet while doing so in a more healthful manner.

NUTRITIONAL ASSESSMENT

Contents

Anthropometry

J Eaton–Evans, University of Ulster, Coleraine, UK

This article is reproduced from the first edition, pp. 1357–1363, © 1999, Elsevier Ltd. with revisions made by the Editor.

Anthropometric measurements include weight, height, length, selected skinfold thicknesses, and head, waist, hip, and arm circumferences. When compared with reference values, these measurements or combinations of these measurements can provide information on body size and the proportion and distribution of body fat and lean body mass in adults; they can also be used to assess growth in children. Anthropometric measurements indirectly indicate present or past nutrition and may be markers of future ill-health.

This article reviews the uses, advantages, and limitations of anthropometric measurements; discusses the technical errors of the measurements; describes the most frequently used measurements, derived nutritional indices, and reference values; and summarizes the laboratory methods that may validate the assessments.

Uses of Anthropometric Measurements

In adults and children, anthropometric measurements can be used to estimate body fat and lean body mass and assess their distribution and change over time. Body fat includes storage fat, found inter- and intra-muscularly, around the organs and gastrointestinal tract and subcutaneously, as well as lipids in bone marrow, central nervous tissue, mammary glands, and other organs. Normal-weight men and women have about 10 and 20% body fat, respectively. Lean body or fat-free mass is mostly water and protein with relatively small amounts of glycogen and minerals. Inadequate diets are associated with low body fat stores and reduced lean body mass in adults and growth failure of children. Consumption of food greater than requirements results in excessive body fat stores in adults and children. Body fat stores that are too low or too high are associated with increased risk of morbidity and mortality. The proportion and distribution of fat and fat-free mass varies with age, sex, genetics, disease, some hormones, and some drug treatments. Extensive physical exercise may be associated with increased muscle mass.

Different anthropometric measurements and combinations of measurements provide information on body composition and fat distribution and, therefore, nutritional status. The choice of measurements depends on the purpose of the assessment, the equipment available, the subjects being measured, and the skills of the observer making the measurements. Measurements can be made in laboratories, clinics, and hospitals using fixed, precision equipment with a high degree of accuracy, or in the field, including peoples' homes or rural centers, with lighter, robust, and portable equipment.

Advantages and Limitations of Anthropometric Measurements

Anthropometric measurements are noninvasive. Compared with other methods of assessing nutritional status, the measurements are quick and easy to make using relatively cheap and simple equipment. They can be made by relatively unskilled people.

Anthropometric measurements cannot identify protein and micronutrient deficiencies, detect small disturbances in nutritional status, nor identify small changes in the proportions of body fat to lean body mass. Some anthropometric measurements may not be socially or culturally acceptable, such as the measurement by men of womens' subscapular and supra-iliac skinfold thicknesses; some measurements may be impractical to make, such as the height in people who are unable to stand straight. Observers with limited literacy skills may not be able to read and therefore record some measurements. A single anthropometric measurement, such as weight, does not normally in itself assess growth and/or body composition and, therefore, indicate nutritional

status. To interpret anthropometric measurements, single measurements or combinations of measurements must be compared with reference values, by age and sex. Such reference values are not available for all population groups nor for all ages.

Errors of Anthropometric Measurements

All anthropometric measurements should be made as accurately as possible. Measurement errors may result in the misclassification of subjects' nutritional status or may lead to changes in nutritional status over time being over- or underestimated. Very precise and accurate measurements are needed for nutrition research and in some clinical situations. The same degree of precision may not be possible in nutritional screening and surveillance programs in field studies. Errors in making measurements arise from the equipment, the physical state and age of the subjects, the time of day when the measurements are made, misreading of measurements by the observer, and as a result of rounding up or down to the nearest half or whole integer. These technical errors of measurement (TEM) vary with the age of the subjects, the measurements being made, and between (inter-) and within (intra-) observers. Values for a particular anthropometric measurement of a group of people by age and sex can be considered accurate if the inter- and intraobserver error is close to a reference value for TEM in a series of repeated measurements and if there are no biases in the measurement. For measurements of subjects outside the age range, the coefficient of variability (R) can be calculated as $R = 1 - [(TEM)^2/(SD)^2]$, where SD is the total intersubject variance including measurement error. It has been recommended that an R of 0.90, that is a measurement 90% error-free, is an acceptable lower limit of accuracy, although an intraobserver R of 0.95 might be more realistic in some circumstances.

TEM can be minimized by careful training of all observers and by making measurements using appropriate equipment in triplicate and then calculating the mean. If measurements for a research study are to be made by more than one person, the interobserver measurements made must be comparable. R can be calculated for interobserver variability by making a series of measurements.

Anthropometric Measurements

Height

Height, or stature, is measured in adults and children over the age of 2 years using a stadiometer, a portable anthropometer, or a moveable headboard on a vertical measuring rod. The measuring device should be checked for accuracy using a standard 2-m steel tape. Subjects should be measured to the nearest 0.1 cm. Subjects, in minimal clothing with bare heads and feet, should stand straight, arms hanging loosely to the side, feet together and with heels, buttocks and shoulder blades in contact with the vertical surface of the stadiometer. Errors occur if subjects do not stand straight, do not keep heels on the ground, or overstretch. Diurnal variation results in people being 0.5–1 cm shorter in the evening than in the morning.

Height cannot be measured accurately in adults with severe kyphosis of the spine and in those who are bed- or chair-ridden. Since knee height is highly correlated with stature, height in such adults can be estimated from the measurement of knee height, using a sliding calliper. The regression equations, derived from a nonrandom sample of American people over the age of 60 years, are:

$$\text{Height (cm) for men} = (2.02 \times \text{knee height, cm}) - (0.04 \times \text{age, years}) + 64.19$$

$$\text{Height (cm) for women} = (1.83 \times \text{knee height, cm}) - (0.24 \times \text{age, years}) + 84.88$$

Variations in the proportion of limb length to trunk length can lead to a standard error in the estimate (SEE) of height from knee height of ± 8 cm. Demispan, which is the distance between the sternal notch of the right collar bone and the left finger root of the middle and ring finger when the subject's arm is horizontal and in line with the shoulders, can also be used to estimate height.

Length, rather than height, is measured in infants and children under the age of 3 years. Length is measured by laying a child face upwards on a measuring board with the head against the fixed headboard, and moving another board up to and resting against the child's heels with the legs straight (**Figure 1**). Small changes in length (± 0.5 cm) may not be significant as it is a difficult measurement to make. Children wriggle and will not stretch out their legs. Length measurements are 1–2 cm longer than height.

Height (stature) or length indicates attained size or growth of adults and children. Long periods of inadequate food intake or increased morbidity result in a slowing of skeletal growth and individuals being short for their age, or stunted. Consecutive measurements of height every 3–6 months can be used to assess growth velocity in children and to indicate the timing of the adolescent growth spurt.

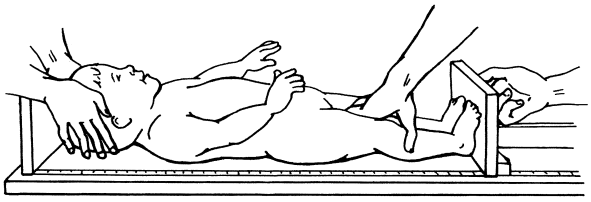

Figure 1 Measurement of recumbent length in children younger than 3 years of age. The head should be in contact with the fixed headboard, with child facing straight up. With legs fully extended, the mobile footboard should be placed firmly against the infant's heels. (Reproduced with permission from Frisancho AR (1990) *Anthropometric Standards for the Assessment of Growth and Nutritional Status*. Ann Arbor: University of Michigan Press.)

Weight

Weight is measured with digital weighing scales, using a pan, basket, sling, standing platform or chair, depending on the age and mobility of the people being measured. Weighing scales must be set on a hard, level, and even surface. Scales should be accurate, sensitive, and robust. They must be carefully maintained, calibrated, regularly checked for accuracy using known weights, and always set at zero before use. Weight is usually measured to the nearest 0.1 kg for adults and 0.01 kg for infants.

Weight measures total body mass but does not provide information on the proportions of fat, water, protein, and minerals. Weight and fat are only synonymous in very heavy people. Adults can be heavy for height if very muscular, overfat, and/or big framed. With accurate scales, small changes in weight are detectable but may not necessarily reflect change in body fat or lean body mass. In healthy persons, day-to-day variation in body weight is usually small (± 0.5 kg). Consecutive measurements of weight can be used to monitor the effects of treatment such as weight loss on reduction diets or weight gain with nutritional interventions and supplementation. Weight changes are assumed to reflect changes in the amount of body fat. However, changes in body weight may also result from differences in hydration, oedema, tumour growth, and trauma, as well as from factors such as the amount of food in the gastrointestinal tract and the fullness of the bladder. Weight may remain constant if the loss of muscle mass is masked by increased fat as seen in sarcopenia, the age-related loss of muscle, or by increased fluid retention.

Weight-for-height (or length) can be used to indicate body composition in adults and is an age-independent measure of body composition in children. Growth can be measured in children by consecutive measurements of weight over time (growth velocity) or by weight-for-age if the children's ages are known.

Head Circumference

Head circumference is measured in infants and young children, to the nearest 0.1 cm, with a narrow flexible nonstretch tape laid over the supraorbital ridges and the part of the occiput which gives the maximum circumference. The head circumference of infants increases rapidly in the first 2 years of life. Increase in head circumference in the first 2 years of life is affected by nutritional status and nonnutritional problems, including some diseases, genetic variation, and cultural practices.

Mid-Upper Arm Circumference

Mid-upper arm circumference (MUAC) is measured in adults and children, to the nearest 0.1 cm, using a flexible nonstretch tape laid at the midpoint between the acromion and olecranon processes on the shoulder blade and the ulna, respectively, of the arm (**Figure 2**). MUAC is a measure of the sum of the muscle and subcutaneous fat in the upper arm. In severe malnutrition both fat and muscle are reduced in the upper arm. Oedema may increase a limb's circumference but it is not usually a problem of the upper arm. MUAC can be used as a indicator of body composition in adults and children. Since MUAC increases little between the age of 6 months and 5 years, it can be used in preschool children as

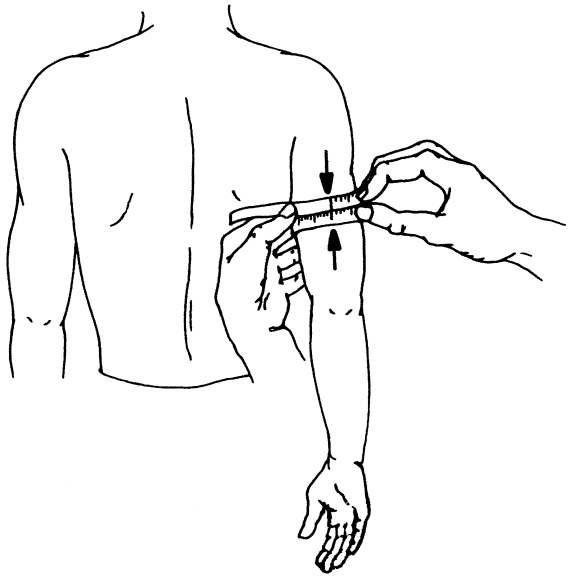

Figure 2 Measurement of upper arm circumference at the mid-point of the upper arm. (Reproduced with permission from Frisancho AR (1990) *Anthropometric Standards for the Assessment of Growth and Nutritional Status*. Ann Arbor: University of Michigan Press.)

an age-independent screening tool for severe malnutrition. A MUAC less than 12.5 cm suggests malnutrition. A MUAC greater than 13.5 cm is normal.

Skinfold Thickness

Precision skinfold thickness callipers are used to measure the double fold of skin and subcutaneous fat to the nearest millimeter. The usual sites of measurement are at the triceps (TSFT), the midpoint of the back of the upper arm (**Figure 3**); the biceps (BSFT) at the same level as the TSFT but to the front of the upper left arm; the subscapular (SSFT) just below and laterally to the left shoulder blade (**Figure 4**); and the suprailiac (SISFT) obliquely just above the left iliac crest. Skinfold thicknesses can also be measured at the mid-thigh, mid-calf, and abdomen.

Skinfold thicknesses are difficult measurements to make with precision and accuracy: It is difficult to pick up a consistent fold of skin and subcutaneous fat; in the very obese, the skinfold may be bigger than the callipers can measure; the fold of skin and fat compresses with repeated measurements; and the careless use of the callipers causes pain, bruising, and skin damage to subjects. There is, therefore, likely to be considerable inter- and intraobserver error in the measurements.

Skinfold thicknesses measure subcutaneous body fat and, therefore, indicate body composition. TSFT and SSFT indicate subcutaneous fat on the limbs and body trunk, respectively. Skinfold thickness measurements mistakenly assume that subcutaneous fat, measured at one or more selected sites, measures total body fat stores. However, subcutaneous fat at one site may not reflect fat stores at another site, and may not be positively correlated with the amount of visceral fat deposited around the internal organs of the body. Subcutaneous fat, and therefore skinfold thicknesses at the different sites, changes at varying rates with age, weight change, with diseases such as diabetes, and in women during pregnancy, postpartum, and at the menopause. Skinfold thicknesses are not useful for monitoring short-term change in fat stores. If only one skinfold thickness measurement is made, TSFT is most commonly selected. TSFT correlates with estimates of total body fat in women and children. SSFT is better than TSFT as an indicator of total body fat in men. SSFT has been shown to be a predictor of blood pressure in adults independently of age and racial group.

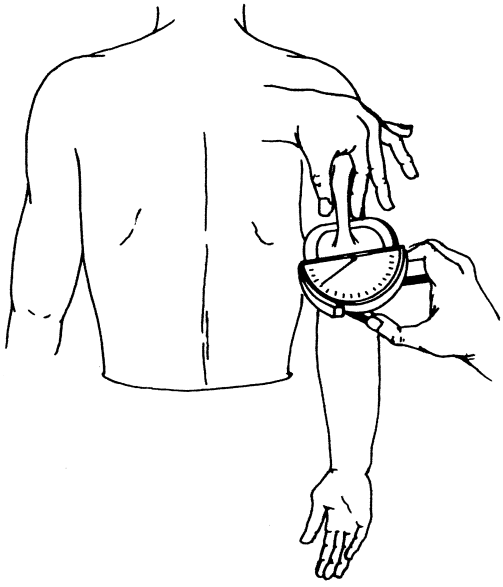

Figure 3 Measurement of triceps skinfold using a Lange caliper. With the subject's arm in a relaxed position, the skinfold is picked with thumb and index fingers at the mid-point of the arm. (Reproduced with permission from Frisancho AR (1990) *Anthropometric Standards for the Assessment of Growth and Nutritional Status*. Ann Arbor: University of Michigan Press.)

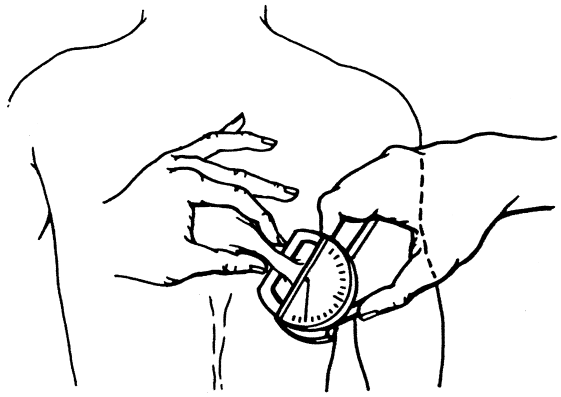

Figure 4 Measurement of subscapular skinfold using a Lange caliper. With subject's arm and shoulder relaxed, a horizontal skinfold is picked approximately 1 cm below the tip of the scapula with thumb and index fingers. The caliper is applied 1 cm from fingers. (Reproduced with permission from Frisancho AR (1990) *Anthropometric Standards for the Assessment of Growth and Nutritional Status*. Ann Arbor: University of Michigan Press.)

Waist and Hip Circumferences

Waist and hip circumferences are measured to the nearest 0.1 cm using a flexible narrow nonstretch tape in adults wearing minimal clothing, standing straight but not pulling in their stomachs. Waist circumference is measured halfway between the lower ribs and the iliac crest, while hip circumference is measured at the largest circumference around the buttocks. Measurement error occurs if the tape is pulled too tight or loose, or if subjects wear clothes with belts and/or full pockets.

With increase in waist circumference there is an increase in insulin sensitivity, while a waist circumference greater than 94 cm in men and 80 cm in women has been associated with increased risk factors for cardiovascular disease.

Elbow Width

Elbow width is the width of the epicondyles of the humerus with the elbow flexed at 90°. Sliding callipers are used to measure elbow width in adults to the nearest 0.1 cm. Elbow width is a measure of bone size. Frame size can be determined by comparison with reference values either by age or by height and sex.

Nutritional Indices

Most single anthropometric measurements do not in themselves assess nutritional status. Nutritional indices are derived either by combining two or more anthropometric measurements, shown in laboratory studies to be predictive of body composition, or by comparison of the anthropometric measurements with reference values of healthy, well-fed populations. A combination of these methods can also be used.

Body Mass Index

Body mass index relates weight (kg) with height (m) by a simple calculation to indicate body composition ($BMI = weight/height^2$). It is the most commonly used screening measurement for both obesity and underweight as very low and high BMI are associated with increased mortality and morbidity. BMI classifies adults as underweight, normal, overweight, or obese (**Table 1**). BMI and percentage body fat is only highly correlated at extremes of the distribution. BMI cannot distinguish between adults who are heavy because of fat or heavy because of muscle, takes no account of frame size, and provides no information on body fat distribution. These limitations may result in heavy, muscled sports people being classified as overweight or obese.

Table 1 Classifications of nutritional status as a percentage of ideal body weight and body mass index

% of ideal body weight for height	*Body mass index*	*Nutritional status*
>120	>30	Obese
110–120	25–29.9	Overweight
90–109	20–24.9	Normal
<90	<20	Underweight

In children, BMI is age-dependent. BMI increases rapidly in the first year of life and then more slowly. Children, at extremes of the distribution of reference values by age and sex, can be identified as being abnormally thin or fat for height. The BMI classification used for adults should not be used for children.

Weight-for-Height

Weight-for-height is an indicator of body composition in adults. Reference values by age, sex, and frame size can be used to estimate desirable body weights (%desirable body weight = (actual weight ÷ ideal body weight) × 100), which are categorized by cutoff points (**Table 1**).

Weight-for-height by sex is a sensitive indicator of body composition in children. It appears to be relatively independent of ethnic group in children aged 1–5 years and age-independent in children aged 1–10 years. Children with weights less than 85% of the median reference weight-for-height are considered wasted. It is a useful screening tool for current malnutrition, especially if used with height-for-age. Oedema and obesity, however, may confound the index.

Weight-for-Age

Weight-for-age can be used to monitor growth in children of known age when a series of measurements are made and compared with reference values by sex. A single measurement of weight-for-age does not discriminate between a child who is light for age because of stunting and/or wasting owing to malnutrition, and one who is small for age but healthy and well fed. Children should gain weight as a percentile of the reference values. Failure to gain weight as expected or a weight loss indicates an inadequate diet, infection, and/or lack of care and should be investigated. Maintenance of weight or weight gain may mask the loss of lean body fat and the increased oedema of kwashiorkor.

Growth Velocity

Growth velocity, or change in weight or height over time, can be used to assess growth in children when compared with reference values by age and sex. Growth rates decline in the first few years of life and then increase with the pubertal growth spurt. Premature and small-for-dates children and those recovering from malnutrition and severe infections tend to have higher growth velocities (catch-up growth). Growth velocities are useful to monitor growth and assess the response to therapy including nutritional supplementation.

Head Circumference-for-Age

Head circumference-for-age by sex is used by paediatricians to identify children up to 2 years of age with severe chronic malnutrition pre- and postpartum and the need for further medical investigations. It is not a good indicator of children's nutritional status.

Mid-Upper Arm Circumference-for-Age

Mid-upper arm circumference (MUAC)-for-age indicates body composition (upper arm fat and muscle) in adults and children when used with measurements of weight and height. MUAC measurements are compared with reference values by age and sex. Since the rate of change of arm circumference is slow, it cannot be used to assess growth or monitor the response to therapy.

Mid-Upper Arm Circumference-for-Height

Mid-upper arm circumference-for-height (the QUAC stick) is a cheap, quick, age-independent screening tool for children with malnutrition. It is a vertical stick on which are inscribed the 80 and 85% median reference values for MUAC and height, respectively. A child is considered malnourished if the MUAC is less than 80% of the MUAC expected for height.

Skinfold Thickness-for-Age

Skinfold thickness-for-age and sex indicates subcutaneous body fat stores in adults and children. Reference values for TSFT, SSFT, and the sum of the TSFT and SSFT are available by age and sex.

Measurement of BMI with skinfold thicknesses can identify people who are heavy owing to excess fat or muscle mass. A high BMI and low TSFT and/or SSFT indicate a large muscle mass; a high BMI and high TSFT and/or SSFT indicate a high subcutaneous body fat.

Mid-Upper Arm Muscle Circumference and Upper Arm Muscle Area

Mid-upper arm muscle circumference (MUAMC) and upper arm muscle area (AMA) are estimates of upper arm muscle and, therefore, body composition. They can be used as indicators of muscle mass and protein stores. Both MUAMC and AMA are calculated from measurements of MUAC and TSFT on the mistaken assumption that the arm is cylindrical, the subcutaneous fat is equally distributed, the bone atrophies in proportion to muscle wastage in malnutrition, and the cross-sections of neurovascular tissue and bone are small. The formula, with MUAC and TSFT in mm, is:

$$\text{MUAMC} = \text{MUAC} - (\pi \times \text{TSFT})$$

AMA can be calculated from revised formulae which take account of errors resulting from the noncircular nature of muscle and the inclusion of nonskeletal muscle with MUAC and TSFT in cm:

$$\text{For men: AMA} = \left[\frac{\text{MUAC} - (\pi \times \text{TSFT})}{4\pi}\right]^2 - 10.0$$

$$\text{For women: AMA} = \left[\frac{\text{MUAC} - (\pi \times \text{TSFT})}{4\pi}\right]^2 - 6.5$$

MUAMC and AMA can be compared with reference values by age and sex. AMA cannot be used to monitor change in muscle stores because of the problems in making this measurement. The ratio of AMA to total body muscle mass changes with age and certain diseases.

Arm Fat Area

Arm fat area (AFA) can be derived from measurements of MUAC and TSFT. AMA is a better indicator of total body fat but not percentage body fat, than TSFT alone. The formula used to calculate AFA (with MUAC and TSFT in mm) is:

$$\text{AMA} = \frac{\text{TSFT} \times \text{MUAC}}{2} - \frac{\pi \times (\text{TSFT})^2}{4}$$

AMA can be compared with reference values by age and sex. Theoretically, limb fat area can be calculated for other limbs and the body trunk, but there are no reference values available.

Total Body Fat

Total body fat can be estimated as a percentage of body fat by comparing the sum of TSFT, BSFT, SSFT, and SISFT with reference values derived from laboratory studies by age and sex, or via the estimation of body density from regression equations with skinfold thickness measurements. There are no specific empirical equations which can be used for specific population groups. Lean body mass is calculated by difference. These calculations may overestimate body fat in lean individuals and underestimate body fat in fat adults. They should not be used in undernourished individuals or in those with diseases where the total body water content may be markedly increased.

Waist-to-Hip Ratio

The waist-to-hip ratio (WHR) in adults discriminates between those with upper body or intraabdominal obesity (WHR greater than 1 in men and 0.8 in women) and those with lower body or

peripheral obesity. Genetics, sex, and age partly determine body fat distribution. A high WHR is associated with an increased risk of premature mortality and morbidity.

Reference Values

Anthropometric assessments are interpreted by comparison with reference values by age and sex. Ideally, reference values should represent the range of 'optimum' measurements for health and longevity of a population of the same ethnic origin. Individuals should be considered at nutritional risk when above or below predetermined reference limits or cutoff points, based on functional impairment, clinical signs of deficiency, or increased risk of mortality and morbidity.

In practice, reference values are derived from large sets of cross-sectional anthropometric measurements of representative samples of populations of the same ethnic origin, who are assumed to be well nourished and free from infection, parasitic disease, and any other environmental factors which may affect growth and nutritional status. These data can be supplemented by data derived from direct laboratory studies of body composition. International reference values are used if local reference data are too difficult, time-consuming, and expensive to obtain.

Normal, healthy, well-fed people vary in size. Therefore, reference values are usually presented as percentiles, with values less than the 5th centile or greater than the 95th centile considered outside the normal range. If international reference values are used, it may be necessary to modify the cutoff points used for identifying those at risk for particular populations. Since the rate of growth of children is age-dependent, growth charts of the most commonly used anthropometric measurements and derived indices have been constructed. Children's growth is best monitored by plotting their sequential measurements on growth charts. A well-nourished healthy child should progress along a centile between the 5th and 95th centile for each measurement. When a child's measurements cross centiles of the growth charts, whether owing to growth faltering, failure-to-thrive, or excessive growth, the cause needs to be investigated. In this way anthropometric measurements can indicate the adequacy of a child's diet, the timing of the introduction of weaning foods, the impact of illness, and the response to treatment. To use growth charts such as weight-for-age, height-for-age, and head circumference-for-age, it is essential to know the age of a child accurately. A child's age cannot be estimated accurately by examination. A malnourished child is smaller and looks younger and less mature than a well-fed, healthy child.

To analyse data for screening, surveillance, or research programmes, measurements can be compared with the median (50th centile) of the reference data and expressed as either a percentage of the median value or a modified statistical z-score transformation, where

$$\text{SD score} = \frac{\text{individuals' measurement} - \text{median value of reference value}}{\text{standard deviation value of reference value}}$$

SD scores are appropriate for use in areas with a high incidence of malnutrition. A high proportion of the population have measurements less than the 5th centile of reference values in these areas. A child with a SD score less than -2, irrespective of the nutritional indices used, is considered malnourished. A SD score greater than 2 suggests obesity.

The most commonly internationally used anthropometric reference values for noninstitutionalized adults aged 25–74 years have been derived from the American NHANES I and NHANES II studies, which were undertaken during 1971–74 and 1976–80, respectively. Reference values by sex, height, and frame size for desirable weights-for-height have also been derived from data on the longevity of holders of life insurance policies. These reference values are not taken from a random sample of the population, as only the more affluent in society are likely to hold life insurance; in addition, these values take no account of body composition and make no reference to the incidence of disease.

Many countries have developed their own reference standards for weight and height of children and adolescents. In the United States, the Centers for Disease Control and Prevention (CDC) published in the year 2000 growth charts for children 0–20 years of age, which for the first time included age-adjusted BMI data. The CDC dataset excluded anthropometric information from the most recent surveys fro certain age groups because of the marked secular trend to higher body weights in the US population.

The United Kingdom, France, and several other countries have developed reference growth curves based on national datasets. The World Health Organization is also leading an international effort to develop a truly global reference standard for growth, including reference values that reflect growth rates of exclusively breast-fed infants, who are known to grow at lower rates than formula-fed

infants during the first year of life. Although growth rates differ across countries, there is general consensus that in healthy populations these differences are encompassed within the boundaries of acceptable percentile ranges, usually the 5th and 95th. Furthermore, environmental rather than genetic factors appear to be the main determinants of differences in growth across populations since migration of individuals from a poor to an adequate nutritional environment is usually accompanied by marked gains in height after only a few generations.

Children's growth is influenced by many factors, including sex, ethnic group, breast or bottle milk feeding, their birth order, gestational age of premature children, as well as the size (height) of their parents. Growth charts do not allow for these factors. With the secular changes in height and weight, growth charts derived from anthropometric measurements of children made over 30 years ago may no longer be appropriate to monitor growth of all children today. However, they may still be relevant to disadvantaged groups in the population. Similarly, growth charts of children derived from reference data of today may not be relevant to the children of the future.

A new reference data set, derived from mostly cross-sectional studies undertaken between 1978 and 1990 of 23 000 British children aged 0–20 years, has been developed by the Human Measurements Anthropometry and Growth Research Group. Growth charts from these data have been produced by sex for weight-for-age, height-for-age, length-for-age, head circumference-for-age, and BMI-for-age.

Biochemical Indices

F Fidanza, University of Rome Tor Vergata, Rome, Italy

Biochemical methods are considered to be the most objective measures for the assessment of nutritional status of the individual. The method employed should cover a range of cutoff points specific and sensitive to depletion of the nutrient body pool or tissue store.

The evolution of deficiency for most nutrients, particularly vitamins, progresses in successive stages. The first stage of deficiency is when nutrient body stores begin to be depleted; in this stage, nutrient urine excretion decreases, whereas homeostatic regulation ensures that the level of nutrient in the blood does not change. In the next stage, depletion is more marked; nutrient urinary excretion continues to decrease and its blood and other tissue concentrations are reduced.

A lowering of nutrient metabolites and/or dependent enzymes often characterizes the following stage. Sometimes, lower hormone concentrations and some physiological alterations are observed. In the last stages, morphological and/or functional disturbances are present; at first they are reversible, and then they become irreversible. Nonspecific signs and symptoms can be present; without therapeutic intervention, death can be expected.

Within the framework of the evolution of nutrient deficiencies, the biochemical static and functional tests most commonly used in nutritional status assessment in humans are discussed here.

Static Biochemical Tests

Static tests measure chemically the content of nutrients, their active or inactive metabolites, or other related components in tissues and urine. The choice of tissue or fluid depends on the information required (short-term or long-term status, body pool or tissue store) and on the condition of the subject.

Various confounding factors affect static biochemical tests. Some are of a general kind, such as age, sex, ethnic group, physiological and hormonal status, seasonality, elevation, and thus cannot be eliminated; others are of a technical nature and can be reduced or eliminated by standardization; and others are biological or environmental (e.g., alcohol intake, smoking habits, and use of medicines). The most relevant confounding factors are considered for

each method; those that occur during infection are examined separately.

Protein Nutritional Status

Total serum protein determination is very seldom used because it is no longer considered a sensitive index of status.

Plasma proteins are albumin, transport proteins (transthyretin (TTR) involved in thyroid hormone transport and formerly called prealbumin, retinol binding protein (RBP), and transferrin (TF)) and fibronectin (FB; an apsonic glycoprotein). Serum albumin, measured by an automated dye-binding method, has a rather large body pool and a long half-life and so it is a less sensitive index of immediate nutritional status. TTR, complexed with RBP in the carriage of vitamin A, TF, and FB have a smaller pool size and a shorter half-life than serum albumin and so their concentrations can change more rapidly. Therefore, they are immediate indicators of protein status. Plasma transport proteins are usually measured on radial immunodiffusion plates or alternatively with laser nephelometry. Useful commercial kits are available. Plasma fibronectin is measured only with laser nephelometry. Albumin and transport proteins are negative acute phase reactants. Other confounding effects of protein-losing diseases, such as reduced protein synthesis diseases, conditions involving an increase in plasma volume, or hemodilution and zinc depletion, have been reported. In addition, RBP is sensitive to deficiencies of vitamin A, and TF is affected by iron status. Insulin has also been demonstrated to interfere with plasma transport protein levels.

Urinary creatinine, usually measured with a colorimetric method (also automated), is used as a biochemical marker of muscle mass. In fact, urinary creatinine is a nonenzymatic product of creatine and cannot be reutilized. Various assumptions are required for correct urinary creatinine determination, and various confounding effects are reported (age, diet, intensive exercise, pregnancy, injury, fever, and renal diseases with impaired creatinine clearance). In a clinical setting, the creatinine/height index is preferred, but because of some limitations, it is not very useful.

Urinary 3-methyl-histidine (3-MH) can be measured by ion exchange chromatography or high-performance liquid chromatography (HPLC). 3-MH is present in myofibrillar proteins, and during breakdown it is excreted quantitatively because it cannot be reused or oxidized. Accordingly, it is used as an indicator of muscle protein turnover. Various confounding effects are reported (sex, age, diet, intensive exercise, stress, hormonal and catabolic states, etc.) and so the use of the urinary 3-MH test is considered to be rather problematic.

Insulin-like growth factor-1 (IGF-1), or somatomedin C, is a regulator of anabolic properties. It has been proposed as a sensitive indicator of protein deficiency. It is assayed in serum by a radioimmunoassay method available also in a kit. IGF-1 can also be used as a nutritional marker in adults receiving total parenteral nutrition. Confounding effects of stress, some hormonal diseases, and obesity have been reported.

Plasma amino acid levels have been used in the past to diagnose protein–energy malnutrition. The ratio of free nonessential amino acid levels (glycine, serine, glutamine, and taurine) to the essential amino acid levels (leucine, isoleucine, valine, and methionine) was proposed for the diagnosis of kwashiorkor. In children with this disease, this ratio can be much higher than the normal value of 2. Plasma amino acids were previously assessed by paper chromatographic methods; automated ion exchange or HPLC techniques are now preferred. However, in recent years there has been much less interest in this test.

Essential Fatty Acid Status

A number of measures can be used to assess deficiency of essential fatty acids. In serum cholesterol esters, fatty acids determination is related to recent intake, in erythrocyte membranes it is related to intake during the previous 2 or 3 months, and in subcutaneous fat tissue it is related to intake of fatty acids for more than 1 year. Essential fatty acids are measured by gas–liquid chromatography.

Vitamin Nutritional Status

Vitamin A (retinol) status can be assessed in the liver and plasma/serum. The best method is determination in the liver, but hepatic biopsy is very invasive and unsuitable in population studies. Plasma retinol is usually measured by HPLC after separation from its carrier (RBP), but its marginal values do not always reflect status because of homeostatic control and confounding effects (e.g., protein–energy malnutrition, infection, parasitic diseases, zinc deficiency, liver disorders, and chronic alcoholism). In the case of inflammation, the degree of depression of serum retinol can be quantified by assessing the concentration of certain acute phase proteins (CRP and AGP).

Because serum retinol is closely correlated with serum RBP, the measurement of this transport

protein by the immunodiffusion technique or a portable apparatus has been proposed to assess vitamin A status.

The RBP:TTR molar ratio has been introduced to detect vitamin A deficiency (VAD) in the presence of inflammation. This test was based on the observation that VAD and inflammation were independent causes of low plasma RBP, whereas plasma TTR concentration was reduced only by inflammation. Nonsatisfactory results were reported from two African population groups.

The deuterated-retinol-dilution (DRD) technique is used to indirectly assess total body vitamin A reserves. A dose of deuterium-labeled retinyl acetate is given orally. After allowing time to reach equilibration (3–20 days), deuterated and nondeuterated retinol is measured by gas chromatography-mass spectrometry. A mathematical formula is used to estimate total body stores of vitamin A. Because of a set of assumptions and technical difficulties, this method is used mostly in research projects. In inflammation, the release of RBP is inhibited, so the test is probably unreliable.

In connection with vitamin A, its provitamins and non-provitamins, the carotenoids, need some consideration. β-Carotene and a few other carotenoids play an independent and specific role in preventing oxidation, genotoxicity, and malignancy. The serum level of carotenoids is correlated with vegetable and fruit intake. Lutein is the best indicator of green leafy vegetable consumption. Lycopene is a good measure of tomato-based product consumption. α-Carotene in industrialized countries is probably a biomarker of carrot consumption and in West Africa a good marker of red palm oil consumption. The plasma level of carotenoids is measured by the HPLC system. However, there are difficulties with peak identification and quantification. Confounding effects of diet and season, sex and age, infection, smoking, and drinking habits are reported. With an appropriate HPLC system, it is possible to measure in a single assay vitamins A and E and individual carotenoids.

Vitamin D status is generally assessed by measurement of serum 25-hydroxyvitamin D (25-OHD) and in some circumstances 1,25-dihydroxyvitamin D ($1,25(OH)_2D$). The current test for 25-OHD and $1,25(OH)_2D$ determination in serum is by radioimmunoassay, also available as commercial kits. The HPLC method with ultraviolet detection can be used as an alternative. Confounding effects of seasons, age, sex, drugs, and liver and renal diseases are reported.

Vitamin E status can be assessed in plasma, erythrocytes, platelets, and adipose tissue. The most common and practical measure is α-tocopherol in plasma by HPLC. Because α-tocopherol is bound to lipoproteins, it is preferred to express plasma α-tocopherol relative to serum cholesterol. The determination of α-tocopherol in adipose tissue biopsy provides information on long-term nutritional status, but this test is too invasive. Confounding effects of chronic enteropathies, protein–energy malnutrition, hemolitic anemia, cholestatic liver disease, and some drugs and heavy metals are reported.

Vitamin K status requires a multiple approach including a functional test. Plasma phylloquinone is measured by reversed-phase HPLC using postcolumn chemical reduction followed by fluorometric detection. Determination of the serum undercarboxylated form of prothrombin (PIVKA-II) by enzyme-linked immunosorbent assay (ELISA) and urinary γ-carboxyglutamic acid by HPLC with fluorometric detection has been proposed. Confounding effects of age, sex, season, malfunction of gastrointestinal tract, osteoporosis, liver diseases, antibiotics, and other drugs are reported.

Thiamin status can be assessed by urinary excretion and erythrocyte thiamin pyrophosphate (TPP) tests. Thiamin urinary excretion is indicative of recent dietary intake; thiamin is detected fluorometrically after conversion to thiochrome. If 24-h urine cannot be collected, thiamin should be determined in the fasting morning urine and expressed in relation to creatinine concentration. Erythrocyte TPP is indicative of long-term nutritional status and is assessed by HPLC using fluorometric detection after precolumn derivatization to thiochrome pyrophosphate. The only limitation is TPP instability, and determination should be carried out within 2 h of blood drawing. Erythrocyte TPP levels present large interindividual variation probably as a results of confounding factors (age and sex, alcohol intake, smoking habits, physical activity, and drugs).

Riboflavin status can be assessed by urinary excretion and whole blood flavinadeninedinucleotide (FAD) tests. Riboflavin urinary excretion is indicative of recent dietary intake; riboflavin is measured by HPLC using fluorometric detection. As for thiamin, if fasting morning urine is collected, riboflavin value is expressed in relation to millimoles of creatinine. Confounding effects of physical activity, bed rest, chronic alcoholism, antibiotics, and other drugs are reported. Whole blood FAD is considered a reliable indicator of long-term nutritional status and is assessed by reversed-phase HPLC using fluorometric detection. This test presents some advantages over the functional test

erythrocyte glutathion reductase activation coefficient (EGR-AC).

Vitamin B_6 status is generally assessed by urinary 4-pyridoxic acid (4-PA) and whole blood or plasma pyridoxal-5′-phosphate (PLP) tests. The 4-PA test is indicative of recent intake but also of a deep compartment with slow elimination rate. 4-PA is measured by reversed-phase HPLC using fluorescence detection. When the completeness of 24-h collection is impossible, 4-PA is expressed in relation to millimoles of creatinine. PLP in whole blood or plasma is considered to be an indicator of depletion of vitamin B_6 reserves. In whole blood, PLP can be measured by reversed-phase HPLC using fluorometric detection. A HPLC system with fluorescence detector for determination of vitamin B_6 vitamers and pyridoxic acid in plasma is available. Plasma PLP can also be measured by radioenzymatic assay using tyrosine decarboxylase apoenzyme, which is more sensitive than other methods of analysis. Confounding effects of age and sex, acute phase status, tissue injury, catabolic state, smoking habits, alcoholism, pregnancy, drugs, physical exercise, organic diseases, and some inborn errors of metabolism are reported.

Niacin status can be assessed by measuring the two end products N'-methylnicotinamide (N'MN) and N'-methyl-2-pyridone-5-carboxamine (2-Py) in urine by HPLC. The ratio of these two urinary products is considered to be the best index of niacin nutritional status. With a single HPLC assay, the previously mentioned two nicotinamide metabolites and N^1-methyl-4-pyridone-3-carboxamide (4-Py) can be measured. The ratio (2-Py + 4-Py)/N'MN is proposed; it has a diurnal variation and decreases with cold. However, for nutritional status assessment further investigation is needed.

Folate status can be assessed by serum/plasma folate, which provides information on recent intake, and erythrocyte folate, indicative of body folate stores and long-term nutritional status. Folate is measured by radioassay kits, sometimes simultaneously with vitamin B_{12}. Less practical, although more accurate, are microbiological assays. In a EC-Flair programme intercomparison study, it was observed that radioassay tends to overestimate serum folate and presents considerable between-kit variability; improved standardization of diagnostic kits and the provision of suitable reference material are still of paramount importance. HPLC, liquid chromatography–mass spectrometry (LC–MS), and LC–MSMS methods are now available. Confounding effects of starvation, dietary folate intake and alcohol abuse, pregnancy, smoking habits, and drugs are reported for serum folate; iron deficiency, age, and other disease states are reported for erythrocyte folate.

Vitamin B_{12} status can be assessed by measuring serum or plasma total cobalamins and serum holotranscobalamin II. Serum or plasma cobalamins are determined by competitive protein-binding assay. Kits are available to measure folate simultaneously. Microbiological assays tend to give lower results. Confounding effects of age, sex, impaired absorption by some diseases or drugs, myeloproliferative disorders, worm infestations, and severe liver disease are reported. Holotranscobalamin II is the transport protein of absorbed cobalamin and has been considered as an early indicator of vitamin B_{12} deficiency and possibly a marker of cobalamin malabsorption. Plasma holotranscobalamina II is measured by microparticle enzyme intrinsic factor assay (together with total vitamin B_{12}) or by indirect immunoadsorption method.

Biotin status can be assessed in whole blood by microbiological assay. Radioimmunoassay tests are also available not only for plasma but also for urine. These tests give slightly higher values than microbiological assay.

Vitamin C status can be assessed by ascorbic acid in plasma, buffy-coat, and leucocytes. Ascorbic acid in plasma is considered an index of the circulating vitamin available to tissues, in buffy-coat it is indicative of the intracellular content, and in leucocytes (particularly polymorphonuclear) it is believed to be a good indicator of tissue stores. Whole blood and erythrocyte ascorbic acid determinations are considered of lesser value than plasma for ascorbic acid status assessment. Ascorbic acid in the previously mentioned blood components is measured with a dinitrophenylhydrazine assay and with a more practical HPLC method coupled with electrochemical or amperometric detectors. Also, a HPLC with fluorometric detection method is available. Confounding effects of acute stress, infection, surgery, smoking habits, chronic alcoholism, sex, and drugs are reported. The urinary excretion of ascorbic acid is an index of recent intake; because of instability of the collected sample, the determination is limited to special cases.

Essential Mineral and Trace Element Nutritional Status

Sodium and potassium in plasma/serum have little meaning in nutritional terms; total body Na or K are measured by radioisotope dilution.

Calcium status can be assessed measuring serum or plasma ionized calcium or indirectly by

measuring bone mass and bone density. Plasma ionized calcium provides information on physiological function and is measured by a calcium-selective electrode; bone calcium content is an index of body calcium stores and is measured by neutron activation analysis or dual-photon absorptiometry. Confounding effects of venous stasis, cardiac arrest, large volumes of citrated blood infusion, and high or low pH are reported for plasma ionized calcium.

Magnesium status can be assessed by measuring magnesium in serum, erythrocyte, leucocyte, and urine. Serum magnesium is the method most commonly used. Confounding effects of haemolysis, energetic exercise, and pregnancy are reported. Erythrocyte magnesium is considered indicative of a long-term status. Confounding effects of age, thyroid disease, and premenstrual tension are reported. Leucocyte magnesium is considered indicative of intracellular status. Urinary magnesium is used as an indicator of magnesium deficiency after a load test. Some precautions are necessary for this test. Magnesium is measured by flame atomic absorption spectroscopy (AAS) or automated colorimetric methods. The serum/plasma free ionized magnesium determination by selective electrode has been considered a better indicator of status. Further studies are required.

Iron status is assessed in relation to three stages of development of iron-deficiency anemia. In the first stage, to evaluate the size of body iron stores, serum or plasma ferritin can be measured by radiometric methods or using ELISA. Commercial kits are available. Confounding effects of infection, liver and malignant diseases, acute leukemia, Hodgkin's disease, rheumatoid arthritis, thalassemia major, alcohol consumption, age, and sex are reported. In the second stage, to determine the adequacy of iron supply to the erythroid marrow, serum iron (measured by the colorimetric method, available as commercial kits; AAS is not recommended because it gives higher values), plasma or serum total iron binding capacity (TIBC; by colorimetric or radioactive methods available as commercial kits), erythrocyte protoporphyrin (by specific hematofluorometer), and serum transferrin receptor (by ELISA using developed monoclonal antibodies) are measured. The percentage of transferrin saturation is computed as follows: serum iron/TIBC $\times$ 100. Confounding effects of infection, chronic alcoholism, folate and vitamins B_6, B_{12}, and C deficiencies, acute viral hepatitis, malignancy, shock, physical trauma, pregnancy, and altitude are reported for serum iron; infection, protein–energy malnutrition, alcoholic cirrhosis, malignancy, nephrotic syndromes, entheropathy, pregnancy, viral hepatitis, and oral contraceptive intake are reported for TIBC; and infection, lead poisoning, and porphyrin disorders are reported for erythrocyte protoporphyrin. In the third stage, as indicators of iron-deficiency anemia, hemoglobin (by spectrophotometry or automatically with an electronic counter), hematocrit or packed cell volume (by specially designed centrifuge or an electronic counter), and red cell indices (mean cell volume and mean corpuscolar hemoglobin, both by electronic counter) are measured. Confounding effects of chronic infection, deficiencies of folate and vitamin B_{12}, chronic diseases, hemoglobinopathies, parasitosis, sex, altitude, and smoking habits are reported. All tests of the third stage present low sensitivity and, for the confounding factors, low specificity. The measure of serum transferrin receptor seems to be a promising technique for the evaluation of iron deficiency or toxicity because it is not influenced by infection, inflammation, and chronic diseases. The assessment of serum ferritin and transferrin receptors is considered valuable in screening iron deficiency. Because the measurement of only one variable is not sufficient for the assessment of mild iron deficiency, and also to avoid other limitations, it is recommended to combine two or more independent variables.

Zinc status can be assessed by using AAS to measure zinc in plasma or serum, leucocyte and leucocyte subsets, urine, hair, nails, and saliva. Plasma or serum zinc is the method most commonly used. Many precautions are required during sample collection to avoid the influence of time of day, proximity of meal, stress, hemolysis, and contamination. There are also many pathophysiological conditions that can negatively influence specificity and sensitivity of serum zinc (e.g., infection, stress, chronic disease, exercise, oral contraceptive use, pregnancy, hypoalbuminemia, diabetes, starvation, severe malnutrition, and other catabolic conditions). Therefore, plasma zinc levels are generally considered a poor measure of marginal zinc deficiency. Leucocyte subset zinc, particularly monocyte zinc, is considered a useful indicator of zinc deficiency, but monocyte separation is difficult and a large blood sample must be collected. Zinc in other fluids or tissues is not considered a useful or reliable indicator of zinc deficiency.

Copper status is most frequently assessed in serum or plasma by AAS, even though this measure is of low sensitivity or specificity in the general population. Levels of copper in other tissues or fluids are difficult to assess or are not considered valid indices of copper status. Confounding effects of infection,

inflammation, pregnancy, leukemia, Hodgkin's disease, some anemias, myocardial infarction, malabsorption, ulcerative colitis, Wilson's disease, hepatitis, high-level physical activity, cigarette smoking, age, and sex are reported.

Selenium status is usually assessed measuring plasma or serum selenium by AAS with a Zeeman background correction and also by the fluorometric technique. Although plasma Se determination provides information on short-term Se status, the determination in whole blood or erythrocytes is indicative of long-term status. Confounding effects of some inborn errors of metabolism, congestive cardiomyopathy, age, and some physiological conditions are reported.

The determination of Se in urine presents some limitations and Se levels in hair and nails display some drawbacks.

Iodine status is generally assessed by measuring urinary iodine using the colorimetric method, which reflects iodine intake within the past few days. If 24-h urine cannot be collected, iodine excretion can be expressed per gram of creatinine but only in areas with very low inter-and intraindividual variation in urinary creatinine. In clinical settings, the measurement of uptake of radioactive iodine is used.

Functional Tests

Functional tests are defined by Solomons and Allen as tests that measure behavioral, physiological, or biochemical functions of the organism dependent on the adequate availability of a nutrient or responses to the regularity process to maintain body stores and harmonic internal distribution for those many nutrients that are homeostatically regulated by the organism.

There are few reliable and specific functional tests; other simpler tests, not commonly used, lack specificity. Further studies are required on these tests because they are important for a correct assessment of nutritional status in humans. Some of the confounding factors reported for static biochemical tests also apply to functional tests.

Vitamin Nutritional Status

Vitamin A functional tests are the relative dose–response (RDR) and the modified relative dose–response (MRDR). The RDR test can provide information on liver store and is indicative of marginal status of vitamin A. It consists of the determination of plasma retinol level at baseline (A0), administration of a small dose of retinyl acetate or retinyl palmitate, and a second determination of plasma retinol 5 h later (A5). The response is related to the release from the liver of holo-RBP, and in deficient subjects the plasma retinol will increase after 5 h. RDR is calculated as follows:

$$\mathrm{RDR} = (\mathrm{A5} - \mathrm{A0}) \times 100/\mathrm{A5}$$

The MRDR uses a metabolite of vitamin A (3,4-didehydroretinol (DR)). After a test dose, DR binds to RBP and after 5 h appears in the serum if vitamin A reserves are low. Serum retinol (SR) and DR (SDR) are measured by HPLC. The ratio is calculated as follows:

$$\mathrm{MRDR} = \mathrm{SDR}/\mathrm{SR}$$

This ratio is abnormal when greater than 0.06. Confounding effects of protein–energy malnutrition, malabsorption, inflammation (due to inhibition of release of RBP), and liver disease are reported for both tests.

The vitamin D functional test can be the measure of serum alkaline phosphatase activity. For determination of serum alkaline phosphatase, automated procedures and commercial kits are available. The specificity is not very high and confounding factors are age, sex, pregnancy, and unrelated pathologies.

Vitamin E functional tests consist of the following assays: erythrocyte hemolysis, erythrocyte malondialdehyde, breath pentane, susceptibility of low-density lipoprotein to oxidation, and diene conjugate second derivatives. For the first two assays, there are methodological limitations; for the other assays, further experimentation is needed.

A vitamin K functional test that has been recently proposed is the determination of serum underdecarboxylated osteocalcin by radioimmunoassay. This test is well correlated with static indices. Commercial kits are available, as is a semiautomated bead-based enzyme immunoassay that is less time-consuming.

A thiamin functional test that is commonly used is the erythrocyte transketolase activation coefficient (ETK-AC) test. Transketolase is a thiamin-dependent enzyme with a specific role in the glucose oxidative pathway. Transketolase activity in haemolysed erythrocytes (ETK) is measured either by the disappearance of pentose or by the appearance of hexose by spectrophotometry. In the case of thiamin deficiency, the quantity of hexose is reduced. When TPP is added to the reaction mixture, the enzyme activity is enhanced in thiamin-deficient hemolysates only. The activation coefficient is given by the ratio of enhanced (with TPP addition) to basal (without TPP addition) activity.

Because of limitations, to obtain a correct thiamin nutritional status, basal activity should be carried out together with the activation test. Automation of this test is available. Confounding effects of chronic ethanol exposure, conditions that reduce thiamin intake or absorption, uncontrolled diabetes, hyperparathyroidism, age, stress, and infections are reported. Because various methods of measurement have been proposed, in order to obtain a better interpretation and comparison of results, the standardization of the procedure and the use of quality control samples at various time points have been recommended.

A riboflavin functional test that is commonly used is the erythrocyte glutathione reductase activation coefficient (EGR-AC) test. Glutathione reductase is a flavoenzyme with FAD as a prosthetic group. By measuring the EGR activity by spectrophotometry in erythrocyte hemolysate without FAD addition (basal) and with FAD addition (stimulated), the activation coefficient (the ratio of stimulated to basal activity) can be calculated. The higher the coefficient, the lower the coenzyme content. Automation of this test is available. Confounding effects of glucose-6-phosphate dehydrogenase deficiency, severe uremia, liver cirrhosis, biliary disorders, diabetes, thyroid diseases, congenital heart disease, chronic alcoholism, pyridoxine deficiency, stress, and drugs are reported.

Vitamin B_6 functional tests are the erythrocyte aspartate aminotransferase activation coefficient test and the tryptophan load test. Erythrocyte aspartate aminotransferase activity is measured spectrophotometrically in erythrocyte hemolysate without PLP addition (basal) and with PLP addition (stimulated). The activation coefficient is given by the ratio of stimulated to basal activity. Automation of this test is available. Confounding effects of renal and liver diseases, cancer, celiac disease, high protein diet, thiamin status, alcohol intake, stress, and drugs are reported. The tryptophan load test was used in the past because vitamin B_6-dependent enzymes are involved in the conversion of tryptophan to niacin. After an appropriate loading dose of tryptophan and under controlled conditions, vitamin B_6-deficient subjects excrete tryptophan metabolites (kynurenine, kynurenic acid, and xanturenic acid) in urine measured spectrophotometrically after thin-layer or ion exchange chromatography separation. Confounding effects of protein intake, exercise, pregnancy, some hormones, and acute phase status in young people are reported. Plasma total homocysteine (tHcy) in the absence of folate and vitamin B_{12} deficiencies can be considered indicative of vitamin B_6 status. For its determination, see the following discussion of folate functional tests.

Folate functional tests are the plasma homocysteine, urinary formiminoglutamic acid (FIGLU), lymphocyte deoxyuridine (dU) suppression, and hypersegmentation of neutrophilic granulocytes assays. Folate and, to a lesser extent, vitamins B_{12} and B_6 are involved in tHcy metabolism. Plasma homocysteine concentration, in the absence of vitamin B_{12} and B_6 deficiencies, is considered a test of folate status. Because an elevated plasma tHcy concentration is associated with an increased risk of cardiovascular diseases, the determination of this amino acid in plasma has become very common. Various methods are available for tHcy determination. The most commonly used is the HPLC method with fluorescence or ultraviolet (UV) detection, which presents some problems for standardization. Capillary electrophoresis methods with laser fluorescent or UV detection have several advantages. Immunoassay methods are all automated, not time-consuming, and easy to use because of the availability of commercial kits. The chromatographic method coupled to mass spectrometry and with isotopic dilution is considered a reference method due to its high level of accuracy and precision. In a Dutch population study, it was observed that after adjustment for confounders (age, intake of other B vitamins and methionine, smoking, and alcohol consumption) folate was independently inversely associated with plasma tHcy concentration. Other confounding factors are renal failure, inborn errors affecting enzymes involved in lowering tHcy level, lack of exercise, hypothyroidism, psoriasis, and a few drugs. FIGLU acid is eliminated due to the inhibition of the conversion of histidine to glutamic acid in folate deficiency. However, the specificity of this test is low and its use limited. The other two tests are too complex, not very specific, and require further investigation.

Vitamin B_{12} functional tests are the urinary/serum methylmalonic acid (MMA), plasma/serum tHcy, and dU suppression assays. MMA increases in vitamin B_{12} deficiency; the loading with valine or isoleucine produces a marked increase in both urine and serum. MMA is measured by gas chromatography–mass spectrometry. In vitamin B_{12} deficiency in the absence of folate and vitamin B_6 deficiencies, tHcy in plasma increases and decreases with B_{12} administration. For tHcy determination, see the discussion of folate functional tests. The dU suppression test is rather complex and not specific for assessment of vitamin B_{12} status.

Vitamin C functional tests are the lingual vitamin C and intradermal 2,6-dichlorphenolindophenol

solution assays. The time to decolorize this solution is inversely correlated with plasma vitamin C levels. However, in humans both methods have low precision.

Zinc functional tests are serum or plasma alkaline phosphatase, erythrocyte metallothionein (MT), monocyte metallothionein mRNA (MTmRNA), and serum thymulin assays. Alkaline phosphatase is a zinc metalloenzyme; rather than being indicative of zinc deficiency, it is considered to be of value after zinc supplementation but with contrasting results. A commercial kits is available for plasma alkaline phosphatase determination. Alkaline phosphatase activity has low specificity and is subject to pathophysiological conditions. Erythrocyte MT decreases in moderate and severe zinc depletion and changes in response to elevated dietary zinc intake. Erythrocyte MT is measured by sandwich ELISA assay. MTmRNA is a new approach to zinc status assessment. It responds more rapidly to zinc supplements than erythrocyte MT. MTmRNA is measured in monocytes by competitive reserve transcriptase-polymerase chain reaction. An improvement of the this method is the determination of MTmRNA on blood samples spotted onto filter paper. Confounding effects are limited to infection. MT and MTmRNA assays are very promising; further studies are needed because of the difficulty in their determination. Serum thymulin activity is decreased in zinc deficiency because it requires zinc to maintain its structure. This test needs further investigation.

Copper functional tests are serum caeruloplasmin, erythrocyte superoxide dismutase (SOD), and leucocyte/platelet cytochrome *c* oxidase assays. Serum caeruloplasmin, an acute phase reactant protein, can be measured for its oxidase activity on various substrates or by radial immunodiffusion (a commercial kit is available). Serum ceruloplasmin levels are increased with exercise, stress, pregnancy, trauma, cigarette smoking, infection, and malignancy and decreased with nephrosis, advanced liver disease, malnutrition, protein-losing enteropathies, and drugs. Cu, Zn SOD is a cytosolic metalloprotein that catalyzes the reduction of superoxide to hydrogen peroxide and oxygen. It is considered to be a better indicator of reduced copper status than serum copper or caeruloplasmin. The major disadvantage of this test is the lack of a standard assay. Reference values depend on the analytical method. For determination, commercial kits are available. Confounding effects of Down's syndrome, uraemia, various anaemies, Duchenne muscular dystrophy, glutathione reductase deficiency, and porphyria are reported. Tests on cytochrome *c* oxidase seem to be more reliable than erythrocyte SOD as indicators of copper stores. They are not affected by sex and hormone use, but the enzyme is rather labile and presents large intersubject variations. For technical improvement, further studies are warranted.

Selenium functional tests are plasma, erythrocyte, and platelet glutathione peroxidase activity (GSF-px) assays. The plasma GSH-px is a useful index only in populations with low Se intake; it responds rapidly to supplementation. Erythrocyte GSH-px presents a plateau at $1.77\,\mu mol\,l^{-1}$, above which it is independent of Se status. In addition, erythrocyte GSH-px responds slowly to depletion and supplementation. Platelet GSH-px responds rapidly to Se dietary changes and presents the maximum activity at Se levels of $1.25–1.45\,\mu mol\,l^{-1}$. Accordingly, it is considered to be a sensitive indicator of changing Se status. GSH-px can be measured with coupled enzyme assay or ELISA; commercial kits are available. Confounding effects of age and sex, physical activity, essential fatty acid deficiency, vitamin B_{12}, and iron deficiencies, and stress from antioxidants are reported.

Iodine functional tests are the determination of the thyroid hormones, thyroxine (T_4) and 3,5,3′-triiodothyroxine (T_3), and pituitary thyroid-stimulating hormone (TSH) in serum by specific competitive radioimmunoassay methods (available in kits).

Choice of Laboratory Tests

The choice of laboratory tests depends on the type of study to be carried out. In field nutritional epidemiology studies, particularly in developing countries, the number of tests will be limited by the sample size, the suspected prevalence of deficiencies, the local laboratory conditions, and the availability of skilled personnel and economic resources. In general, the following common tests can be suggested: hemoglobin, hematocrit, serum iron, TIBC, serum ferritin, blood protoporphyrin, serum albumin, plasma transport proteins, and serum zinc. In specific cases, serum retinol, other vitamins in blood or urine, and some hormones (thyroxine and TSH) and minerals (urinary iodine) can be added.

In population studies to be carried out in developed countries with high-level laboratory facilities, the selection of laboratory tests depends on the purpose of the study, sample size, and financial resources. The assessment of protein status is in general limited to plasma transport proteins, unless there are other specific reasons for using other variables. Essential fatty acid status is assessed in lipid pattern studies; the choice of test is determined by

Table 1 Summary of Flair Concerted Action No. 10 recommended methods

Micronutrient	*Recommended method*	'*Best available*' *method*	*Additional methods of use in some circumstances*
Vitamin A		Serum retinol	RDR test MRDR test Isotope dilution technique RBP:TTR ratio
Carotenoids		Serum carotenoid profile	Serum lutein Serum lycopene Serum α-carotene
Vitamin E	Lipid standardized serum α-tocopherol		
Vitamin D	Serum 25-OH vitamin D		Serum 1,25-dihydroxyvitamin D Serum calcium Serum phosphate Serum alkaline phosphatase
Thiamin	ETK stimulation test		RBC TPP
Riboflavin	EGR stimulation test		
Vitamin B_6	Plasma PLP		EAST stimulation test
Vitamin B_{12}	Serum cobalamins		Serum MMA
Folate	RBC folate		Serum folate
Vitamin C	Plasma vitamin C Leucocyte ascorbate		
Selenium		Plasma selenium	RBC GSHPx
Iron	Serum ferritin	Transferrin receptors	
Copper		Serum copper (?)	RBC SOD
Zinc		Serum zinc	RBC metallothionein

RDR, relative dose–response; MRDR, modified relative dose–response; RBP, retinol binding protein; TTR, transthyretin; ETK, erythrocyte transketolase; RBC, red blood cell; TPP, thiamin pyrophosphate; EGR, erythrocyte glutathione reductase; PLP, pyridoxal-5′-phosphate; EAST, erythrocyte aspartate aminotransferase; MMA, methylmalonic acid; GSHPx, platelet glutathione peroxidase; SOD, superoxide dismutase.Adapted with permission from van den Berg H, Heseker H, Lamand M, Sandstrom B and Thurnham D (1993) Flair Concerted Action No 10 Status Papers—Introduction, Conclusions and Recommandations. *International Journal for Vitamin and Nutrition Research* **63**: 247–251, with changes suggested by D. Thurnham (personal communication).

the interest in recent intake or long-term status. In association with this test, serum cholesterol and triacylglycerols and also lipoprotein fractions are measured. The selection of micronutrient tests can be determined by the suspected deficiencies from previous dietary surveys; in the absence of dietary data, several tests should be measured because preclinical deficiencies are common in developed societies. A sensible selection can be found in **Table 1**. In the US Third Nutritional Health and Nutrition Examination Survey, most of the recommended and best available methods were used. This is also the case for vitamin status analysis in the recent UK government diet and nutrition surveys of specific population groups.

In a hospital setting, the selection of laboratory tests depends on the clinical conditions of patients on admission and during the subsequent course of injury or illness. Because protein–energy malnutrition can be present in some cases, protein status should be assessed using laboratory tests for serum albumin, plasma transport proteins, and urinary creatinine and 3-methylhistidine, and also for acute phase proteins. Using some of the previous values associated with other variables (immunological functions and anthropometric measurements), indices relating nutritional status to clinical outcome can be computed. Among hospital patients, vitamin and trace element deficiencies are also common; the determination of deficient variables suspected on the basis of history and physical examination is suggested.

Because on various occasions major differences in interlaboratory comparisons and ring tests have been observed, it is essential in the selection of laboratory tests to favor definitive reference methods or, in their absence, standardized and validated methods for which careful collection and handling of samples is compulsory and also appropriate quality control. Commercial-quality control samples or external quality assurance schemes are available only in some cases. For quality control of in-house samples, it is suggested to prepare one sample with low or deficient content and one with normal or

high content. Interlaboratory cross-comparison is highly recommended.

Evaluation of Laboratory Indices

In general, reference values are population specific; accordingly, each major laboratory in homogeneous areas has to derive them from a clinically healthy reference population selected with very specific criteria. These values should preferably be given in percentiles.

In general, cutoff points for an appropriate interpretation of results have been derived statistically from reference values. A current procedure for constructing cutoff point consists of determining the biochemical values that correspond to the earliest determinable physiological, metabolic, functional, and morphological alterations. Such an approach has been followed only in a very few cases, and consequently most available cutoff points should be considered as tentative.

For albumin, the guidelines for interpretation suggested in 1974 are still in use. For children and adults, values $<28\,g\,l^{-1}$ are indicative of a deficient (high-risk) status, and for pregnant women this value is $<30\,g\,l^{-1}$. A marginal (moderate-risk) status is indicated by the following values: infants, $<25\,g\,l^{-1}$; children 1–5 years, $<30\,g\,l^{-1}$; children 6–17 years, $<35\,g\,l^{-1}$; adults, 28–34 $g\,l^{-1}$; pregnant women at first trimester, 30–39 g/l^{-1}; and pregnant women at second and third trimester, 30–34 $g\,l^{-1}$. All values above the moderate risk are indicative of an acceptable (low-risk) status.

Reference values for transport proteins are provided by plate producers. Tentatively, $0.10\,g\,l^{-1}$ for prealbumin and $25\,mg\,l^{-1}$ for retinol binding protein are considered indicative of protein deficiency. For transferrin, values less than $1\,g\,l^{-1}$ are considered indicative of severe protein depletion; marginal status values are between 1 and $2\,g\,l^{-1}$.

For the interpretation of serum phospholipid essential fatty acid values, the ratio triene–tetraene (C 20:3 n-9/C 20:4 n-6) above 0.2 was considered by Holman to be the upper limit of normalcy. The ratio C 22:5 n-6/C 22:6 n-3 can be a sensitive index of n-3 fatty acid deficiency.

The cutoff points for the most widely used micronutrient tests in adults are reported in **Table 2**. Cutoff points are different for children, pregnant and lactating women, and the elderly. These values can be found in reference texts. For antioxidant vitamins and provitamins to prevent chronic diseases, the following optimal plasma levels have been proposed: retinol, $>2.5\,\mu mol\,l^{-1}$; β-carotene, $>0.40\,\mu mol\,l^{-1}$; α-tocopherol, $>30\,\mu mol\,l^{-1}$; and ascorbic acid, $>50\,\mu mol\,l^{-1}$.

Confounding Effects of Infection on Laboratory Assessment

As already indicated, many confounding effects of infection have been observed in many laboratory tests for nutritional status. For protein status, confounding effects of infection are reported for almost all laboratory tests, excluding that for total serum protein. In particular, serum albumin, plasma transport protein, and fibronectin levels decrease because of the increase of acute phase proteins.

For vitamin A, severe systemic infections (e.g., pneumonia, bronchitis, diarrhoea, septicaemia, rheumatic and scarlet fever, malaria, and measles) cause a marked decrease in serum retinol level. This decrease may be due to various factors (e.g., increased retinol excretion in urine and reduced liver release of retinol and RBP to plasma). A reduction of vitamin A liver reserves assessed by the RDR test has been observed in children with chickenpox.

Plasma vitamin E is reduced in malaria-infected patients. This influence is retained via the lipoproteins and not directly. Tests for thiamin status can be confounded by infections that prevent normal absorption (diarrhea and dysentery) or increase the requirement (fever).

For vitamin B_{12}, fish tapeworm or hookworm infestations give a low level of serum vitamin B_{12} because of their preferential consumption of this vitamin. For vitamin C, acute and chronic infections can depress markedly the serum ascorbic acid level due to a decrease in vitamin C reserves.

For iron status tests, infection induces an increase in serum ferritin and blood protoporphyrin levels and a decrease in serum iron binding capacity, serum iron, and hemoglobin. Zinc status tests are influenced by acute and chronic infections. A decrease in plasma zinc has been reported, due initially to redistribution of zinc within the body tissues and then to a negative body balance. This is due to anorexia, which reduces dietary intake, and also to increased losses via the faeces (diarrhea), sweat, and urine.

Regarding copper status tests, infection results in an increase in serum copper level because the leucocytic endogenous mediator induces an increase in serum ceruloplasmin. Jodine status can be influenced by infection because the synthesis of TTR is markedly suppressed.

In nutrition surveys, to correct misclassification of laboratory values due to positive acute phase proteins, the concurrent serum determination of these proteins has been suggested.

Table 2 Tentative cutoff points for interpretation of results of micronutrient tests in adults

	Severe deficiency	*Marginal deficiency*	*Physiological level or range*
Lv retinol (μmol g^{-1})	<0.07		
P retinol (μmol l^{-1})	<0.35	0.35–1.05	>1.05

Clinical Examination

B Caballero, Johns Hopkins Bloomberg School of Public Health and Johns Hopkins University, Baltimore, MD, USA

The clinical evaluation of nutritional status is a fundamental component of health assessment at any age. Along with anthropometry, dietary assessment, and laboratory tests, the physical examination is one of the key tools to evaluate nutritional status.

The two most common settings for a clinical examination are the hospital (inpatient or outpatient) and the field health care unit. In the first situation, the physician or examiner may have access to resources that are usually not available in the field. Because of this and other constraints, the assessment of nutritional status in the field is frequently more narrowly aimed at identifying a specific clinical condition or set of signs and symptoms. In either case, it is essential that information on history and physical findings be collected in a standardized manner in terms of both format and procedures. The former is usually best achieved by the use of preprinted or computerized forms. Electronic forms can be programmed to perform immediate range checking as values are entered, thus alerting the operator when values out of range are entered. Procedures for examination must be clearly defined in writing, and any health worker should be able to follow the instructions and perform an acceptable measurement. Although many components of the examination are subjective, it is important to standardize as much as possible terms such as 'minor,' 'average,' and 'large' within the group of examining persons, attributing a numeric value whenever possible. If data entry requires selecting from a numeric scale, they should be also standardized by cross-validation with experienced personnel or by means of photographs or models.

The two components of the clinical assessment are the medical history and the physical examination (**Table 1**).

Table 1 Major components of a nutrition-oriented medical history

Medical history
History of weight loss or gain
Gastrointestinal symptoms (nausea, diarrhea, flatulence, pain, etc.)
History of changes in color or texture of skin, hair, conjunctiva, buccal mucosa
Use of medications
Physical activity level (work-related, leisure)
History of fatigue, shortness of breath, muscle cramps
Other lifestyle practices
Places of residence, travel (exposure to toxins, sunlight, food contaminants)
In children and adolescents
– Growth history
– Neurodevelopmental history
– General school performance
– Parental and siblings' body size (body mass index)
– Pubertal stage
– Food preferences, fads
Dietary history
Habitual dietary intake and preferences
Past diet history
Alcohol consumption
Food allergies and intolerances
Assessment of dietary intake
– 24-hr recall
– Food frequency questionnaire

Medical History

The medical history for nutritional assessment is no different from a general medical history, in which familial and past and present environmental factors and their possible association with specific diseases or disease risk are considered. For the purpose of nutritional assessment, this information will be used to determine if any nutritional finding or complaint may be caused by an underlying medical condition, particularly one that remains unrecognized at the time of the examination. Additionally, specific medical conditions and their current status are important factors altering nutrient requirements and dietary prescriptions.

One specific focus of medical history in a nutritional assessment context is the exploration of gastrointestinal function. Conditions such as chronic diarrhea, gastroesophageal reflux, and colonic disorders may be associated with reduced nutrient absorption or food avoidance that result in impaired nutritional status. Past history of gastrointestinal problems and/or surgery may also point to current alterations in nutrient digestion or absorption. Other important components of the medical history are history of weight loss or gain, past and present use of medications, use of special foods or formulas, changes in taste or smell, and food allergies and intolerances.

In children and adolescents, the medical history must also obtain information on neurodevelopmental stages, history of behavioral problems, and overall school performance. Food preferences must be noted, particularly in adolescence, when adoption of unconventional dietary practices is more likely to occur.

Physical Examination

As noted previously, anthropometric measurements are a key component of the physical examination. Measurement of weight and height is perhaps one of the most frequently performed nutritional measurements. Although its value is limited with regard to identifying specific nutrient deficiencies, it is invaluable to evaluate growth and adequacy of past and present diet in infants, children, and adolescents and to identify undernutrition and obesity in adults. Measurements should be done by trained personnel and following standard protocols. In addition to anthropometry, the physical examination focuses on signs of nutrient deficiency or excess. These signs usually appear only when the deficiency is advanced and are not to be expected in marginal deficiencies. Furthermore, the time that it takes for a deficient intake of a given nutrient to cause clinical manifestation of deficiency varies considerably, depending on whether the nutrient is stored in the body and on the initial status of the reserves. Typical signs for selected nutritional deficiencies are presented in **Table 2**. Virtually none of these signs, with the exception of Bitot's spots, are pathognomonic for one specific deficiency. However, they are useful in indicating a specific nutrient impairment and prompting further evaluation.

The physical examination should start with a general visual assessment of the patient. In children, state of alertness, willingness to engage in play, or

Table 2 Typical clinical signs of selected nutritional deficiencies

Deficiency	*Signs*
Protein–energy malnutrition	Hair: depigmentation, thinning, pluckability
	Edema in lower extremities (generalized in severe cases)
	Muscle wasting
	Decreased subcutaneous fat
	Skin: diffuse depigmentation, flaky dermatosis
	Liver enlargement
Vitamin A	Bitot's spot
	Conjunctival xerosis
	Corneal xerosis
	Keratomalacia
	Night blindness
Riboflavin	Angular stomatitis
	Cheilosis
	Scrotal (vulvar) dermatosis
	Red tongue
	Corneal vascularization
Thiamin	Edema
	Hyporeflexia
	Muscle tenderness
	Cardiac enlargement
	Tachycardia
Niacin	Pellagroid dermatosis
	Scarlet, raw, fissured tongue
	Malar and supraorbital pigmentation
Vitamin C	Bleeding, spongy gums
	Petechiae
	Ecchymoses
	Epiphyseal enlargement
	Atrophy of lingual papillae
	Follicular hyperkeratosis
Vitamin D	Active rickets: rib beading, epiphyseal enlargement, persistently open fontanelle, craniotabes, hypotonia
	Residual rickets: frontal or parietal bossing, bowlegs, knock-knees, thorax deformities
Iron	Pale conjunctiva
	Atrophy of lingual papillae
	Koilonychia
Folic acid, B_{12}	Usually associated with pallor of anemia
	Peripheral neuropathy (B_{12})
Iodine	Thyroid enlargement

resisting examination are important clues to energy level and physical strength. A generalized loss of fat depots, or excess adiposity as in the obese, is readily identifiable in most circumstances. A general overview can also identify pallor, loss of muscle mass, and skin changes.

Numerous signs of nutritional deficiencies can be identified in the skin and hair. Because skin exhibits a relatively rapid turnover, impairments in protein synthesis can result in fragile, flaky, and discolored skin. Vitamin A deficiency typically causes a dry, hyperkeratotic skin. The dermatitis of pellagra consists of patchy areas of hypo- or hyperpigmentations, usually in sun-exposed body regions, eventually progressing to hardened, broken surfaces. In protein–energy malnutrition, hair may become brittle, thin, and easily pluckable. Fluctuations in the rate of synthesis of hair protein may result in band discoloration, where pale and normal colors alternate, resulting in the 'banner sign,' typical of kwashiorkor. Petechiae or hematomas may result from protein–energy malnutrition or vitamin K or vitamin E (in the newborn) deficiencies.

One of the most specific signs of nutritional deficiency can be identified in the eye. Vitamin A deficiency produces a series of alterations in the conjunctiva and the cornea that not only indicate a deficiency of this nutrient but also help grade its severity. The most commonly used classification of vitamin A deficiency is primarily based on eye findings, from Bitot's spots to perforated keratomalacia. Conjunctival pallor has been a classic sign of anemia, but its sensitivity varies substantially depending on ethnicity, ambient lighting, and experience of the observer.

The mouth and tongue are also areas where typical manifestations of deficiency can be detected. A red tongue is a classic sign of riboflavin deficiency but has also been associated with niacin deficiency; the latter may also include fissures. Conversely, a pale tongue may indicate iron deficiency. Glossitis, with or without color changes, has been linked to pyridoxine deficiency. A similar condition, including pain and intense red color, has been associated with biotin deficiency. Angular stomatitis and ulcerations and other lip lesions are associated with riboflavin or ascorbic acid deficiencies. In the latter, extensive involvement of the gums (swelling and bleeding) is also typical. Atrophy of the papillae occurs in vitamin B_{12}, niacin, and folate deficiencies. Excess vitamin A intake may result in discoloration of the gingival mucosa.

Rib beading (also known as rickets rosary) is a typical sign of vitamin D deficiency in children, but a similar manifestation may appear in vitamin C deficiency (scurvy). Ephyphiseal enlargement and bowlegs are other classic signs of rickets. A distended abdomen is characteristic of protein–energy malnutrition in children. In the lower limbs, inspection must ascertain the presence of edema, which is also associated with protein–energy malnutrition.

Peripheral neuropathies such as those associated with beriberi or vitamin B_{12} deficiencies may result in visible impairment of limb movements, such as the 'foot drop' of dry beriberi.

In preadolescents and adolescents, assessment of sexual maturation (usually following the Tanner staging) is an important component of the physical examination, although it is not always feasible due to cultural and practical reasons. Alternatively, more limited information may be obtained in girls by self-reported menarcheal status. Self-assessment of Tanner stage by comparison with photographs is another useful alternative, but use of these photographs with children may not be acceptable in some communities.

In order to obtain a unified rating of a person's nutritional status, it is desirable to integrate clinical, laboratory, and functional data into a single scoring system. Several approaches to achieve this have been proposed, and their use will depend primarily on the target population and the intended use of the score. The Subjective Global Assessment is an approach that relies primarily on data from the physical examination and thus can be readily performed after this examination has been completed. Other scoring systems, such as the Prognostic Nutritional Index or the Instant Nutritional Index, rely to variable degrees on combinations of clinical and laboratory data.

NUTRITIONAL SUPPORT

Contents

In the Home Setting

M Elia and R J Stratton, University of Southampton, Southampton, UK

The prevalence of nutritional problems in developed societies is a cause of growing concern. At one end of the nutritional spectrum, the obesity 'epidemic' is spreading at an alarming rate. At the other end of the spectrum, protein–energy malnutrition and nutrient deficiencies are also common, especially in the elderly and in those with disease. **Table 1** shows the frequency of specific vitamin deficiencies and underweight (body mass index <20 kg/m^2) in people aged 65 years or older resident in the United Kingdom. Complimentary information on protein–energy status can be obtained by considering simple criteria, such as those used by the 'Malnutrition Universal Screening Tool' (MUST) (**Figure 1**). This tool, which depends on weight loss and body mass index (and an acute disease effect, which does not normally apply to community patients), has been used to estimate that 10–15% of older people in the United Kingdom are at medium to high risk of malnutrition. The prevalence of malnutrition increases with age, and it is more common in the presence of disease and in institutions, where about one in five people are at risk. With the growing number of older people, especially those living in nursing homes and alternative care facilities, the overall prevalence of malnutrition may increase. It is disturbing that malnutrition is underrecognized and undertreated, despite its adverse effects on the individual and society.

The first important step in the management of malnutrition is identifying it using one of a number of validated nutritional screening tools. MUST was developed specifically for all types of patients in all health care settings. The potentially broad application of the same tool encourages consistency of thought and continuity of care through different health care settings. The care plan linked to this tool varies from dietary restriction in the case of obesity to supplementation and other forms of nutritional support in the case of malnutrition. For special situations, enteral tube feeding (e.g., in some patients with swallowing problems) and parenteral (intravenous) nutrition are required.

This article focuses on the treatment of malnutrition (rather than obesity) in the home setting. This treatment includes dietary counselling and fortification, oral nutritional supplementation (mixed macro- and micronutrient supplements), and artificial nutritional support (enteral tube feeding (ETF) and parenteral

Table 1 Proportion of subjects 65 years or older with selected vitamin deficiencies and body mass index <20 kg/m^2

	Free living (%)	*Institutions (%)*[a]	*Criteria*	
Vitamin deficiencies				
Folate deficiency	29	35	Red blood cell concentration	<345 μmol/l
– Severe deficiency	8	16		<230 μmol/l
Thiamine deficiency	9	14	Erythrocyte transketolase activation coefficient (ratio)	>1.25
Vitamin B_{12} deficiency	6	9	Plasma concentration	<118 pmol/l
Vitamin D deficiency	1–2	1–5		<12 μmol/l
Vitamin C deficiency	14	40	Plasma concentration	<11 μmol/l
– Severe deficiency	5	16		<5 μmol/l
Underweight	3	16	Body mass index	<20 kg/m^2

nutrition (PN)). The simplest and most commonly used treatment involves oral nutritional support, which is considered before home enteral tube feeding (HETF) and home parenteral nutrition (HPN).

Oral Nutritional Support

Dietary Counselling and Fortification

Dietary counselling, usually provided by a dietitian, is an integral part of oral nutritional support. It includes advice on dietary fortification, which is often the first-line treatment of malnutrition in the home and other care settings. Counselling may involve advice on eating patterns (e.g., eating certain types of snacks at particular times of day) or addition of energy- and protein-rich food ingredients (e.g., cream, milk, oil, butter, sugar, and skimmed milk powder) to meals. Commercial energy- and protein-containing supplements can also be used to improve intake without substantially altering the taste of food and drink. The use of nutritionally fortified food snacks as part of the diet may improve both the intake and the status of micronutrients. However, the success of these dietary strategies is limited in patients with severe anorexia, those living in poverty and due to other social factors, and in those with inadequate motivation. Thus, patients may find it difficult to purchase, manipulate, or prepare their meals. Financial or other forms of social support, such as help with shopping, cooking (or provision of 'meals on wheels'), and help with eating, may do much to improve intake in some individuals. Although dietary counselling, with or without dietary fortification, is widely used in clinical practice, there is little research supporting its clinical efficacy in patients at risk of malnutrition in developed countries.

Oral Nutritional Supplements

Mixed macro- and micronutrient liquid sip feeds and other oral nutritional supplements (bars, powders, and puddings) are widely used in the treatment

Table 2 Summary of significant functional and clinical outcome improvements following oral nutritional supplementation in community patients from randomised controlled trials

Patient group	*Functional/clinical outcome*
Chronic obstructive pulmonary disease	Respiratory muscle function Hand grip strength Walking distances
Elderly	Reduced number of falls Increased activities of daily living Muscle power
HIV/AIDS	Cognitive function
Liver disease	Lower incidence of severe infections Lower frequency of hospitalisation
Malignancy	Immunological benefits
Osteoarthritis	Increased activities of daily living[a] Improved osteoarthritis index[a]

[a]Nutritional supplement also containing immunoglobulin G (90 mg).
Based on Stratton RJ, Green CJ, and Elia M (2003) *Disease-Related Malnutrition: An Evidence Based Approach to Treatment*. Oxford: CABI Publishing.

of malnutrition in the community setting. A systematic review of 78 randomized controlled trials (RCTs) (including 44 RCTs from the community setting) suggests oral nutritional supplements can improve energy and nutrient intakes, improve body weight (or attenuate weight loss), and improve a number of functional and clinical outcomes in various patient groups (**Table 2**). Meta-analysis of RCTs from both hospital and community settings suggests significantly lower mortality (odds ratio, 0.62; 95% confidence interval, 0.49–0.78) and complication rates (infections and postoperative complications) (odds ratio, 0.29; 95% confidence interval, 0.18–0.47) in patients given oral nutritional supplements (typically 1.05–2.5 MJ (250–600 kcal) daily).

For some patients, nutrition via the oral route is either unable to meet the nutritional requirements (e.g., patients with a poor appetite) or contraindicated (e.g., a cerebrovascular accident patient with aspiration and intestinal failure). For such patients, HETF and HPN may be required, although the treatment is usually initiated in hospital.

Artificial Nutrition Support: Home Parenteral Nutrition and Home Enteral Tube Feeding

Patients suffering from chronic conditions often prefer to be treated in the familiar surroundings of their home rather than in hospital. When the treatment involves sophisticated techniques, it is essential that either the patient or the caregiver is adequately trained to distinguish between problems that can be easily remedied at home and those that need expert advice and treatment in hospital. With the increasing pressure for hospital beds and the increasing cost of hospital care, many forms of treatment that were previously restricted to the hospital environment have extended to the community, including renal dialysis, cytotoxic drug therapy, HETF, and HPN. HETF has grown rapidly so that its prevalence in several developed countries is now several times greater than in hospital. In contrast, PN is still practiced less commonly outside hospital than in hospital and is likely to remain so in the foreseeable future. Both forms of treatment have led to the development of professional teams specialising in nutritional support in both the hospital and the community. These teams deal with problems ranging from simple day-to-day management issues to difficult ethical problems, such as concerning withholding or withdrawing nutritional support.

Origins and Development

The first report of HPN appeared in 1970 in North America, and in Europe the first reports appeared in the late 1970s. The number of people receiving HPN has increased considerably since then but remains substantially lower than for HETF (**Figure 2**).

HETF is a much older technique than HPN, with the first reports appearing centuries ago. Accurate information on the numbers of people receiving HETF is difficult to obtain because HETF tends to be initiated from many centres and centralized reporting and record keeping in most countries are not fully established. There has been rapid growth in HETF attributable to developments in tube technology (flexible fine bore tubes) and endoscopic procedures for placement of gastrostomy tubes (facilitating easier initiation and management of long-term feeding), as well as the development of home care services provided by commercial enteral

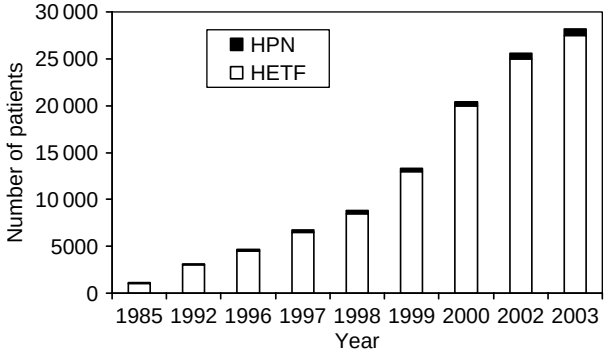

Figure 2 Estimated growth in point prevalence (amount of feeding taking place at a given point in time) in home enteral tube feeding (HETF) and home parenteral nutrition (HPN) in the United Kingdom.

feeding companies. In many developed countries there is considerably more ETF taking place in the community than in hospital. In Britain, there continues to be steady growth (10–20% per year) in the numbers of people receiving HETF, and in 2003, 21 527 people were registered with the British Artificial Nutrition Survey (BANS), with an estimated total number receiving HETF in excess of 25 000. As with HPN, HETF is less common in Europe than in North America and is practised much less in Eastern Europe, India, and China than in industrialized Western countries.

In addition to the differences in prevalence of HETF and HPN between countries, there may also be marked variations within countries. Even within one region of the United Kingdom (south and west regions) the number of individuals receiving HETF in 2002 within different primary care trusts varied from 82 to 632 per 1 million people. Similarly, considerable variation in the point prevalence of HPN was found to exist in different regions of the United Kingdom in 1999 (0 to 36 per 1 million). This large variation, which is unlikely to be due to chance, can be explained by variations in the availability of expertise and support staff, resources to fund such treatment, or local differences in attitudes/policies toward the use of artificial nutrition.

The wide variations in the prevalence of home artificial feeding throughout the world are related to health care economies. There is a relationship between expenditure on health care, as a percentage of gross domestic product (GDP), and the incidence of HPN and HETF. In India, Pakistan, and Africa, where spending on health is low, home artificial nutrition is less common. In Western Europe, where health care accounts for a greater proportion of GDP, home artificial nutritional support is more common. In the United States, with an even greater expenditure on health care, the prevalence of HPN and HETF is higher than anywhere else in the world.

Indications

Home enteral tube feeding The indications for HETF are different for adults and children. In adults, the most common indications are neurological disorders of swallowing resulting from cerebrovascular accidents, Parkinson's disease, and obstructive lesions of the upper gastrointestinal tract. These mainly affect older individuals so that in various countries approximately half of HETF is administered to individuals aged 65 years or older. In children, HETF is usually used in conditions that lead to failure to thrive, such as cerebral palsy, cystic fibrosis, congenital malformation, and metabolic disorders.

As with HPN, one of the main differences between countries in the indications for HETF concerns malignant disease. In North America, ~40% of people receiving HETF have been reported to have malignant disease, and up to ~70% in Italy. In the United Kingdom, the number of patients receiving HETF because of malignancy has steadily increased in both adults and children so that by 2000, 1 in 4 adults and 1 in 12 children who started HETF had cancer, usually of the upper gastrointestinal tract (mainly oesophageal, head and neck, and oropharyngeal). The age distribution of people receiving HETF is influenced by the indications. Because disorders of swallowing (strokes, motor neurone disease, and other neurological conditions) and cancer of the upper gastrointestinal tract tend to occur in older age groups, adults receiving HETF tend to be elderly (with more than 60% of those in the UK being older than 60 years and 46% older than 70 years). In recent years, there has been a trend to provide HETF to an older and more disabled population. Recent surveys in the UK suggest that approximately 50% of patients are house or bed bound and require total help to manage their tube feeding. Because the majority of these patients with high levels of disability are at home (spending <1% of their time in hospital), there are resource implications associated with the provision of health care by the underrecognized and underappreciated voluntary caregivers. Approximately 20% of those receiving HETF are children, and many children who started HETF because of cerebral palsy or congenital handicap continue tube feeding into adulthood.

Home parenteral nutrition The main indications for HPN are Crohn's disease, ischaemic bowel disease, motility disorders, or bowel and malignant disease. Patients receiving HPN are usually younger than those who receive HETF, although there is an overlap. There are also differences between the practice of HPN in different countries. One of the main differences concerns malignant disease. In the United States, 40–50% of patients receiving HPN have been reported to have cancer, and similar if not higher percentages have been reported in some European countries, such as Italy. Early reports from the United Kingdom and Denmark suggested that only a small proportion of HPN (~5%) involved patients with cancer, although this has increased with time. For example, in the United Kingdom it has steadily increased so that by 2003, one in seven patients starting HPN had cancer.

Table 3 Standards of practice for home enteral tube feeding (HETF)

Structure	*Process*	*Outcome*
There will be a training program for the health care professionals involved in the care of patients receiving HETF.	Discharge planning will be performed only by professionals who have the necessary experience or who have undertaken a course of training in the topic.	The patient has confidence in the hospital team planning his/her discharge.
There will be a model of care for patients needing HETF.	The members of the multidisciplinary team will be involved in writing the 'mission statement' on which the model is based.	The patient will know the benefits, aims and objectives of the HETF team.
There will be a relaxed, quiet area suitable for private discussion.	There will be a caring and compassionate atmosphere with adequate time for discussion.	The patient will feel able to express his/her fears and expectations.
The discharge planning documentation will include sections on domestic, family and social circumstances.	The nutrition team will evaluate, with the patient and family, how HETF will alter his/her way of life.	The patient will believe that the feeding system can be integrated into an acceptable way of life.
There will be written patient/carer learning goals for HETF.	A designated nurse or dietitian will be responsible for teaching the patient according to his/her individual capacity for learning.	The patient will be able to demonstrate the necessary skills and achieve all the learning goals.
There will be an instruction manual for HETF.	Information and procedures will be regularly updated in order to reflect developments and innovations in tube feeding, access, nutrients and delivery systems.	The patient will perform therapy based on current practice.
A relative, friend or appropriately trained health care professional will be available to deliver therapy if the patient is unable to do so.	The nurse/dietitian will help the patient identify the most appropriate carer. A community nurse will be given the opportunity to visit the patient in hospital and observe therapy before the patient is discharged.	The patient has confidence that safe care will be available at home.
Access to the gastrointestinal tract will be achieved by a tube suitable for long-term use.	The patient, nurse and doctor will choose the most appropriate tube and access site.	The patient will use a feeding tube which is acceptable and accessible.
There will be a policy for sharing care with the patient's General Practitioner (GP).	The GP will be contacted and a shared care protocol agreed.	The patient will know the responsibility of each health care professional.
Written information describing HETF will be available for the GP.	The hospital team will provide the GP with the information before the patient is discharged, together with the discharge date and on-call telephone numbers.	The patient will have confidence in his/her GP's knowledge of HETF.
There will be written procedures for the management of feeding tubes.	The nurse/dietitian will adapt the procedures according to the patient's physical skills and domestic circumstances.	The patient's daily life will not be restricted by prolonged inappropriate procedures.
There will be a written prescription for the enteral feed (and other prescribable items).	The patient's GP will be contacted and advised on how to prescribe the feed.	The patient will have the enteral feed available at home on the day of discharge.
There will be a list of the required equipment, e.g., syringes, connectors, administration sets, pump, drip stand, telephone.	Before discharge the patient's home health authority will be provided with the list and asked to arrange supply by making local arrangements or establishing a contract with a commercial supplier.	The patient will have all the necessary supplies in his/her home on the day of discharge.
There will be an on-call system for providing expert advice to the patient by telephone day and night.	The nurse/dietitian/doctor will explain the system to the patient and identify the professions involved.	The patient will know the names and telephone numbers of health care professionals to contact in case of emergency day or night.
Information will be available describing how the nutrient solutions and supplies will be provided following discharge.	The nurse/dietitian will explain the ordering system and discuss storage, depending on the patient's home circumstances.	The patient will know how to obtain supplies and store and dispose of unwanted material.
There will be a post-discharge monitoring protocol, established by the nutrition team.	Monitoring will be performed by a designated health professional as defined by the protocol.	The patient will know what the follow-up arrangements are.

There has also been an increase in age (due at least partly to the increasing use of HPN in patients with cancer and ischemic bowel disease) so that by 2003 nearly one-fourth of all patients receiving HPN in the United Kingdom were older than 60 years of age.

Organization

The organization and management of HETF and HPN has evolved over time. For example, delivery of feeds and equipment to the first patients who received HPN or HETF was undertaken by the hospitals that initiated the treatment. As the number of patients receiving such treatment increased, commercial organizations have established an organizational infrastructure for delivering feed and ancillary equipment through a national and international network. Some companies employ doctors, nurses, and other staff so that they can provide most of the care, although this practice varies from country to country. In many countries, there is joint care between commercial companies and the national health care systems.

HETF is initiated by many centers or hospitals, and some patients are followed up as outpatients. However, it is impractical to follow up many severely disabled patients in hospital, because they are house bound. Patients receiving HPN are often managed by centres with expertise in nutritional problems (e.g., in France, Denmark, and the United Kingdom). It has been suggested that all patients on HPN should be managed at such centers, but travelling to distant centers may require considerable time, effort, and expense. It is possible for patients to be managed more locally, especially if they are uncomplicated. It remains to be demonstrated if locally managed patients have better satisfaction and similar outcomes as those managed by larger centers. Of course, it is possible to have a system that combines local care and more distant specialist care when required.

Funding arrangements also vary. In several countries, home nutritional support is either totally or partially funded by the national health service, but payment may also be provided by private insurance and individual patients. The overall pattern of funding differs considerably among countries. Sometimes, confusion exists about the funding arrangements even in the same country, and this may limit and delay the use of HETF or HPN.

Patient organizations have developed in some countries, such as Patients on Intravenous and Nasogastric Nutrition Therapy (PINNT) in the United Kingdom. This organization provides support and information to people on home feeding, and it contributes to all levels of the operation of the British Association for Parenteral and Enteral Nutrition (BAPEN), through which it influences policy and decision making. Furthermore, since the feeding equipment for use at home was found to be impractical because it was originally designed for hospital use, PINNT has redesigned the equipment specifically for home use.

Standards of Care

Several surveys have identified inadequacies in training, support, and follow-up of patients receiving HETF and HPN. Specific problems include lack of written instructions about how to manage simple problems that may arise during feeding, lack of telephone contacts for use in emergency, lack of confidence, and inadequacy of equipment for home use. Such surveys have also highlighted the importance of a multidisciplinary approach and the need to undertake home visits to assess the status of severely disabled patients who cannot easily attend a hospital. Pressure on hospital beds has meant that some patients are discharged home before they have been adequately trained, and the care of such patients is sometimes passed on to other health care workers who have little experience of home nutritional support. Since HPN is relatively uncommon in the population, general practitioners may have never encountered patients on this form of therapy and are therefore poorly equipted to manage them. Patients' needs may change during the course of their treatment; therefore, there is a need to establish an organisational infrastructure for continuity of care for HETF and HPN over time and from one health care setting to another. Many hospitals do not have a nutrition team or policies that embrace the needs of people receiving artificial nutrition at home.

A series of guidelines for the management of artificial nutrition in the community have been developed by BAPEN (**Tables 3** and **4**). The guidelines cover aspects of training prior to discharge from hospital (although training can take place at home) and the support required from trained specialist staff once the patient is at home. A national and local organizational structure for delivering the support would aid the process.

Monitoring

The basic elements of monitoring are similar for both HETF and HPN. They include an assessment

Table 4 Standards of practice for home parenteral nutrition (HPN)

Structure	*Process*	*Outcome*
There will be a training program for health care professionals involved in the care of patients receiving HPN.	Discharge planning will be performed only by professionals who have the necessary experience or who have undertaken a course of training in the topic.	The patient has confidence in the hospital team planning his/her discharge.
There will be a model of care for patients needing home intravenous nutrition.	All members of the multidisciplinary team will be involved in writing the 'mission statement' on which the model is based.	The patient will know the beliefs, aims and objectives of the HPN Care Team.
There will be a relaxed, quiet area suitable for private discussion.	There will be a caring and compassionate atmosphere with adequate time for discussion.	The patient will feel able to express his/her fears and expectations.
The discharge planning documentation will include sections on domestic, family and social circumstances.	The nutrition team will evaluate with the patient and family how the HPN will alter his/her way of life.	The patient will believe that the feeding system can be integrated into an acceptable way of life.
There will be written patient/carer learning goals for HPN.	A designated nurse will be responsible for teaching the patient according to his/her capacity for learning.	The patient/carer will be able to demonstrate the necessary skills and achieve all the individual learning goals.
There will be an instruction manual for HPN.	Information and procedures will be regularly updated in order to reflect developments and innovations in venous access, nutrient solutions and delivery systems.	The patient will perform therapy based on current practice.
A relative, friend or appropriate health care professional will be available to deliver therapy if the patient is unable to do so (e.g., parent or guardian of a child).	The health care professional will help the patient to identify the most appropriate carer. The district nurse will be given the opportunity to visit the patient in hospital and observe therapy before the patient is discharged.	The patient has confidence that safe care will be available at home.
Venous access will be achieved by a central venous catheter suitable for long-term use.	The patient, nurse and doctor will choose the most appropriate catheter and access site.	The patient will use a central venous catheter that is acceptable and accessible.
There will be written procedures for the management of central venous catheters.	The nurse will adapt the procedures according to the patient's physical skills and domestic circumstances.	The patient's daily life will not be restricted by prolonged inappropriate procedures.
There will be a policy for sharing care with the patient's general practitioner (GP).	The GP will be contacted and a shared care protocol agreed.	The patient will know the responsibility of each health care professional.
Written information describing HPN will be available for the GP.	The hospital teams will provide the GP with the information before the patient is discharged, together with the discharge date, and on-call telephone numbers.	The patient will have confidence in his/her GP's knowledge of HPN.
There will be a written prescription for the nutrition solutions (and other prescribable items).	The patient's GP will be contacted and advised on how to prescribe the feed.	The patient will have the feeding solution available at home on the day of discharge.
There will be a list of the required equipment, e.g., refrigerator, infusion pump, syringes, sterile gloves, telephone.	Before discharge, the patient's home health authority will be provided with the list and asked to arrange supply by making local arrangements or establishing a contract with a commercial supplier.	The patient will have all the necessary supplies at home on the day of discharge.
There will be an on-call system for providing expert advice to the patient by telephone day and night.	The nurse will explain the system to the patient and identify the professions involved.	The patient/carer will know the names and telephone numbers to contact in case of emergency by day or night.
Information will be available describing how the nutrient solutions and supplies will be provided following discharge.	The nurse will explain the chosen supply system and discuss storage depending on the patient's home circumstances.	The patient will know how to obtain supplies, store them and dispose of unwanted material.
There will be a post-discharge monitoring protocol, established by the nutrition team.	Monitoring will be supervized by the nutrition team.	The patient will know the date of the first outpatient visit and what monitoring will be performed.

of the activity of the underlying disease, the nutritional and metabolic state of the patient, and complications associated with nutritional support (**Table 5**). The clinical history alerts the attending health professional to the general well-being, as well as the likelihood of specific problems, such as dehydration, electrolyte imbalance (e.g., diarrhoea), local infection (e.g., local redness and swelling near the

Table 5 Some complications associated with parenteral nutrition and enteral tube feeding

	Parenteral	*Enteral tube feeding*
Mechanical	Catheter malposition. Insertion trauma (e.g., pneumothorax, brachial plexus injury, cardiac arrhythmia) Catheter blockage, kinking or occlusion Catheter embolus Air embolus Clot embolus (from catheter tip) Lack of access site	Tube malposition (e.g., into lung) Insertion trauma: drainage to stomach and bowel: peritonitis and peristomal leakage and inflammation Tube blockage, e.g., kinking or occlusion
Feed/flow	Nutrient overload (e.g., hyperglycemia, infusional hyperlipidemia)	Diarrhea or constipation Bloated adbomen/cramps Regurgitation/aspiration of feed
Infections	Catheter-related sepsis Infected feed/administration set	Infected feed administration set Infection around gastrostomy
Metabolic	Fluid and electrolyte disturbances Hyperglycemia Deficiency syndromes, e.g., trace elements and vitamins Nutrient overload (see above) and toxicity (e.g., some trace elements)	Fluid and electrolyte disturbances Deficiency syndromes (rate with standard feeds given to typical patients) Hyper/hypoglycemia
Organ tissue dysfunction	e.g., Abnormal liver function, intestinal atrophy, metabolic bone disease	Mainly disease related, abnormal liver function Aspiration pneumonia
Psychological	Anxiety, depression, disturbance in self-image, social isolation	Anxiety, depression, disturbance in self-image, social isolation
Financial	Economic issues vary from centre to centre and country to country	Economic issues vary from center to center and country to country

catheter exit site or peristomal area), blocked tubes and catheters, and so on. Catheter-related sepsis is an important complication of PN, and aspiration pneumonia is an important complication of ETF. The patient/caregiver should have written instructions about basic procedures, which aim to reduce complication rates, and how to deal with simple problems and to recognize those that they cannot readily deal with. Specialist advice should be available 24 h a day. The frequency of complications depends at least partly on the support provided by health professionals.

Dietary intake should be monitored, especially in patients whose clinical status is changing. Appropriate dietary advice may facilitate return to normal oral feeding in some patients. In those with a swallowing difficulty, it may be necessary to assess whether swallowing has improved, with input from speech and language therapists, so that unnecessary HETF is not continued when full oral feeding becomes possible. Studies in the United Kingdom suggest that 15% of patients receiving HETF can revert to full oral feeding after 1 year. Blood tests should be carried out at intervals to check for metabolic stability and specific nutrient deficiencies (e.g., vitamins, minerals, and trace elements) and toxicities. The frequency with which tests are carried out depends on the patient (e.g., whether the patient is receiving HETF or HPN), the duration of feeding, the extent of oral intake, and disease activity.

Outcome

The most important predictor of outcome in patients receiving home artificial nutritional support (enteral or parenteral) is the underlying disease. Therefore, mortality statistics strongly depend on the initial indications. Nevertheless, a few conclusions can be made. First, the complications associated with artificial nutritional support vary but are reported to be responsible for less than 3–5% of deaths. Second, the outcome is dependent not only on the type of disease but also on the stage of the disease (e.g., patients with advanced HIV who start HPN are only expected to survive a few months, whereas patients with less advanced disease are expected to survive longer). Third, the outcome of patients receiving HPN and HETF for a variety of conditions is available from the British Artificial Nutrition Survey (**Table 6**). For patients on HPN, overall mortality at 1 year is 11%, with 16% returning to oral feeding and the majority continuing with HPN. Patients with Crohn's disease often have a good prognosis (with 4% mortality and 38% returning to oral feeding within 1 year). For patients on HETF, typically an older patient group, mortality

Table 6 Twelve-month outcomes for patients receiving home parenteral nutrition (HPN) and home enteral tube feeding (HETF)

	Continuing		*Discontinuing*		
	Continues (%)	*In hospital (%)*	*Transferred to oral (%)*	*Withdrawn/refused (%)*	*Died (%)*
HETF					
All adults ($n=26\,501$)	45.7	0.6	16.2	1.1	36.3
– CVA ($n=9326$)	49.2	0.5	11.5	0.8	38.0
– Oesophageal cancer ($n=2050$)	26	0.7	22.6	2.0	48.8
All children ($n=5419$)	72.9	0.6	18.7	0.9	6.8
– Cerebral palsy ($n=903$)	87.5	0.3	5.2	0.9	6.3
– Congenital handicap ($n=561$)	86.8	1.2	6.4	0.4	5.2
HPN					
All adults ($n=765$)	71.2	0.4	15.7	1.7	11
All children ($n=68$)	77.9	1.5	10.3	0	10.3

Based on British Artificial Nutrition Survey (2004).

is higher overall (36% at 1 year) and outcome varies according to age and condition. The outcome data for two common conditions in adults and children receiving HETF are shown in **Table 6**.

Assessments of quality of life, using EuroQol, suggest that the majority of patients receiving HETF and HPN have some problems (moderate or extreme) with mobility, self care, usual activities, pain/discomfort, and anxiety/depression (five EuroQol dimensions). Mean quality-of-life scores (0, 'worst imaginable health state'; 100, 'best imaginable health state') in adults receiving HPN (53 ± 18) are higher than those for adults receiving HETF (42 ± 27), but both are considerably lower than the scores obtained from the general population, even when adjusting for age. For HETF patients, quality-of-life scores have been found to be similar for those living at home and those in nursing care.

Intestinal Transplantation

In some patients with irreversible intestinal failure, intestinal transplantation can be considered as an alternative to long-term PN. The first intestinal transplantation in humans was undertaken in the early 1960s. Limitations in technical expertise and immunosuppressive therapy meant that none of the original patients survived beyond 76 days. From 1985 to 1990, a series of 20 patients were given cyclosporine but only 2 patients were able to resume normal nutrition and most of the grafts failed. The development of new immunosuppressive agents, particularly tacrolimus, resulted in renewed interest in intestinal transplantation. Furthermore, since 1990, there has been greater standardization of patient selection, operative procedures, and postoperative care mainly in centers specializing in intestinal transplantation. The total international experience is still limited, involving less than 1000 transplants by 2004 (some of the transplants were isolated intestinal grafts, others were intestinal–liver transplants, and the remaining few were multivisceral transplants that included the intestine). Better graft and patient survival rates have been reported in the more experienced centers. In a series of 165 intestinal transplants at the University of Pittsburgh, patient survival was reported to be more than 75% at 1 year, 54% at 5 years, and 42% at 10 years. More than 90% of patients resumed an unrestricted oral diet.

It appears that intestinal transplantation has become a realistic life-saving option for some people who cannot be maintained on HPN. However, it is not yet the treatment of choice in patients who can be successfully maintained on HPN without noteworthy complications. Nor is it the treatment of choice in patients who are likely to deteriorate rapidly from other causes, such as aggressive multisystem disease, or likely to improve so that they can resume oral nutrition (e.g., patients with healing intestinal fistula or those with short bowel syndrome, in which benefits from intestinal adaptation may continue for up to 1–3 years). A better understanding of the immune response to the transplanted intestine and better immunosuppressive therapy, surgical techniques, and postoperative management are required. Appropriate selection and referral of patients to specialist centers are also important criteria that affect clinical outcomes.

Ethical Issues

The provision of nutritional support to people who are chronically sick, who have rapidly progressive disabling diseases, or who are terminally ill raises many ethical questions. Opinions about withholding or withdrawing artificial nutritional support vary

from country to country because of different clinical, religious, and social beliefs and differences in national economies, some of which cannot support large-scale expensive long-term treatments. Thus, there is little home artificial nutrition in countries with poor economies. In more developed economies, the types of patients being fed may also vary considerably. For example, parenteral and enteral nutrition in patients with cancer are used more frequently in Italy than in the United Kingdom, suggesting that clinical attitudes to this type of nutritional support vary. The sanctity of human life is a belief that is strongly held by many religions, but when these conflict with medical judgment, public policies normally override personal religious beliefs. A common ethical controversy concerns the need to provide food and fluid to prolong life in severely disabled patients, such as those with severe neurological problems (e.g., cerebrovascular accident) or those approaching the end of their lives. Although health professionals have a duty to prolong life, it seems inappropriate to prolong suffering. There has been controversy as to whether the provision of food and fluid by a feeding tube placed in the stomach or small intestine should be regarded as an essential part of care or medical treatment. The highest legal authorities in countries such as the United States and England have ruled that this is medical treatment. From an ethical perspective, there is no difference between withholding and withdrawing treatment, but in practice it is often more difficult to withdraw treatment once it has begun than to not initiate it. Joint discussions at the outset between mentally capable patients, family members, and health care workers can do much to prevent future ethical dilemmas.

Conclusions

Home nutritional support, including both oral and artificial (enteral and parenteral) methods of feeding, is an important modality of treatment that is being used for an increasing number of people with disease and disability who are managed in the community. The identification of individuals who are at increased risk of malnutrition and who may benefit from additional nutritional support is a vital first step, which can be undertaken using a validated screening tool (such as MUST; **Figure 1**). Oral nutritional support, including liquid multinutrient supplements, is of value in improving the nutritional intake and functional well-being of patients with malnutrition in the community. Without ETF, many patients with persistent swallowing difficulties would die; similarly, without PN, many patients with persistent intestinal failure would not survive. Although these forms of home therapy can be life-saving, they may restrict normal lifestyle and lead to life-threatening complications. These complications can be prevented or treated by establishing an adequate organizational infrastructure. This should include education and training of both health workers and patients/caregivers as well as a management structure that allows all patients to be followed up and, when necessary, admitting patients to the hospital for more intensive investigations and therapy. Ethical difficulties about withholding or withdrawing artificial nutritional support are likely to continue and to vary with time and from country to country. Intestinal transplantation is becoming a potentially realistic option for a few patients with irreversible intestinal failure who cannot be adequately maintained on long-term PN, but it has not yet become part of routine clinical care in the same way as renal transplantation has become routine in patients with renal failure, who would otherwise receive a lifelong treatment with dialysis.

Adults, Enteral

K N Jeejeebhoy, University of Toronto, Toronto, ON, Canada

Nutrients are normally taken by eating a diet composed of a variety of natural foods. In instances in which a normal oral diet cannot be taken, it becomes necessary to nourish the individual by either the enteral or parenteral (intravenous) route. In this article, the use of the enteral route is considered.

Definition of Enteral Nutrition

Enteral nutrition (EN) is the process of nourishing an individual by the administration of a liquid diet of defined composition, usually through nasogastric (NG), nasointestinal (NI), gastrostomy, or jejunostomy tubes (tube feeding). However, palatable enteral products may be taken as supplemental or complete enteral feeding by mouth.

Indications for Enteral Nutrition

Enteral nutrition is the preferred way of feeding patients who cannot eat, absorb, or use a normal diet in the presence of a usable gastrointestinal tract. The following are indications for EN:

1. Critical care patients, including those with trauma and burns, and also after major surgery.
2. Anorexia in patients with malignant disease, sepsis, liver and renal failure, and inflammatory bowel disease (IBD).
3. Upper gastrointestinal obstruction or ulceration of the pharynx, esophagus, stomach, and duodenum may prevent the ingestion of normal food. Examples of these conditions are cancer, central nervous system disorders, and stenosis following ulceration.
4. Pancreatic disease: In patients with pancreatitis it may be possible to feed a low-fat enteral formula through a NI route beyond the duodenum without causing increased disease activity or pain.
5. Short bowel and severe malabsorption: In controlled trials enteral diets are not better absorbed than normal food. Therefore, the presence of a short bowel per se is not an indication for enteral feeding. On the other hand, some patients with severe malabsorption may benefit from the use of elemental diets.
6. Inflammatory bowel disease: In IBD, enteral feeding is useful under the following situations:
   i. Profound anorexia preventing the ingestion of a normal diet.
   ii. Abdominal discomfort due to partial bowel obstruction or intestinal inflammation.
   iii. Growth retardation resulting from insufficient nutrient intake.
   iv. In Crohn's disease some controlled trials have suggested that enteral feeding induces a remission comparable to that seen with steroids.
7. Dementia: Patients unable to feed themselves because of profound mental changes.

Selection of Patients and Timing of Nutritional Support

The process of nutritional support should be an integrated continuum from normal diet to EN based on a plan. This plan should be developed at the moment of each patient's entry and implemented with modifications until discharge. It is undesirable to have to make an urgent decision on a weekend after realizing that the patient has been starving for the previous 2 weeks. I favor an approach in which the nutritionist examines the needs of each patient at entry and follows the algorithm given in **Figure 1**.

Target Nutrient Intake Possibly Achievable

The nutritionist discusses with the patient alternatives to dietary intake and the use of oral nutritional supplements that may include enteral diets taken by mouth. These supplements include liquid formula diets as well as specific supplements (e.g., potassium, magnesium, calcium, zinc, and vitamins). If during a trial period there is progressive improvement in intake or the patient meets the target, this process is continued. If the patient cannot meet the target or is clearly unable to progress toward it, then formal EN is started.

Target Nutrient Intake Achievement Failed or Impossible

These patients are prime candidates for NG or NI feeding if the gastrointestinal tract is normal, as in the case of critical care, anorexia (usually secondary

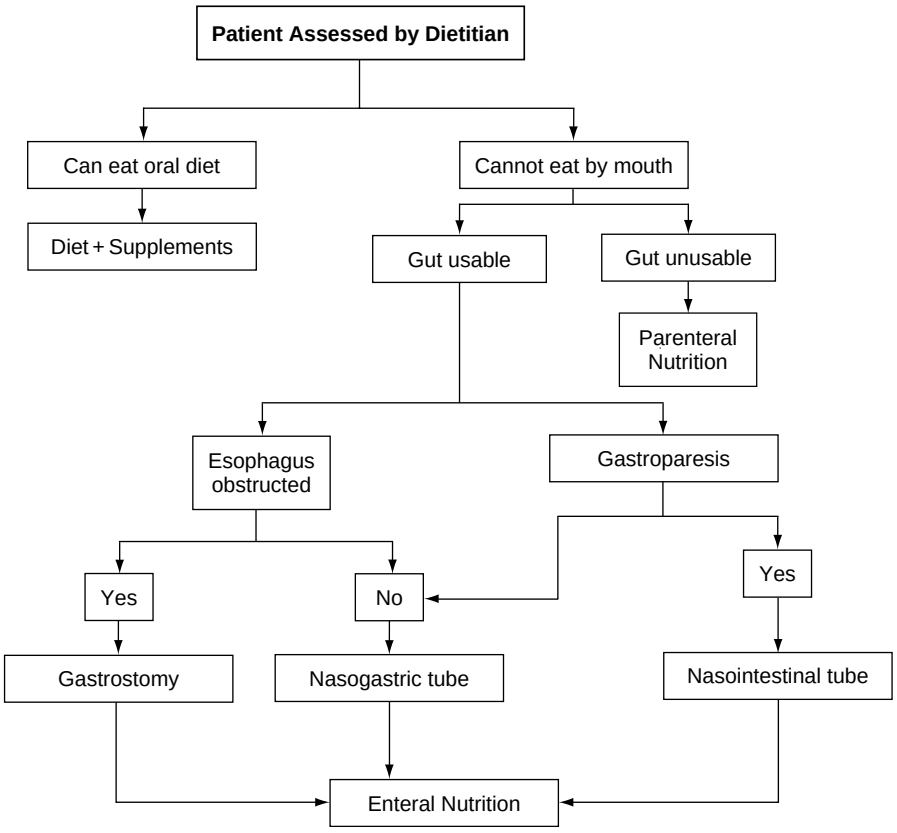

Figure 1 Algorithm for nutritional support.

to disease and malnutrition), neurological impairment preventing oral feeding, substantially increased requirements with relative anorexia (e.g., in burn cases), or chronic obstructive lung disease with severe dyspnea. However, for diseases of the pharynx, esophagus, or stomach or in cases of surgery of the esophagus, stomach, or pancreas, patients usually require intubation of the stomach or intestine by percutaneous gastrostomy or operative jejunostomy to allow feeding beyond the site of obstruction. If there is an abnormality of the intestinal tract, such as short bowel with more than 60 cm of available small intestine, IBD, or chronic partial bowel obstruction, diets must be delivered carefully with the aid of a pump to avoid surges of delivered fluid diets and consequent distension of the bowel. Despite careful selection, a proportion of patients expectantly fed via the nasogastric or nasoenteral route will show intolerance, complications, or inability to meet target nutrient intake without clinically unacceptable side effects. For example, in trials of patients with Crohn's disease, approximately 20% of patients could not tolerate nasogastric feeding. When EN fails or cannot be used for reasons given previously, then parenteral nutrition (PN) must be used.

Home Enteral Nutrition

In some patients, the oral route may be unusable for long periods of time or even permanently. This includes patients with indications given by Nos. 2, 3, and 5 in the list near the beginning of the article. In these patients, a percutaneous endoscopic gastrostomy is placed, and the patients are trained to feed themselves during the night and disconnect themselves during the day to go to school or work. This technique is invaluable to get patients with "gut failure" out of the hospital and rehabilitated.

Enteral Diets

The enteral diets are all complete and will meet the RNIs when fed to meet total energy requirements but may be deficient in meeting micronutrient requirements if given as supplements or in hypocaloric (not meeting total requirements) amounts. The types of diets are as follows:

1. Polymeric: Composed of whole proteins and oligosaccharides with fat partly as long-chain triglycerides and partly as medium-chain triglycerides. They are low in osmolality and palatable and can be taken by mouth.

Table 1 Specialized formulations

Formulation	*Use*
Branched-chain amino acids	Treat hepatic encephalopathy.
Glutamine	Reduce intestinal permeability, improve immunity, and promote mucosal regeneration.
ω-3 fatty acids	Reduce inflammatory response.
Arginine	Improve immunity.
High-fat diets	Reduce insulin requirements in diabetics. Reduce CO_2 output in patients with respiratory disease.

2. Peptide-based diets: The same as above but the protein is given in the form of peptides, which in theory are absorbed better than amino acids or proteins.
3. Elemental diets: They contain amino acids, are very low in fat, and the carbohydrate may be in the form of glucose. These diets are hyperosmolar and unpalatable. They are best given through a tube as a continuous infusion.
4. Special diets: They may be enriched in branched-chain amino acids, glutamine, ω-3 fatty acids, and arginine. Others have a high-fat content (**Table 1**).

Techniques of Administration

To ensure full calorie intake and to avoid gastrointestinal discomfort, enteral diets are best infused through a tube at a constant rate using a pump. The objective is to infuse at a rate that is equal to the rate of absorption so that intestinal distension does not occur. The diet should be stored in a sterile container so as to prevent bacterial growth while it is being infused. The routes of administration are as follows:

1. Nasogastric tube made of silicone rubber or polyurethane, 9–12 Fr in size: It is passed into the stomach and positioned in the antrum.
2. Nasointestinal tube: These tubes are similar to nasogastric tubes but longer. They are advanced under fluoroscopy into the duodenum. They may also be advanced by endoscopic guidance into the duodenum.
3. Percutaneous gastrostomy and buttons: Under sedation and local anesthesia, a gastrostomy can be placed using an endoscope. It can also be advanced into the duodenum. In long-term feeding the gastrostomy is replaced with a 'button' that is flush with the skin and can be intubated for feeding.
4. Percutaneous jejunostomy: This is placed at operation and can be used to feed into the intestine.

Evidence of the Benefits of Enteral Nutrition

EN has not been compared to standard care (SC) in the same systematic way as PN. Systematic reviews of EN compared to PN have consistently shown increased infectious complications with PN. However, all showed significantly elevated blood glucose in the PN group. It is likely that hyperglycemia was more frequent with PN because patients randomized to PN received more energy than those on EN, despite the intent to make both groups isocaloric. Data from a large controlled trial in intensive care unit (ICU) patients showed that keeping blood glucose below 7 mmol/l irrespective of the route of feeding significantly reduced mortality and multisystem organ failure arising from sepsis. This study indicated that hyperglycemia in the PN arm of the study would have significantly increased the risk of sepsis. None of these studies prove that EN is better than standard therapy; they show that it is less likely to cause infection than PN given without regard to the rigid control of blood glucose. This conclusion is supported by a large study (562 patients) comparing EN and PN that mirrors the conventional practice of NS. Using modest energy intake and avoiding hyperglycemia, the study showed that nutritional intake below 80% of the target was observed in 75% of randomized EN patients and 25% of randomized PN patients ($p < 0.001$). There was no significant differences in the incidence of septic morbidity between patients receiving PN and those given EN. The inability of EN to deliver target energy intake was also seen in several other trials, in which outcome was also no different between PN and EN.

Early Enteral Nutrition, Parenteral Nutrition, and Bacterial Translocation

In animal models, burns and trauma have been associated with the appearance of organisms in the mesenteric lymph nodes (MLNs). This process has been called bacterial translocation. Enteral feeding has been associated with reduced translocation in guinea pigs. In other animal studies, early enteral feeding reduced nitrogen loss and the level of catabolic hormones. However, human studies in patients who have been traumatized have not show any benefit of early (<24 h) enteral feeding. In addition, a prospective sampling of portal blood in trauma patients failed to confirm that translocation occurs in traumatized humans. A meta-analysis of early vs late enteral feeding showed no difference in outcome. In obese patients, a quasi-randomized trial

showed that early feeding with a higher energy intake increased sepsis.

Special Formulations

Immunonutrition

Enteral formulations enriched in arginine, omega-3 fatty acids, and glutamine nucleotides are considered to enhance the immune response, and treatments with these formulations are collectively referred to as immunonutrition. The formulations under consideration vary in composition. They are distinguished by high (12–15 g/l) or low (4–6 g/l) arginine, the presence or absence of glutamine and nucleotides, and the concentration of omega-3 fatty acids. The proceedings of the summit on immune-enhancing enteral therapy concluded that immunonutrition should be given to malnourished patients undergoing elective gastrointestinal surgery and trauma patients with an injury severity score of $\geq$18 or those with an abdominal trauma index of $\geq$20. Despite lack of evidence, it was recommended for patients undergoing head and neck surgery and aortic reconstruction, those with severe head injury and burns, and for ventilator-dependent nonseptic patients. The summit did not recommend it for patients with splanchnic hypoperfusion, bowel obstruction distal to the access site, and after major upper gastrointestinal hemorrhage.

In contrast to the conclusions of the summit, systematic reviews of the evidence have given mixed results. The reviews suggested that although immunonutrition did reduce septic complications, the reduction did not result in reduced mortality. In a meta-analysis of 22 randomized controlled trials performed in 2419 critically ill or surgical patients, it was concluded that the amount of arginine in the formulations influenced the results. Taken as a whole, in critically ill patients there were no treatment effects on mortality or rates of infectious complications. In fact, there was a suggestion that in critical illness these formulations may increase mortality. To support this possibility, a trial suspended the use of immunonutrition in seriously ill patients after an interim analysis showed increased mortality with immunonutrition in these patients. However, in elective surgical patients immunonutrition reduced complications and length of stay. Since many trauma and septic patients may be critically ill, the recommendations made in the two publications referred to previously are at variance. Other meta-analyses have not separated critically ill and nonseptic patients and have concluded that immunonutrition reduced septic complications and length of stay but criticized the component studies as being variable and overall not altering mortality.

Enteral Glutamine Supplementation

Glutamine is released into the circulation from muscle continuously in healthy people and especially in those with catabolic illness. The glutamine in the circulation is an important nutrient for immunocytes such as lymphocytes and for the mucosa of the intestine. In septic and malnourished patients, muscle glutamine is depleted, and it is hypothesized that in these patients the availability of glutamine for lymphocytes and the gut is reduced, resulting in increased risk of sepsis. Although enteral mixtures designed to improve immunity have given variable results, glutamine supplementation has not been shown to be harmful and has reduced complications in patients with bone marrow transplantation, after surgery, and in those with critical illness and burns.

Enteral Branched-Chain Amino Acid Formulations

Patients with hepatic encephalopathy have low levels of enteral branched-chain amino acids (BCAAs) and increased levels of phenylalanine and tryptophane. It has been postulated that since BCAAs compete with phenylalanine and tryptophane for transport through the blood–brain barrier, reduced levels of BCAAs promote the accumulation of these amino acids in the brain, where they are metabolized to false neurotransmitters that then cause encephalopathy. To reverse this state, BCAA-enriched formulas were developed, and in a meta-analysis of randomized controlled trials of these formulations in hepatic encephalopathy, they were shown to reduce the duration of encephalopathy in comatose patients.

Enteral Formulation Enriched in Protein

High-protein formulations are available to feed patients with adequate amounts of protein at a lower energy intake. These formulations are especially useful in patients who are critically ill and become hyperglycemic on standard formulations. Using high-protein formulations has allowed the administration of up to 2 g/kg protein in patients with protein losses, such as those with fistulas, burns, and abscesses, and in calorie-intolerant patients. One controlled trial has shown that a high protein intake reduces mortality in burn patients, whereas high energy intake in sepsis appears to increase mortality.

High-Fat Formulations

The average fat content of enteral formulations is approximately 30% of total energy. The main source of energy in these formulations is carbohydrate. The high carbohydrate has two relevant metabolic effects. First, it increases the need for insulin secretion. Second, when fed in amounts that exceed energy requirements, it increases CO_2 production. Diabetics potentially would therefore have reduced insulin requirements and a lower risk of hyperglycemia if fed high-fat formulations. Similarly, malnourished patients with chronic obstructive pulmonary disease (COPD) would have a lower risk of CO_2 retention if given a high-fat diet with a high calorie intake to promote weight gain. Therefore, high-fat formulations have been developed to feed patients with diabetes and COPD. However, there is little evidence that they are significantly better than standard formulations.

Enteral Omega-3 Fat Supplementation

Omega-3 fats are composed of polyunsaturated fatty acids, in which the first double bond 3 carbon atoms are located away from the methyl end of the fatty acid chain. The fatty acids found in fish oil, called eicosapentanoic and docosahexaenoic, are precursors of prostaglandins and thromboxanes that antagonize the prothrombotic effects of similar compounds derived from linoleic acid. In humans, when infused, they reduce the production of proinflammatory cytokines from stimulated mononuclear cells. They potentially have anti-inflammatory effects and have been shown in controlled trials to benefit patients with ARDS.

Enteral Nutrition with Probiotics

The administration of a probiotic, *Lacobacillus plantarum*, indicates that probiotics with EN may have a role in reducing septic complications in patients with pancreatitis and those after liver transplantation.

Optimizing Enteral Nutrition and Reducing Risk of Aspiration Pneumonia

Enteral feeding is associated with several factors that may result in reflux of gastric contents and aspiration: the supine position of the patient, the presence of a nasogastric tube, gastric contents, and delayed emptying of the stomach. Intuitively, placing the tip of the feeding tube into the intestine rather than the stomach should reduce aspiration, and the Canadian clinical practice guidelines recommend postpyloric feeding. On the other hand, a meta-analysis comparing gastric and postpyloric feeding did not show any significant difference in the incidence of pneumonia between patients fed into the stomach and those fed beyond the pylorus. Although enteral feeding is widely practiced as the route of choice, in a study of 103 patients admitted to an ICU who were observed prospectively for the development of nosocomial pneumonia, there was evidence that feeding contributed to pneumonia. In that study, a multivariate analysis concluded that continuous enteral feeding, but not the nasogastric tube, was an independent risk factor for nosocomial pneumonia and patients who developed pneumonia had a significantly higher mortality of 43.5% compared to 18.8% for those who did not develop pneumonia. Clearly, more studies need to be done to determine the best approach to prevent pneumonia.

The use of prokinetics is another way of promoting gastric emptying. In a placebo controlled randomized trial of 305 patients receiving enteral feeding, giving metoclopramide did not reduce the incidence of pneumonia. Erythromycin, a motilin receptor agonist, is another powerful prokinetic agent. In a randomized controlled trial the benefit of erythromycin was questionable. There was no difference in the rate of pneumonia between the placebo and erythromycin-treated patients. The previous studies unfortunately involved small numbers of patients, and there is a need for larger trials of small bowel feeding and prokinetics to establish their role in promoting enteral feeding and reducing the risk of aspiration.

Perioperative Enteral Nutrition

Infusing a diet enriched with arginine, omega-3 fatty acid, and RNA preoperatively and postoperatively has resulted in a significant reduction in total but not major complications. In patients undergoing abdominal surgery, progressive postoperative oral supplementation without formal EN reduces complications and raises the question as to whether EN, total parenteral nutrition (TPN), or immunonutrition are even necessary for the majority of patients. Complications can be reduced by introducing early sip feeding of liquid diets without formal EN.

A small but provocative study from India raises the same questions about the routine use of EN. Sixty postoperative patients were randomized to either a standard ward diet or a diet with a home-made liquid supplement (10 patients per group). They were also stratified to mild, moderate,

and severe malnutrition groups of 20 patients each. There was no mortality in the study and patients were discharged after approximately 10 days. The supplemented groups received significantly more energy and protein. However, only in the severely malnourished patients was there a difference in the incidence of complications—7/10 in the control and 4/10 in the supplemented group. In the mild malnutrition group, there were 1/10 complications in each arm and 2/10 in the moderate malnutrition group. This study suggests that a very modest oral intake of supplements reduced complications but did so only in the severely malnourished group. It is likely that the aggressive nutritional support, as is practiced currently, may not be necessary and may even be detrimental in some situations. Larger randomized trials of oral supplements should be considered.

Enteral Nutrition and Head Injury

A systematic review of controlled trials of nutritional support in cases of head injury showed that the relative risk (RR) for death with early nutritional support was 0.67 (95% confidence interval (CI), 0.41–1.07), and the RR for death or complications at the end of follow-up was 0.75 (95% CI, 0.50–1.11). The findings suggested that early nutrition showed a trend toward reduced mortality and complications.

Nutritional Support of Bone Marrow Transplant Patients

A review found that although EN is the current standard for nutritional support, it has not found favor for patients undergoing bone marrow transplant because these patients have severe mucositis, often vomit the tube, and do not tolerate nasogastric tubes because of discomfort and ulceration. Veno-occlusive disease with encephalopathy may occur in bone marrow patients, which is another indication for TPN with branched-chain amino acids rather than EN. A controlled trial of EN versus TPN in bone marrow transplant patients showed that outcome was no different but body composition and magnesium levels were better maintained on TPN. In contrast, TPN patients had more fluid overload and hyperglycemia. It should be noted that 'enteral nutrition' in this trial was not tube feeding but a combination of snacks, diet counseling, and tube feeding. The authors concluded that TPN should be reserved for patients with severe mucositis. Review of the Cochrane database concluded that the relative effectiveness of EN versus TPN could not be evaluated. In addition, patients with gastrointestinal failure should consider TPN with the addition of glutamine if EN is not possible.

Alcoholic Hepatitis and Enteral Nutrition

Seventy-one patients with severe alcoholic hepatitis were randomized to prednisone 40 mg/day or EN giving 2000 kcal/day for 28 days and then followed for 1 year or until death. The EN was a branched-chain-enriched diet and patients on steroid therapy were encouraged by dietitians to eat 2000 kcal/day with 1 g/kg/day of protein. No patients from the steroid arm dropped out, whereas 8/35 patients from the EN arm did not receive EN for the entire period but were included in the analysis (intent to treat analysis). It is of interest that all patients in the steroid arm ate 80% of the prescribed diet. Using intent to treat analysis, there were no differences in mortality or complications in the hospital between groups. After discharge, even when confounding variables were adjusted, the EN group had a significantly better survival. Since both groups seemed to receive the same energy intake, the reason for better long-term survival with EN needs further study. Was it because of the use of branched-chain amino acids or because steroid therapy had an undesirable catabolic effect?

Pancreatitis and Enteral Nutrition

Oral feeding is known to increase abdominal pain in patients with pancreatitis. Therefore, TPN has been used in these patients to 'rest' the pancreas. One study aimed to define the indications and evaluate the cost-effectiveness of nutritional support in a series of patients with pancreatitis. The patients were given nothing orally and only intravenous fluids for 48 h. Those who improved were fed orally (O group). The remainder were randomized to receive nutrients either infused into the jejunum (EN group) or by vein (TPN group). A total of 156 patients were included, of whom 75% improved (O) and were discharged within 4 days. In the randomized patients, 56% of the EN group received inadequate energy intake but were fed for a significantly shorter period (mean, 6.7 versus 10.8 days) and had less metabolic ($p < 0.003$) and septic complications ($p < 0.01$). More than 50% of TPN patients were hyperglycemic, in contrast to only approximately 15% of the EN group. Despite fewer complications in the EN group, the mortality was similar in the

two groups. The authors concluded that hypocaloric enteral feeding is better than TPN. This study is similar to many others, showing that EN providing less than estimated energy intake is associated with reduced hyperglycemia and sepsis. The conventional interpretation is that the EN route reduces sepsis. The trial by van den Berghe *et al.* showed that irrespective of the route of nutritional support, control of hyperglycemia reduced mortality in the ICU. Their findings support the alternative explanation that the EN route protects the patient because it results in hypocaloric feeding, which prevents hyperglycemia. The study shows that EN can be given as a cheaper source of nutrition, but since EN was needed only for 6.7 days with less than adequate energy intake, it raises the question as to whether any nutritional support was required. Another important question is whether TPN should be hypocaloric rather than meet target energy intake in patients who are unable to take oral nutrition or EN for periods exceeding 7–10 days. In order to settle these issues, larger multicenter randomized trials are required.

Adults, Parenteral

J Binkley, S Daniell and G L Jensen, Vanderbilt Center for Human Nutrition, Nashville, TN, USA

Parenteral nutrition (PN) is a compounded formulation of amino acids, dextrose, and lipid emulsions, along with electrolytes, multivitamins, and trace elements. The development of this form of nutrition intervention gave new hope to patients who suffered from intestinal compromise or failure.

PN had its modern beginnings in the mid-1960s as Dr. Stanley Dudrick and colleagues researched infusion of hypertonic glucose and protein solutions into the superior vena cava of beagle puppies. Normal growth and development of the beagles were maintained for 36 months using this approach. The first research that established the use of intravenous feedings in humans was reported by Dudrick and colleagues in 1969. From its early beginnings, PN was known as 'hyperalimentation,' with the belief that it was desirable to feed in excess of standard requirements. Years of clinical practice has shown that PN should be provided in more limited amounts in order to prevent some of the complications associated with its overzealous use.

This article focuses on components of PN for adult nutrition support, indications and contraindications for its use, implementation and monitoring for safety and efficacy, complications associated with use of PN, and consideration of its use for home patients. Prudent patient selection and careful monitoring will help to ensure the safe and effective administration of PN. A multidisciplinary approach to PN management is suggested to help optimize the use of this therapy.

Indications for PN

PN should be considered for patients when oral intake or enteral feedings are not possible or are contraindicated for a prolonged period of time. Enteral feedings are the preferred route of administration for specialized nutrition support for many reasons. Enteral feedings are more physiologic and facilitate maintenance of gastrointestinal integrity and function. In comparison with PN, enteral feedings are considerably less expensive and are associated with fewer serious adverse effects. Enterohepatic circulation and barrier function of the gastrointestinal mucosa can be preserved with even small quantities of enteral stimulation. Enteral feedings are associated with a decreased incidence of bacterial translocation and associated sepsis in animal models. PN is indicated when the gastrointestinal tract is not functional, when the safe placement of an enteral feeding access device is not possible, or when the enteral route cannot adequately meet the nutritional needs of a patient. **Table 1** lists common indications for PN. When enteral feedings cannot be established within 7–10 days, PN should be considered. **Table 2** lists contraindications to the use of enteral feedings.

Bowel Rest

PN is often used when continued use of the gastrointestinal tract may not be advisable. PN may be selected for inflammatory bowel disease patients with severe acute exacerbations or for perioperative care. For patients with Crohn's disease, PN may aid the management of complications such as intestinal obstruction, fistula formation, short bowel syndrome, and severe diarrhea. Otherwise, enteral nutrition support is frequently used for nutrition support in inflammatory bowel disease with comparable efficacy.

PN can be used for bowel rest in severe acute pancreatitis, when its duration is anticipated to be more than 7–10 days. Various scoring systems are used to classify the severity of pancreatitis and together with sound clinical judgment can help to

Table 1 Common diagnoses with indications for PN

Perioperative support in severe malnutrition
Inflammatory bowel disease and related complications
Short bowel syndrome
Severe acute pancreatitis
Mechanical intestinal obstruction or pseudo-obstruction
High-output entercutaneous fistula
Prolonged postoperative ileus
Severe malabsorption
Bone marrow transplant/peripheral stem cell transplant
Severe hyperemesis gravidarum

Table 2 Contraindications to enteral nutrition

Diffuse peritonitis
Intestinal obstruction that prohibits use of the bowel
Intractable vomiting
Paralytic ileus
Intractable diarrhea
Gastrointestinal ischemia

Adapted from ASPEN Board of Directors and the Clinical Guidelines Task Force (2002) Guidelines for the use of parenteral and enteral nutrition in adult and pediatric patients. *Journal of Parenteral and Enteral Nutrition* **26**(1 supplement): 18SA.

assess the need for bowel rest with PN. Studies using nasojejunal or jejunostomy feeding tubes with elemental low-fat enteral formulas in patients with mild to moderate pancreatitis have demonstrated effectiveness. Patients who exhibit feeding intolerance with enteral nutrition should be considered for PN therapy.

Bowel rest may also be indicated for selected enterocutaneous fistulas, which can occur as a result of complicated Crohn's disease, gastrointestinal or abdominal abscesses, abdominal surgery or trauma, ischemia, or tumors or their accompanying treatment regimens such as chemoradiation. Bowel rest can help to promote potential closure of fistulas and can improve nutritional status of these patients. Depending on the output of the fistulas, many of these patients are at risk for malnutrition as well as dehydration and electrolyte abnormalities.

Perioperative Support in Severe Malnutrition

Increased morbidity and mortality risks are associated with malnourished surgical patients. The Veteran's Affairs Parenteral Nutrition Cooperative Trial evaluated the benefits of preoperative PN in patients with varying degrees of malnutrition. Significant benefit was demonstrated only among those patients who were severely malnourished (albumin <3.0 g/dl). Interestingly, an increased rate of infectious complications was observed in mildly and moderately malnourished patients receiving PN compared to the control group. If enteral access is available and feeds are tolerated, preoperative enteral nutrition support has been found to be equally effective when utilized for 7–14 days or longer in malnourished surgical patients. Early studies that suggested increased adverse outcomes with parenteral compared to enteral support were often based on management techniques that are no longer consistent with standard of practice, which included the overfeeding of macronutrients, rapid infusion rates, and a much less aggressive approach to the prevention of hyperglycemia. Therefore, many of the studies demonstrating more favorable outcomes with enteral support need to be repeated using current standards of care.

Postoperatively, in patients who have undergone intraabdominal procedures with extensive bowel manipulations, paralytic ileus is commonly observed. Use of narcotics or other pain medications, paralytic agents, and electrolyte abnormalities may also contribute to slow gastrointestinal motility and ileus. If a patient's gastrointestinal tract is not functional for more than 7–10 days, PN should be considered.

Gastrointestinal Inability to Absorb Adequate Nutrients

PN is indicated if the patient is unable to absorb adequate nutrients via the gastrointestinal tract. Short bowel syndrome can result from extensive bowel resection or dysfunction. Initially, fluid and electrolyte management is often the most critical aspect of nutrition care. Losses can be extensive. The resulting degree of malabsorption, and therefore the specific nutrition management requirements, depends on the remaining intestinal length or function, the presence or absence of large bowel continuity, and the presence or absence of the ileum. Enteral nutrition support is preferred over parenteral support; however, the adaptive phase for the remaining gastrointestinal tract often necessitates a period of PN requirement, often months to a few years. Sometimes patients with extensive bowel resection (less than 100 cm of remaining bowel) may require lifelong PN or small bowel transplantation.

Other Possible Indications for Use

The importance of adequate nutrition in pregnancy is widely recognized. Hyperemesis gravidarum (HG) is severe nausea and emesis that can persist throughout the gestation period, preventing the patient from receiving adequate calories and protein for fetal growth. HG usually occurs before the 20th week of gestation and is characterized by weight loss, changes in fluid and electrolyte status, and disturbances in acid–base balance. After attempting to achieve weight gain and resolution of symptoms with antiemetics, intravenous hydration, and diet modifications without success, specialized nutrition support with enteral feedings or PN may be appropriate for refractory cases. Enteral feedings are preferred, but PN is indicated if enteral feedings are not tolerated.

Another potential need for PN occurs in patients treated with high-dose chemotherapy with or without radiation, followed by hematopoetic stem cell transplantation. This treatment regimen may be associated with significant gastrointestinal side effects, including nausea, emesis, diarrhea, mucositis, esophagitis, xerostomia, and odynophagia. Nutritional compromise is possible due to the persistence of these symptoms for protracted time periods. Specialized nutrition support with enteral nutrition or PN may be indicated if patients are unable to maintain adequate oral intake or if they demonstrate persistent gastrointestinal side effects. PN has been suggested to improve posttransplantation survival, reduce disease relapse, and shorten

hospital stay, although enteral feedings have also been successfully administered to such patients.

Nutrition Components of PN

Amino Acids

Amino acids yield 4 kcal/g when oxidized for energy. Nitrogen content varies somewhat, depending on the individual amino acid formulation and mixture of amino acids. Mixtures of buffered essential and nonessential amino acids are available as stock concentrations ranging from 3 to 20%. Specialty amino acid products are also available for specific disease states or pediatric populations. For example, formulations containing a higher concentration of branched-chain amino acids may be considered for patients with hepatic insufficiency with accompanying encephalopathy.

Dextrose

The carbohydrate energy source for PN is hydrated dextrose, which yields 3.4 kcal/g. Dextrose is available commercially in concentrations ranging from 2.5 to 70%. Dextrose solutions are acidic, and their osmolarity depends on concentration. Higher concentrations of dextrose must be administered directly into central veins instead of peripheral veins in order to prevent thrombophlebitis.

Lipid Emulsions

PN regimens include lipid emulsions as the source for fat calories and essential fatty acids. In the United States, commercially available intravenous lipid products contain largely n-6 long-chain fatty acids derived from vegetable oils. Long-chain lipid emulsions provide the most concentrated source of calories in PN (9 kcal/g). Other lipid-containing products are currently available in Europe, including lipid emulsions containing medium-chain fatty acids and structured triglycerides. The latter are custom synthesized triglycerides that contain both long-chain and medium-chain fatty acids on the same glycerol moiety. These lipid substrates may offer certain metabolic and immune tolerance advantages.

Controversy surrounds the use of intravenous lipid emulsions (IVLEs) due to early reports of adverse immune function and pulmonary effects in critically ill patients. These early reports of alterations in immune function were associated with excessive infusion rates or doses of IVLEs in comparison with today's standard dosing regimens. Concerns have also been raised that n-6 fatty acids may fuel inflammatory eicosanoid pathways. Lipids are contraindicated in patients with significant hypertriglyceridemia. When lipids are restricted, modest doses of lipids (30–40 g twice weekly) should be provided to prevent essential fatty acid deficiency (EFAD). Linoleic acid (18:3n6) and α-linolenic acid (18:3n3) are required to prevent EFAD. To prevent EFAD, 2–4% of calories should be provided as linoleic acid and 0.5% as α-linolenic acid.

Electrolytes

Specific patient electrolyte requirements can be determined and added, as feasible, to PN solutions. Usually, maintenance doses of electrolytes are determined and provided in daily amounts of electrolytes added to the PN solution. Additional repletion and replacement of losses can occur in electrolyte doses given outside the PN admixture. Sodium and potassium can be added as chloride or acetate, depending on acid–base needs. Physicochemical incompatibilities exist for large quantities of electrolytes added to the same PN formulation. In particular, calcium and phosphorus concentrations must be carefully scrutinized to prevent precipitation. Many factors may influence the solubility of these electrolytes in the PN solution, including the concentration of electrolytes, the pH of the final formula, temperature, and the presence of other components. A nutrition support pharmacist can be a resource to address compatibility concerns.

Multivitamins

Multivitamin preparations, including both water-soluble and fat-soluble vitamins, are available for inclusion in the PN admixture. These products have been formulated to meet the guidelines established by the American Medical Association Nutrition Advisory Group and the Food and Drug Administration. **Table 3** lists the composition of

Table 3 Contents of parenteral multivitamin preparations

Vitamin component	*Current FDA requirements*
Vitamin A	3300 IU
Vitamin D (ergocalciferol or cholecalciferol)	200 IU
Vitamin E (α-tocopherol)	10 IU
Vitamin K (phylloquinone)	150 μg
Vitamin C	200 mg
Folic acid	600 μg
Niacin	40 mg
Vitamin B_2	3.6 mg
Vitamin B_1	6 mg
Vitamin B_6	6 mg
Vitamin B_{12}	5 μg
Pantothenic acid	15 mg
Biotin	60 μg

standard adult multivitamin products. Some individual vitamin preparations, such as vitamin K, are available for injection as well.

Trace Elements

Intravenous trace element preparations are commercially available as single-entity products as well as a variety of combination products. Commonly used trace elements include zinc, copper, manganese, chromium, and selenium (**Table 4**). Other elements may be included as single additives.

Titration of Volume

Final fluid volumes of PN can be titrated to a desired amount using sterile water for injection. Concentrated substrates may be used to minimize volume of PN to provide the desired components. Typical PN volumes range from 800 to 2500 ml daily.

Compounding and Technical Requirements for PN

Access Devices and PN Concentrations

PN is administered into the venous system either through peripheral venous lines or through centrally placed access devices. Lower concentrations of dextrose and amino acids may be administered through peripheral veins for a short duration of therapy. Such formulas usually do not provide the patient's full nutrition needs, may require large volumes of fluid, and can only be used for short durations due to the difficulty of maintaining peripheral intravenous access. Osmolarity of peripheral formulas is best maintained at approximately 600 mOsm/l or less. This requirement means that peripheral PN formulas should contain no more than 5–10% dextrose and 3.5–5% amino acids. Potential complications of peripheral PN include phlebitis, infiltration, or fluid-overload issues. When higher concentrations of dextrose and amino acids are used, such as those generally needed to provide adequate daily nutrient requirements via PN, the hyperosmolar formula must be administered directly into the superior or inferior vena cava to facilitate rapid dilution. Commonly used central venous catheters that may be used to administer PN include subclavian vein catheters, peripherally inserted central catheters, subcutaneously tunneled percutaneous catheters, or implanted subcutaneous infusion ports. Catheter type will be determined by expected duration of need, specific patient condition, patient care setting, as well as physician or patient preference.

Table 4 Contents of a common parenteral trace element preparation

Component	*Dose*
Zinc	5 mg
Copper	1 mg
Manganese	0.5 mg
Chromium	10 μg
Selenium	60 μg

Standard versus Individualized Preparations

Institutions or patient care providers may choose to provide PN solutions as standardized formulas or as customized admixtures, specially tailored to the individual's needs. Commercially available premixed PN solutions typically contain 5–25% dextrose and 2.75–5% amino acids, and they may vary by electrolyte content. Individualized formulations are selected to ensure the highest quality in patient safety and product efficacy; however, premixed solutions are often used in settings in which the demand for PN is low.

Two-in-One versus Total Nutrient Admixture

PN admixtures can be compounded by one of two methods: as a dextrose–amino acid solution with lipids infused separately or as a three-in-one formulation, also known as total nutrient admixture, in which all three macronutrients are combined in the same infusion bag. There are benefits and limitations with both methods, and the choice of administration depends on the care setting and institution or practitioner preference.

Cyclic PN

PN therapy may be infused continuously 24-h daily, or the same volume may be infused over a shorter period of time, such as a cycle of 12-h PN infusion and 12-h free of infusion. Infusion pumps can be programmed to adjust infusion rates according to the desired volumes and administration times. Continuous infusion is generally selected when PN is first initiated for an acutely ill patient. Benefits for a cyclic total PN regimen are particularly notable for long-term patients. A cycled PN regimen allows more mobility for the patient, thus enabling the patient to achieve a more active lifestyle. Limitations to a cycled PN regimen include fluid intolerance or glucose intolerance. When initiating a PN cycle, blood glucose concentrations should be checked to ensure that hyperglycemia or hypoglycemia is not an issue for the patient. Because of the potential for 'rebound hypoglycemia' upon abrupt cessation of infusion,

the rate of administration is often tapered down at the end of the cycle to allow for downregulation of pancreatic release of insulin. Many infusion pumps have programmable taper functions.

Quality Control

Safety of PN solutions is a paramount objective and includes ensuring accuracy in compounding and avoiding both particulate matter and microbial contamination. PN solutions must be prepared using a strict aseptic technique in a class 100 environment using a laminar flow hood. All PN additives should always be added in the sterile environment to prevent risk of contamination. Many incompatibility issues exist when considering mixtures of PN solutions with other medications. Practitioners should assume that medications are incompatible unless data otherwise prove compatibility exists. Some medications have been demonstrated to be compatible as a component of PN solutions, such as heparin, regular insulin, H_2-receptor antagonists, and corticosteroids.

Calculating Nutritional Needs

Accurate height and weight measurements are important to make appropriate estimations of energy and protein needs. Several formulas exist to calculate ideal body weight (IBW). The following are commonly used:

$$\text{Men} = 50\,\text{kg} + 2.3\,\text{kg} \times \text{each inch over 5 feet}$$

$$\text{Women} = 45.5\,\text{kg} + 2.3\,\text{kg} \times \text{each inch over 5 feet}$$

Adjusted body weight can be calculated utilizing the following formula:

$$\text{Adjusted body weight} = \text{IBW} + 25\%\ \text{of (actual body weight} - \text{IBW)}$$

Calculating Energy Needs

Calorie requirements are estimated to meet a patient's energy requirements, which are dependent on the patient's size, clinical condition, concurrent organ failure, and activity level. Determination of the appropriate energy prescription for a patient is crucial for meeting metabolic demands and helping to prevent erosion of lean body mass. Overzealous feeding is associated with significant risks, including difficulties with glucose control and other metabolic complications such as excessive carbon dioxide production. Common methods to estimate calorie requirements include simple weight-based algorithms (e.g., 25–30 kcal/kg body weight/day) (**Table 5**). The Harris–Benedict equations are also frequently used to estimate basal energy expenditure (BEE) using the following formulas:

Table 5 Determination of energy needs

Condition	*Need (kcal/kg)*
Overnourished/obese	20 (upper end IBW)
Maintenance	25
Undernourished	30
Stressed/critically ill	25

IBW, ideal body weight.
Adapted from the National Advisory Group on Standards and Practice Guidelines for Parenteral Nutrition (1998) Safe practices for parenteral nutrition formulations. *Journal of Parenteral and Enteral Nutrition* **22**: 49–66.

$$\text{Males: BEE (kcal)} = 66.5 + [13.8 \times \text{weight (kg)}] + [5 \times \text{height (cm)}] - 6.8 \times \text{age (years)}]$$

$$\text{Females: BEE (kcal)} = 655.1[9.6 \times \text{weight (kg)}] + [1.8 \times \text{height (cm)}] - [4.7 \times \text{age (years)}]$$

The BEE is then adjusted for the perceived degree of stress. Recent trends of providing fewer calories to seriously ill patients in order to prevent complications such as hyperglycemia, hypercapnia, and hepatic steatosis have been described as 'permissive underfeeding.' Trials have been conducted in obese hospitalized patients using hypocaloric regimens. These studies demonstrated that most patients achieved positive nitrogen balance and improved clinically with high-protein, hypocaloric PN formulations without experiencing significant adverse effects.

When an accurate assessment of energy needs is desired, indirect calorimetry may be considered. Such patients may include those who are otherwise difficult to assess or those who will require protracted nutrition support. A metabolic cart is used to measure oxygen consumption (VO_2) and carbon dioxide production (VCO_2). The modified Weir equation is used to estimate resting energy expenditure. The respiratory quotient (RQ) is determined as $RQ = VCO_2/VO_2$. The RQ gives an indication of net substrate oxidation, with $RQ > 1.0$ consistent with carbohydrate oxidation associated with overfeeding, and $RQ < 0.68$ consistent with lipid oxidation or starvation ketosis. Gas leaks or elevated FiO_2 requirements (>0.60%) are common limitations to this approach.

Protein Requirements

Determining appropriate protein goals is important in order to help maintain lean body mass and to promote positive nitrogen balance. Initial requirements are adjusted by a subjective assessment of the patient's degree of catabolism and an evaluation of renal and hepatic function (**Table 6**). Subsequently, the protein prescription should be adjusted based on clinical response and continued reevaluation. The likelihood of achieving nitrogen balance or improvement in visceral protein status will depend on the degree of ongoing inflammatory response. Reductions in protein doses may be warranted in patients with significant hepatic failure with encephalopathy. Reductions may also be indicated for renal insufficiency, depending on the severity of renal failure and whether dialysis is initiated. For the morbidly obese patient, ideal body weight should be used to estimate protein needs.

Dextrose Prescription

Dextrose in PN solutions generally provides 40–60% of total energy requirements. Hyperglycemia is a common complication of PN due to diabetes, medications, or stress response, so the dextrose load is often initiated below goal until tolerance is demonstrated. The maximum glucose utilization rate is 5–7 mg/kg/minute. Doses that exceed this may result in glucose intolerance or hepatic steatosis. Studies have demonstrated that aggressive blood glucose management is associated with fewer septic complications in critically ill patients.

Fat Requirements

Fat calories usually comprise 20–30% of total PN energy. Doses may represent 0.5–1.0 g/kg body weight/day in the PN regimen. Patients with preexisting lipid disorders should be evaluated for potential hypertriglyceridemia. Baseline triglyceride levels will aid the practitioner in safe determination of lipid dosing. Rapid piggyback lipid infusion with PN should be avoided in critically ill subjects.

Table 6 Estimation of protein needs

Condition	*Need (g/kg/day)*
Mild stress	1.0
Moderate stress	1.2–1.5
Severe stress	1.5–2
Acute renal failure, no dialysis	0.6
Hemodialysis/CVVHD	1.1–1.5
Peritoneal dialysis	1.2–1.5
Liver failure without encephalopathy	1.2–1.5
Liver failure with encephalopathy	0.4–0.6

Adapted from the National Advisory Group on Standards and Practice Guidelines for Parenteral Nutrition (1998) Safe practices for parenteral nutrition formulations. *Journal of Parenteral and Enteral Nutrition* **22**: 49–66.

Fluid Requirements

A patient's fluid intake and output should be considered when determining fluid requirements. Urinary losses, along with other losses such as diarrhea, nasogastric suction, emesis, fistula, or other drainage losses, can significantly increase the patient's need for additional fluid. In general, adult patients will need approximately 30 ml/kg body weight daily to meet volume requirements. Monitoring should include adequate urine output, skin turgor, and adequate mucous membrane hydration. Fluid overload in conditions such as compromised cardiac, hepatic, or renal function may dictate use of volume-concentrated formulations.

PN Implementation

Monitoring and Management

Appropriate monitoring of PN therapy is critical to ensure optimal nutrition therapy is achieved and to prevent complications of PN. Evolution of clinical course and patient condition may warrant changes in the frequency of tests and reevaluation of therapy. Additionally, as PN is transitioned to enteral feedings, tolerance should be monitored and PN should be weaned and discontinued.

PN tolerance should be carefully evaluated upon initiation of therapy. The managing practitioner should consider the patient's clinical condition and concurrent organ function, laboratory measurements, nutrition, and fluid status parameters. Laboratory measurements should include a complete metabolic profile and liver function tests at baseline and subsequent measurements after initiation of PN (**Table 7**). Electrolytes should be monitored daily until the patient is stable. Monitoring for acute care patients usually requires more frequent laboratory evaluations and more frequent changes to the PN formula than in long-term patients.

Evaluation of visceral proteins, such as albumin or prealbumin, has historically been an important part of nutrition assessment. These markers, however, may not adequately reflect an accurate picture of nutritional status or response to therapy because of other conditions, such as nephropathy, enteropathy, liver disease, or volume overload. Additionally, these visceral protein levels are often

Table 7 Suggested laboratory monitoring

Parameter	*Baseline*	*Initiation*	*Critically ill patients*	*Stable patients*
CBC with differential	Yes		Weekly	Weekly
PT, PTT	Yes		Weekly	Weekly
Electrolytes (Na, K, Cl, CO_2, Mg, Ca, PO_4, BUN, Cr)	Yes	Daily $\times 3$	Daily	1 or 2 times per week
Serum triglycerides	Yes	Day 1	Weekly	Weekly
Transferrin or prealbumin	Yes		Weekly	Weekly
Serum glucose	Yes	Daily $\times 3$	Daily	1 or 2 times per week
Capillary glucose		As needed	TID until consistently <200 mg/dl	As needed
Weight	Yes	Daily	Daily	2 or 3 times per week
Intake and output	Yes	Daily	Daily	Daily unless fluid status assessed by physical exam
ALT, AST, ALP, total bilirubin	Yes	Day 1	Weekly	Monthly
Nitrogen balance	As needed		As needed	As needed

A.S.P.E.N. does not endorse the use of this material in any form other than its entirety.

reduced by stress or injury due to a cytokine-mediated inflammatory response.

Because of significant protein binding, serum calcium levels should be evaluated in light of the patient's visceral protein status. The unbound calcium or 'ionized' calcium is physiologically active. Both bound and unbound calcium are included by standard serum calcium measurements. Laboratory testing for ionized calcium provides a more accurate depiction of calcium status in comparison to standard calcium samples.

Blood glucose levels should be carefully monitored throughout the course of PN infusion in order to detect and prevent hyperglycemia or hypoglycemia. Capillary blood glucose monitoring devices provide a convenient means of determining blood sugars. Blood capillary glucose levels should be obtained more frequently during the initial days of PN therapy and subsequently as needed for 'spot checks' or to verify glucose levels obtained by serum blood sampling. Insulin management may warrant a separate intravenous insulin infusion, subcutaneous coverage with sliding-scale insulin, or the addition of insulin as a component of PN. Because insulin needs are often acutely elevated in infection or stress, sliding-scale subcutaneous insulin or a separate insulin infusion may be used in combination with the addition of insulin to the PN.

Baseline triglyceride levels may be obtained prior to PN administration and periodically during the duration of therapy. Lipid doses should be reduced or held temporarily in adult patients with triglyceride levels >400 mg/dl. EFAD may develop after prolonged administration of PN without lipids; therefore, at least weekly or biweekly doses should be considered for all patients.

Complications of PN

Short-term complications of PN therapy may be divided into three classes: mechanical, infectious, and metabolic. Longer term complications can include overfeeding, hepatobiliary complications, and metabolic bone disease.

Central catheter placement can be associated with serious mechanical complications, including pneumothorax, arrhythmias, catheter-related thrombosis, and catheter occlusion. Radiologic confirmation of line placement is necessary before initiating PN therapy. Catheter occlusion is the most common mechanical complication and may require thrombolytic treatment or line replacement. Catheter flushing protocols should be carefully followed to reduce risk of occlusion.

Infection due to catheter-related sepsis is another serious complication of PN that is associated with appreciable morbidity and cost. Prudent and meticulous catheter care and sterile technique should be emphasized. Catheter infections comprise a significant percentage of all nosocomial infections. Fever and unexplained hyperglycemia may be potential warning signs of catheter-related sepsis. It is important to note that there are frequently no external signs of catheter infection visible at the insertion site. Aseptic technique in manipulating the central line and related administration lines can help prevent introduction of infectious sources such as endogenous skin flora or contamination of the catheter

hub. Appropriate methods and a sterile environment in compounding PN will reduce chances of contamination of the PN admixture during preparation. Treatment of catheter-related sepsis often includes access device removal and administration of appropriate antibiotic or antifungal therapy. With selected pathogens in patients with limited access options, salvage antimicrobial therapy may be considered to prevent the necessity of line removal.

The incidence of metabolic complications in PN patients is estimated to be 5–10%. Metabolic complications may include intolerance to fluid or macronutrients, or imbalances in electrolyte or vitamin and trace element homeostasis or function. Hyperglycemia is the most common complication associated with PN therapy.

Refeeding syndrome is a potential phenomenon of metabolic complications that may be observed when severely malnourished patients are re-fed in an overzealous manner. The rapid provision of macronutrients is associated with serum depletion and intracellular shifts of phosphorus, potassium, and magnesium as well as fluid retention and vitamin derangements. These abnormalities may result in the development of clinical sequellae such as arrhythmias, heart failure, respiratory failure, and death. Prevention of this phenomenon is achieved by identifying the patient at risk, repletion of electrolytes prior to initiation of nutrition support, and the slow advancement of PN with careful daily monitoring of electrolytes, including phosphorus and magnesium levels, as well as weights and fluid intake and output.

Electrolyte adjustments warrant close clinical evaluation. For example, hyponatremia can represent sodium deficiency or water excess. Electrolyte loss or shifts may occur from renal or gastrointestinal losses, hormonal imbalances, medication use, or acid–base disturbances. Accumulation of electrolytes may occur with fluid or acid–base shifts, renal insufficiency, or overzealous exogenous replacement. Generally, a consistent PN formula is recommended, with additional acute electrolyte replacements provided separately from the PN. Lower concentrations or even elimination of selected electrolytes from PN are often indicated in patients with renal failure.

Hepatobiliary complications, including steatosis and cholestasis, are associated with PN patients due to the lack of enteral stimulation and limited gastrointestinal motility. Cholestasis is universal in patients receiving PN for more than 6 weeks without enteral feedings. Transition to enteral or oral feedings will help prevent the potential development of gallstones associated with cholestasis. In adults, hepatic steatosis, or fatty liver, is generally associated with normal or mildly increased bilirubin levels and mild elevations in alkaline phosphatase and hepatic transaminases. In rare cases, hepatic steatosis may progress to steatohepatitis. In order to reduce the potential for hepatobiliary complications, the practitioner should attempt enteral feedings as soon as possible. Overfeeding with excessive lipid and dextrose loads should be avoided. The PN infusion can also be cycled to provide a rest period for the liver's macronutrient processing. Administration of a cholecystokinin–octapeptide may also help to reduce cholestasis.

Osteoporosis or osteomalacia may develop in long-term PN patients. Metabolic bone disease may develop due to underlying disease, inadequate intakes or malabsorption of calcium and vitamin D, corticosteroid therapy or other medications, and hypercalciuria. For selected long-term PN patients, treatment with bisphosphonates, calcium, and vitamin D should be considered to prevent the development of complications.

Home Parenteral Nutrition

Many patients are able to receive PN in the home setting. If the patient's medical condition is stable and careful patient selection has been employed, home parenteral nutrition (HPN) can be considered. The patient and caregiver must be able to be taught to use an infusion device, administer PN safely, and search for signs of infection, fluid issues, or other complications. Appropriate education should begin in the hospital and continue in the home setting. Psychosocial and socioeconomic issues, such as family support, private or government payer status, and patient emotional status, are important to consider when assessing the appropriateness of HPN.

Nocturnal administration of PN over 12 h can aid with patient mobility and quality of life and may also help to minimize hepatobiliary complications. Cycled PN infusion should generally begin in the inpatient hospital environment so tolerance of cycling can be safely evaluated. Since greater infusion rates are required for cycling, close monitoring during the transition phase is of particular importance for those with glucose or volume tolerance concerns.

Conclusions

PN offers a viable way to provide essential nutrients to individuals who are unable to use their gastrointestinal tracts effectively for a prolonged time period. Although this medical intervention is

associated with significant risks, for many patients it can be a life-saving or life-prolonging therapy. Practitioners who manage patients who receive PN warrant specialized nutrition support training. PN management is most effective through a multidisciplinary approach, utilizing the expertise of physicians, pharmacists, dietitians, nurses, case managers, and social workers.

Infants and Children, Parenteral

S Collier and C Lo, Children's Hospital, Boston, Harvard Medical School, and Harvard School of Public Health, Boston, MA, USA

Parenteral nutrition (PN) is a technique that allows provision of complete nutrient requirements intravenously, containing adequate amounts of energy, carbohydrate, protein, fat, minerals, and vitamins, while bypassing the gastrointestinal tract. It has allowed survival of many thousands of patients who cannot or will not eat or absorb enough to maintain their weight or nutritional balance because of disease or surgery. From its beginnings only approximately 30–40 years ago, it has expanded rapidly to become available for many patients, especially in the United States and then in Europe, but its expense and complications preclude wide availability in many countries. Before the availability of PN, as many as 30–50% of hospitalized patients had unrecognized malnutrition from chronic diseases and would remain for weeks without adequate nutrition to maintain weight or lean body mass, making them susceptible to infections and poor wound healing. Surprisingly, it has been difficult to demonstrate substantial reductions in morbidity or mortality with PN except in moderately or severely malnourished patients or those with long-term intestinal failure. It is difficult to estimate the exact impact, but a US registry, the Oley Foundation, enumerated 10 035 Medicare beneficiaries on home PN in 1992, giving a rough estimate of 40 000 patients on home PN in the United States. Approximately 15–20% of these patients were children.

One of the first attempts at PN was carried out by Sir Christopher Wren in 1656. He infused ale, opium, and beer intravenously into animals. Complete intravenous nutrition that we are most familiar with for patient support has been available for approximately 40 years. The research carried out by Dr. Stanley Dudrick and others allowed the support of the first pediatric patient on intravenous nutrition. The provision of intravenous nutrition was challenged by the development of several factors prior to its completed use in patient support, including catheter access, sterility of solutions, and the optimal form of each macro- and micronutrient.

Indications for Parenteral Nutrition

The often repeated adage continues to be true, "If the gut works, use it." However, there are many circumstances in which PN is necessary and life sustaining. The indications for use have not changed dramatically throughout the years since the development of PN. Congenital malformation of the intestine, specifically small bowel atresia, was the diagnosis the first time PN was used in the infant and young child. Congenital malformations of the gastrointestinal tract continue to be one of the leading reasons for its use. Other indications include severe malabsorption, intestinal dysmotility, other congenital defects, and patients with hematology–oncology diseases (**Table 1**).

Table 1 Conditions commonly requiring parenteral nutrition

Condition	*Examples/comments*
Surgical gastrointestinal disorders	Gastroschisis, omphalocele, tracheoesophageal fistula, intestinal atresias, meconium ileus, peritonitis, malrotation and volvulus, diaphragmatic hernia, prolonged postoperative ileus, Hirschsprung's disease, intestinal dysmotility
Short bowel syndrome	
Prematurity	
Congential heart disease	
Pancreatitis	
Gastrointestinal fistulas	
Bone marrow transplantation	
Acute intestinal disease	Antibiotic colitis, necrotizing enterocolitis, inflammatory bowel disease, chronic or secretory diarrhea
Hypermetabolic states	Burns, multiple trauma
Chronic idiopathic intestinal pseudo-obstruction

Dextrose

The primary source of energy during intravenous therapy is usually provided by dextrose (D-glucose). This is especially true in infants and children when higher energy requirements often necessitate glucose infusion rates of up to 15 mg/kg/min or more. Not until 1945 did Zimmerman report the first attempt at infusing intravenous solutions through a catheter placed in the superior vena cava. Experiments performed by Dudrick in beagle puppies advanced the glucose infusion solutions closer to what is utilized currently with hypertonic dextrose solutions. In current practice, hypertonic solutions are infused through a catheter with its tip centrally located in the superior vena cava or inferior vena cava. It continues to be the major energy component of intravenous support.

Initial doses of glucose should be approximately 5–7 mg carbohydrate/kg/min with incremental increases by 2–5 mg/kg/min. Frequent monitoring of blood glucose and urine for glucosuria is important to assess tolerance to increasing glucose infusion rates. It is important to avoid excessive carbohydrate intake to minimize complications from potential hyperglycemia with subsequent osmotic diuresis and over the long-term hepatic steatosis from increased fat synthesis that can occur with overfeeding. Hyperglycemia may ensue even without excess carbohydrate infusion in certain clinical situations, such as sepsis and renal failure, and also with the use of medications such as steroids. Glucose infusion rates should be decreased if hyperglycemia ensues; however, it may still be necessary to add insulin to control blood glucose to provide adequate support.

Protein

Another vital macronutrient that needed to be provided was protein. Initial experiments in the 1930s were done with plasma as the protein source, and investigators achieved positive nitrogen balance. In the early 1900s, research began on the development of protein hydrolysates and crystalline amino acids. Vitrum, a Swedish company, produced the first commercially available casein hydrolysate solution. It was developed by Arvid Wretlind, who hydrolyzed casein enzymatically and then dialyzed the mixture to remove large polypeptides. The crystalline amino acid solutions that we are more familiar with were first developed by Bansi in 1964. Wretlind went on to modify it further and eventually replaced the hydrolysates in the 1970s.

The development of amino acid solutions specifically for infants occurred in the early 1980s. These solutions provided conditionally required amino acids for the immature organ systems of premature infants and newborns. They were formulated based on the postprandial plasma amino acid levels of breast-fed infants. Special amino acid solutions for renal or liver failure are also available that have increased amounts of branched-chain amino acids. Studies on the solutions for liver failure have shown that they are probably beneficial in adult patients with encephalopathy. Glutamine is a much researched amino acid that could not initially be added to PN solutions due to shelf instability in liquid form. When added as a dipeptide, it has been found to be more stable. Not all studies have shown clear benefit to its addition in patients for gut adaptation or prevention of bacterial translocation.

The recommendation for initiation of protein is 1 g/kg/day and that for advancement is 1 g/kg/day to goal (**Table 2**). Blood urea nitrogen is monitored for tolerance to amino acid infusion.

Lipid Emulsions

Glucose was the only nonprotein source of energy until intravenous lipids were developed during the 1920s to the 1960s. The first emulsion available for clinical use was Lipomul, a cottonseed oil-based formulation. Because there were many adverse effects from its use, it was withdrawn from clinical use in the mid-1960s. After extensive testing, Wretlind developed Intralipid, a soybean-based emulsion, in 1961. It was well tolerated and is the most familiar intravenous fat emulsion currently available. It is available in 10, 20, and 30% solutions. The advantage of the 20 and 30% solutions over the 10% solution is the lower ratio of phospholipids to triglyceride, which minimizes the increase in plasma lipoprotein X levels. Lipid emulsions provide essential fatty acids in addition to a concentrated energy source, which is particularly advantageous for patients requiring fluid restriction. Trials are under way on the use of emulsions that contain a blend of long-chain fat with medium-chain fats and those with fish oil blends. Also, structured fat emulsions are being studied for clinical use. These specialized emulsions may have advantages in patients with liver disease and those with sepsis.

Lipid emulsions are usually initiated at 1 g/kg/day and advanced to 2 or 3 g/kg/day or 30–50% of total energy. Serum triglyceride levels are monitored for tolerance. Hypertriglyceridemia may occur in situations of stress, sepsis, and renal and liver insufficiency/failure. In addition, a number of medications can cause hypertriglyceridemia. In these situations, a reduction in fat infusion is warranted, usually by infusing over 18–20 h instead of 24 h.

A minimum of 3–5% of total energy requirement is necessary to meet essential fatty acid requirements. In infants with indirect hyperbilirubinemia, it may be prudent to lower intravenous fat infusion to avoid potential risk of kernicterus since free fatty acids may displace bilirubin from albumin binding sites.

Table 2 Pediatric parenteral nutritional requirements

	<2000 g	*0–4 years*	*5–18 years*
Energy (kcal/kg/day)	120	90–108	40–70
Protein (g/kg/day)	3–3.5	2.0–3.0	1–1.5
Fat (g/kg/day)	<3	<3	<2
Sodium (mEq/kg/day)	2–3	2–4	2–4
Potassium (mEq/kg/day)	2–3	2–4	2–4
Chloride (mEq/kg/day)	2–3	2–4	2–4
Calcium			
mEq/kg/day	3–4.5	2–3	0.5–2.5
mg/kg/day	60–90	40–60	10–50
Magnesium (mEq/kg/day)	0.35–0.6	0.25–0.5	0.25–0.5
Phosphate (mM/kg/day)	1.5–2.5	1–2	1–2
Zinc (μg/kg/day)	400	300	100
Selenium (μg/kg/day)	1–3	1–3	1–2
Trace elements (ml/l)	2	2	2
Multi vitamins (ml/day)	5	5	5–10

Micronutrients

To provide complete nutritional support, micronutrients, electrolytes, and minerals also need to be in the parenteral solution. The addition of adequate amounts of calcium and phosphate in one solution may be particularly problematic since precipitation may occur. Solubility guidelines are available that account for the brand and percentage of amino acids, which impact the pH of the solution. Compounding guidelines for the order of addition of calcium and phosphorus, amounts of other additives, and the temperature of the solution are other factors to optimize the solubility. Filters in the delivery system also help to minimize the risk of occlusion of the catheter if a solution should precipitate, especially with trimix solutions, in which lipids are mixed with the glucose/amino acid solution. Studies have evaluated the stability of the variety of nutrient components in trimix solutions.

Before the availability of vitamins and minerals, plasma levels of micronutrients decreased rapidly

while infusing only macronutrients. The only commercial preparation initially available was a trace element solution that had iron and iodide. The first commercial preparation of multivitamins for intravenous use, introduced in the 1960s, lacked folic acid, vitamins B_{12} and K, and biotin. It also had very high concentrations of vitamins A and D and thiamin. Because of the variability in practice, there was increased risk of toxicity to vitamins A and D and deficiencies of other vitamins. Recommendations were made for intravenous pediatric and adult intravenous preparations in 1975. By 1978, there was a commercial multivitamin preparation that met these recommendations. Current preparations contain all vitamins for which there are Dietary Reference Intake values, with the exception of choline. A recent Food and Drug Administration mandate requires the addition of vitamin K to all preparations. Differences between the pediatric and adult forms of MVI include amounts of B vitamins and vitamin D (**Table 3**). There is currently no multivitamin preparation specifically for the premature infant. Dosing recommendations of Pediatric MVI for this group are based on weight (one-third vial for <500 g, two-thirds vial for 500–1000 g, and full vial for more than 1000 g).

A few trace element deficiencies have been noted in patients receiving long-term PN support. The first case of chromium depletion was reported in 1977, that of selenium deficiency in 1979, and that of molybdenum in 1981. There are now many trace element solutions available with a variety of combinations of minerals and that are appropriate to meet the needs of premature infants through the adult population. They are also available as single elements to tailor a solution as necessary. Contamination of trace elements can occur in parenteral solutions. Aluminum is one element that has been under scrutiny by the Food and Drug Administration mandate to minimize the amount patients receive for safety issues. It was initially found in high concentrations in the casein hydrolysates and continues to be found in high concentrations in a variety of intravenous preparations. Over time, aluminum can deposit in the bone, interfering with bone calcium uptake, and deposition in the brain may impair neurological development.

Table 3 Comparison of parenteral multivitamin preparations for pediatric and adult populations

Vitamin	*MVI Pediatric (Mayne)*	*Infuvite (Baxter) and MVI Adult with vitamin K (Mayne)*
A (IU)	2300	3300
D (IU)	400	200
E (IU)	7	10
K (μg)	200	150
Ascorbic acid (mg)	80	200
Thiamine (mg)	1.2	6
Riboflavin (mg)	1.4	3.6
Niacin (mg)	17	40
Pantothenate (mg)	5	15
Pyridoxine (mg)	1	6
B_{12} (μg)	1	5
Biotin (μg)	20	60
Folate (μg)	140	600

Metabolic Complications

Liver Disease

Although PN may be life sustaining, long-term use may be detrimental to the liver. The severity of injury ranges from reversible transaminase elevations to severe cholestasis and cirrhosis, especially in infants with short bowel syndrome. It is not clear whether this is due mainly to a nutrient deficiency, toxicity, or some physiological process missing because of the lack of enteral feeding. Prevention and treatment strategies continue to include minimizing or preventing episodes of sepsis, providing enteral feedings, moderating energy intake to provide for adequate growth but not to overfeed, cycling parenteral nutrition infusion, reduction of copper and manganese, use of an amino acid solution developed for infants, treatment/prophylaxis for bacterial overgrowth, and the use of ursodeoxycholic acid. Another drug that has been studied but is not available for clinical use is cholecystokinin, which promotes gallbladder contraction. A recent and controversial recommendation is the adjustment of the dose of intravenous lipid emulsion to ≤ 1 g/kg/day. Intravenous lipid emulsions are a rich source of linoleic acid, an omega-6 polyunsaturated fatty acid, and may enhance production of the proinflammatory cytokines. Increased leukotriene B4 synthesis by the hepatic macrophages will draw additional polymorphonuclear leukocytes that intensify the inflammatory response to endotoxin by release of reactive oxygen species.

Bone Disease

The development of osteopenia is another complication that is common with long-term PN support. The reasons are multifactorial and include relative immobility, inability to provide adequate calcium and phosphorus with solubility limitations, and hypercalciuria. It has also been suggested that the dose of vitamin D in the multivitamin preparation

may contribute to bone disease. Excessive vitamin D may suppress parathyroid hormone secretion and directly cause bone resorption. Although aluminum is still present in some intravenous solutions, including calcium gluconate, vitamins, and trace elements, the amounts are much less than those seen with the casein hydrolysates and are not believed to be a significant contributor to the development of metabolic bone disease. Prevention and treatment strategies include maximizing calcium and phosphorus in PN solutions, especially for growing children; providing enteral supplementation of these minerals as feasible; and providing weight-bearing physical therapy if possible.

Micronutrient Deficiency and Excess

If a patient is entirely PN dependent, certain micronutrients need to be provided. Some PN solutions require the addition of carnitine and selenium (if not provided in multi-trace element solutions) and iron dextran (if the patient is not receiving transfusions). All serum levels should be monitored on a monthly basis or every 6–12 months if in the long-term phase of support. There may be other micronutrients not yet identified that may be deficient in the purified PN solution, which is another reason to begin enteral feedings as soon as feasible. Monitoring for excess losses is also important. For example, with increased stool/ostomy losses, the patient may require increased zinc in the PN solution (**Table 4**).

Excess micronutrients can be caused by contamination, such as the case with aluminum, or clearance. Copper and manganese can accumulate and become directly hepatotoxic since both elements depend on the biliary pathway for excretion. Therefore, in the presence of cholestasis, there will be increased intrahepatic accumulation. Manganese has also been reported to deposit in brain tissue, so copper and manganese levels should be monitored routinely.

Table 4 Suggested monitoring schedule for inpatients receiving parenteral nutrition

Parameter	*Daily*	*Weekly*[a]	*Periodically*[a]

Catheter Complications

Complications with central venous catheters most frequently include obstructions, infections, and occasional leakage and perforation. Although PN can be temporarily provided through peripheral intravenous catheters, the high osmolarity of intravenous glucose–electrolyte solutions often causes phlebitis and loss of access. Therefore, long-term access requires placement of a central venous catheter placed via the internal or external jugular vein or a subclavian vein. There is also increased placement of peripherally inserted catheters by a team of specially trained staff and/or an interventional radiologist. Tip position in the superior vena cava or right atrial junction should be verified radiographically to reduce complications from venous thrombosis or rare perforations. Central placement allows rapid dilution of hypertonic solutions in a large-diameter vein to minimize obstruction or thrombosis. Catheters for central venous access have been made of polyvinyl chloride, polyurethane, and silastic, often with a Teflon cuff to anchor the catheter subcutaneously. However, formation of a fibrin sheath is still common, often with a biofilm that may harbor infectious organisms and prevent penetration of antibiotics. Central catheter obstructions can often be visualized by ultrasound or inserting radio-opaque dye in the catheter. A thrombus can often be lysed with installation of a small bolus of tissue plasminogen activator. Long-term anticoagulation with coumadin, low-dose coumadin, or low-molecular-weight heparin has been advocated by some to avoid repeated catheter obstruction, venous thrombosis, superior vena cava obstruction, and potential pulmonary emboli.

Obstructions caused by precipitation of calcium phosphate salts or medications may be susceptible to installation of a small amount of dilute acid, and those due to fatty material may be dissolved with dilute ethanol. For long-term home parenteral use, some patients prefer the use of implantable ports, which can be accessed through the skin daily with a special needle. Recently, peripherally inserted central catheters have been used for periods up to 1 month or longer without requiring a surgical procedure.

Infections

Patients who require PN are often predisposed to infectious complications. The catheter hub is often the entry site, with skin flora such as *Staphylococcus epidermidis*, *Staphylococcus aureus*, or *Candida* being the most common organisms, along with gram-negative enteric bacteria possibly from bacterial translocation. Antibiotic treatment through the central line is often successful without replacement of the catheter using antibiotic combinations such as vancomycin and gentamicin or with an antibiotic lock.

Summary

Advancements in the technology, production, and manufacturing of intravenous solutions have progressed during the past 40 years. In addition to improvement in the solutions available for dextrose, amino acids, and lipid emulsions, there has been progress with the delivery systems, catheters, and sterile techniques for line and skin care to reduce overall complications.

Ongoing research and product development in areas associated with long-term PN support are vital for future patient management to be able to continue to provide optimal support with minimal risk for those patients for whom PN is life sustaining.

NUTRITIONAL SURVEILLANCE

Contents

Developed Countries

N R Sahyoun, University of Maryland, College Park, MD, USA

There has been increasing recognition in the past three decades that dietary intake patterns are associated with the development of chronic diseases and that improving nutritional intake may be a means of improving the well-being of the population and of reducing the cost of health care. Hence, nutritional surveillance has become an important topic on the health political agenda in many areas of the world and may become an integral part of surveillance systems. In addition, as new technology has enabled faster data collection and analysis, surveillance systems have evolved and become more sophisticated in the past decade.

This article defines nutrition surveillance and its usefulness. It also describes the types of surveillance activities and systems in place in the industrialized countries of Europe, the United States, Australia, New Zealand, and Canada. Emerging issues in nutrition and health are also discussed. Note that although the structures of surveillance systems in industrialized and developing countries have many similarities, the type of activities, target populations, and outcomes may be different. Thus, there is a need to describe the nutritional surveillance systems in place in industrialized countries separately.

Nutrition Surveillance and Its Usefulness

Nutrition surveillance is a system established to continuously monitor the dietary intake and nutritional status of a population or selected population groups using a variety of data collection methods whose ultimate goal is to lead to policy formulation and action planning. The term 'nutrition monitoring' is often used in addition to or interchangeably with 'nutrition surveillance' and is defined as surveillance that is carried out on selected individuals. In this article, the term nutrition surveillance is used to include all data collection methods that are described.

The information obtained through nutrition surveillance is used for three broad purposes: policy development, nutrition research, and monitoring. As **Figure 1** illustrates, there are strong interrelationships between these three purposes. Specifically, the information generated by nutrition surveillance activities is used to describe the nutritional status of the population and identify population groups at high nutrition risk. Programs are then targeted to those in need. The efficacy of the programs is assessed and nutrition policy developed. Trends in health status and food intake are monitored and food supply needs are estimated. Also, linkages between food consumption, nutritional status, and health status are examined. For example, normative data collected from surveys in the United States have been used to develop new growth charts, released in 2000, to monitor nutritional status and health of children. Similarly, the World Health Organization, using international data, is also in the process of developing new international growth charts. Monitoring trends in child

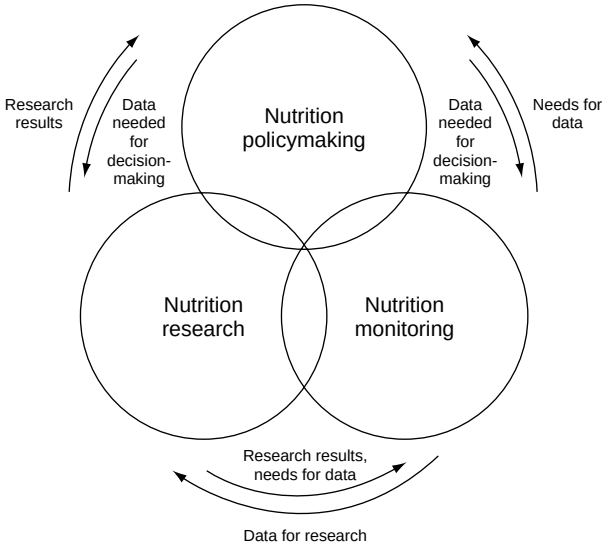

Figure 1 Relationships among nutrition policymaking, nutrition research, and nutrition monitoring. (From the US Department of Health and Human Services/US Department of Agriculture (1993) Ten-year comprehensive plan for the National Nutrition Monitoring and Related Research Program. *Federal Register* **58**: 32752–32806.)

growth helps to identify populations in need, evaluate nutritional and health interventions, and raise political awareness of nutritional problems.

Food fortification is another example of an interaction between monitoring, research, and policy, and it highlights the importance of nutrition surveillance systems. Folic acid supplementation, in addition to normal dietary folate intake, was recognized to significantly reduce the incidence of neural tube defects, one of the most common birth defects. This led to the mandatory fortification in 1998 of enriched grain products with folic acid in Canada and the United States. Survey data were used to determine the amount of folic acid that needed to be added to the food supply to provide beneficial effects without the harmful effect of potentially excessive intake. Surveys that examined the impact of folic acid supplementation showed a 19% reduction in neural tube defects. Continuous monitoring is essential to ensure that the added intake of folic acid does not have longer term negative impacts on the different population groups.

Nutrition Surveillance Systems

A nutrition surveillance system ideally collects information on all components in the relationship between food and health. This includes collecting data on food production, food supply and availability for consumption (national and household), food consumption patterns, dietary composition of foods, nutrient intake, nutrient utilization, and nutritional status. It also includes variables that may influence these processes, such as food culture, food security, lifestyle, knowledge, attitude and behavior toward food, and sociodemographic factors. **Figure 2** depicts the relationship of food to health outcome and illustrates the various levels of influence. A nutrition surveillance system would ideally obtain nutrition information along that continuum from food supply to health. At the core of a nutrition surveillance system is the collection of dietary intake patterns because they provide a basis for nutritional risk assessment. These dietary data include information obtained from the national food supply and from food consumption by households and by individuals. Each type of data collected corresponds to a different stage in the food distribution chain and is obtained by different methods. Some of these methods are described next.

Dietary Data Collection Methods

Food supply data Food supply data provide information on the type and amount of food available for human consumption to the country as a whole. The most common method of measuring this available food is through the use of food balance sheets. It is a method of indirectly estimating the amounts of food consumed by a country's population at a certain time. It provides data on food disappearance rather than on actual food consumption. It is calculated by using beginning and ending inventories, and the

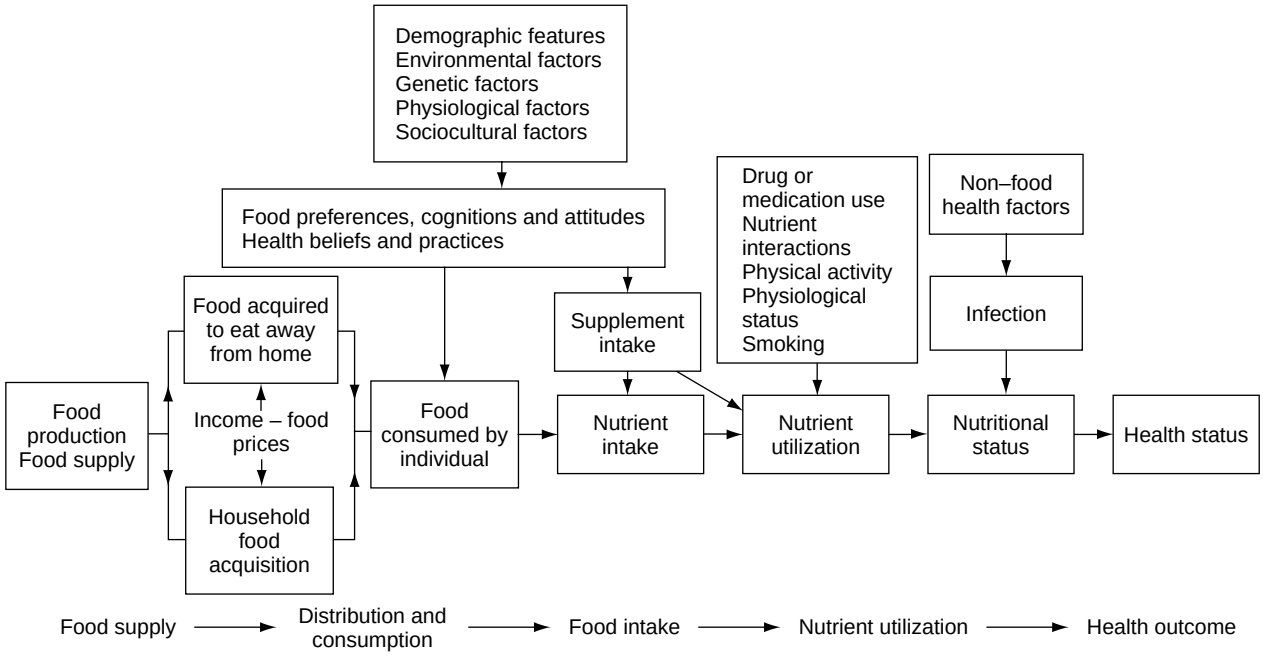

Figure 2 A conceptual model of the relationships of food to health. (Life Sciences Research Office, Federation of American Societies for Experimental Biology. Nutrition Monitoring in the United States – An Updated Report on Nutrition Monitoring. Washington, D.C.: U.S. Government Printing Office, 1989.)

difference is the amount of food consumed. The beginning inventory includes data on food production, imports and exports, and adjustments for non-human food consumption and an estimate of waste. Results are then converted to per capita basis food availability. To obtain the mean per capita annual consumption of food, total disappearance of food is divided by the country's population. Quantities of each food commodity are then multiplied by the appropriate nutrient values, and the results are expressed either in kilograms per year or in grams per day of individual food commodities and nutrient availability per person. No deduction is made for household food waste or the loss of nutrients in food preparation. Food is not distributed equally among a country's population, so this method only indicates the amount of food that leaves the food distribution system and is available for human consumption to the country as a whole. The best and most useful use of this data is to compare available food supply within and between countries and to monitor trends and forecast food consumption patterns over time. For example, **Table 1** illustrates the use of food balance sheets data and shows the worldwide and regional increase in the average supply of dietary fat from 1967–1969 to 1997–1999. Caution is needed, however, in comparing data between countries because food balance sheets, although compiled in a similar manner, may differ in food groupings, level of processing of commodities, and nutrient conversion of factors.

The Food Agriculture Organization (FAO) has published international food balance sheets yearly since 1949 and also covering the period 1934–1948. FAO food balance sheets are compiled from data supplied by approximately 200 countries. FAO uses the United Nations Population Division mid-year estimates of population size for its food balance sheet data and to calculate per capita values. International food balance sheets have also been compiled and published by the Organization for Economic Cooperation and Development on 23 countries (18 European countries, Australia, Canada, Japan, New Zealand, and the United States), whereas the Commission of the European Communities (EURO-Stat) publishes data for its 12 member countries. In addition, individual countries publish their own data. For example, Canadian data on per capita food availability have been prepared annually by Statistics Canada since 1979. In the United States, annual estimates of commodity foods consumed by the civilian population are calculated and have been reported since 1909.

Food consumption by households Methods have been devised to obtain information on the availability of food and beverages for consumption by a household, family group, or institution. The basic concept is to collect the types and amounts of food that enter a household and that are available for consumption. These methods vary by the level of respondent burden and extent of recall expected, and there are four main ones: the food account, list-recall, inventory, and food record methods. Generally, the information is collected for a period of 7 days. In the food account method, the head of household records daily all types and quantities of food that enter the household within a 7-day period. In the list-recall method, the head of household is interviewed and must recall the foods used by the household on an 'as purchased' basis. The inventory and food record methods require daily recording of food acquired and of changes in the food inventory and also detailed weighing and measuring of food, placing a heavy burden on the respondent.

These household food consumption methods do not provide actual food intake by individuals within the household. Instead, individual food consumption and nutrient intake are calculated by dividing household food consumption by the number of members in the household regardless of age or sex. This information is then reported in terms of household income level, family size, and other general characteristics of interest. Several countries have used household methods for their national

food consumption surveys. In Canada, household food consumption surveys were conducted at approximately 4-year intervals and then yearly since 1997. The United Kingdom originally used the household inventory method but in 1950 changed methods because it had too high of a respondent burden. In the United States, nationwide household food surveys started in the 1930s and used the household food record method, but in the 1980s household food consumption surveys collected food intake of individual household members in addition to household food expenditure. In Europe, an ongoing project of the European Union is to harmonize dietary exposure from household surveys to improve comparisons of these data between countries.

Food consumption by individuals Collecting information on dietary intake of individuals provides a level of detail that allows the exploration of relationships between dietary intake, nutritional status, and health outcomes. It also provides information on intake distribution and patterns by age, gender, and other well-defined criteria, thereby identifying population groups at risk. Individual dietary intake data is collected in a variety of ways. The three most common methods are food record, 24-h recall, and food frequency questionnaires (FFQs). Food records are used to measure dietary intake over a single time period, usually 3–7 days. Respondents are asked to measure and weigh their food intake. Although this method provides details on the amount and kind of food consumed, it places a heavy burden on respondents, requiring motivated, trained, and literate individuals. The 24-h dietary recall also requires a trained interviewer who asks and probes respondents on the kind and amount of all food and drink consumed during the previous day. This method is used to monitor group mean intakes in the population. It is currently recommended that a second recall be collected to better estimate the population distribution of usual intake of nutrients and to correct for reporting error. Methods of collecting this data have become progressively more sophisticated as computerized systems have been developed to include standardized probes and multiple passes of intake over the day to prompt recall. These innovations have led to improved estimates of nutrient intake. FFQs are most often self-administered instruments in which respondents are presented with a list of food items and asked to report usual frequency of consumption over a specific time period (usually 1 year). FFQs are designed to obtain data regarding usual intake, are less costly to administer and code than recalls or records, and vary in the number of foods included in the food list. FFQs are semiquantitative and lack the detail of records or recalls.

Several variations of these methods of individual data collection have been devised. However, each of these dietary assessments provides advantages and limitations, and their applicability depends on the setting and the purpose of the data collected. Collecting individual dietary intake patterns is more time-consuming than collecting information on the food supply or household intake; however, most industrialized countries now collect these data or are making plans to do so. **Table 2** presents some of the surveys conducted by various industrialized countries and the method of dietary data collection selected by each country. The methods are quite varied, which limits comparability across surveys.

Examples of Nutrition Surveillance Activities

The 1990s saw a proliferation of nutrition surveys as local governments and international bodies such as the European Commission, the World Health Organization (WHO) and the International Union of Nutritional Scientists called for the establishment of a nutrition surveillance system. Most countries in Europe have a health interview survey, and some countries have a health examination survey as well. The dietary information gathered from these surveys varied considerably, from including one question on diet to including a FFQ. A few countries even measured nutritional biomarkers, whereas others did not collect any dietary intake data at all. Again, these methodological differences limit comparability of the results.

Most of the European Union member states have or are establishing a nutritional policy as an independent field of multidisciplinary research. The European Food Consumption Survey Method (EFCOSUM) was created as a project of the European Union Programme on Health Monitoring. One of its functions is to define a method for monitoring food consumption in nationally representative samples of all age–sex categories in Europe in a comparable way. It made recommendations about the best and most cost-effective data collection methods to use and the minimum variables needed to assess the nutritional status of populations. In addition, another objective of EFCOSUM is to indicate how to make existing food consumption data comparable and available to the health monitoring system. Also, WHO is stimulating regional and international networking and is strengthening community-based activities to prevent major

noncommunicable diseases (NCDs) or chronic conditions. An international assessment of national capacity for the prevention and control of these diseases conducted in 2001 indicated that many countries lack policies to deal with the prevention of chronic diseases and lack legislation for food and nutrition.

The United States has the most extensive and comprehensive nutrition surveillance system in the world. Food consumption surveys were initiated in the 1930s and the surveillance system has expanded since then to include many cross-sectional and longitudinal surveys and surveillance systems. Due to the large number of surveys conducted in the United States, only a partial list is presented in **Table 2**. In 1990, the National Nutrition Monitoring and Related Research Program was established by the US Congress to strengthen food and nutrition data collection efforts via a 10-year plan. One of the outcomes of this effort was the establishment in 1999 of a continuous nutrition survey, the number one source of nutrition status information on the US population, which aims to collect a representative sample of 5000 individuals yearly. Similarly, in 1992, Australia launched a national food and nutrition policy for ongoing monitoring and surveillance of the food and nutrition system, which was established in 1998 and aimed to consolidate and strengthen data collection efforts. In Canada, the Canadian Community Health Survey began in 2000 to provide timely cross-sectional estimates of health determinants, health status, and the health system in a 2-year collection cycle. A nutrition component of the survey was implemented in 2004. The National Nutrition Survey of Japan has been conducted annually since 1946. Recently, Japan modernized the handling and processing of the data, which will allow for more rapid and greater data gathering capabilities and more accurate and timely reporting.

The assessment of nutritional status not only includes collecting dietary intake but also anthropometric measures, biochemical tests, and clinical examination. The measures of nutritional status collected in the different surveys vary considerably, as shown in **Table 2**. The simplest and most common anthropometric measures of nutrition status are height and weight, which are used to calculate body mass index, a widely accepted measure of overweight and obesity. Waist circumference and hip-to-waist ratio are also frequently measured to obtain an estimate of body fat distribution. Alternatively, a number of surveys have collected self-reported height and weight measures. Also, biological samples such as blood, urine, saliva, and hair have been collected, particularly in US surveys, as biomarkers of dietary intake to validate dietary data collection instruments, to relate to environmental exposure, and to study diet–health relationships. The selection of

biomarkers for inclusion in a survey is subject to budgetary constraints and survey logistics as well as health and methodological priorities determined by each country. For example, Germany has analyzed blood for ferritin, minerals, and certain vitamins such as folate and vitamin B_{12}, whereas the United Kingdom has analyzed blood for folate and vitamins D and C. In an effort to prioritize and standardize data collection, EFCOSUM has recommended at a minimum the analysis of biomarkers for folate, vitamin D, iron, iodine, and sodium. Finally, the most common clinical measure incorporated in surveys is that for blood pressure. Additionally, self-reported or physician-reported medical conditions are frequently collected from survey participants. In the United States, a wide array of clinical exams are conducted as part of the National Health and Nutrition Examination Survey, including dental health and vision.

Emerging Nutrition and Health Issues

Several emerging health issues that are related to dietary intake and lifestyle choices have made it essential to track eating habits and nutritional status over time. For example, obesity is an escalating epidemic through the world among both children and adults and a major concern because of its health consequences. Obesity has been linked to an array of health disorders, such as type 2 diabetes, cardiovascular disease, and disability. In 1995, WHO estimated that there were approximately 200 million obese adults worldwide and 18 million children younger than 5 years old classified as overweight. As of 2000, the number of obese adults had increased to more than 300 million. In the United States, 64.5% of adults were classified as overweight in 1999–2000, up from 46.0% in 1976–1980. Also, the percentage of overweight children in the United States (aged 5–14 years) has doubled in the same period from 15 to 32%. In England, the prevalence of obesity has doubled since 1980. Australia, New Zealand, Canada, and European countries have all reported an increase in the proportion of obese adults and children. WHO has begun to formulate a Global Strategy on Diet, Physical Activity, and Health under a 2002 mandate from the World Health Assembly. The overall goal of the strategy is to improve public health through healthy eating and physical activity.

Another issue of emerging international importance is that both the number and the proportion of people 60 years of age or older are increasing in almost all areas of the world, and these worldwide trends are expected to continue. In 2002, there were an estimated 605 million older people in the world. **Table 3** shows the countries with the highest percentage of the population older than 60 years of age. As a consequence of this demographic change, NCDs have been estimated to account for approximately 60% of global deaths and 45% of the global burden of disease. Attention to this demographic change has resulted in changes in health policies in order to help the population achieve healthy and active aging. WHO has developed a policy framework that focuses on preventing and reducing the burden of disabilities and reducing the risk factors associated with NCDs. These policies include healthy eating and physical activity.

Data from the United Nations (www.who.int/hpr/ageing/ActiveAgeingPolicyFrame.pdf).

Research has consistently demonstrated that sufficient daily intake of fruit and vegetables could help prevent major NCDs, such as cardiovascular diseases, type 2 diabetes, obesity, and certain cancers. According to the 2002 World Health Report, up to 2.7 million lives could potentially be saved each year if fruit and vegetable consumption were increased. However, surveys conducted in Europe and the United States have indicated that the consumption of fruit and vegetables is lower than recommended for health. According to Kraisid Tontisirin, the director of FAO's Food and Nutrition Division, "FAO faces the challenge to increase worldwide awareness of the health benefits of increased fruits and vegetable consumption. To effectively promote more consumption of fruit and vegetables, prevailing diets need to be more systematically assessed for their nutrition and health implications."

These emerging issues linking nutrition and health outcomes reinforce the importance of developing and maintaining a nutrition surveillance system. However, direct and indirect methods of dietary data collection that can easily be applied in the field need to be developed further.

Developing Countries

L M Neufeld and L Tolentino, National Institute of Public Health, Cuernavaca, Mexico

Nutritional surveillance was defined in the previous article as a system established to continuously monitor the dietary intake and nutritional status of a population or selected population groups using a variety of data collection methods, with the ultimate goal of having a direct impact on actions to improve the situation. The challenges to meet this goal in developing countries are many, and they differ from those of more industrialized countries for a number of reasons. First, in most developing countries the prevalence of problems related to nutritional deficiency is higher than in industrialized countries and the prevalence varies greatly within and between regions and countries. Second, continuous national monitoring (e.g., through the health care system) is not well established in many countries and resources in many countries are scarce. Finally, during the past decade there has been a dramatic increase in the prevalence of overweight and obesity and their related morbidities. Together, the problems related to under- and overnutrition present unique challenges to national and international policymakers and heighten the need for nutritional surveillance systems that are able to provide useful information to policymakers.

To date, the major shortfall of nutritional surveillance has been the link between the data collected and its use in policy and programs, particularly in developing countries, where the need for nutrition interventions is great. Health and nutrition policies and programs should use information from nutritional surveillance systems to identify needs of specific populations within regions and countries and to help design appropriate interventions that address the relevant causes of these problems. This implies an open communication between those involved in data collection and those who would ultimately use the information. Unfortunately, the number of concrete examples in which this link has resulted in nutritional surveillance information being directly used to influence policy is still limited.

The responsibility for making nutritional surveillance action-oriented lies with all parties involved—donors, agencies or researchers involved in data collection and analysis, and policymakers. In many developing countries, the lack of existing information systems and limited local resources implies that external funds, often from donor agencies, will be required for surveillance activities. At all stages of planning, those responsible for data collection should interact directly with policymakers to ensure that the information is collected, analyzed, and presented in a way that is meaningful to them. Once data on the nutrition situation become available, policymakers should seek technical assistance from experts in the field to assist with the design of interventions with high potential for impact. Evaluation of policy and programs is essential to complete the cycle and permit new assessments and analyses based on these outcomes. This again implies the need for external funds in many cases. Researchers or national or

international agencies may need to become advocates to promote dialogue with policymakers and to convince donors of the importance of this process.

The Nature of Nutritional Surveillance Data in Developing Countries

Information collected as part of a nutritional surveillance system should include not only documentation of the nutritional problems but also an analysis of their direct and indirect causes. A conceptual framework, such as that of UNICEF, for understanding the causes of malnutrition should be used to determine the types of information that are needed. The exact information needed therefore may be context specific, depending on what preexisting information is available. The following are examples: (1) If recent national data show an adequate national food supply, but a high prevalence of malnutrition in children younger than 5 years of age still exists in the country, information related to household food security, individual food consumption, as well as other causes of childhood malnutrition such as infections may be needed; and (2) if the prevalence of obesity has increased recently in a country, information on dietary intake and physical activity patterns will be needed to understand the causes of this increase and to design appropriate interventions.

Details of different methods to collect data at the national, household, and individual level are described in the previous article and will not be reviewed here. Rather, this article focuses on some of the specific strengths, limitations, and applications of each type of data as they apply to nutritional surveillance in developing countries and describes some additional methods that have been adapted for use in developing countries.

National Food Supply Data

The Food and Agriculture Organization (FAO) compiles and monitors food supply data for many developing countries. The estimates are typically based on food balance sheets supplied from each country's national records. The information is usually converted to per capita food availability and is presented for developing countries as a whole, by region, subregion, and for more than 100 individual countries. Information is also available for many countries (e.g., in Latin America—Mexico, Brazil, Argentina, and Chile) from national statistical institutes as well as regional statistical organizations (e.g., the Council for Statistics in Latin America). Much of this information can be accessed free of charge through local Internet sites.

Food supply data are essential to make comparisons between and across regions and to monitor trends. For example, according to the FAO food supply data, approximately 10% of the worlds' population now lives in countries where the food supply is low (<2200 kcal/person/day). This is down from 57% in the mid-1960s. Nonetheless, according to 2001 FAO data, there are still 30 countries with low food supply. Ideally, this type of information should be used to promote agricultural policies that will enhance food supply.

Despite these important uses, these data should be interpreted with caution, particularly in the developing country context. Although many countries show national increases in food supply, this does not address the issue as to how food is distributed within the country. Increases in access among the most vulnerable groups may not parallel increases in national production. Thus, although food supply data are useful for trend analysis, they should not be used to assess changes in food consumption or food security.

Trends toward a decline in the food supply can also be identified using food balance information. This may be a reflection of an unstable political environment or some severe natural disease that influenced food production. Ideally, this information should be used to influence agricultural policy to stimulate higher levels of production. However, war or other political strife may impede this process. The data should not be used to predict food shortages or famine because it is not useful to identify vulnerable groups within a population and because vulnerable groups may already be experiencing shortages by the time that this information is available and processed.

The quality of data used to generate food balance sheets can vary greatly between countries. In general, the methods are thought to underestimate total per capita energy availability in developing countries. In some countries, particularly those where small-holder agriculture is still common, this may be related to underestimates of true production due to a less centralized economy.

Household Food Consumption Data

The documentation of household food security in developing countries continues to be of great interest because of its relationship to specific health and nutrition indicators and as a means of monitoring the impact of political and environmental change on these outcomes. There have also been a number of efforts to document the impact of poverty alleviation programs on food security. Food security is

often measured by quantifying household food consumption, which provides an estimate of the food available to be consumed on a per capita basis.

Traditional methods to assess household food consumption include those that collect data over a period of time, often 7 days, by asking the respondent to keep a record of food entering the home (food account method) or by quantifying the food consumed at each meal (household food record method). Other methods may include an inventory of food available in the home over a period of time or the list-recall method, whereby the respondent is asked to recall all food purchased, quantity, and purchase price over a given time. These methods have many limitations in a developing country. For example, respondents may have limited literacy and numeracy skills. In this case, field-workers would be responsible for data collection, resulting in increased survey time and costs. Many poor households have little or no food stores in the home and inventory methods may not provide an adequate estimate of household consumption. Furthermore, these methods often rely on telephone or costly house-to-house surveys, the resources for which may not be available. Thus, these types of household consumption methods have been excluded from many large-scale surveillance systems in developing countries and efforts have been made to develop more appropriate methods.

In the past decade or so, there has been considerable interest in dietary diversity as an indicator of household consumption. (The dietary diversity score is also used to assess intake of individuals. The principle is the same, but the respondent is asked to list all foods or food groups consumed by the individual.) This method provides qualitative information on all foods or food groups, including meals and snacks, that were consumed over a given period of time (often 1, 3, or 7 days) by all members of the household. Each food or food group is assigned a value based on its nutrient density, bioavailability, and typical portion size. Portion size is included because although some foods (e.g., nuts) may have high nutrient density, they are typically consumed in small quantities. Points are then summed and the adequacy of dietary diversity is assessed based on this score. Reasonable correlations have been found between dietary diversity, household socioeconomic status, and household consumption as assessed by more traditional methods. The major advantage of this type of instrument is that it is simple and less time-consuming than other household consumption methods, with important implications for its use in large surveys. Although the use of this type of instrument in nutritional surveillance systems is still limited, its potential as a simple method to assess and monitor household food security appears promising.

Individual Nutritional Status and Dietary Intake Data

Information on the dietary intake and nutritional status of individuals in a population is essential for monitoring trends in these indicators over time and in response to political and environmental changes, as a means of identifying groups for intervention, and to assess the impact of interventions on nutritional status of the population. Although dietary intake and simple anthropometric measurements, such as weight and height, have often been the focus of health and nutrition surveys, it is essential that other indicators of nutritional status such as micronutrient deficiencies also be documented because they continue to be important public health problems in most developing countries. Furthermore, as discussed previously, information on factors that are direct (e.g., the prevalence of infections) and indirect (e.g., maternal education and family socioeconomic status) causes of nutritional problems increases the usefulness of nutritional surveillance information for policymakers.

Many nutritional surveillance systems have dealt with this daunting list of indicators by focusing efforts on specific high-risk groups—a logical decision in light of limited resources. Thus, more information is available for children younger than 5 years of age and women of reproductive age than for olden children, adolescents, adult men, and older adults. With the increasing prevalence of overweight and obesity, particularly in school-age children and adults, this strategy may need to be modified. Although not evident in all developing countries, this paradox is particularly striking in some middle-income Latin American countries, such as Mexico and Chile, but is also documented in India and many other countries.

The coexistence of malnutrition and "over-" nutrition represents an important challenge to all those involved in nutritional surveillance. For funders, the population groups being monitored may need to be expanded, with important cost implications; malnutrition in children and pregnant and lactating women has not disappeared in developing countries with the increase in overweight and obesity. For those involved in data collection, these additional nutritional problems imply the development and validation of new instruments to measure causes of overweight and obesity (e.g., physical activity). For policymakers, the burden lies in the need for policies and programs that respond to two extremes of nutrition problems, often occurring in the same communities and even households. For example, programs designed to improve dietary intake in household members at risk for nutritional deficiencies

(e.g., children younger than 2 years of age) should not cause an increase in energy intake among those members of the household at risk for overweight and obesity (e.g., school-aged children). Thus, program evaluations must be designed to detect both desirable and unexpected or undesirable outcomes.

The choice of which indicators are most appropriate for monitoring the nutritional status and dietary intake of the population depends on the country context and the specific objective of the surveillance system. For example, in countries where food shortages are common, indicators that are particularly sensitive to change, such as the prevalence and severity of malnutrition in children younger than 5 years of age, should be used. If the objective is to determine the impact of improving the nutritional status of a population in which stunting and anemia are the principal problems, then the prevalence of these should obviously be monitored.

Information on the intake and nutritional status of individuals is available from a variety of sources in developing countries. We present a description of the types of information available for children younger than 5 years of age (**Table 1**) and adults (**Table 2**) from a variety of information sources. Much of this information is obtained from large-scale multination health and nutrition surveys and from databases maintained by international organization, such as FAO and the World Health Organization (WHO). A number of countries conduct periodic nationally representative health and nutrition surveys, and information may also be available from smaller scale health and nutrition surveys and from routine growth monitoring and promotion programs. The following sections provide a brief discussion of each of these types of information in the developing country context.

Multination Health and Nutrition Surveys

During the past few decades, the Demographic and Health Surveys (DHS) have been conducted in many countries in all regions of the world. The DHS surveys are nationally representative surveys that include household and individual health and nutrition indicators. The surveys are large, typically 5000 to 30 000 households, and are conducted periodically, often at 5-year intervals. The data included in the survey vary slightly by country (**Tables 1** and **2**) but typically include as a minimum anthropometric measurements and hemoglobin concentration (prevalence of anemia) of children and women of reproductive age and breast-feeding and complementary feeding practices. One of the major strengths of the DHS surveys is that they use standard questionnaires that allow for comparisons across survey years and between countries. Information from DHS surveys is readily available on the Internet.

The WHO Global Database on Child Growth and Malnutrition provides a compilation of information from nationally representative and smaller scale surveys conducted in a number of countries. In order to be included in the database, a number of criteria must be met for data collection, analysis, and presentation. This facilitates the comparison of information that has been collected in different countries and regions. Nutrition Country Profiles are also compiled by FAO and include national-, household-, and individual-level data. The national-level data are obtained from the United Nations global data banks and are supplemented for many countries by data from local institutions and independent experts. Considering this broad range of sources, many differences in methodology of data collection, analysis, and presentation may exist and should be taken into consideration when comparing data from different countries.

National Health and Nutrition Surveys and Small-Scale Surveys

Both the WHO and FAO databases may include information obtained from nationally representative health and nutrition surveys conducted by individual countries and from small-scale health and nutrition surveys. The former has the major advantage that data may be representative of the population in the country. The latter does not usually provide representative data but has the strength that the survey may be targeted to specific high-risk groups, thus providing data for those to whom policymakers may need to target interventions.

Information on nutritional status of individuals, particularly children, may also be collected at the local community level through national growth monitoring and promotion activities conducted as part of government or nongovernmental agency development activities. Many such activities stress a high level of local involvement in data collection and can be very useful to provide feedback for decisions on resource allocation that need to be made at a local level. Data can then be aggregated to higher administrative levels and can be used for regional and national resource allocation. Although this type of surveillance may not have the same level of data quality control as the larger, more heavily supervised surveys, they have the advantage of being readily available and may promote a higher level of community involvement.

NUTS AND SEEDS

J Gray, Guildford, UK

In botanical terms, the word 'nut' is used to describe a wide range of seeds, mostly from trees, with a tough, often lignified, seed coat or shell. True nuts include the chestnut, brazil nut, and hazelnut. In practice, these are usually classified together with certain other so-called nuts, for example the almond, cashew, and peanut, and other seeds which are all used in similar ways in the diet. Nuts and seeds come from a diverse range of different plants, so their nutritional composition is quite varied, but like most plant seeds they contain a food reserve designed to meet the needs of the developing plant embryo. In many nuts and seeds this is fat, but in others it is starch or other polysaccharides.

Therefore, these foods are concentrated sources of dietary energy, as well as sources of protein, unsaturated fatty acids, various micronutrients, and fiber (nonstarch polysaccharides, NSP).

Nuts and seeds have a wide range of uses. In the typical Western omniverous diet they tend to be used either as snack items or added as minor ingredient to savory and sweet dishes, but they have wider applications in vegetarian diets as important sources of protein and other nutrients. Certain nuts and seeds are also made into spreads, for example peanut butter and tahini (sesame seed spread).

Types

The major types of nuts and seeds grown for human consumption are shown in **Table 1.**

Nuts

Almond The almond (*Prunus amygdalis* var. *dulcis*), sometimes called the sweet almond, is one of the oldest nut crops. It is believed to have originated in Southeast Asia but is now grown more widely, including in southern Europe, Africa, southern Australia, and California. It is closely related to peaches and plums, but in the almond, in contrast to these other fruits, the 'flesh' or mesocarp becomes hard and dry as it matures, and splits open to leave the thin shell or endocarp which contains the edible almond seed or 'nut.' The nuts are eaten fresh, often in the ground form in prepared dishes, as well as roasted and salted.

Another species, *Prunus amara* or the bitter almond, is inedible but is cultivated for its oil, which is also present in the sweet almond and in the kernels of apricots and peaches. This oil contains benzaldehyde, the essential oil, and hydrocyanic acid, from which the benzaldehyde is separated to be used in flavorings and perfumes.

Brazil nut The triangular-shaped Brazil nut (*Bertholletia excelsa*) grows in large forests in the Amazon river basin in South America. The nuts are actually hard-shelled seeds which are produced in groups of between 12 and 30 within a large, hard, thick-walled woody fruit or pod. The sweet-tasting nut meat is consumed in the fresh state and Brazil nut oil may be extracted for use as a lubricant.

Table 1 Major types of nuts and seeds grown for human consumption

Almond	Pecan
Brazil	Pine nuts
Cashew	Pistachio
Chestnut	Walnut
Coconut	Pumpkin seeds
Hazelnut	Sesame seeds
Macadamia	Sunflower seeds
Peanut	

Cashew nut The cashew (*Anacardium occidentale*) originated in Brazil but is now cultivated extensively in all tropical areas, notably in India and East Africa. The cashew fruit, which contains the seed or 'nut,' hangs at the end of what is referred to as the cashew 'apple'—the edible swollen fruit stem or pedicel. The fruit itself is kidney-shaped, about the size of a large bean, and has a two-layered shell. The outer layer of this shell contains a caustic oil that must be burned off before the nut is touched. The nuts are then roasted again or boiled to remove other toxic substances and the second shell is removed. The nuts may also be used as a source of oil.

Chestnut The sweet or Spanish chestnut (*Castanea sativa*) is a native tree of southern Europe, believed to have been introduced into Britain by the Romans. The fruit consists of two to four compartmentalized seeds or burrs, covered with numerous needle-sharp branched spines and containing the seeds or 'nuts,' which are covered with a tough outer coat. The flesh of the nut is hard and inedible and is cooked, often by roasting or boiling, before being eaten. The cooking process changes the texture so that the chestnut becomes much softer than other nuts and more like a vegetable, largely as a result of its high carbohydrate content (see below).

Coconut The coconut (*Cocos nucifera*) grows on the coconut palm, which is common in tropical areas throughout the world. The native origin of the palm is uncertain, as the nuts were easily dispersed between both islands and continents by ocean currents and by early explorers. The fruits are borne on the tree in clusters of about 15 to 20 and are enclosed in a thick outer husk and covered in a mass of fibers (the mesocarp and exocarp), which is normally removed when the coconut is harvested. The familiar hard shell of the coconut is the endocarp, or inner layer, of the mature ovary of the fruit, and within the shell is the actual seed, covered with a thin brown seed coat. The white coconut 'meat,' which can be eaten either fresh or desiccated, is actually part of the endosperm (storage tissue) of the seed. Coconut 'milk,' which is found in the unripe nut and is drunk or used in cooking, is the liquid form of the endosperm, which solidifies as the fruit ripens. The coconut meat may be dried

to produce copra, which is pressed to remove the coconut oil used widely as a food oil and in soap and cosmetic manufacture.

Hazelnut (cobnut; filbert) The most widely grown hazelnut (*Corylus avellana*) is a native of Europe, although about 10 different species of *Corylus* grow throughout Europe, North America, and Asia. There is evidence that these nuts were cultivated in Ancient Greece and collected by Mesolithic peoples. The shell of the hazelnut is the matured ovary wall of the flower and the edible nut meat within this is the matured embryo.

Macadamia nut The macadamia nut (*Macadamia integrifolia*), smooth-shelled; *M. tetraphylla*, rough-shelled) is native to eastern tropical Australia but was subsequently introduced to Hawaii, which is now the leading producer of these nuts, and also to parts of Africa and South America. It is the smooth-shelled variety that has been developed commercially. The edible kernel of the nut is the seed, consisting mostly of the cotyledons of the embryo. It is enclosed in a hard, thick, brown shell, which is itself encased in a fibrous husk that splits open when the husk dries. This occurs after the fruit falls, or when it is removed from the tree at maturity. After harvesting, the nuts are dried (to a moisture level of 1.5%), roasted (traditionally in coconut oil, or dry-roasted), and salted.

Peanut The peanut (*Arachis hypogaea*), sometimes referred to as the ground nut or monkey nut, originated in South America. Although referred to as a nut, it is in fact part of the legume family. The plant was introduced to Africa by early European explorers and to North America by the slave trade; it was also introduced to India and China. The name 'ground nut' derives from the fact that the flower withers after pollination to leave a stalk-like part of the plant, which pushes under the soil and carries the fertilized ovules in its tip. Underground, the tip continues to develop into the characteristic pod of the peanut, containing the seeds, or 'nuts.' The shape and size of the pod, and the number and color of the seeds, are variable, depending on the peanut cultivar. On a worldwide basis, two-thirds of the peanut crop is crushed for oil (arachis oil) and peanut products are used widely in both food processing, with peanut butter as an important product, and for animal feed. The peanut itself may be eaten fresh or roasted and salted.

Pecan The pecan (*Carya illinoinensis*) is a member of the walnut family, and the tree is classified botanically as a hickory. The tree is a native of North America, grown in the southern central states. After harvesting, the nuts are air-dried to remove 10–20% of their moisture. The nut is similar to the walnut, but with a more mild and sweet flavor. The pecan nut kernel is eaten fresh and in the US it is used widely in confectionery and baked goods.

Pine nuts Pine nuts or kernels are small edible seeds which are extracted from the cones of various species of pine. The most commonly eaten variety is that from the European stone pine (*Pinus pinea*), which is native to northern Mediterranean regions. The small, oil-rich seeds are encased in a hard shell. The seeds are sometimes referred to as pignolia nuts, whereas the seeds of the pinyon pines (*Pinus edulis* and *Pinus monophylla*), which grow in the south-western US and in northern Mexico, are known as pinon nuts.

Pistachio nut The pistachio nut is the seed of the pistachio tree (*Pistacia vera*). It is a native of central Asia, Pakistan, and India, where it was cultivated 3000 years ago, and it has also been cultivated for many years in Mediterranean regions and more recently in California. The pistachio fruit is similar to a peach; the outer 'husk' (the exocarp and mesocarp of the fruit) encloses a hard but thin off-white shell (the endocarp). This splits open just before the nut matures to reveal the edible embryo, which consists mainly of two green cotyledons covered in a thin seed coat. The green nut kernels are highly prized and are eaten roasted and salted as well as in various Middle Eastern dishes.

Walnut The walnut (*Juglans* spp.) is the common name given to about 20 species of trees in this family. The most important species is *Juglans regia*—the English or Persian walnut—which is believed to have originated in Ancient Persia, later taken to Greece, and eventually distributed throughout the Roman empire. There are records of its growth in England in the sixteenth century. It was taken to America and called the English walnut to distinguish it from the native American black walnut (*Juglans nigrans*) and the butternut (*Juglans cinerea*), both of which have much thicker, less brittle shells. The walnut fruit has an outer leathery husk and an inner furrowed stone, which is the shell of the nut, within which is the edible seed.

Seeds

Pumpkin seeds The large flat seeds of the members of the pumpkin family (*Cucurbita maxima; C. moschata*

and related species) can be dried and eaten raw, used in both sweet and savory cooked dishes, or roasted.

Sesame seeds The sesame plant (*Sesamum indicum*), which is a native of Africa, grows in tropical and subtropical regions and is now common in Asia. The seeds are small and off-white in color. They may be eaten whole or used in confectionery and baked goods and as a source of oil used in cooking. The seeds are also ground to a paste called tahini.

Sunflower seeds The sunflower (*Helianthus annus*) is a member of the Compositae or daisy family. It is believed to have originated in North America, where it was cultivated by the native Indians, and was introduced to Europe in the sixteenth century. The flat seeds may be dehusked and eaten raw or cooked, but the plant is generally cultivated for the oil they contain, which is a rich source of polyunsaturated fatty acids (see below), and is widely used for cooking and in margarine manufacture. The residual oil-cake is used for animal feed.

Macronutrient Content

Green nuts, as harvested, may contain 50% or more water, but these nuts must be cured or semidried for storage, so the moisture content of most nuts, as eaten, is low (1–6%). The exceptions are fresh coconut and chestnuts, with a moisture content of 45 and 52%, respectively. The water, macronutrient, and energy content of the nuts and seeds discussed in this article are shown in **Table 2**.

Fat

The total fat content of most nuts and seeds is high because, as the seed ripens, the fat store increases and its starch content declines. However, the amount of fat is quite variable, ranging from about 78% in the macadamia nut and 70% in the pecan to around 50–55% in nuts such as the almond, cashew, hazelnut, and pistachio, and as low as 3% in chestnuts. The fat content of the edible seeds is between 45 and 60%.

The different fatty acid fractions contained in these nuts and seeds are also quite variable, as shown in **Table 3**. The vast majority of nuts and seeds are rich in monounsaturated and polyunsaturated fatty acids. However, in some nuts, such as the peanut, hazelnut, and macadamia nut, monounsaturated fatty acids predominate, whereas in the walnut and in sunflower seeds polyunsaturated fatty acids predominate. The exception is the coconut, in which saturated fatty acids constitute the major fat fraction.

Carbohydrate

With the exception of the starch-rich chestnut (almost 37% carbohydrate), the carbohydrate content of most nuts is relatively low at around 3–7%. However, peanuts, cashews, pumpkin, and sunflower seeds contain more carbohydrate (13–19%). In most nuts and seeds this carbohydrate is a variable mixture of starch and sucrose, although in some there are small quantities of glucose and fructose as well, and in sunflower seeds there are some oligosaccharides.

[a]No data available.
Data from Holland *et al.* (1992) and The Ministry of Agriculture, Fisheries and Food.

Protein

The protein content of nuts is quite variable, but most nuts are considered to be a good source of protein. It is low (2–3%) in the chestnut and coconut, between 8 and 15% for most other nuts, but high (18–26%) in the cashew, pistachio, almond, and peanut, so that the amount of protein in many nuts is about the same as in meat, fish, or cheese. Pumpkin, sesame, and sunflower seeds are also rich in protein.

However, the proportions of indispensable amino acids in any one particular type of nut or seed, and in fact all plant foods, differ from those needed in the human diet, with one or sometimes more 'limiting amino acids.' In most nuts and seeds, with the exception of pistachio nuts and pumpkin seeds, it is lysine that is the limiting amino acid. Thus, although the total amount of protein in nuts and seeds may be high, these foods must be complemented by other sources of plant protein, such as legumes and/or animal sources of protein (meat, fish, eggs, milk, cheese), to ensure that the overall protein quality of the diet is adequate.

Micronutrient Content

The vitamin and mineral contents of the nuts and seeds discussed in this article are shown in **Tables 4** and **5**, respectively.

In general, nuts and seeds are a good source of the B vitamins, including folic acid, and of the tocopherols (vitamin E), although some, such as almonds, hazelnuts, and sunflower seeds, contain much more vitamin E than others. Nuts and seeds do not contain vitamin C, and many nuts have little or no vitamin A activity.

Nuts and seeds contain quite large amounts of many minerals. In particular, many nuts and seeds, especially sesame seeds, are good sources of calcium. They are also generally rich in potassium, magnesium and phosphorus, iron, and in trace elements such as copper, zinc, manganese, and others such as chromium. Brazil nuts are particularly rich in selenium.

Fiber Content

Compositional values for the total amount of fiber (nonstarch polysaccharides, NSP), and the different fiber fractions where available, are shown in **Table 6** for the nuts and seeds discussed in this article. It can be seen that nuts and seeds contain significant amounts of fiber, similar to the amounts found in vegetables and fruit. Although nuts and seeds do contain some soluble fiber, most of the fiber in these foods is of the insoluble type, much of which is cellulose. Of the insoluble noncellulosic polysaccharides, arabinose predominates in most nuts, although the coconut contains large quantities of mannose. Most nuts and seeds are likely to contain quite large amounts of lignin, particularly those with a tough seed coat such as sesame seeds, although actual values are not available.

Toxins and Contaminants

Phytic Acid

Phytic acid (*myo*-inositol hexaphosphoric acid) is present in all seeds, where it is believed to act as a store of phosphate and trace elements for the developing plant embryo. The phytate content of the commonly eaten nuts and seeds is variable. In general, the oil seeds, such as sesame and sunflower, and a number of the tree nuts, have higher phytate levels than the leguminous peanut, although the oils expressed from the seeds do not contain phytate. The phytate content of the coconut and chestnut is particularly low.

Because of its molecular structure, phytic acid is a highly effective chelator, which forms insoluble complexes with mineral cations. Its presence in plant foods has led to concerns that it may reduce the bioavailability of various dietary minerals and trace elements, including calcium, magnesium, iron,

Table 6 Total dietary fiber, as measured by the Englyst method, and fiber fractions in selected nuts and seeds (g per 100 g, kernels only)

		Fiber fractions			
			Noncellulosic polysaccharide		
	Total fiber	*Cellulose*	*Soluble*	*Insoluble*	*Lignin*
Almond	7.4[a]	1.9[a]	1.1[a]	4.4[a]	N[b]
Brazil	4.3	1.6	1.3	1.4	N

Data from Holland *et al.* (1992).

zinc, and copper. Although nuts are rich in iron, there is evidence that the addition of nuts to a meal can have a substantial inhibitory effect on iron absorption, presumably because of their phytate and polyphenol content. However, it appears that this can be overcome by the addition of a source of vitamin C to the meal, thereby underlining the need to mix different groups of foods within a meal, particularly when plant foods are the main source of nutrition.

The significance of dietary phytate intake to overall mineral nutriture is still uncertain. It is likely that in a mixed diet of animal and plant foods, dietary phytate may be of less significance than among people consuming diets where plant foods are the sole source of nutrition (vegans). Available data suggest that the trace element status of most adult vegetarians is adequate, but because of increased requirements for growth, vegetarian children may be more vulnerable to the reduced bioavailability of minerals and trace elements, notably zinc, which could be a consequence of the ingestion of large amounts of phytate-containing plant foods.

Intolerances/Allergies to Nuts

Intolerances to nuts, or more specifically, allergies to nut proteins, occur in a relatively small minority of people. However, there is evidence that such adverse reactions have become more common, and the severity of the reaction that occurs in these sensitive individuals means that they must be taken very seriously. Peanuts are the most commonly cited cause of these severe reactions, estimated to affect between 0.1 and 0.2% of the population, but allergic reactions to tree nuts, incuding Brazil nuts, almonds, hazelnuts, and cashews, and also to sesame seeds, have been reported.

Contaminants

Nuts and seeds may be subject to mould growth during storage if the conditions are inappropriate. Certain moulds produce secondary metabolites which are toxic to humans and animals, known as the mycotoxins. Of these mycotoxins, the aflatoxins, notably aflatoxin B1, are produced by three closely related species of mould: *Aspergillus flavus*, *A. parasiticus*, and *A. nomius*. These moulds may contaminate various food commodities in tropical and subtropical regions, including tree nuts, but one of the most important crops to be affected is the peanut. Aflatoxins are acutely toxic to the liver and may also be involved in the etiology of human liver cancer in certain parts of the world. Ochratoxins, which are produced by other *Aspergillus* species, have also been found to contaminate nuts.

Some species of mould are able to proliferate within growing crops even before they are harvested, forming an endophytic relationship with the plant. This relationship has been found to exist between *Aspergillus parasiticus* and peanuts. It appears that

when the plant is growing normally, no aflatoxin is produced by the mould, but when the plant is stressed, as occurs in drought conditions, then the mycotoxin may be produced. The concentrations of aflatoxins produced in this way are lower than would ensue from poor postharvest storage, but the economic consequences still may be considerable.

There are regulatory limits for the aflatoxin levels in foods. In the UK, the sale of nuts for direct consumption is prohibited if the aflatoxin content exceeds $4\,\mu g\,kg^{-1}$ or $10\,\mu g\,kg^{-1}$ for nuts which are to be subjected to further processing before being sold. A proportion of nuts imported into the UK, especially peanuts, are contaminated with aflatoxin. In 1994, 3% of samples examined under a European surveillance program were found to exceed the UK limit. Nonetheless, such findings should be kept in perspective: The numbers are low and their significance in public health terms, relative to other diet-related risks, is small.

Role in the Diet

Nuts and seeds can make a useful contribution to the dietary intake of macronutrients, notably protein and unsaturated fatty acids, micronutrients, dietary fiber, and energy. Although these commodities play a relatively minor role in the average Western diet, they are more important in the diets of Western vegetarians, especially vegans. Even on a worldwide basis, the nutritional contribution of nuts and seeds is relatively small: Plant foods are estimated to supply around 65% of edible protein, but only 8% of protein and 4% of total dietary energy is estimated to derive from pulses, oil crops, and nuts (Young and Pellett, 1994).

In the UK, average weekly household consumption of nuts and their products, as recorded by the National Food Survey, is about 14 g per capita, with only 11% of households purchasing these commodities; there are no separate data for nuts eaten as out of home snacks. Data from the Dietary and Nutritional Survey of British Adults indicate that average weekly intake of people consuming unsalted nuts and nut mixes is 63 g per week, but again only 12% of the adults surveyed were consuming these commodities. Therefore, even for nutrients which are present in relatively large amounts in nuts, such as vitamin E, magnesium, and copper, these foods only provide about 1% of the average daily intake in the UK.

O

OBESITY

Contents

Definition, Etiology and Assessment

A Pietrobelli, Verona University Medical School, Verona, Italy

Obesity is a situation of excess body fat accumulation, and a clinical diagnosis of obesity should be based on an accurate direct or indirect measure of total body fat. The most widely used measurement to define obesity in adults is body mass index (BMI; weight in kg/height in m^2). It is a predictor of body fat from a population perspective, but it has limitations on an individual level and is only a proxy measurement of body fat. BMI shows significant variations during childhood; thus, age- and gender-specific reference standards must be used, and in adolescents the pubertal status should also be evaluated. An expert committee convened by the International Obesity Task Force (IOTF) in 1999 determined that although BMI is not an ideal measure of adiposity, it has been validated against other measures of body fat and may therefore be used to define overweight and obesity in children and adolescents. Because it is not clear at which BMI level adverse health risk factors increase in children, the group recommended cutoffs based on age-specific values that project to the adult cutoffs of 25 kg/m^2 for overweight and 30 kg/m^2 for obesity. Using data from six different reference population (Great Britain, Brazil, The Netherlands, Hong Kong, Singapore, and the United States), Cole and colleagues derived centile curves that passed through the points of 25 and 30 kg/m^2 at age 18 years. **Table 1** is useful for epidemiological research because children and adolescents can be categorized as non-overweight, overweight, and obese using a single standard tool.

There are differences in body composition across adult ethic groups, with one study of whites and Asians showing a difference of 2 or 3 BMI units in adults with the same body composition. It has been found that African American, Mexican American, and Mohawk Indian children carry more central fat than white children. Several studies have compared the US NHANES criteria for defining overweight or obesity using age- and gender-specific 85th and 95th percentile cutoffs with those of the Centers for Disease Control and Prevention (CDC) using similar percentile cutoffs and the IOTF alternative set of cutoffs based on centiles passing through BMI 25 and 30 at age 18 years. Using the NHANES III data, the different methods (i.e., NHANES/WHO, CDC, and IOTF) give approximately similar results but with some discrepancies, especially among younger children.

Definition

Obesity is an increase in body fat. This increase in fat can be evenly distributed over the body, or it can be concentrated in specific regions. Differences in body fat distribution are gender specific. Women tend to deposit fat more on their buttocks (gynoid distribution), and men tend to deposit fat on their waist (android distribution).

Table 1 International cutoff points for body mass index (BMI) for overweight and obesity by sex between 2 and 18 years

Measures of Body Fatness

Studies of adipose tissue distribution, its causes, and its effects on morbidity and mortality are fundamental in the field of obesity. An ideal measure of body fat should be "precise with small measurement error; accessible, in terms of simplicity, cost, and easy to perform; acceptable to the subject; well documented with published reference values." There is no consensus as to which methods best define and describe adipose tissue and its distribution. Several studies have noted that the increased risk of obesity is related to mesenteric and portal depots of adipose tissue. However, subcutaneous adipose tissue, particularly around the hips and buttocks, appears not to increase health risk.

The different methods used to estimate total fat and adipose tissue are discussed next and presented in order of decreasing accuracy.

Cadaver analysis The main use of cadaver studies is to validate other methods that can be used to study patients *in vivo*.

Imaging techniques Total adipose tissue and its distribution can be quantified using imaging techniques such as computed tomography (CT) and magnetic resonance imaging (MRI). Both methods produce high-resolution cross-sectional images from signals resulting from exposure of the subject to an X-ray source (CT) or electromagnetic field (MRI). Total body fat volume, total fat mass, and percentage fat mass can be estimated. In addition to providing total adipose tissue, imaging techniques are able to separate adipose tissue into subcutaneous, visceral, and intraorgan components. An accuracy of better than 1% error for body fat measurement is possible with these techniques.

Dual-energy X-ray absorptiometry This method is based on the principle that transmitted X-rays at two energy levels are differentially attenuated by bone mass and soft tissue mass, and the soft tissue mass is subdivided into fat mass and lean mass. Reproducibility of dual-energy X-ray absorptiometry (DXA) is approximately 0.8% for bone, 1.7% for fat, and 2.0% for body weight. One concern regarding DXA is whether changes in soft tissue hydration influence body fat estimates. A few studies have shown small but systematic and predictable errors in DXA soft tissue composition analysis with body fluid balance changes. Using DXA, it is possible to obtain abdominal fat estimates. Unfortunately, these cannot be separated into subcutaneous and visceral components.

Bioimpedance analysis This method measures the resistance in the body to an imperceptible electrical current. The measurement is based on the relationship among the volume of the conductor (body), the conductor's length (height), and its electrical impedance. Bioimpedance analysis assumes fat mass is anhydrous and that conductivity reflects fat-free mass. Conceptually, a human devoid of adipose tissue could have minimum impedance, and impedance would increase to a maximum when all lean tissue is replaced by fat/adipose tissue. This approach estimates total body water, which can be transformed using appropriate formulas and in turn can estimate fat-free mass and hence fat mass.

Anthropometric measurements Anthropometric measurement can be used to estimate total body fat, regional fat, and fat distribution. Anthropometric measures of relative adiposity or fatness are BMI, skinfold thickness, waist, hip, and other girth measurements. BMI is widely used as an index of relative adiposity among children, adolescents, and adults. The World Health Organization classifies a person with a BMI of 25 kg/m^2 or higher as overweight, whereas a person with a BMI of 30 kg/m^2 or higher is classified as obese. This measurement has low observer error, low measurement error, and good reliability and validity. However, BMI may not be a sensitive measure of fatness in subjects who are short, tall, or who have highly developed muscle. There may also be racial differences in the relationship between proportion of body fat and BMI.

The amount of subcutaneous fat can be estimated by measuring thickness directly using a skinfold caliper at different sites on the body. The sites most often used are the upper arm (biceps and triceps), under the scapula (subscapular), and above the iliac crest (suprailiac). Increasing the number of measurement sites reduces errors and corrects for possible differences in fat distribution among individuals within the same age and gender group.

Anthropometric methods are also applicable as 'surrogate' measurements of visceral adipose tissue. Circumferences are more reliable than skinfolds, and in recent years the most widely used anthropometric technique has been the waist circumference. Waist circumference is measured at the minimum circumference between the iliac crest and the rib cage using an anthropometric tape. It is an indirect measure of visceral adiposity, which is strongly correlated with risk for cardiovascular disease in adults and an adverse lipid profile and hyperinsulinemia in children.

Etiology

Obesity is a multifactorial disease. The relative contributions of genetics and the environment to the etiology of obesity have been evaluated in several studies. Approximately 30–40% of the variance in BMI can be attributed to genetics and 60–70% to the environment. Clearly, the interaction between genes and the environment is fundamental. In a given population, some subjects are genetically predisposed to become obese, but the genotype may be expressed only with adverse environmental situations (i.e., high-fat, energy-dense diets and sedentary lifestyle).

Development of obesity occurs when caloric intake is higher than energy expended. Three metabolic factors have been reported to be predictive of weight gain: a low sedentary energy expenditure, a high respiratory quotient, and a low level of physical activity. Resting metabolic rate is highly correlated with fat-free mass. Sedentary lifestyle has an impact on weight gain. Several other factors are also associated with overweight. Gender, age, race, and socioeconomic status could influence weight gain, with overweight and obesity being more likely among women, older subjects, minority races, those with a low socio-economic status, and those with low levels of education.

It is well-known that obesity runs in families. In fact, high birth weight, maternal diabetes, and obesity in family members are factors that may influence the degree of adiposity. For a subject, if one parent is obese, the odds ratio is approximately 3 for obesity in adulthood, and if both parents are obese, the odds ratio increases to 10. There are critical periods of development for excessive weight gain. The duration of breastfeeding was found to be inversely associated with risk of being obese later in life, possibly mediated by physiologic factors present in human milk. Adolescence is another critical period for development of obesity. The risk of obesity persisting into adulthood is higher among obese adolescents than among younger children.

Lifestyle changes during the past several decades have affected childhood patterns of physical activity as well as diet. Leisure activity (e.g., television and computer games) is increasingly sedentary, and there is generally a decreased amount of routine physical activity. Taken together, these factors play a potential role in the development of the overweight epidemic.

Assessment for Therapy

One of the goals of assessment of overweight/obesity is to decide whom to treat. Three main issues must be evaluated: whether treatment is indicated, whether treatment is safe for the patient, and whether the patient is ready and motivated to lose weight. In addition, routine assessment of eating and activity patterns in adults as well as in children must be considered. Recognition of excessive weight gain relative to linear growth is essential throughout childhood.

Proper identification and classification of obesity through body composition assessment are important steps to initiate before beginning weight-loss treatment. Dietary management, physical activity,

surgery, pharmacotherapy, and psychological and familial support must be considered together as part of obesity assessment. Before beginning a weight-loss program, patients should be evaluated for number and severity of cardiovascular risk factors. These conditions may require that treatment be initiated along with weight-loss strategies.

Fat Distribution

J Stevens and K P Truesdale, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA

In 1956, the French physician, Jean Vague, noted that an upper body, or masculine, fat distribution was associated with adverse health consequences. It has now been clearly demonstrated that obesity-related chronic diseases are associated with the location, as well as the amount, of adipose tissue on the body. Although the relative importance of total adiposity versus type of adiposity continues to be debated, the notion that an 'apple-shaped' (or android) body is associated with greater obesity-related health risks than a 'pear-shaped' (or gynoid) body is well accepted (**Figure 1**). Imaging techniques such as computed tomography (CT) allow measurement of visceral adipose tissue and layers of subcutaneous fat. Anthropometric studies do not provide precise measures of fat depots but nevertheless have provided clues to the causes and consequences of differences in fat distribution. Guidelines are being developed for the use of anthropometric assessments of fat distribution in clinical and public health settings.

Measurement of Fat Distribution

Fat patterning, the distribution of fat, is measured using either imaging or anthropometric

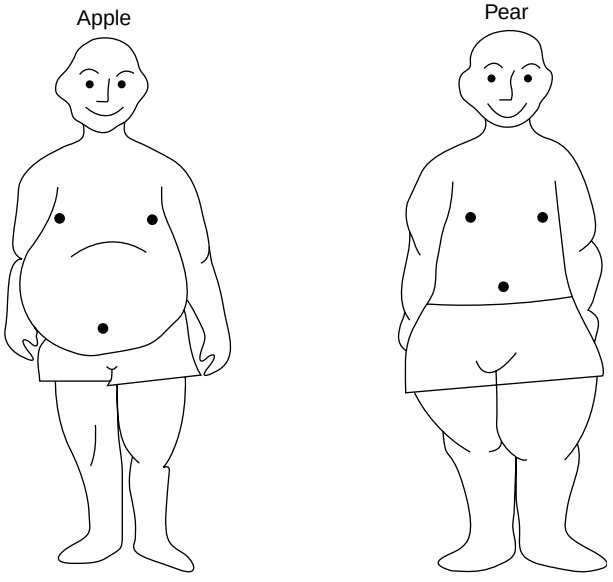

Figure 1 The apple (android) and pear (gynoid) body shapes.

techniques. Measurement has focused on assessment and differentiation of subcutaneous and intraabdominal (visceral) depots; however, recently measurement of fat residing in muscle has become of interest. Imaging techniques have the advantage of providing separate measurements of fat in these three different depots, but they remain too expensive for use in most clinical and community settings. Anthropometric measurements cannot provide a direct assessment of the amount of fat in different depots, but they can provide variables that correlate with assessments from imagining techniques and are quick, inexpensive, and noninvasive.

Imaging Techniques

Computed tomography and magnetic resonance imaging (MRI) are considered the most precise methods for measuring body fat distribution. MRI has the advantage of not exposing subjects to radiation. Dual energy X-ray is primarily used to measure bone mineral content and total body fat. This technique can measure total abdominal fat, but it cannot differentiate between visceral and subcutaneous fat.

Figure 2 shows two different cross-sectional images of the abdomen obtained by MRI. These images are constructed from 256×256 pixels, which vary from white to black with different shades of gray. Each pixel represents $2.4\,mm^2$. The fat regions are depicted as the lighter portions of the images. The subcutaneous fat area delineates the perimeter of the abdomen, whereas the visceral area is contained within the subcutaneous area. **Figure 2A** represents a cross section of an abdomen with a relatively small subcutaneous fat area in comparison with an enlarged visceral fat area. **Figure 2B** shows a subject with a small visceral fat-to-subcutaneous fat depot ratio.

CT scans have shown that approximately 12% of fat in normal weight subjects is among and inside muscles. Some researchers advocate considering this fat in a separate compartment, which, from a metabolic standpoint, is more closely related to visceral fat. Some researchers have suggested that subcutaneous fat be separated into deep and superficial layers separated by the 'fascia superficialis.'

Anthropometric Techniques

Anthropometric indices used to measure fat patterning include skinfold thicknesses, circumferences, sagittal diameter, and ratios such as waist-to-hip, waist-to-thigh, waist-to-height, and subscapular-to-triceps skinfolds. Skinfold thicknesses and skinfold ratios have not been found to be very well correlated with metabolic measurements or with visceral fat and are not recommended for use as indicators of fat patterning. Numerous equations using combinations of anthropometric measurements to predict the amount of visceral fat have not offered substantial improvement over the simpler measurements, and an accurate equation has yet to be developed.

Waist circumference (WC) alone and waist-to-hip ratio (WHR) are the most popular anthropometric methods used to measure fat distribution in both clinical and community settings. Both measures are correlated with visceral fat, with a correlation coefficient (r) generally ranging from 0.5 to 0.8. It is problematic that there is no uniform method of defining the location at which the waist and hip measurement should be assessed (**Table 1**). Waist

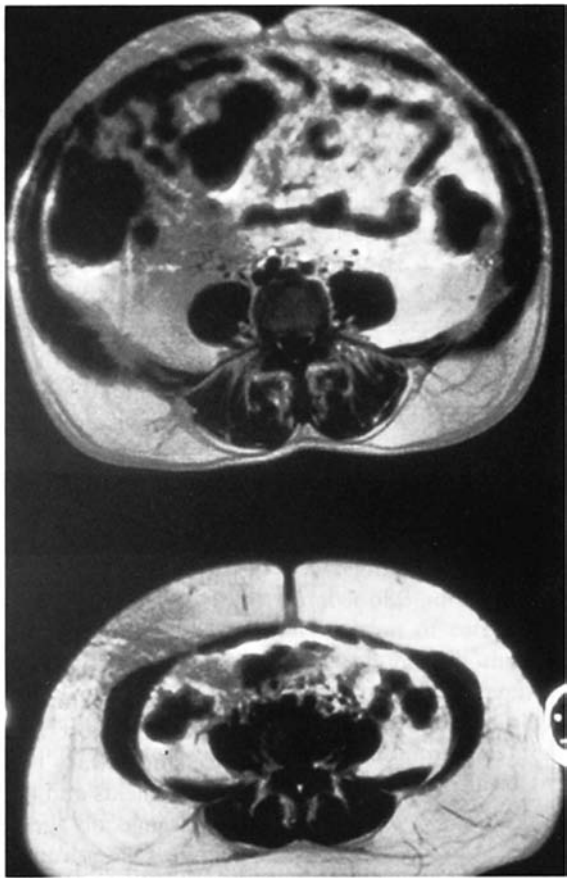

Figure 2 Cross-sectional images of the abdomen obtained by MRI. (A) Small subcutaneous fat area and enlarged visceral fat area. (B) Small visceral fat area in comparison with subcutaneous fat depot.

Table 1 Anatomical locations used to measure waist and hip circumferences

Waist circumference
One-third between the xyphoid process and umbilicus
Narrowest part of torso
Midway between xyphoid process and umbilicus
Midway between lower rib and iliac crest
One inch (~2.5 cm) above umbilicus
Level of umbilicus
Level of iliac crest
Immediately below the lowest rib
Immediately above the iliac crest
Hip circumference
Largest horizontal circumference around the buttocks
Level of iliac crest
Maximal circumference between superior border of iliac crest and thigh region 4 cm below superior iliac crest

circumferences measured at four sites (immediately below the lowest rib, at the narrowest point, midpoint between the lowest rib and the iliac crest, and immediately above the iliac crest) have been compared and found to differ from each other. Other work has shown that the highest correlations with risk factors were obtained when WHR was calculated as the waist measured at the point midway between the lower rib margin and iliac crest (approximately 1 inch (~2.5 cm) above the umbilicus) or when the waist was measured at the umbilicus and hips measured at the widest point of the buttocks. Although two different waist measurements have been demonstrated to perform equally well, the bony landmark measurement (the point midway between the lower rib margin and iliac crest) may be preferred since the umbilicus may shift position when an individual gains or loses weight. The World Health Organization (WHO) has recommended measuring the waist at the midpoint between the lowest rib and the iliac crest, whereas immediately above the iliac crest is the site recommended by the National Institutes of Health (NIH).

Sagittal diameter, the height of the abdomen measured with the subject in the supine position, can be measured anthropometrically or by imaging. **Figure 3** shows a technique for the anthropometric measurement of sagittal diameter using a caliper. Measurement is usually taken at the largest supine anteroposterior diameter between the xyphoid process and umbilicus. Some studies have found sagittal diameter to be a better indicator of visceral fat than WHR. Correlations between sagittal diameter and amount of visceral fat range from $r = 0.51$ to $r = 0.87$, with higher correlations occurring when sagittal diameter is measured using imaging techniques. In general, correlations tend to be higher in men than women.

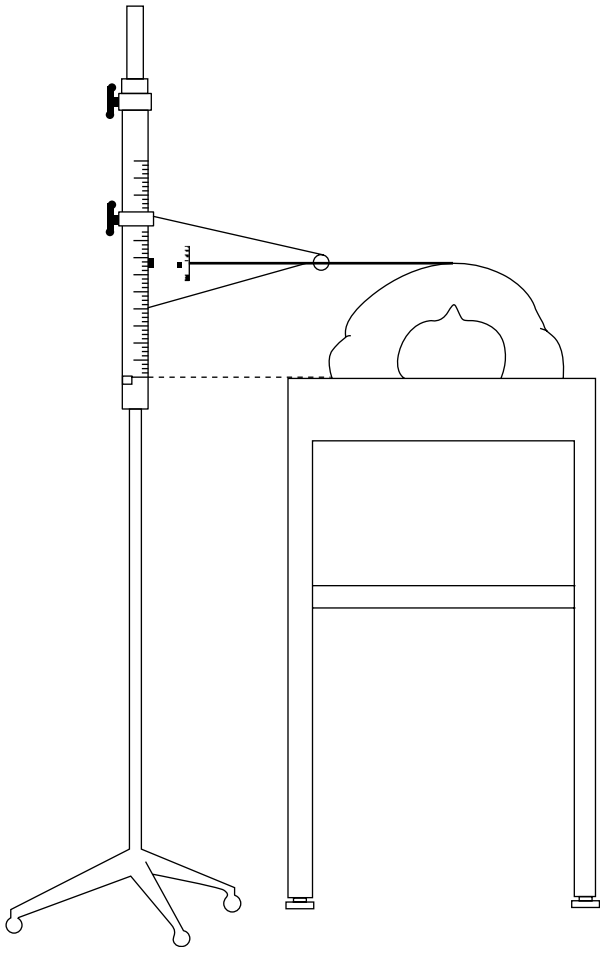

Figure 3 Sagittal diameter measured anthropometrically using calipers.

Metabolic Characteristics of Visceral and Subcutaneous Fat

The main function of adipose tissue is to store and break down fat based on energy excess or need, respectively. The uptake of fat is regulated by the enzyme lipoprotein lipase (LPL). This enzyme hydrolyzes triacylglycerols into free fatty acids, which can then be transported into the adipocyte and reesterified for storage. Greater LPL activity is associated with greater accumulation of fat. In premenopausal women, its activity is higher in the gluteal–femoral adipose areas than in the abdominal areas. The opposite is true in men, in whom LPL activity is the same or higher in the abdominal adipose areas than in the gluteal–femoral regions.

The breakdown of fat (lipolysis) is regulated by the enzyme hormone-sensitive lipase (HSL). This

enzyme releases free fatty acids, which are then released into the bloodstream and taken up by tissues, with the exception of the brain and red blood cells, for energy use or storage. The rate of basal lipolysis is higher in gluteal–femoral fat tissue than in abdominal tissue in both men and women. This may be due to greater cell size in that region. In the abdominal area, basal lipolysis is higher in subcutaneous fat than in visceral fat. However, when stimulated hormonally, rates of lipolysis may differ between men and women. Lipolytic rates have been shown to be higher in the visceral compared to the subcutaneous region in men, whereas the opposite trend is seen in women.

Regulators of Lipolysis and Fat Storage

The processes of lipolysis and fat storage are regulated by hormonal factors, which either enhance or suppress the activities of HSL and LPL. Through the action of glucocorticoid receptors, glucocorticoids enhance LPL activity and promote abdominal deposition of fat. The density of glucocorticoid receptors is greater in the visceral abdominal depot than in the subcutaneous abdominal depot. Therefore, an increase in glucocorticoid secretion is associated with increases in abdominal fat deposition compared to other fat depots.

Insulin favors fat storage by increasing LPL and decreasing HSL activity. Insulin has stronger antilypolytic effects in adipose located in the abdominal region compared to the femoral regions in both men and women. Paradoxically, insulin binding is stronger in the gluteal–femoral region than the abdominal region. Therefore, it has been hypothesized that insulin regulates lipolysis at the postreceptor level.

Catecholamines regulate lipolysis through α_2- and β-adrenoreceptors. The β-adrenoreceptors increase lipolysis, whereas the α_2-adrenoreceptor inhibits it. Although both the α_2- and the β-adrenoreceptors coexist in adipose tissue, they are regionally specific such that there may be an excess of one type of receptor relative to the other in various adipose regions. The lipolytic effect of catecholamines is 10–20 times greater in the abdominal region than in the gluteal–femoral region, as marked by a twofold increase in the number of β-adrenoreceptors in both sexes. The lipolytic action of catecholamines is more pronounced intraabdominally than in the abdominal subcutaneous tissue. Sex differences are displayed with the α-adrenoreceptor. Although the number of receptors is similar in both sexes, the sensitivity of the receptors is reduced by a factor of 10–15 in the abdominal compared with the gluteal–femoral region.

Sex hormones, such as estrogen, testosterone, and progesterone, also affect the balance of fat accumulation/mobilization, although their effects vary in men and women and the mechanisms are not clearly understood. Studies show that estrogen decreases LPL expression and activity in adipose tissue. It has been shown that testosterone stimulates lipolysis by increasing the number of β-adrenoreceptors. Estrogen and progesterone, on the other hand, stimulate fat storage and inhibit lipolysis, preferentially in the gluteal–femoral area compared to the abdominal area.

An increased androgenic profile is associated with upper body fat accumulation in women, but studies on men are conflicting. Significant inverse associations between fat distribution and testosterone have been found in population studies on men. Reduced visceral fat has also been observed when testosterone treatment was administered to men. These findings challenge the hypothesis that an androgenic hormone profile contributes to a more 'male type' of fat pattern and the associated metabolic sequelae.

The controversy over the effect of sex hormones on fat distribution is complicated by the metabolism of sex hormones. Sex hormone-binding globulin (SHBG) binds circulating testosterone and estrogen. Decreased SHBG concentration may be associated with an android shape. Therefore, studies need to distinguish between total circulating and unbound sex hormones and SHBG.

Sequelae of Altered Metabolism in Visceral Fat

Intraabdominal adipose tissue has metabolic characteristics that are different from those of adipose tissue from other sites. These differences seem to be most pronounced in the regions that are drained by the portal circulation. These 'portal adipose tissues' have a sensitive system for the mobilization of free fatty acids due to a preponderance of β-adrenergic receptors and little α-adrenergic inhibition.

The hypothesis has been advanced that the heightened responsiveness of intraabdominal fat to lipolytic agents results in increased lipolysis with venous drainage of the released free fatty acids directly to the liver. These fatty acids may contribute to increases in triacylglycerol synthesis and hyperinsulinemia secondary to decrements in insulin degradation. Hyperinsulinemia could produce insulin resistance and eventually type 2 diabetes in susceptible individuals. However, the hypothesis that increased release of free fatty acids from intraabdominal adipose tissue leads to insulin resistance through effects on the liver lacks supporting evidence *in vivo*.

The proposed mechanism of action of fat patterning on metabolic syndrome is linked to

hyperinsulinemia. Hyperinsulinemia may lead to increased blood pressure through increased sympathetic stimulation of the vessels, heart, and kidneys. In addition, insulin resistance combined with a relative increase in androgenic activity may lead to an unfavorable lipid profile. In addition to the effects of free fatty acids on insulin and glucose, an increased visceral depot decreases the activity of LPL. This causes an increase in very low-density lipoprotein (VLDL) secretion and a decrease in its catabolism. The production of high-density lipoprotein (HDL) therefore decreases, the transfer of lipids (i.e., VLDL to LDL and HDL) increases, and an enrichment of triacylglycerols results.

In obesity and type 2 diabetes, there is an increased content of lipids within and around muscle fibers. Researchers have suggested that the accumulation of triaclyglycerols within the skeletal muscle may play an important role in insulin resistance. In obese individuals with elevated amounts of visceral adipose tissue, there is a strong correlation between visceral adipose tissue and insulin resistance independent of subcutaneous (abdominal and nonabdominal) adipose tissue and cardiovascular fitness. It has been suggested that the discrepancies in the literature regarding the independent effect of visceral or subcutaneous adipose tissue on insulin resistance are due to the large variations of abdominal obesity within the study populations.

Leptin is a hormone that is produced in the adipose cells and can act on the hunger center in the hypothalamus to reduce hunger and appetite and thereby lower food intake. Plasma leptin levels are correlated with body fat. Researchers have discovered a leptin receptor gene that is responsible for obesity due to the mutation or absence of the gene. This condition is extremely rare in humans. In general, in obese humans the leptin levels are elevated (hyperleptinemia).

There is a progressive increase in plasma levels during puberty in girls due to the increase in body fat during this period and in response to the effect of estrogens. Circulating leptin levels tend to decrease in response to testosterone in boys, thus resulting in higher plasma leptin levels in women compared to men. Leptin levels are also affected by insulin and glucocorticoids.

Correlates and Possible Determinants of Fat Distribution

A large number of studies have examined correlations between fat distribution and genetic, behavioral, and physiological variables. Many factors, including heredity, overall fatness, gender, age, smoking, alcohol consumption, physical activity, and ethnicity, are associated with either an android or a gynoid shape. The underlying reasons for the observed associations between these variables and fat patterning remain to be elucidated. Correlates of fat distribution are important to understand since they may confound relationships between fat patterning and physiological outcomes or morbidity or mortality outcomes. There is evidence that body shape and amount of visceral fat are partially determined by genetics. After eliminating effects of age and overall fatness, studies have shown that heritable factors can account for as much as 20–50% of the variability in waist-to-hip ratio.

Fat distribution becomes more central or android as overall fatness increases. The correlation between overall fatness and fat patterning indices ranges from $r = 0.5$ to 0.9, depending on which measure of fat patterning is used. The more obese an individual, the more difficult it is to measure the waist and hip circumferences and the higher the measurement error.

Fat distribution has long been known to vary by gender, with men more android (apple shaped) than women, who are more gynoid (pear shaped). Men have a higher WHR and significantly more intra-abdominal adipose tissue than women. During weight gain in normal weight men, fat is preferentially deposited abdominally in the subcutaneous and visceral regions—proportionately more in the upper compared to the lower abdomen. In men, little fat is deposited in the gluteal–femoral regions until they become obese. Women have a higher percentage of body fat and higher proportion of fat in the gluteal–femoral regions than men. The gender differences are sufficiently large that recommended cutpoints for indices of fat distribution must be gender specific.

Aging is accompanied by changes in both weight and fat distribution. The largest increase in body weight occurs between young adulthood and middle adulthood. Independent of weight gain, abdominal fat increases with aging. This increase tends to be most pronounced between young adulthood and middle age in men and between middle age and old age in women (related to menopausal status).

Although cigarette smokers tend to be leaner than nonsmokers, they have more central adiposity (as indicated by larger waist circumference and WHRs) compared to nonsmokers, after the effects of age and body mass index (BMI) are eliminated. Furthermore, WHR increases progressively with an increase in the number of cigarettes smoked daily. The WHR increases with increasing 24-h cotinine excretion, indicating that central fat accumulation is dependent on the dose of smoke inhaled. Some studies have found a more androgenic hormone profile

in cigarette smokers, although this finding has been inconsistent. Increased cortisol secretion, an endocrine response to stressors associated with upper body fat deposition, may explain some of the association between smoking, alcohol consumption, and fat distribution.

Although alcohol consumption has been postulated to be correlated with fat distribution, studies have been inconclusive. There is evidence that beer and spirits are associated with higher levels of WHR, whereas wine is not. Not only frequency but also intensity of alcohol consumption may be important. One study showed that frequency of alcohol consumption was inversely associated, but intensity was positively associated, with abdominal adiposity (measured by sagittal diameter), even after the effects of age, education, physical activity, smoking, and grams of alcohol had been controlled. After combining the effects of frequency and intensity, the high frequency (daily) but low intensity (<1 drink/day) group had the lowest sagittal diameter, whereas the low frequency (<weekly) but high intensity (>3 drinks/day) group had the largest sagittal diameter.

Physical activity is inversely correlated with fat distribution in both men and women. Negative associations exist between WHR and various sports and exercise indices after controlling for the effects of BMI, smoking, and education. There is evidence that activity may be associated with a preferential mobilization of abdominal fat. Endurance training has been shown to increase aerobic fitness and decrease body mass and fat mass. Resistance training results in an increase in fat-free mass and muscle strength.

Fat distribution varies by ethnicity. African Americans have less visceral fat than whites at the same BMI, whereas Asians have a larger percentage of visceral fat. At the same BMI, African Americans have greater bone density and muscle mass than whites. Asians have smaller body frames, less muscle mass, and a larger percentage of fat mass at the same BMI as African Americans and whites. A study comparing migrant and British-born South Asian women to a general population of women in Scotland found that after controlling for the effect of age, migrant South Asians had larger waist circumference and WHR. However, after also controlling for physical activity, cigarette smoking, alcohol consumption, and parity, only WHR remained different between the two groups.

Fat Distribution and Disease Risk

Numerous studies have examined associations between fat patterning and mortality and morbidity. Since fat distribution is correlated with age as well other risk factors for disease, such as smoking, alcohol consumption, physical activity, and menopause in women, it is important to control for the effects of these variables in order to obtain an estimate of the independent effect of central obesity on morbidity. The impact of some of these correlates of fat distribution may be subtle and unlikely to seriously distort relationships between fat patterning and disease. However, age, the ultimate risk factor for disease and death, is sufficiently highly correlated with fat distribution to result in substantial distortion. Similarly, cigarette smoking is related adequately strongly to fat patterning and to various diseases and outcomes to make analyses that do not adjust for smoking difficult to interpret.

The large correlation between fat patterning and overall adiposity also influences the interpretation of results, making it difficult to differentiate between the two effects. Some researchers compare the size of the correlation between fat distribution (usually measured as WHR) and total adiposity (usually measured as BMI) in an attempt to show the relative importance of each. Others examine effects within tertiles (or other categories) of BMI and WHR simultaneously or test for an independent effect of WHR or BMI in multiple regression models that include both variables. In the latter type of analysis, the associations of both WHR and BMI with an outcome can be greatly reduced or even disappear because of collinearity between the two measures.

Researchers have found positive correlations between fasting glucose, insulin, blood pressure, total cholesterol, LDL cholesterol, and triaclyglycerols using imaging techniques, sagittal diameter, waist circumference, and WHR in most, but not all, studies. Visceral fat and HDL cholesterol are inversely associated. The strength of the associations varies but tends to be largest for triaclyglycerols. Associations are reduced after controlling for BMI and age.

There is strong evidence to link waist circumference and WHR with the risk of developing type 2 diabetes, even after eliminating the effects of age, smoking, BMI, and other important correlates. An individual who is obese (>150% ideal body weight) and has an elevated WHR (>0.8) may have as much as a 10-fold increased risk for developing type 2 diabetes compared with an individual who is of normal weight (<120% ideal body weight) and has a low WHR (<0.72).

Elevated WHR has been positively associated with cardiovascular disease in some population studies, although not as consistently as diabetes. Scientists have recognized that several of the cardiovascular

disease risk factors, including abdominal obesity, cluster in individuals. This cluster of risk factors is referred to as metabolic syndrome. The other risk factors in metabolic syndrome are insulin resistance/glucose intolerance, dyslipidemia (high triaclyglycerols and low HDL cholesterol), and high blood pressure.

Applications

Waist circumference can be used to assess obesity-related health risks in public health and clinical settings. Because it consists of only one measurement instead of two, it introduces less measurement error than WHR. A large waist has been shown to reflect both generalized obesity and centralized body fat distribution, which suggests that waist circumference could replace both BMI and WHR as a simple indicator of the need for weight management. Also, waist circumference tends to be more highly correlated with visceral fat than WHR.

It has been shown that hip circumference alone is inversely associated with cardiovascular disease risk after controlling for age, BMI, smoking, and waist circumference. Therefore, some predictive information may be lost if hip circumference is not assessed. If an index of body shape, independent of total body fatness, is desired the WHR may be preferred over waist alone because it is less highly correlated with total adiposity. Waist-to-hip ratio is a widely accepted form of fat patterning assessment. It is a good predictor of disease and metabolic disorders, with an increasing WHR indicating increased risk. Cutpoints used to define elevated WHR range from 0.90–1.00 in men to 0.80–0.90 in women.

Guidelines for the use of waist circumference in combination with BMI have been issued by NIH and WHO. NIH guidelines use BMI cutoffs for an initial assessment of overweight and obesity and recommend waist circumference cutoffs as a supplementary indicator of health risk. Increased relative risk for the development of obesity-associated risk factors in most adults is predicted for adults within the BMI range of 25–35 when the waist is $\geq$102 cm (40 in.) in men and $\geq$88 cm (35 in.) in women.

Conclusions

The relationship of body fat distribution to metabolic abnormalities and disease has now been well recognized. Individuals with a more android than gynoid body shape tend to have a more adverse metabolic profile and an increased risk for type 2 diabetes and cardiovascular disease.

Although much has been learned about fat distribution, there are several issues that need further exploration. The question of whether body type can be changed through behavior needs to be more fully addressed. Standardized anthropometric measurements need to be established, and the implications of differences in fat distribution among ethnic groups need to be elucidated. A better understanding of the risks associated with fat residing in muscle is needed, and this information must be integrated with what is known about visceral and subcutaneous fat. Finally, more research is needed to identify mechanisms of action. An increased abdominal depot may not necessarily be the cause of metabolic disturbances but an effect of underlying genetic and endocrine abnormalities.

Childhood Obesity

E M E Poskitt, London School of Hygiene and Tropical Medicine, London, UK

This article discusses obesity in children and adolescents with regard to prevalence, epidemiology, clinical features, and management/prevention. Obesity not associated with a recognized underlying clinical condition is the focus of this article since this represents far the majority of children with obesity. However, obesity associated with congenital or acquired medical conditions is discussed briefly. Management and prevention are also discussed.

Obesity is increasing in prevalence among children in virtually all developed countries. In the United Kingdom, 8.5% (twice the rate of 10 years ago) of 6-year-old and 15% (three times the rate of 10 years ago) of 15-year-old children are obese. Childhood obesity is also increasing in prevalence among the affluent in less well-developed countries. Since it has been estimated that in Western countries one-third of obese adults were obese in childhood, and since both adult and adolescent obesity carry significant risk of health complications, obesity in childhood is currently seen as a concern for families, communities, and nations.

Body Composition in Childhood and Definition of Childhood Obesity

Obesity is an excess of body fat. However, the percentage of body weight that is fat varies normally throughout childhood (**Table 1**). The infant is born with modest amounts of fat. More than 50% of the energy in breast milk comes from fat, and young infants lay down fat very rapidly so that in the 4 or 5 months that it takes a normal infant to double birth weight, the weight of fat in the body has tripled. By 6 months of age, infants are increasing weight-bearing activity and fat deposition slows relative to lean tissue growth. From 1 year onward, there is a natural process of slimming with less fat than lean tissue deposited so that the child of 5 years often has a lower percentage body weight as fat than at any other time in life. This is followed by the 'adiposity rebound,' when fat deposition accelerates only to slow again with the onset of the pubertal growth spurt in males. In pubertal girls, very brief slimming early in the female growth spurt is followed by vigorous fat deposition particularly around the breasts and hips.

Assessment of Overweight and Obesity in Childhood

Precise methods of estimating body fat are complicated and expensive. There are no accepted age-related 'norms' for percentage body weight as fat in childhood. For these reasons, anthropometric indices involving weight and height are widely used to estimate relative fatness. Such methods are relatively simple, noninvasive, well tolerated, and can be used in clinical practice and large population studies. However, they provide only indirect measures of fatness.

Weight can be related to height and age in various ways. Until recently, there was no consensus

Table 1 Percentage of body weight as fat at different ages in childhood

Age (years)	*% body weight as fat*	
Birth	11[a]	
0.3	25[a]	
1.0	24[a]	
	Males	*Females*
5	12.5[b]	15.3[b]
10	17.6[b]	16.0[b]
15	11.4[b]	23.3[b]

[b]Widdowson EM (1974) *Changes in body proportions and compositions during growth.* In Davis JA, Dobbing J. *Scientific Foundations of Paediatrics.* London: Wm Heinemann. pp. 152–63.

definition of overweight/obesity from weights in relation to height and age. In adults, body mass index (BMI; weight in kg/(height in m)^2) is used as a proxy for fatness. A BMI >25 kg/m^2 (overweight) is associated with a significant increase in the risk of mortality and with an increased prevalence of complications of obesity. In childhood, BMI varies with age in a nonlinear fashion. Since at different ages children tend to retain their growth positions in relation to those of their peers, the International Obesity Task Force has defined childhood overweight and obesity as those points on the BMI centile, or standard deviation, for age distribution charts that, if followed to the age 18, would meet the adult cutoff points for overweight and obesity (BMI, 25 and 30 kg/m^2). This definition involves no direct assessment of body fat or lean body mass for age. It needs evaluating against other evidence of excessive body fat and the prevalence of complications of obesity, particularly since it presumes a constant prevalence of obesity in childhood at every age, which clinically seems unlikely. Nevertheless, the method does allow the opportunity to compare relative fatness between different studies and to demonstrate changes in population distribution of BMI for age over time.

Waist circumference is widely used in adult assessment of obesity because high waist circumference is associated with increased abdominal fat and increased risk for the morbid complications of obesity in adult life. Consensus regarding cutoff points for normal waist circumference measurements in childhood has not been reached, but high (compared with age-related populations) waist circumferences do seem to predispose to developing obesity comorbidities.

Risk Factors for Childhood Obesity

There is no clear evidence that obese individuals eat more or exercise less than their nonobese peers. Methods of measuring energy intakes and outputs are not precise when used over time and in community settings. The range of normal requirements and normal basal metabolic rates is large and obscures the energy imbalances of individuals. However, for the individual, obesity occurs when energy intake (food) exceeds the energy expenditure (basal metabolism, physical activity, growth, counteracting infection, maintaining body temperature, and thermodynamic action of food).

Familial Obesity

Most studies from developed countries show that approximately 80% of obese children have at least one parent, and 40% have both parents, overweight or obese. Twin and adoption studies indicate that genetic factors play a role in this family predisposition to obesity, although lifestyles almost certainly also influence familial similarities in habitus. In most cases of familial obesity, there is no recognised genetic explanation or apparent Mendelian inheritance, suggesting a genetic susceptibility expressed in an obesogenic environment.

Socioeconomic and Environmental Deprivation

Although it is the affluent who tend to become obese in countries undergoing industrialization, it is children from socioeconomically deprived environments in Europe and from families in which child care and nurture are poor irrespective of income who show the greatest predisposition to obesity.

Early Feeding

There is no consistent evidence that breast feeding protects children from later obesity. Any associations between breast feeding and a low prevalence of obesity may simply indicate that both obesity and a low prevalence of breast feeding are common in socioeconomically deprived communities. Furthermore, breast feeding is not a passive process but one that involves maternal emotions and close mother–child contact. The process of feeding and recognizing readiness to feed may teach a mother subtle subconscious understanding of her child's needs. Thus, the process of breast feeding may have positive influences on mothers' attitudes to child nurture—attitudes that are less readily acquired through formula feeding. Likewise, studies of early weaning, although occasionally showing evidence of an association with later obesity, are certainly not consistent in finding relationships between weaning practices and later overweight. Early feeding studies can never be double-blind controlled, and differences may only reflect common aspects of nurture rather than specific effects of a particular infant feeding procedure.

Diet and Dietary Change

Studies from several countries suggest that the childhood obesity epidemic has developed despite secular trends toward lower energy intakes by children. These estimates may have failed to account for recent increases in food eaten outside the home in the United Kingdom and other countries. The eating habits of most families in industrialized countries have changed during the past 30 years in ways that seem likely to make it easy for individuals to overeat. Foods are readily available and children have money to buy them. Much advertizing of snack foods is aimed at children. Manufactured foods

have varied forms and packaging. Small differences in flavor or appearance may reduce the satiety effect usually associated with eating large amounts of the same food. Most snacks aimed at children and the well-advertised prepared-before-sale meals are energy dense and high in saturated fats, refined carbohydrates, and sugar. In addition, the portion sizes in restaurants and of confectionery items have increased. It is too easy to eat without being aware of energy intake.

Physical Activity

Trends to lower energy expenditure, as well as dietary change, must have significance for the development of obesity. Opportunities for vigorous physical activity in sport have declined in many schools and communities, but the increase in long periods of almost complete inactivity (such as when watching television) may be having greater effects on children's nutritional status than the loss of relatively brief periods of intense activity. Studies in the United States and Mexico indicate that in adolescent boys obesity increases in proportion to the hours spent watching television.

Characteristics of Obese Children

Children without Recognizable Pathology

Obese prepubertal children are relatively tall for age (many in the upper quartile and most in the upper half of the population distribution for height). Advanced growth may be associated with advanced maturity of bones (advanced bone age), early onset of puberty, and cessation of growth with only average stature in adult life. However, some children remain tall and obese into adult life, and others slim dramatically with the adolescent growth spurt. It is not clear whether obesity drives accelerated maturation or whether obesity is one manifestation of a predisposition to exuberant growth of both lean and fat tissue also expressed by early puberty.

Obesity Associated with Recognized Medical Condition

There are conditions in which obesity is part of a recognized genetic defect, clinical syndrome, or acquired pathological condition (**Table 2**). Together, these conditions account for only a very small

Table 2 Specific conditions associated with obesity in childhood

Conditions	*Inheritance*	*Clinical example*
Congenital conditions		
Congenital obesity	Single gene defect affecting leptin metabolism	Congenital leptin deficiency Leptin receptor defect Prohormone convertase-1 defect Melanocortin-4 receptor defect Peroxisome proliferators activated receptor POMC deficiency
Inherited syndromes associated with childhood obesity	Autosomal dominant Autosomal recessive	Biemond's syndrome Alstrom's syndrome Bardet–Biedl syndrome Biemond's syndrome (some) Carpenter's syndrome Cohen's syndrome
	X-linked recessive	Borjeson–Forssman–Lehmann syndrome
Inherited syndromes affecting mobility	X-linked recessive Polygenic inheritance	Duchenne muscular dystrophy Spina bifida
Inherited disorders of growth	Autosomal dominant	Achondroplasia
Chromosomal abnormalities	Deletion or uniparental disomy for q11–q13 fragment of chromosome 15	Prader–Willi–Labhart syndrome
	Trisomy 21	Down's syndrome
	Abnormalities of sex chromosomes	Klinefelter's syndrome Turner's syndrome
Acquired conditions		
	Hormonal abnormalities	Hypothyroidism Growth, hormone deficiency Cushing's syndrome Polycystic ovarian syndrome
	Hypothalamic damage	Hydrocephalus Meningoencephalitis
	Drug treatment	Steroid treatment Sodium valproate

proportion of obese children. With the exception of very rare single gene defects in leptin metabolism, obesity is a secondary feature in these conditions and presentation is usually for some other aspect of the condition. Single gene defects affecting leptin are associated with progressive gross obesity from early life and may respond with dramatic fat loss with leptin treatment. Where obesity is only a part of a spectrum of abnormalities, common associated features are short stature, developmental delay, and craniofacial and other bony abnormalities.

Chromosomal abnormalities are more frequent causes of a predisposition to obesity. Prader–Willi syndrome, due to deletion or uniparental disomy of part of the long arm of chromosome 15, is associated with characteristic facies, small hands and feet with tapering fingers, hypogonadism, early hypotonia, difficulty feeding, and initially failure to thrive. From the second year of life many of these children show voracious appetite, progressive obesity, and negative behavior (stealing food and refusing to follow a diet). Many also commonly have psychodevelopmental problems with moderate mental retardation that exacerbates the difficulties maintaining normal weight for height and age. Gross obesity commonly leads to early death associated with hypoventilation (Pickwickian syndrome) and/or complications of type 2 diabetes mellitus.

Down's syndrome children are also prone to develop obesity in late childhood and adolescence. This is generally unrelated to recognized pathophysiological explanations for the obesity, although the syndrome is associated with an increased incidence of autoimmune thyroiditis and hypothyroidism (which exacerbates obesity).

Obesity may be an associated feature of other pathology in childhood. Endocrine problems, such as hypothyroidism and Cushing's syndrome, lead to obesity, but linear growth retardation does also, which often draws attention to the problem before obesity is severe. Hypothalamic damage (e.g., hydrocephalus and meningoencephalitis) and problems leading to immobility (e.g., spina bifida and Duchenne's muscular dystrophy) may also predispose to obesity. Nonpathological childhood obesity is usually associated with normal intelligence, relatively tall stature before puberty, and no overt abnormalities, so brief assessment of growth, general health, and intelligence usually distinguishes obese children for whom investigation for possible underlying pathology is required.

Complications of Childhood Obesity

Childhood obesity used to be considered relatively free of serious medical complications compared to adult obesity, although psychological consequences were recognised as common. Today, many obese children and adolescents show evidence of significant pathophysiological changes. Thus, the increasingly gross obesity of children and adolescents in North America, western Europe, and some other affluent societies has become a matter of major public health concern.

Cosmetic Problems

Orthopedic problems Flat feet and knock knee, perhaps related to the excess weight and need to internally rotate the knees to accommodate fat thighs when bringing the legs together, are common and can lead to ungainly gait. Slipped upper femoral epiphysis is a more serious problem, which is particularly common in overweight young adolescents and may also be associated with hormonal abnormalities such as hypothyroidism.

Skin problems Intertrigo, seborrheic eczema, and thrush are common in the thick heavy skinfolds of severely obese children. Pink or pale cutaneous striae, distinct from the purplish striae resulting from thinning of subcutaneous tissues in Cushing's syndrome, are common on the abdomen and upper limbs and may be a source of embarrassment. Hirsutes (abnormal facial and body hair) occurs particularly in adolescent girls with polycystic ovarian syndrome, which is associated with obesity and insulin resistance. Acanthosis nigricans, a velvety, pigmented, thickening of the skin usually at the back of the neck, is another important marker for insulin resistance, affecting up to 90% of children with type 2 diabetes mellitus.

Psychological problems Some overweight/obese children maintain high self-esteem and have little concern about their body image. These children may excel in sports in which their excess weight and tall stature are advantageous. However, many obese and overweight children have low self-esteem, dissatisfaction with their body image, and difficulty with peer relationships. Often, they underachieve at school. For some obese children, psychological problems antedate the obesity. Low self-esteem and difficulty with peer relationships have led to withdrawal, inactivity, and seeking solace in food. For other obese children, however, obesity is the prime cause of their psychological problems. Studies using silhouettes of figures with different body builds show that most children perceive obese silhouettes very negatively, prefering those portrayed by slimmer figures as friends.

Severe Complications

Adult obesity The extent to which childhood obesity progresses to adult obesity depends on the ages of children and adults at the time of study, the severity of obesity, the duration of obesity, and the family history of obesity. In one study fewer than 20% of males younger than 17 years of age remained obese as 35-year-old adults, whereas 20–39.9% of females younger than 17 years of age were still obese at 35 years of age. The probability of being obese at age 35 increased with increasing age and increasing BMI in childhood at the time of study. Where there is a strong family history of obesity in adult life, it seems likely that the obese child will follow the family pattern. Progression from child to adult obesity still only accounts for a minority of obese adults, although with the increasing prevalence of childhood obesity, this may change since it is highly unlikely that equal proportions of fat and thin children become obese adults.

Type 2 diabetes mellitus and the metabolic syndrome Although hyperinsulinemia has long been recognized from research studies in obese children, overt type 2 diabetes mellitus has been considered a rarity in childhood until recently. Studies in the United States show that among grossly obese children, type 2 diabetes mellitus is now disturbingly common, not only in adolescence but also in children younger than 10 years old. The problem is less common, but certainly present, in Europe also. Although hyperinsulinemia seems most prevalent in obese children from the Indian subcontinent, hyperinsulinemia and overt type 2 diabetes mellitus are also described in obese Caucasian children. Seventy-five percent of UK children with type 2 diabetes mellitus are overweight and 50% have a family history of type 2 diabetes mellitus. Girls are proportionally more likely (3:2) to develop type 2 diabetes than boys.

The metabolic syndrome (insulin resistance syndrome; syndrome X) is a clustering of problems associated with resistance to insulin and/or hyperinsulinemia that includes obesity, high central (i.e., intra- and peri-abdominal) distribution of fat, hypertension, and dyslipidemia. Females with polycystic ovarian syndrome also show clustering of these features. The criteria for diagnosis of the insulin resistance syndrome in childhood have not been defined, but some obese children show clustering of extreme values for the parameters of the metabolic syndrome. Hypertension, hyperinsulinemia, and dyslipidemia in obese children are indications for vigorous intervention to prevent morbidity and early mortality.

Pickwickian syndrome Very severe obesity may be associated with hypoventilation and/or upper respiratory obstruction with sleep apnoea. (The sleepy fat boy in Charles Dicken's *Pickwick Papers* is the origin of the syndrome's name.) Underventilation leads to increased circulating carbon dioxide levels, which may precipitate pulmonary hypertension and right-sided heart failure. Rising circulating carbon dioxide levels may result in the respiratory centre of the brain ceasing to respond to carbon dioxide buildup and instead responding to falling oxygen levels as stimulus to breathe. Thus, if affected individuals are given oxygen because of increasing cyanosis, the stimulus to breathe may be removed with potentially disastrous consequences.

Management

Goals

Ideally, the goal of fat reduction in obesity should be to restore normal body composition and retain it for the rest of life. However, evidence suggests that morbidity and mortality are reduced with even small reductions in excess fat. Thus, loss of some excess fat and the pursuit of healthy eating and activity may be beneficial even if normal fatness is not restored. Parents and children need realistic guidance on achievable goals and on the time required to achieve them. Fat reduction programs should be sustainable, able to maintain normal linear growth, and follow overall healthy lifestyle practices.

For young children, it may not be necessary to lose weight since the normal rates of weight and height gain mean that keeping weight stationary while linear growth occurs allows children to grow 'into their weight.' However, most children presenting for help with obesity are so overweight that it would require years of static weights for current weights to decrease to normal for their heights. Gradual weight reduction should aim for weight losses of approximately 500–1000 g/month. Dramatic weight losses suggest excessive energy deficit with perhaps reduced lean tissue deposition, shorter adult height, and potentially reduced peak bone mass. The fattest children are unlikely to ever achieve normal BMI for age and normal fatness, but they need to be encouraged that significant fat reduction will improve their self-image, ability to exercise, and reduce late complications of obesity.

Dietary Management

Treatment must alter energy balance so that energy intakes are less than energy expenditures in metabolism and activity. Diets should be adequate for protein and micronutrients. They should aim to *change the quality and energy density* of the food eaten more than *reduce the quantity* of food eaten, although reducing

the amount of snacking will probably be appropriate (**Table 3**). There is no consistent evidence that reduction of any particular energy source is more effective than any other in promoting fat loss, so 'balanced diets' conforming to the 'healthy diet' principles of WHO and many governments should be followed.

Physical Activity

More time is spent in relatively minor activity than in strenuous physical activity, so policies that increase energy expenditure in activity must include reductions in sedentary 'activities.' People, not only children, tend to eat more when they are inactive

Table 3 Management of childhood obesity: dietary measures

Purpose of action	*Policy*	*Action*
Organize eating	Control number of eating events	Restrict eating to recognized meal and snack periods with perhaps two snacks only for children and three snacks for adolescents
	Eat meals, as a family whenever possible, at table rather than in front of the television	Where possible, eat meals prepared at home and served on a plate rather than ready-to-eat, microwaved individual meals
Be aware of the nutrient content of meals	Meals prepared at home	Where possible, prepare meals at home so that the cook at least is aware of the nutritional makeup of the meal
	Precooked/ready to eat meals	Read the nutritional information given on the packet and observe not only the content/100 g but also the weight (and thus nutrient content) of the food bought and fed to each member of the family
Reduce the energy content of the food intake	Portion sizes	Portion sizes can be reduced—using smaller plates may make this less obvious; avoid second helpings
	Change the form of food used to low-energy density versions	Use 'low-calorie' margarines, spreads, mayonnaise, yoghurts, soups, baked beans, etc. Use semi-skimmed milk, sugar-free fruit squashes, etc. Grill and bake and boil without added fat rather than frying foods
	Avoid added fats and sugars	Do not add fats to vegetables when preparing them for table Avoid (or reduce) added sugar to stewed fruit dishes; sweeteners dissolved in boiled water can be used instead if necessary
Reduce energy content of drinks	Fruit juices, etc.	Eat whole fruit rather than fruit juices (which are usually many fruits compressed and often with added sugar) Use 'low-calorie' fruit squashes Preferably drink water Avoid added sugar
	Tea, coffee, etc.	Try to avoid sweeteners so as to accustom child to less sweet tastes
Increase satiety	Increase intake of foods that require chewing, that take time to eat, or that increase satiety	Increase vegetable, salad, and fruit intake Increase whole-meal cereal intake Encourage 'jacket' potatoes, boiled potatoes rather than chips, crisps, and mashed potatoes
	Take more time over meals	Eat as a family when possible to allow social interaction during eating, slower eating, and thus greater sense of satiety after the meal

Table 4 Management of childhood obesity: increasing energy expenditure

Purpose	*Type of action*
Reduce sedentariness	Reduce time spent watching television
	Develop interests/hobbies that give children things to occupy them at home and that may give them activities outside the home
	Encourage children to participate in family life by helping parents around homes, doing simple domestic tasks, running up- and downstairs to fetch for other members of family, etc.
Increase activity in everyday life	Walk or cycle rather than go by car whenever possible
	Use public transport rather than car so at least have to walk to bus stop
	Use stairs rather than elevators and escalators when practical
	Walk up escalators
	Do short walking errands for family as much as possible
	Send child out into garden for activity when he or she comes home from school before doing homework, etc.
Increase family activity	Make a habit of going for walks, taking part in physical activity in garden or parks, etc. in leisure time
	Plan activities during holidays and weekends
Encourage and support child to participate in physical activity at school	Obese children may be very successful at swimming (but may be too self-conscious to wear bathing suit)
	Dancing and aerobics may be more acceptable than contact sports, especially for girls
Increase energy expenditure as heat	Reduce home heating a few degrees to increase need for energy to keep warm in cold weather
	Encourage family to become accustomed to relatively cool environments

and relaxing rather than when they are occupied and active. Keeping children from being bored or from spending their leisure time watching television, when food can be consumed almost unnoticed, should reduce eating opportunities. Overweight children should be encouraged to take up hobbies in order to keep their minds off eating. **Table 4** outlines how their physical activity can be increased without necessarily subjecting them to the often perceived misery of sports and gym (although these should also be encouraged). Embarrassment and fear of ridicule as well as the high energy expenditure required for activity on the sports field are exacerbated by mechanical difficulties associated with gross weight.

Television

It is important to reduce time spent watching television for most of these children. Energy utilization is very low when viewing, and much advertising is aimed at encouraging children to eat foods that are energy dense, high in fat, and of low satiety. Viewing as a family should be encouraged, with the television in the living room rather than in children's bedrooms, so parents are involved in their children's viewing and can advise on the significance and nature of advertizements. Viewing time should be limited, but wise negotiation rather than didactic action will probably be necessary to avoid intrafamily conflict. Indeed, parents should be involved in children's slimming regimens, particularly because so many parents are overweight. Many children who watch television express preference for other activities but indicate that they are not given the opportunities to participate in other activities. Children cannot be expected to implement slimming behavior if an obesogenic family lifestyle continues unchanged around them.

Very severe childhood obesity (particularly if accompanied by a life-threatening complication such as Pickwickian syndrome) may require more dramatic interference than described previously. Very low-energy diets have been used quite successfully for short-term weight reduction. However, such diets are intrusive, carry some risk for nutrition and growth, and unacceptable to many obese. No drugs are currently approved for treatment of obesity in childhood. Drug treatment has not been associated with notable successes in the past.

Prevention of Obesity in Childhood

The prevention of obesity involves creating lifestyle changes at the family, school, community, and national level. Initiatives need to be affordable and sustainable so that those most at risk of obesity are reached and feel ownership of community programmes. **Table 5** suggests changes needed to reduce the obesogenic factors in the current Westernized environment. If the obesity epidemic is to be halted, governments and international industries have to work with communities to bring about effective change.

Table 5 Possible national and community measures to reduce epidemic of childhood obesity in Western societies

Purpose	*Action*
Reduce snacking on energy-dense foods	Act to reduce all advertising of energy-dense foods to children
	Possibly ban advertising to children on television
	Remove sweetened drinks and confectionery dispensing machines in schools
	Review foods on sale at school
Increase children's and parents' knowledge of nutrient content of foods	Programmes to educate parents and children on interpreting nutrition labels on foods
	Consider indicating energy content of foods in terms of minutes/hours of activity necessary to balance energy intake from food
	Practical nutrition teaching in schools
Encourage intake of whole foods, fruits and vegetables, and home-prepared foods so there is more awareness of content of foods eaten	Consider subsidising fresh fruits/vegetables and whole-meal cereals and making them more accessible in deprived communities
	Teach families how to cook rather than purchase ready-to-eat meals
Reduce energy intakes generally	Review nutritional content of school dinners
	Develop policies to encourage and make consumption of whole foods, fruits, and cereals attractive and fashionable to children
Increase energy expenditure in activity	Increase play areas, safe parks, and playing fields in communities
	Consider opening school playing fields off hours and on holidays
	Develop safe integrated community transport systems so children can use public transport
	Develop bike paths
Increase energy expenditure in heat	Reduce environmental temperature of public places by a few degrees; encourage people to wear more clothes if they find this uncomfortable

Complications

A Ahmed and R L Atkinson, Obetech Obesity Research Center, Richmond, VA, USA

Obesity is a serious chronic disease associated with complications and comorbidities that involve most systems of the body (**Table 1**). The common factor in all obese people is the presence of excess adipose tissue stores and an increased percentage of body fat. Even in the absence of complications and comorbidities, obesity increases the risk of early mortality. It has been estimated that there are 300 000 obesity-related deaths in the United States each year. In addition to medical complications, obesity is associated with psychological and social problems that may overshadow the medical problems in the quality of life for many obese people.

Table 1 Complications of obesity

Metabolic complications
Metabolic syndrome
Type 2 diabetes
Insulin resistance, hyperinsulinemia
Dyslipidemia
Gout
Abnormalities of hormones and other circulating factors
– Growth hormone
– Hypothalamic–pituitary–adrenal axis
– Cytokines
– Renin–angiotensin system
– Leptin
– Ghrelin
Diseases of organ systems
Cardiac and vascular diseases

Psychological complications
Social complications
Economic impact

Role of Distribution of Body Fat in the Complications of Obesity

The distribution of excess adipose tissue contributes to the complications of obesity. Obese individuals may be classified as those whose excess fat is deposited in the upper body versus those with increased lower body obesity. Upper body obesity may be localized to the subcutaneous space versus the intraabdominal space (visceral fat). Waist circumference and the ratio of waist to hip circumferences correlate with the morbidity and mortality of obesity. Individuals with increased visceral fat, as measured by the cross-sectional area on computed tomography or magnetic resonance imaging, are at greater risk for systemic complications of obesity compared to people with fat localized to abdominal subcutaneous depots or to the lower body. The mechanisms of these differences are not clear, but research has shown that visceral fat has a higher triglyceride turnover rate and releases greater amounts of fatty acids into the circulation than do other adipose tissue depots. Since blood vessels from the visceral fat drain into the portal vein, some investigators postulate that exposure of the liver to high levels of free fatty acids produces insulin resistance, which is known to be correlated with many of the complications of obesity described here. There are significant racial differences in deposition of visceral fat. Asians and Hispanics tend to selectively deposit fat in the abdominal cavity with excess energy intake, whereas blacks have less visceral fat than other groups.

Metabolic and Organ System Complications of Obesity

Obesity is a syndrome that resembles premature aging. Multiple metabolic, hormonal, and organ system dysfunctions occur in aging. Similar changes occur in obesity, but at an earlier age. This section reviews generalized metabolic changes that occur with obesity and discusses individual organ systems.

Metabolic Syndrome

The term 'metabolic syndrome' has been given to a cluster of abnormalities that classically include insulin resistance, glucose intolerance, hypertension, and dyslipidemia. Several other abnormalities, such as sleep apnea, gout, and pseudotumor cerebri, have been associated with insulin resistance and the metabolic syndrome.

Type 2 Diabetes

A strong association of obesity with the prevalence of type 2 diabetes mellitus (DM) is well documented. The risk of developing type 2 DM increases with the

degree and duration of obesity—as much as 50-fold with severe obesity. The US National Diabetes Commission reported that the risk of diabetes doubles for every 20% of excess body weight. The risk of type 2 DM is greater with visceral obesity. Type 2 DM is frequently associated with other complications, such as hypertension and dyslipidemia, resulting in additive risks for atherosclerosis and cardiovascular disease. Poor glycemic control in type 2 DM may lead to severe microvascular complications, including nephropathy, retinopathy, and neuropathy. Weight loss is a very effective treatment for type 2 DM and can prevent the onset of type 2 DM in susceptible individuals. Type 2 DM, once very rare in children, has increased greatly in prevalence with the obesity epidemic.

Insulin Resistance and Hyperinsulinemia

'Insulin resistance' refers to the phenomenon of insensitivity of the cells of the body to insulin's actions. Different tissues may have different insulin sensitivities. For example, adipose tissue may be more sensitive to insulin than muscle tissue, thus favoring the deposition of fatty acids in adipose tissue and diminished fatty acid oxidation in muscle. Insulin resistance is usually associated with hyperinsulinemia. Hyperinsulinemia is an independent marker that predicts the development of atherosclerosis. A causal relationship between hypertension and hyperinsulinemia has not been well established. Hypertension associated with hyperinsulinemia could be due to increased renal sodium retention, increased intracellular free calcium, increased sympathetic nervous system activity, or increased intraabdominal pressure due to increased visceral fat deposition.

The mechanisms of insulin resistance with increasing obesity are not clear, but increased production of cytokines such as tumor necrosis factor-α (TNF-α) and interleukin-6 (IL-6) is thought to play a role. Basal insulin levels increase with the degree of overweight, perhaps due to increased insulin secretion and/or reduced clearance by the liver. A reduced receptor number and/or post–insulin receptor defects may play a role in insulin resistance. Both basal hyperinsulinemia and insulin resistance decrease with weight reduction.

Dyslipidemia

Obesity, particularly visceral obesity, is associated with increased serum levels of cholesterol, triglycerides, low-density lipoproteins (LDL), very low-density lipoproteins (VLDL), apolipoprotein B, and reduced levels of high-density lipoprotein (HDL) cholesterol. Every 10% increase in relative body weight is associated with a 12 mg/dl increase in serum cholesterol concentration. The correlation of serum cholesterol with body mass index (BMI = kg/m^2) is greater for men than women. Increased serum triglycerides with weight gain may be due to increased intake of fats, hyperinsulinemia, and impaired removal of triglycerides into tissues because of low levels of lipoprotein lipase activity. Insulin resistance promotes lipolysis and increased circulating free fatty acids, which enhance the formation of VLDL in the liver. Dyslipidemia contributes to increased atherosclerosis in obesity. Weight reduction usually reduces serum cholesterol and triglycerides, increases HDL cholesterol, and may reduce atherosclerosis.

Gout

Serum uric acid and the prevalence of gout correlate positively with BMI. High serum uric acid levels correlate with insulin resistance and an increased risk of atherosclerotic cardiovascular disease in obesity. Serum uric acid levels may temporarily increase with acute weight loss, but they usually decrease with large amounts of weight loss. The lower uric acid levels are maintained with continued weight loss.

Abnormalities of Hormones and Other Circulating Factors

Growth hormone Obesity is typically accompanied by a decrease in growth hormone (GH) levels and an increase in growth hormone binding protein levels. An inverse relation exists between GH levels and percentage fat mass. GH levels fall with increasing age. GH is released by the anterior pituitary and affects lipid, carbohydrate, and protein metabolism. GH also controls the rate of skeletal and visceral growth. GH is lipolytic in adipose tissue. Animal studies show enhanced catecholamine-induced lipolysis and increased β-adrenoreceptors in adipocytes of GH treated animals. The rises in GH after meals, with sleep, and in response to secretogogues such as arginine or levodopa are blunted in obese people. GH stimulates secretion of insulin-like growth factor-1 (IGF-1). However, IGF-1 is increased in obesity, suggesting a difference in sensitivity to GH. The defects in GH and IGF-1 are reversed by weight reduction.

The hypothalamic–pituitary–adrenal axis The hypothalamic–pituitary–adrenal (HPA) axis may be abnormal in obesity. Patients with Cushing's syndrome display a number of clinical features that resemble those seen in patients with the metabolic

syndrome, including abdominal obesity, insulin resistance, impaired glucose homeostasis, hypertension, and lipid abnormalities. These similarities led to the hypothesis that a dysregulation of the HPA axis in the form of functional hypercortisolism could potentially be a cause for abdominal obesity and its different metabolic consequences. High levels of emotional or physical stress are thought to increase cortisol secretion or turnover and thereby increase visceral obesity.

Another potential mechanism involves the peripheral metabolism of cortisol. The enzyme 11-β-hydroxysteroid dehydrogenase, which converts steroid precursors to cortisol, is expressed in adipose tissue. With increasing obesity, more cortisol is derived from cortisone in adipose tissue due to the increased activity of this hormone. Urine studies in obesity also show an increase in the ratio of tetrahydrocortisol to tetrahydrocortisone, indicating a relative increase in the pathways leading to cortisol formation.

Cytokines Adipose tissue secretes a number of cytokines, such as TNF-α and interleukins, which may play a role in fat metabolism and insulin resistance. TNF-α has been shown to alter basal and glucose-stimulated insulin secretion and to produce insulin resistance in isolated cell lines. Adipocytes also produce IL-6, -10, and -11, which stimulate C-reactive protein, a systemic marker of inflammation. All of these ILs are increased in obesity. IL-6 and its subsequent inflammation have been postulated to play an etiologic role in the increased risk of thromboembolism observed in obese patients. Adipose tissue is also capable of producing plasminogen activator inhibitor-1, which may play a role in the increased risk of thromboembolism. Plasma IL-8 is increased in normoglycemic obese subjects and is related to fat mass and to TNF-a levels. Circulating IL-8 is also acutely upregulated by hyperinsulinemia. An increase in circulating IL-8 may be one of the factors linking obesity with greater cardiovascular risk.

Renin–angiotensin system Several components of the renin–angiotensin system are expressed by the adipose tissue. Angiotensinogen levels are increased and have been linked to hypertension and increased cardiovascular risk in obesity.

Leptin Leptin, the product of the *ob* gene, is made predominantly in adipose tissue. Leptin receptors are present in the hypothalamus. Leptin was postulated to act as a signal from adipose tissue to the brain to regulate fat stores. However, serum leptin levels correlate positively with body fat stores and are higher in obese people. Females have higher serum leptin levels than males, but this association does not appear to be due to estrogen levels. Leptin is found in greater concentrations in abdominal subcutaneous fat compared to visceral fat. The mechanisms for these differences are not known, but it is possible that this may play some role in the differential metabolic responses of subcutaneous and visceral fat.

Ghrelin Ghrelin is a potent growth hormone secretagogue that is produced mainly by the stomach. Administration of ghrelin increases food intake, and ghrelin levels increase with dieting and weight loss. However, serum ghrelin has a negative correlation with percentage body fat, so levels in obese people are lower than in nonobese people.

Diseases of Organ Systems

Atherosclerotic and Arteriosclerotic Vascular Diseases

Diseases of the vascular system provide the greatest contribution to the increased mortality associated with obesity. In both sexes, the excess mortality due to vascular disease increases linearly with BMI greater than 25 kg/m^2. The vascular complications of obesity can be categorized into five major groups: coronary heart disease, hypertension, congestive heart failure, cerebrovascular disease, and thromboembolic disease.

Coronary heart disease Longitudinal studies show a positive correlation of BMI with coronary heart disease (CHD), and obesity is an independent predictor of CHD. However, in the presence of other risk factors, such as hypertension, high serum cholesterol and triglycerides levels, low serum HDL cholesterol levels, and insulin resistance, all of which are increased by obesity, the risk of atherosclerotic CHD increases dramatically. Weight loss reduces all of these risk factors associated with cardiovascular disease, but because long-term reductions in body weight have been difficult to achieve, there are few long-term studies of changes in cardiovascular mortality due to weight loss. A very low-fat diet (10% of total calories as fat) has been shown to reduce the size of atherosclerotic plaques in coronary arteries. Such low-fat diets almost invariably produce weight loss.

Hypertension The prevalence of hypertension among overweight adults in the United States is 2.9 times higher than that of nonoverweight individuals.

Every 10-kg increase in body weight is associated with an increase of 3 and 2 mm Hg in systolic and diastolic blood pressures, respectively. Persistent hypertension can contribute to the development of left ventricular hypertrophy, coronary ischemia, and stroke.

The etiology of the association between hypertension and obesity is unclear. The following are some of the mechanisms offered to explain the association between obesity and hypertension:

Hyperinsulinemia due to insulin resistance leading to increased renal reabsorption of sodium
Sodium retention due to a decreased renal filtration rate, increased intraabdominal pressure, and/or increased plasma renin activity
Increased sympathetic nervous system activity

Except in long-standing cases, weight reduction is usually accompanied by a decrease in blood pressure. The reductions in blood pressure with weight loss are not dependent on decreases in salt intake. Many studies have shown that even modest weight losses, in the range of 5–10% of initial body weight, may produce reductions or even normalization of blood pressure in obese individuals.

Congestive heart failure Total blood volume increases with excess body weight. Higher oxygen consumption in obesity and increased blood flow to the splanchnic bed and adipose tissue increase cardiac output. Also, the transverse diameter of heart, thickness of the posterior wall, and thickness of the interventricular septum increase with body weight. Left ventricular mass is a stronger predictor of morbidity and mortality than blood pressure. A combination of these factors may result in the congestive heart failure seen in severely obese people. The heart rate, stroke volume, blood volume, cardiac output, and left ventricular work return to normal with weight reduction. One study that compared weight loss by dieting to treatment with antihypertensive drugs demonstrated a greater improvement in cardiac hypertrophy with weight loss, despite similar reductions in blood pressure.

Cerebrovascular disease Obesity-related atherosclerosis and arteriosclerosis increase the risk of cerebrovascular disease and strokes. Obesity is an independent risk factor for strokes, even in the absence of other comorbidities.

Thromboembolic disease The risks of venous stasis, deep vein thrombosis, and pulmonary embolism are increased in obesity, particularly in people with abdominal obesity. Lower extremity venous disease may result from increased intraabdominal pressure, impaired fibrinolysis, and the increase in inflammatory mediators described previously.

Respiratory System

Obesity is associated with reduced lung volume, altered respiratory patterns, and an overall reduction in the compliance of the respiratory system, including a diminished vital capacity and total lung capacity. More severe obesity is associated with the 'obesity–hypoventilation syndrome,' which is characterized by excessive daytime sleepiness and hypoventilation. The increased work required to move the chest wall, a decrease in arterial oxygenation in the lungs, and a diminished sensitivity of the respiratory center to the stimulatory effect of carbon dioxide are postulated to contribute to the obesity–hypoventilation syndrome.

The obesity–hypoventilation syndrome may be associated with, or exacerbated by, obstructive sleep apnea, a syndrome characterized by repeated collapse of the upper airway and cessation of breathing with sleep. Obstructive sleep apnea occurs when the tongue obstructs the glottis and prevents entry of air into the trachea. Up to 50% of massively obese people have sleep apnea. The risk of arrhythmias and sudden death increases during apneic episodes. Weight reduction usually reduces the severity of sleep apnea, and massive weight reduction, such as that after gastric bypass surgery, eliminates the disease in most patients.

Digestive System

Gallbladder disease The risk of gallbladder disease, particularly gallstone formation, is increased in obesity and occurs with greater frequency in women. The prevalence of gallbladder disease in obese individuals increases with age, body weight, and parity. The etiology of increased gallstones is unclear, but genetic factors play a role. Increased cholesterol production, which leads to increased excretion of cholesterol in bile, is known to occur in obesity and correlates with increases in body weight. Many obese people skip meals and the reduced number of meals may result in less frequent emptying of the gallbladder. The resulting bile stasis may contribute to gallstone formation. Although long-term weight loss and maintenance may reduce the occurrence of gallbladder disease, the risk of gallstone formation actually increases during the active weight loss phase. The etiology of this increase is thought to be the mobilization of cholesterol from adipose tissue during rapid weight loss. This increased load of cholesterol in the circulation produces supersaturation of the bile,

leading to gallbladder sludge in approximately 25% of patients and to symptomatic disease in approximately 1–3%. Treatment with ursodeoxycholic acid reduces or eliminates the risk of gallstone formation during weight loss.

Hepatic disease Abnormalities in hepatic function are commonly reported in obese people. Fatty liver, due to increased concentrations of fatty acids, diglycerides, and triglycerides in hepatocytes, is reported in obese people. The frequency of fatty liver has been reported to be as high as 94% in very obese subjects. A small number of very obese subjects will develop micronodular cirrhosis. Abnormal liver enzymes on laboratory screening are very common in obese people and do not require further evaluation unless they are markedly elevated. Weight loss results in disappearance of the excess fat and normalization of the liver function tests.

Reproductive System

Hormonal Complications: Males Obese men have elevated levels of plasma estrone and estradiol that correlate with the degree of obesity. Plasma total testosterone and free testosterone (the biologically active moiety) are reduced in obese men, and the reductions correlate negatively with the degree of obesity. The reduced levels of free and total testosterone are not generally accompanied by hypogonadism or a decrease in libido, potency, or sperm count in obese men. Free and total plasma testosterone levels normalize upon significant weight reduction. Also, estrogen levels are normalized if individuals attain normal weight but not if the weight loss is modest and significant obesity persists.

Hormonal Complications: Females Obese women have normal levels of total plasma estradiol but reduced levels of sex hormone binding globulins (SHBG). Thus, free estradiol (the biological active moiety) is significantly elevated. The high levels of free estradiol are postulated to increase the risks of endometrial and breast cancer and to reduce fertility. Estrone, derived in adipose tissue from androgen precursors, is also increased in obesity. Obesity in women is associated with the polycystic ovary syndrome (PCOS), characterized by hyperestrogenism, hyperandrogenism, polycystic ovaries, oligomenorrhea or amenorrhea, hirsutism, and infertility. Women with PCOS also have insulin resistance and are at high risk for developing impaired glucose tolerance and diabetes mellitus. Weight loss usually normalizes SHBG and estradiol levels for individuals with simple obesity, but weight loss may not restore fertility to patients with severe PCOS.

Obstetric complications Obesity increases the risk of complications during pregnancy and child birth. Increased body weight, hypertension, and fluid retention during pregnancy can lead to toxemia of pregnancy. Heavier women have a longer duration of labor and a greater frequency of abnormal labor and caesarian sections.

Nervous system

Pseudotumor cerebri This syndrome is characterized by increased intracranial pressure, headaches, blurred vision or loss of vision, and papilledema. It is most common in massively obese individuals and may be seen in association with sleep apnea or with the obesity–hypoventilation syndrome. It may be associated with retinal hemorrhage or loss of vision from severe papilledema. Some investigators believe that increased intraabdominal pressure with massive obesity is an etiologic factor for pseudotumor cerebri. Major weight loss, particularly after obesity surgery, results in dramatic improvement.

Adiposis dolorosa This is a syndrome of unknown etiology characterized by pain in subcutaneous adipose tissue. Adiposis dolorosa occurs predominantly in postmenopausal women (female: male ratio of about 30:1) and has been described over all areas of the body. The painful areas of fat may occur as subcutaneous lumps on physical examination, but more commonly there are no differences from normal adipose tissue. The disease usually begins gradually with mild pain and tenderness of the area involved, but it may progress to severe pain, particularly with movement or exercise. Intravenous infusions of lidocaine are reported to relieve pain short term or even permanently. The mechanism involved in the relief of pain from lidocaine is unknown.

Alzheimer's disease Obesity has been linked to an increased prevalence of Alzheimer's disease. The etiology of this increase is unknown.

Immune System

Animal studies have shown an increased rate of infection and mortality in obese dogs compared to lean animals experimentally infected with canine distemper virus. Cell-mediated immune response is impaired in obese individuals. Maturation of monocytes into macrophages after *in vitro* incubation is significantly

less for obese compared to lean subjects. Impaired cell-mediated immune response in children was demonstrated to be due to subclinical deficiencies of zinc and copper. The impairment in the immune response was reversed after 4 weeks of zinc and copper supplements. As described previously, there are changes in numerous cytokines with obesity. The role of these changes in immune function is not clear.

Skin

Obese people may have several disorders of the skin. The most common is stasis changes of the skin of the lower legs in massively obese people. The etiology of this finding is venous stasis, edema, and breakdown of the skin. Fragilitas cutis inguinalis is a condition of fragile skin in the inguinal area of obese people. This condition is diagnosed by stretching the skin of the inguinal area. A linear tear appears at right angles to an applied force that is insufficient to tear the skin of a normal person. This condition is unrelated to the sex and age of the person.

Acanthosis nigricans, seen occasionally in obesity, is characterized by darkening of the skin in the creases of the neck, axillary regions, and over the knuckles. An association between acanthosis nigricans and insulin resistance is reported in people who have circulating antibodies to the insulin receptors. Since acanthosis nigricans also may be associated with highly malignant cancers such as intraabdominal adenocarcinomas, physicians should be alert to this possibility and not attribute the condition simply to the presence of obesity.

Eye Disease

Obesity is associated with an increased prevalence of cataracts. People with abdominal obesity are at greater risk than those with lower body obesity, insulin resistance may be involved in the pathogenesis of cataract formation, and diabetes is a well-known risk factor.

Cancer

Obesity increases the risk of cancers of the breast, colon, prostate, endometrium, cervix, ovary, kidney, and gallbladder. Studies have also found a somewhat increased risk for cancers of the liver, pancreas, rectum, brain, esophagus, and non-Hodgkin's lymphoma.

Although there are many theories about how obesity increases cancer risk, the exact mechanisms are not known. The mechanisms may be different for different types of cancer. Also, because obesity develops through a complex interaction of heredity and lifestyle factors, researchers may not be able to determine whether the obesity or other factors led to the development of cancer.

Mechanical Complications of Obesity

Arthritis

Obesity is frequently complicated by degenerative arthritis (DJD). Increased body weight leads to trauma of the weight-bearing joints and speeds the development of osteoarthritis in obesity. Knee and hip joints are particularly affected. However, obese patients have increased DJD of the hands, perhaps due to cytokines produced by adipose tissue, which may damage the cartilage in joints. Flattening of the arc of the planter surface of the feet (flat feet) occurs more frequently in obese people, presumably due to the stress of carrying excess body weight. Flat feet may lead to unsteady gait and aches and pains after walking. Increased fat deposition, particularly in the abdominal region, can change the natural curvature of the spine, causing lordosis and resulting in backache in obese people.

Intraabdominal Pressure

In severely obese people, the excess visceral fat is thought to increase intraabdominal pressure. Animal research shows that experimentally induced acute increases in intraabdominal pressure to the levels seen in the abdomens of very obese people cause increases in pleural pressure, intracranial pressure, and central venous pressure. The investigators postulated that in humans, increased intraabdominal pressure may contribute to hypertension, insulin resistance and type 2 DM, obesity–hypoventilation syndrome, pseudotumor cerebri, incisional hernia, and urinary incontinence. Massive weight loss following obesity surgery normalizes the increased intraabdominal pressure and reduces or eliminates all the symptoms listed previously.

Surgical Complications

Obese patients are at an increased risk of surgical and perisurgical complications, including an increased risk of complications and death from anesthesia, longer operating times, delayed wound healing, increased postoperative wound infections and pneumonia, and a higher frequency of incisional hernias after surgeries involving the abdominal wall. Many surgeons recommend weight reduction before elective surgery, but there are few data to document that acute weight reduction improves the outcome of surgery.

Psychosocial Complications

Psychological Complications

Obesity is associated with negative emotions, low self-esteem, decreased marital satisfaction, and body image disparagement. All of these conditions and beliefs show improvement with weight reduction.

Dieting efforts correlate positively with the prevalence of eating disorders, particularly binge eating. A correlation of eating disorders with abuse of drugs and alcohol has been shown. In strictly dieting female college freshmen who were not alcohol abusers at baseline, the frequency of alcohol abuse was reported to increase after 1 year compared to nondieters.

Social Complications

Obesity carries a social stigma that dramatically affects the quality of life for obese individuals, particularly for women. Factors contributing to the social bias against obese people are beliefs that obesity is due merely to overeating and therefore obese people must lack will power. Many members of the general public, and even health professionals, ignore the evidence for the genetic contribution to obesity, believe that obese people are responsible for their own plight, and believe that they do not deserve sympathy for their disability. Despite similar intelligence (as judged by IQ values and the Scholastic Aptitude Test scores), a significantly lower number of obese females were admitted to certain colleges compared to nonobese females. The choice of mates is adversely affected by obesity. Obese individuals tend to marry mates with less education and from a lower socioeconomic class. It is more difficult for an obese person to find a job or to be promoted once hired, so lower earnings and a lower socioeconomic status are correlated with obesity. Obese employees are viewed as less competent, less productive, inactive, disorganized, and less successful by employers.

The bias against obesity has been shown to begin in early childhood. Obese children are considered lazy, stupid, slow, and self-indulgent by both children and adults. Because of these societal attitudes, many obese children and adolescents have lower self-esteem than do their nonobese counterparts.

Economic Impact

In the United States, the direct cost of obesity has been estimated at more than $100 billion per year. The indirect costs of early retirement and increased risk for disability requiring financial support are also considerable. Because obese people have more health problems, health care costs for the obese are higher than for nonobese individuals.

Prevention

T P Gill, University of Sydney, Sydney, NSW, Australia

There can be little doubt that obesity has become a major public health and economic problem of global significance. According to World Health Organization (WHO) estimates, approximately 1 billion people

throughout the world were overweight in 2002 and more than 300 million of these were obese. Prevalence rates continue to rise rapidly in all areas of the world, including low-income countries, and obesity-associated illness are now so common that they are replacing the more traditional public health concerns, such as undernutrition and infectious disease, as the most significant contributors to global ill health.

The health impact of obesity is considerable, and obesity impacts on both quality and length of life. Overweight and obesity are associated with a wide range of chronic conditions, such as diabetes, hypertension, cardiovascular disease (CVD), and certain cancers, as well as non-life-threatening but painful conditions, such as arthritis, back pain, and breathlessness. Obesity also places enormous financial burdens on governments and individuals and accounts for a significant proportion of total health care expenditure in developed countries. Analyses suggest that obesity is fast approaching cigarette smoking as the major preventable cause of mortality.

In recent years, our understanding of the epidemiology and causation of obesity has improved dramatically and there is an acceptance that urgent action is required to address the problem. However, there are very few examples of successful, large-scale obesity prevention initiatives from any area of the world. Despite these limitations, sufficient understanding has been gained from smaller scale obesity prevention initiatives together with experiences from the management of other epidemics of noncommunicable diseases to allow effective planning and implementation of obesity prevention programs to proceed.

Principles of Obesity Prevention

Rational for Obesity Prevention

There are a number of reasons why prevention is likely to be the only effective way of tackling the problem of overweight and obesity. First, obesity develops over time, and once it has done so, it is very difficult to treat. A number of analyses have identified the limited success of obesity treatments (with the possible exception of surgical interventions) to achieve long-term weight loss. Second, the health consequences associated with obesity result from the cumulative metabolic and physical stress of excess weight over a long period of time and may not be fully reversible by weight loss. Third, the proportion of the population that is either overweight or obese in many countries is now so large that there are no longer sufficient health care resources to offer treatment to all. It can be argued, therefore, that the prevention of weight gain (or the reversal of small gains) and the maintenance of a healthy weight would be easier, less expensive, and potentially more effective than to treat obesity after it has fully developed.

Objectives of Obesity Prevention

There remains a great deal of confusion regarding the appropriate objectives of an obesity prevention program. It is often assumed that to be effective, any intervention to address the problem of excess weight in the community should result in a reduction in the prevalence of overweight and obesity. However, such an objective is unrealistic and may be counterproductive. Most communities are experiencing significant increases in the average weight of the population as a result of a sizeable energy surplus resulting from reduced energy expenditure combined with an increased energy intake. This is leading to rapidly escalating rates of overweight and obesity. To reverse this trend will require not only the removal of this energy surplus but also the creation of a negative energy balance that will need to be maintained by the whole population for a significant period of time. Few (if any) interventions are capable of reducing energy intake, or increasing energy expenditure sufficiently, or are sustained long enough and with sufficient reach to achieve this effect. More appropriate objectives would relate to a reduction in the level of weight gain or the maintenance of weight stability in adults and the achievement of appropriate growth and development in children. The achievement of these objectives would result in a slowing in the rate of increase, followed by stabilization and then an eventual decline in the level of overweight and obesity in the community.

However, even the goal of weight stability within a population may be difficult to achieve in the short term because it would require the maintenance or reestablishment of energy balance in time of significant energy surplus. Therefore, it may be necessary to identify more sensitive short- and medium-term outcomes to evaluate obesity prevention programs. Such process outcomes may relate to the achievement of appropriate changes in energy intakes or outputs, food or physical activity behaviors, or changes to the environment that are significant enough to positively impact upon the achievement of energy balance.

Importance of Weight Gain Prevention in Adults

There are a number of important reasons why it is preferable to focus on weight gain prevention as the key individual and population objective of obesity prevention initiatives in adults (**Box 1**). The association between elevated body mass index (BMI) and increased risk of ill health is clear and consistent.

Box 1 Why focus on weight gain prevention?

- Weight gain in adulthood carries an independent risk of ill health.
- Risk for chronic disease begins to increase from low BMI levels and significant weight gain can occur within normal limits.
- Extended periods of weight gain are difficult to reverse.
- Weight gain in adulthood is mostly fat gain.
- The relationship between absolute BMI and health risk varies with age and ethnicity but no such variations occur in the relationship between weight gain and ill health.
- A focus on weight gain prevention avoids exacerbation of inappropriate dieting behaviors.
- Weight maintenance can serve as a first stage goal for weight treatment programs.
- The message is equally relevant to all sections of the adult population.
- It avoids further stigmatization of people with an existing weight problem.
- It avoids reference to poorly understood terms such as 'healthy weight.'

Figure 1 Levels of obesity prevention intervention. (Adapted from Gill TP (1997) Key issues in the prevention of obesity. *British Medical Bulletin* **53**(2): 359–388.)

However, research has demonstrated that weight gain per se is also associated with increased health risk, and that this risk is independent of absolute BMI (provided a person is not underweight). A number of studies have shown strong relationships between weight gain and increasing levels of diabetes, hypertension, gall bladder disease, and coronary heart disease. Therefore, a large weight gain in a lean individual may carry equivalent risk to maintaining a stable but slightly elevated BMI in an overweight individual. The combination of an elevated BMI and ongoing weight gain, however, leads to greatly magnified levels of risk.

Who Should Obesity Prevention Strategies Target?

Deciding where to invest limited time and resources in obesity prevention is a difficult task but finite health resources make this a necessity. WHO has identified three distinct but equally valid and complementary levels of obesity prevention (**Figure 1**). The specific 'targeted' approach directed at very high-risk individuals with existing weight problems is represented by the core of the figure, the 'selective' approach directed at individuals and groups with above average risk is represented by the middle layer, and the broader universal or populationwide prevention approach is represented by the outer layer. This replaces the more traditional classification of disease prevention (primary, secondary, and tertiary), which can be confusing when applied to a complex multifactorial condition such as obesity.

Universal prevention is the domain of public health, whereas selective and targeted prevention are predominantly dealt with in community and health care service settings. Community settings include schools, colleges, worksites, community centers, and shopping outlets.

Whole Community

Overweight and obesity are public health problems of relevance to the whole community and require strategies that focus on populationwide change rather than attempting to address individuals or small groups in isolation of the community in which they live. An effective population strategy needs to both improve population knowledge about obesity and its management and reduce the exposure of the community to obesity-promoting factors in the environment. Action at a population level requires coordination at a central level and the investment of resources to be maintained over a long period of time to achieve population change.

Family Focus

There are numerous reasons why children should be a major focus of any obesity prevention strategy. There is strong evidence that a high proportion of overweight or obese children will become obese adults. Childhood obesity also has immediate effects on health, and weight-related conditions are becoming more prevalent and their effect more pronounced as the rates of childhood obesity increase. However, children grow rapidly and increase the level of lean body mass as they age, and so reducing or keeping fat mass constant allows the normalization of weight over time. Thus, childhood

(particularly younger children) is a period during which prevention efforts have a higher chance of success.

However, children also have little direct control over the environment in which they live. Parents and other caregivers mostly control decisions regarding the food available and the opportunities for activity. In addition, the behaviors of parents and other siblings have a profound effect on the diet and physical activity behaviors of children. For this reason, it is preferable to focus childhood obesity prevention efforts on the family environment rather than directly on children.

High-Risk Groups

There are a number of groups that appear to be at higher risk of developing overweight and obesity (**Table 1**). These groups warrant special attention and include the following:

- Those with a family history of weight problems
- Socially disadvantaged and isolated communities
- Certain ethnic groups
- Smokers who have recently quit smoking
- Those who have recently lost weight

In addition, there are certain times in a person's life when the person is more prone to weight gain (**Table 1**). These age groups could be considered for selective prevention interventions. These times include the following:

Prenatal
Adiposity rebound (5–7 years)
Adolescence
Early adulthood
Pregnancy
Menopause

Table 1 Identifying at-risk groups for obesity

Critical ages and life stages	*Reason for increased risk*
Prenatal	There is evidence that in utero development has permanent effects on later growth and energy regulation.
Adiposity rebound (5–7 years)	Body mass index begins to increase rapidly after a period of reduced adiposity during preschool years. Food and activity patterns change as a result of exposure to other children and school. Early and rapid weight rebound often precedes the development of obesity.
Adolescence	Period of increased autonomy that is often associated with irregular meals, changed food habits, and periods of inactivity during leisure combined with physiological changes that promote increased fat deposition, particularly in females.
Early adulthood	Early adulthood usually correlates with a period of marked reduction in physical activity. In women this usually occurs between the ages of 15 and 19 years but in men it may be as late as the early 30s.
Pregnancy	Excessive weight gain during pregnancy often results in retention of weight after delivery, particularly with early cessation of breast feeding. This pattern is often repeated after each pregnancy.
Menopause	In Western societies weight generally increases with age but it is not certain why menopausal women are particularly prone to rapid weight gain. The loss of the menstrual cycle does affect food intake and reduce metabolic rate slightly.
High-risk groups	
Family history of weight problems	There is no longer any doubt that given the same environment some individuals are more prone to depositing fat. The basis of these differences in individual susceptibility to obesity is yet to be fully elucidated but is believed to involve a number of physiological processes associated with fat deposition and oxidation and involuntary energy expander.
Certain ethnic groups	In NSW, recent migrants from southern Mediterranean countries and the Middle East are more likely to be obese and their children are more likely to develop a more severe form of obesity that to immediate health consequences.
Socially or economically disadvantaged	In NSW, there is an inverse association between income and education level and obesity which is most pronounced among women and children. It is argued that cheaper foodstuffs are usually high in fat and energy dense and those with less financial resources spend more time in sedentary activities such as watching TV.
Recent successful weight reducers	Successful weight reduction is usually followed by the regain of one-half to one-third of the weight loss over the following year. It is believed that biological and behavioral processes act to drive body weight back to baseline levels.
Recent past smokers	Smokers are usually thinner than nonsmokers because smoking tends to depress appetite, increase the basal metabolic rate, and, after each cigarette, induce a surge in heart and metabolic rate. The effect on metabolism of smoking 24 cigarettes per day has been estimated at approximately 200 kcal per day.

Adapted from Gill TP (1997) Key issues in the prevention of obesity. *British Medical Bulletin* **53**(2): 359–388.

Those with an Existing Weight Problem

In developing weight gain prevention strategies, it is important not to neglect those with an existing weight problem who could benefit from more intensive efforts to help prevent further weight gain.

Key Elements of a Weight Gain Prevention Plan

Weight gain and obesity develop when the energy intake from food and drink exceeds energy expenditure from physical activity and other metabolic processes. It is often assumed that the prevention of weight gain should focus solely on attempting to alter these behaviors within individuals and communities. However, research has consistently shown that numerous and diverse factors, including environmental and social factors, influence the behaviors that lead to excessive weight gain. Addressing aspects of the obesogenic (obesity-promoting) environment, as well as individuals' eating and physical activity patterns, is considered to be critical to the success of any obesity prevention program.

The 2003 WHO report on diet, nutrition, and the prevention of chronic disease undertook a detailed review of the literature and identified a range of key factors that either increase or decrease the risk of weight gain and the development of obesity (**Table 2**). These factors were rated on the quality of evidence available to support their contributory role. This analysis serves as a very useful guide as to the focus of weight gain prevention initiatives.

Diet and Physical Activity Behaviors

The WHO analysis identified a number of key dietary and physical activity behaviors, amenable to change, that could conceivably influence energy balance sufficiently to contribute to the prevention of weight gain and obesity. Behaviors that reduced the risk of obesity included regular physical activity, high dietary fiber intake, and possibly breast-feeding and low glycemic index diets. Behaviors that increased the risk of obesity included a high intake of energy-dense foods, a high intake of sugar-sweetened drinks and juices, time spent in sedentary behaviors, and possibly large portion sizes, a high intake of fast foods, and a restrained eating pattern.

The area of dietary and physical activity antecedents to weight gain and obesity is still poorly understood and new research findings, which help clarify our understanding, are being presented on a regular basis. In addition, different behaviors are more prevalent or pronounced in different regions of the world. It is therefore difficult to give definitive recommendations on the most important and useful behaviors to target in obesity prevention strategies. However, strong evidence exists to support the inclusion of some key behaviors.

Reducing Energy Intake

Reducing the intake of high energy-dense foods (i.e., foods high in fat/sugar) There is a high level of agreement that the overconsumption of energy-dense foods is a major contributor to excess energy intake and weight gain and that restriction of energy-dense food items is a useful strategy for the prevention of weight gain. However, discussion continues as to whether fat or refined carbohydrate is the major contributor to energy density in the modern diet and thus should be the target of programs to control weight. The debate is being fuelled by dietary data from many developed countries that show that dietary fat intakes have leveled out or declined

Table 2 Summary of the strengths of evidence of factors that may promote or protect against weight gain and obesity

Evidence	*Decreases risk*	*Increases risk*
Convincing	Regular physical activity	High intake of energy-dense foods[a]
	High dietary fiber intake	Sedentary lifestyle
Probable	Home and school environments that support healthly food choices for children	Heavy marketing of energy-dense foods and fast-food outlets
	Promoting linear growth	Adverse social and economic conditions in developed countries (especially for women)
		Sugar-sweetened soft drinks and juices
Possible	Low glycemic index foods	Large portion sizes
	Breast-feeding	High proportion of food prepared outside of home
		Rigid restraint/periodic disinhibition eating patterns
Insufficient	Increased eating frequency	Alcohol

[a]Energy-dense foods are high in fat/sugar and energy-dilute foods are high in fiber and water, such as vegetables, fruits, legumes, and whole grain cereals.

Adapted from WHO (2003) *Joint WHO/FAO Expert Report on Diet, Nutrition and the prevention of Chronic Disease*, WHO Technical Report Series 916. Geneva: WHO.

slightly and intakes of carbohydrates have increased dramatically. However, research has shown that dietary fat (along with water and fiber) is a major contributor to the energy density of foods and that ad libitum low-fat diet plans are an effective dietary approach to weight gain prevention or moderate weight loss. There is also strong evidence that excess carbohydrate, particularly high glycemic index carbohydrate, contributes to weight gain and its restriction aids weight loss and improves cardiovascular risk factor profiles.

Increasing the intake of high-fiber, energy-dilute foods (especially vegetables and fruits) There is less evidence on the effectiveness of increasing the intake of energy-dilute foods such as vegetables and some fruits in the diet. Such a strategy would assist weight gain prevention only if the inclusion of such foods leads to a reduction in the intake of more energy-dense alternatives and thus creates a reduction in energy intake. Few studies have addressed this issue in a comprehensive manner, but the additional health benefits of these foods makes such a strategy low risk in nutritional terms.

Reducing the consumption of sugar-sweetened soft drinks and juices Evidence is accumulating from a variety of studies that energy consumed as sweetened drinks is less well compensated for than energy consumed as solid food. Longitudinal studies have also indicated that sweetened drinks (soft drinks or sodas) are associated with weight gain in both children and adults. Recent work has also demonstrated that the simple strategy of reducing the intake of sweetened drinks can be effective in preventing or limiting inappropriate weight gain.

Reducing the level of food prepared outside of the home The proportion of food purchased and consumed at food outlets outside of the home has increased dramatically in recent decades in both developed and developing nations. In the United States, approximately 40% of the household food budget is spent on food eaten away from home, and much of this is spent at fast-food outlets. A number of analyses have linked increased consumption of fast food with increased risk of obesity. Although few studies have evaluated the effect of reducing the consumption of fast food, it would seem to be a valuable strategy with few nutritional negatives.

Reducing portion sizes The portion size of packaged foods and snacks, as well as restaurant serving sizes, has increased rapidly in recent times and has been identified as an important factor in the consumption of excess energy. Evidence suggests that people will consume the portion of food they are provided rather than respond to satiety signals to stop eating and leave food. Also, as the serving size increases, the ability of consumers to estimate accurately how much they have consumed decreases. Reducing portion sizes is a simple but immediately effective mechanism for reducing energy intake.

Increasing Energy Expenditure

Regular physical activity Although it is difficult to obtain accurate assessments of physical activity, there is little doubt that energy expenditure from activity has decreased in the past 50 years in most countries throughout the world. In contrast to popular belief, participation rates in organized leisure-time physical activity have increased in recent times in many countries. This supports the contention that the greatest contributor to this reduction in energy expenditure is associated with substantial changes in occupational and incidental physical activity. Changes in employment patterns and work practices together with a reliance on motorized transport and the removal of almost all manual labor from our daily lives have led to a dramatic reduction in daily physical exertion.

Studies that have examined the association between physical activity and weight gain and the impact of increasing physical activity on weight gain prevention have been limited by the ability to accurately measure physical activity and to engage people in sufficient levels of physical activity to prevent weight gain. However, there is sufficient evidence to support an important role for increasing physical activity in any weight gain prevention strategy, although questions remain about how much exercise is necessary and what type of exercise is appropriate to promote. The issue of the amount of extra time that people should spend in moderate physical activity to prevent weight gain remains hotly debated, but it is clearly substantially more than the 30 minutes on 5 or more days each week recommended by experts to reduce cardiovascular disease risk. The type of exercise that should be the focus of weight gain prevention strategies is also under review. It has been suggested that the most effective ways to include regular physical activity in daily living are through increased incidental activity, increased participation in active recreation, and increased use of active transport.

Reduced time spent in sedentary behaviors (especially TV watching) Changes in societal structures and improvements in technology have allowed a reduction in time spent at work or on domestic chores, leaving a greater proportion of the day for leisure. At the same time, most of the entertainment options developed to fill this time, such as watching television, playing video games, and using computers, are sedentary activities that require very little energy expenditure. These forms of entertainment, which initially complemented other forms of leisure activity, are occupying more hours of the day and are displacing more active pursuits and games. As a consequence, a number of studies have identified clear links between time spent in this sedentary behavior and weight gain. However, it is important to make a distinction between a lack of physical activity and sedentary behavior because their mechanisms for impacting on body weight may be different and a person with a high level of physical activity can also have a high level of sedentary behavior. Although the precise pathway by which sedentariness influences weight gain is not known, it is believed to involved both a reduction in physical activity and an increase in dietary energy intake through inappropriate food intake that is often stimulated by and accompanies sedentary activities.

Some studies in children have shown that programs that seek to reduce time spent in sedentary behaviors are more effective in controlling weight than programs that aim to increase physical activity alone. In some cases, a simple program to reduce the amount of time spent watching television was sufficient to significantly limit inappropriate weight gain in children.

Creating Supportive Environments

The external physical, social, political, and economic environments in which people exist have a profound effect on their attitudes and behaviors. Each day, people interact with a wide range of services, systems, and pressures in settings such as schools, the workplace, home, restaurants, and fast-food outlets. In addition, laws, policies, economic imperatives, and the views of governments, industry, and society as a whole influence these settings. Each of the features of this complex system, which shapes the environment in which we live, has the capacity to inhibit or encourage appropriate dietary and physical activity patterns. The availability of open space, access to public transport, the design of suburbs, access to buildings, the perceived level of safety, provision of lighting, and many other factors influence our capacity and desire to be more physically active in our daily lives. Similarly, advertising pressures, access to appropriate food choices, school food policies, and nutrition information and labeling all potentially influence food selection. Today, there is also a large commercial drive to promote obesogenic behaviors (cars and food are the two most advertised products on television).

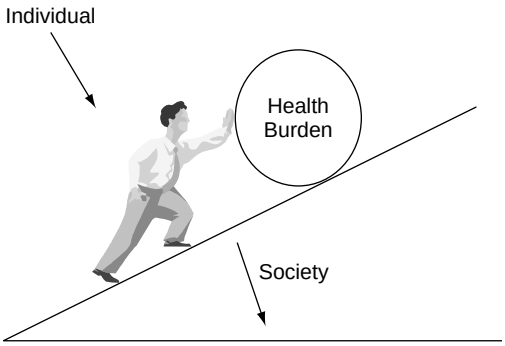

Figure 2 Influence of societal and environmental factors on development of obesity. (From House of Commons Health Committee (2004) *Obesity: Third Report of Sessions 2003–04. Volume 1. Report Together with Formal Minutes*. London: The Stationery Office Ltd.)

Trying to motivate people to make healthy choices when the external environment works against such behaviors is a recipe for failure. **Figure 2** illustrates the role that the social environment plays in assisting or inhibiting personal behavior choices made by individuals, which ultimately impact upon their health. Great success is likely to be achieved by creating a supportive environment and then promoting the healthy dietary and physical activity choices within such an environment.

Lessons from Past Prevention Efforts

Obesity Prevention Programs

A number of systematic reviews have assessed the current scientific literature on programs addressing the prevention of obesity in both children and adults and have identified only a limited number of evaluated programs. The reviews concluded that there was simply too small a body of research conducted in a limited number of settings to provide firm guidance on consistently effective interventions. However, reviews of childhood obesity prevention initiatives indicated that certain approaches appear to be associated with greater success. Intensive intervention in small groups was a successful management strategy in children, as was involving the entire

the family. Reducing levels of inactivity was successful at both treating and preventing weight gain. Some interventions that increased time spent in formal physical activity were successful in controlling weight gain, but generally multicomponent programs that addressed a range of strategies were deemed to hold the most promise.

There was general agreement that efforts should be heavily oriented toward preventing obesity in children because of the greater likelihood of success at a younger age. More effort needs to be directed at creating environmental and policy changes that will support the adoption of behaviors conducive to weight control rather than simply relying on education approaches.

Large-Scale Community Coronary Heart Disease and Diabetes Prevention Trials

Conducting large-scale, communitywide trials to address the prevention of obesity is a very expensive and difficult process; consequently, evidence of this nature is very limited. However, a number of large CVD and diabetes prevention trials have included weight as an intermediary outcome, which can also provide useful information about effective strategies to address obesity, and have demonstrated that it may be possible to prevent weight gain if not reduce weight at a population level.

The results of early large-scale community CVD prevention trials, such as the Stanford Three Community and Five Community studies as well as the Minnesota Heart Health Program, had limited impact on weight status and reinforced the difficulty of preventing weight gain in the community. However, later programs, such as the Pawtucket Heart Health Program, were able to make a modest impact on weight gain in the intervention community after 10 years. These programs demonstrate the time lag that can be expected between the implementation of a truly communitywide program and the extent of behavior change likely to be required to impact upon the weight status of the community. It has been suggested that unless weight is the primary outcome of the intervention, it is unlikely that sufficient focus will be placed on achieving the level of change required to impact on energy balance and community weight status.

Strong and consistent evidence of the success of large-scale weight gain prevention initiatives has been obtained from diabetes prevention trials that have addressed the progression to diabetes in people identified as glucose intolerant. Four large-scale trials have produced significant reductions in the rate of diabetes by focusing on exercise and diet, which resulted in small weight losses of approximately 3 or 4 kg on average. The largest trial conducted in the United States found that advice to reduce the energy and fat in the diet together with modest increases in physical activity, which was reinforced with regular follow-up from a 'coach,' led to an average weight loss of 5.6 kg and 58% reduction in the number of people progressing from impaired glucose tolerance to diabetes.

Lessons from Other Prevention Efforts

Although the number of successful large-scale obesity prevention programs is limited, there is a wealth of information from past public health programs that can be used to address other chronic diseases and risk factors. The International Obesity Task Force identified 10 key principles on which efforts to prevent obesity at a population level should be based. These are presented in **Box 2** and are drawn from experiences addressing cardiovascular disease, smoking, alcohol and drug problems, dental disease, road accidents, and other public health issues.

Although much has yet to be elucidated about the development of obesity and its effective management and prevention, there is a consensus that action to address the problem must not be delayed. Efforts to prevent weight gain need to be well

Box 2 IOTF principles for the development of population obesity prevention initiatives

1. Education alone is not sufficient to change weight-related behaviors. Environmental and societal intervention is also required to promote and support behavior change.
2. Action must be taken to integrate physical activity into daily life, not just to increase leisure time exercise.
3. Sustainability of programs is crucial to enable positive change in diet, activity, and obesity levels over time.
4. Political support, intersectoral collaboration, and community participation are essential for success.
5. Acting locally, even in national initiatives, allows programs to be tailored to meet real needs, expectations, and opportunities.
6. All parts of the community must be reached, not just the motivated healthy.
7. Programs must be adequately resourced.
8. Where appropriate, programs should be integrated into existing initiatives.
9. Programs should build on existing theory and evidence.
10. Programs should be properly monitored, evaluated, and documented. This is important for dissemination and transfer of experiences.

Treatment

E C Uchegbu, Royal Hallamshire Hospital, Sheffield, UK

P G Kopelman, Queen Mary's, University of London, London, UK

Introduction

Increasing body weight is associated with increasing health risks (**Table 1**). Randomized controlled trials demonstrate that weight reduction reduces these health risks and confirm the value in treating overweight and obesity.

Obesity is a chronic disease of multiple etiologies characterized by an excess of adipose tissue. Recent research has begun to unravel the biochemical and genetic factors implicated in its etiologies. As a result of the factors that determine its severity, health risks, and response to therapy, treatment must be tailored to specific needs. The ability of a treatment to maintain long-term weight reduction is as important as its ability to cause the initial weight loss. In several studies inability in maintaining the lowered weight is the cause of the treatment failure.

Nevertheless, a successful program should also lead to an improvement in the quality of life, self-esteem, social functioning, anxiety, and depression.

Several professional, governmental, and other organizations have drawn up guidelines for obesity management. These strategies for providing care to the obese patient provide useful evidence-based guidance for clinical management.

Health Risks due to Overweight/Obesity

Increasing body fatness is accompanied by profound changes in physiological function. These changes are, to a certain extent, dependent on the regional distribution of adipose tissue. Generalized obesity results in alterations in total blood volume and cardiac function while the distribution of fat around the thoracic cage and abdomen restricts respiratory excursion and alters respiratory function. The intra-abdominal visceral deposition of adipose tissue, which characterizes upper body obesity, is a major contributor to the development of hypertension, elevated plasma insulin concentrations and insulin resistance, hyperglycemia, and hyperlipidemia. The alterations in metabolic and physiological function that follow an increase in adipose tissue mass are predictable when considered in the context of normal homeostasis.

Table 1 Obesity-associated diseases and conditions

Disorder	*Associated diseases and conditions*
Cardiovascular disorders	Coronary heart disease
	Hypertension
	Cerebrovascular disease
	Deep vein thrombosis
	Pulmonary embolism
Respiratory disorders	Obstructive sleep apneas
	Obesity hypoventilation syndrome
	Breathlessness
Gastrointestinal disorders	NASH (nonalcoholic steatohepatitis)
	Cirrhosis
	Gallstones
	Colorectal cancer
	Hiatus hernia/ gastroesophageal reflux
Renal disorders	Proteinuria
Reproductive disorders	Primary ovulatory infertility
	Development of gestational diabetes
	Increased risk of neural tube defects
Musculoskeletal disorders	Osteoarthritis
	Gout
	Nerve entrapment
Genitourinary	Endometrial cancer
	Prostate cancer
	Stress incontinence
Metabolic and endocrine disorders	Artherogenic lipid profile
	Insulin resistance
	Type 2 diabetes mellitus
	Polycystic ovary syndrome
	Postmenopausal breast cancer
	Hirsuitism
Skin disorders	Acanthosis nigricans
	Lymphoedema
	Sweat rashes

Ethnicity has an impact on body fat distribution and adipose tissue metabolism. Overweight currently is defined as a body mass index (BMI) $>25\,kg\,m^{-2}$ and obesity as a BMI $>30\,kg\,m^{-2}$. The evidence for this is drawn from large population studies that suggest people with a BMI of $19–25\,kg\,m^{-2}$ have the lowest mortality. However, there have been proposals to define race-specific standards according to ethnic background. Specifically, Asians have greater visceral fat and associated morbidity than do Caucasians. A BMI as low as $23\,kg\,m^{-2}$ may be associated with weight-related diabetes or insulin resistance in these groups. For any given weight category, the presence of certain complications moves the individual into a higher health risk category. Evaluation of such risks should be part of the intervention program.

Patient Selection

Obesity and overweight are chronic conditions. Short-term programs are likely to be ineffective, with rapid weight regain once treatment is stopped. Treatment programs must be for the longer term and include measures to prevent relapse. Preventing further weight gain in those at risk should also form part of obesity management and help ensure an appropriate use of resources. Those at risk will include moderately overweight subjects and those who have upper body obesity. Weight loss is indicated in adults with a BMI of more than $25\,kg\,m^{-2}$ and/or abdominal girth of more than or equal to 102 cm in males and more than or equal to 88 cm in females. Additional important treatment areas include weight gain in infancy, adolescence, and pregnancy. A family history of obesity or associated diseases, fat distribution, and risks for coronary heart disease are individually important factors that may influence treatment mode.

Treatment Aims and Realistic Weight Loss Goals

Treatment aims to improve health and well being and decrease the risks of ill health later in life, through reducing the amount and possibly distribution of body fat. The success or failure of any treatment program may be judged by an arbitrarily chosen weight or percentage weight loss. Hence, the evidence that modest degrees of weight loss produce significant health gain influences the success or failure of any treatment. With this background it is logical to redefine successful treatment in terms of a decrease in the severity of obesity rather than a return to normal weight. Even weight stabilization without weight loss represents a modestly successful outcome compared to the natural history of obesity, which is progressive weight gain. A weight loss of between 5 and 10% of the initial body weight is associated with clinically useful improvements in terms of blood pressure, plasma cholesterol, and a significant improvement in diabetic control (see **Table 2**). Weight loss should be approached incrementally with new weight goals negotiated with the patient if the original target is achieved. Goals for older patients (>65 years) will be different from those who are young; data suggest that a population becomes heavier with age whereas the risk from obesity does not increase proportionately.

Dietary Treatment of Obesity

The primary determinant of weight loss is energy deficit. Short-term weight loss has been achieved by

Table 2 Benefits of 10 kg weight loss

Condition	*Health benefit*
Mortality	Fall of more than 20% in total mortality
	Fall of more than 30% in diabetes-related death
	Fall of more than 40% in obesity-related cancer death
Blood pressure	Fall of 10 mm Hg systolic blood pressure
	Fall of 20 mm Hg diastolic blood pressure
Diabetes	Fall of 50% in fasting glucose
	Reduces risk of developing diabetes by 50%
Lipids	Fall of 10% in total cholesterol
	Fall of 15% in LDL cholesterol
	Fall of 30% in triglycerides
	Rise of 8% in HDL cholesterol

Adapted with acknowledgment from the Scottish Intercollegiate Guidelines Network (SIGN) Obesity in Scotland: integrating prevention with weight management. A national clinical guideline recommended for use in Scotland. Edinburgh (1996).

energy reduction in diets of varied macronutrient composition. Obesity is a chronic and relapsing disease; hence, it is the long-term efficacy of these dietary strategies in maintaining lowered weight (and minimizing the risk of diet-related chronic diseases) that is of fundamental importance.

Types of Dietary Treatment

There are several dietary strategies available both in a clinical and commercial setting. These diets vary greatly in the degree of caloric restriction, relative amounts of macronutrients (protein, carbohydrate, fat), medical supervision, scientific basis, and cost. These diets can be broadly divided into:

- low-calorie diets ($\geq$3400 kJ (800 kcal) day^{-1}, typically 3400–6300 kJ (800–1500 kcal) day^{-1})
- very low-calorie diets ($<$3400 kJ (800 kcal) day^{-1})

Traditionally, low-calorie diets that incorporate various methods for restricting food intake have been recommended for weight management.

Such treatment requires a period of supervision for at least 6 months. A review of 48 randomized control trials (RCTs) shows strong and consistent evidence that an average weight loss of 8% of the initial body weight can be obtained over 3–12 months with a low-calorie diet (LCD) and this weight loss causes a decrease in abdominal fat, the adipose tissue deposition that is associated with the highest disease risk. Very low-calorie diets (VLCD) have been shown to reduce weight at a greater rate in the first 2–3 months compared to low-calorie diets but have not been associated with superior maintenance of lost weight after a year. A review of weight loss trials of LCD and VLCD with available follow-up during 2–7 years showed that long-term weight loss in most trials is in the range of 2–6 kg.

Low-fat, high-carbohydrate diets Low-fat, high-carbohydrate diets have played a central role in the dietary management of overweight and obesity. Generally, these strategies aim to provide a macronutrient composition of 25–35% energy from fat, 45–60% from total carbohydrate, and 15–20% from protein, thereby moving individuals towards national dietary guidelines (COMA reports). A review of controlled clinical trials demonstrated that a 10% reduction of dietary fat leads to a $\sim$3–4-kg weight loss in normal overweight subjects and $\sim$5–6-kg weight loss in the obese. Evidence from a recent systematic review suggests that a low-fat diet is equally as effective in achieving long-term weight loss in overweight and obese subjects as alternative dietary strategies. Low-fat high-carbohydrate diets may have a role in weight maintenance. Combined with physical activity and behavioral strategies, the American Diabetes Prevention Program and the Finnish Diabetes Prevention Trial demonstrated maintenance of modest weight loss (3–4 kg) with a marked reduction in the risk of developing type 2 diabetes mellitus over a 4-year study period.

Low glycemic index diets The glycemic index (GI) is a dietary concept originally developed for the therapy of diabetes, which has recently become popular despite scant evidence of its effectiveness in weight management. The GI is a property that describes the effect of carbohydrate from a given food on postprandial blood glucose. It is measured by comparing the blood glucose response of the test food with that of a reference food (usually white bread). Low-GI foods are more slowly absorbed leading to an attenuated and prolonged insulin and metabolic response to foods; it is suggested that more moderate blood glucose and metabolic response may sustain satiety and energy balance to a greater extent than larger metabolic shifts would.

Epidemiological analyses link low-GI load diets to a more favorable lipids profile and reduced incidence of type 2 diabetes mellitus and cardiovascular disease. Evidence from interventional studies supports the benefits of low-GI diets in reducing the risks of coronary heart disease and diabetes but there are no long-term studies that have evaluated its weight-loss efficacy. Therefore, it is appropriate to promote the constituents of a low-GI diet (increased legumes, wholegrain cereals, and fruit consumption) as part of a well-balanced hypo-caloric diet for the long-term management of obesity and its metabolic complications.

High-protein, low-carbohydrate diets High-protein diets have recently been popularized as a means of rapid weight loss despite the lack of objective evidence in long-term efficacy and safety. Typically, these diets offer wide latitude in protein food choices,

and are restrictive in other food choices (mainly carbohydrate). Animal protein rather than plant protein is advocated leading to a higher intake of total fat – mainly saturated fat and cholesterol. Many of the popular high-protein diets promote protein intake of 28–64% of dietary energy, which exceeds established requirement of 10–15%, and severely limit carbohydrate dietary energy to 3–10%. A recent popular high-protein, low-carbohydrate diet, the Atkins diet, provides on average 27% energy from protein, 5% energy from carbohydrates, and 68% energy from fat. The diet results in the avoidance of important staple foods, such as bread, pasta, rice, potatoes, and cereals, as well as foods high in sugars. Consumption of fruits, vegetables, whole grains, and low-fat dairy products, foods associated with lowering blood pressure and protecting against cancer and heart disease, are all limited.

The initial weight loss in high-protein diets is high due to fluid and glycogen loss related to low carbohydrate intake, overall caloric restriction that is encouraged by structured eating plans, restricted range of foods allowed, and limited tolerance of high-protein foods. This often promotes a misconception about weight loss by suggesting that it is not related to total energy intake but is due to exclusion of certain foods.

A recent systematic review of the efficacy of low-carbohydrate, high-protein diets demonstrates that the amount of weight loss is principally associated with decreased caloric intake rather than reduced carbohydrate content. Researchers have yet to establish whether individuals can maintain long-term weight loss with a high-protein, low-carbohydrate diet because of the short duration of these studies, and long-term adverse effects are also unknown. Possible negative effects include increased risks of cardiovascular disease, renal disease, cancer, osteoporosis, and compromised vitamin and mineral status.

Energy prescribed diet This dietary strategy determines the daily energy requirement for weight loss by calculating energy expenditure, adjusting for physical activity, and subtracting an energy deficit to induce weight loss –usually 2100–2520 kJ (500–600 kcal) for 0.05 kg weight loss. As a result the prescribed diet will often be in excess of 3400–6300 kJ (800–1500 kcal). The popularity of this approach relates to the findings of improved compliance in those advised on a 2520 kJ (600 kcal) deficit diet compared to a traditional fixed energy intake of 5040 kJ (1200 kcal) day^{-1}.

Formulas and meal replacements Meal replacements are another category of calorie-controlled diets. These include nutritional fortified shakes, snack bars, and low-calorie frozen meals. An entire meal or snack is replaced with a portion controlled prepackaged meal or drink that provides approximately 840–1260 kJ (200–300 kcal), although formulations and nutrient content vary. Meal replacements are designed to be eaten with additions of conventional foods that supply dietary fiber, other nutrients, additional calories, and water. Most weight loss programs that use meal replacements recommend replacing two meals and one snack a day to lose weight and then replacing one meal per day to maintain weight loss. This strategy generally provides 5040–6729 kJ (1200–1600 kcal) day^{-1} and the regular meal should meet the recommendations of a healthy diet.

A recent meta-analysis that summarized the efficacy of this approach compared to conventional energy-restricted diets suggests that it is an effective weight-loss strategy both in the short and long term in a clinical trial setting. There is no information about the efficacy outside a clinical trial where meal replacement products need to be purchased, and are frequently discontinued at an early stage.

Very low-calorie diets Very low-calorie diets are formula foods; they are designed to provide larger and more rapid weight loss than the standard low-calorie diets. They are commonly given in liquid form to completely replace usual food and snack intake providing in the region of 1890–3400 kJ (450–800 kcal) day^{-1}. To reduce the potential risks from loss of lean body tissue, VLCDs are enriched in protein of high biologic value and also includes the full complement of recommended daily allowance for vitamins, minerals, electrolytes, and fatty acids. However, diets providing such low-energy intakes are often associated with a feeling of fatigue, constipation, nausea, and diarrhea. A most serious complication associated with VLCD is the development of symptomatic cholelithiasis associated with the rapid weight loss (1–2 kg $week^{-1}$).

Owing to the potential adverse effects of these diets, they are generally reserved for short-term treatment in individuals who are moderately to severely obese (BMI $>35\,kg\,m^{-2}$) and who have failed at more conservative approach to weight loss, in particular in those with medical conditions that may respond to weight loss such as obstructive sleep apnea, type 2 diabetes mellitus, or prior to surgical procedure.

Weight regain is common with the reintroduction of food. Studies show that in the long term, VLCDs are no more effective than more modest dietary restriction.

Commercial Slimming Organizations and Products Such organizations are profit-making ventures. However, they have been shown to be economical, practical, and an effective way of providing care for a large number of moderately obese people in the community. Weekly meetings serve to encourage and reinforce active participation by members, who learn through the exchange of ideas within the group. Weight losses achieved by commercial groups are comparable to those seen in general practice or hospital outpatient clinics. When behavioral techniques are added to the basic program of balanced diet, the results are further improved.

Over recent years there has been increasing use of weight loss-related web sites on the Internet, which are directed mainly at females. The content and structure of these web sites vary widely. They often lack professional contact and the expertise to deal with medical complications.

Behavior Treatment

Behavior therapy provides an important approach to losing and maintaining weight. The focus is on behaviors related to body weight, namely food intake and physical activity. It serves to identify the abnormal eating behaviors and life style developed over the years and helps to unlearn them and allow body weight to return to normal. The behavior techniques used include self-monitoring, stimulus control, and, recently, cognitive therapy, which involves identifying and changing negative thoughts.

The key difference between behavioral methods and other forms of treatment is that the individual must take responsibility for initiating and maintaining treatment rather than relying on external forces.

There are several elements of behavioral treatment (see **Table 3**). Evidence from RCTs confirms that behavioral strategies reinforce changes in diet and physical activity in obese subjects to produce weight loss of 10% over 4 months to 1 year. Longer term followup shows a return to baseline in the absence of continuing behavioral intervention.

Eating patterns and behaviors are, to a greater extent, acquired by learning, and for this reason there has been much interest in modifying the behavior within the family setting. Obese children are more likely than nonobese children to become obese adults. Behavior therapy seems to be effective in arresting this process in some children.

Table 3 Elements of behavioral treatment

Element	*Intervention strategy*
Self-monitoring	Observe, record, and provide feedback on: • food consumption (food diary) • physical activity (activity diary, pedometer) • weight record
Goal setting	Realistic weight-loss goals Separate short-term from long-term goals Focus on health benefits
Stimulus control	Identify and modify environmental barriers: • healthy eating, normalize eating pattern • increasing daily energy using activities
Problem solving	Handling emotional issues and social events: • examine situation • choose a solution and implement it • evaluate the outcome
Cognitive change	Changing inaccurate belief about weight loss • examine thought and feelings • challenge inaccurate ones • use positive self-affirmations

Exercise and Physical Activity

Exercise produces fat loss in obese and normal weight subjects, although losses rarely exceed 5% of body weight. For any given weight loss, fat-free mass (FFM) is better preserved in exercising than nonexercising subjects: this is likely to be important in the long term because FFM is the best predictor of resting metabolic rate, which is the largest contributor to daily energy expenditure for all but active athletes.

There are other beneficial effects of exercise that are independent of its effects on weight loss. Regular exercise reduces blood pressure, improves insulin sensitivity, both in association with or independent of weight loss. Favorable effects on the atherogenic lipid profiles have also been reported with exercise and physical training in obese subjects. Such benefits are substantial and should be emphasized to all patients; however, persuading an obese person to participate in regular physical activity and to maintain exercise as a part of daily routine is not easy.

One of the most consistent findings in studies of physical activity is enhanced weight maintenance for at least 2 years from the start of the intervention. It is not necessary to increase maximal oxygen uptake in the obese to derive benefit from exercise: metabolic evidence of fitness is achieved with less vigorous exercise.

Physical activity recommendations suggest 30 min of moderate activity on at least 5 days of the week. This level of activity is associated with improved fitness and protection from cardiovascular diseases. When using exercise solely as a strategy for weight reduction, longer duration of daily activity of a moderate intensity lasting 45–60 min is required.

Reduction in the time spent in sedentary behaviors (such as television watching) is an important

strategy for increasing physical activity and energy expenditure. Similarly, encouraging findings have been observed in children and adolescents advised to include more lifestyle activity (e.g., walking versus car use) compared to those with traditional programs of activity.

Drug Treatment of Obesity

Rationale

Diet restriction even when combined with behavioral therapy and increased exercise is often unsuccessful in achieving weight loss and maintenance in obese subjects. Obesity is not a single disorder but a heterogeneous group of conditions with multiple causes. Although genetic differences are of undoubted importance, the marked rise in the prevalence of obesity is best explained by behavioral and environmental changes that have resulted from technological advances. In such circumstances, it is appropriate to consider pharmacological treatment as an adjunct to the other treatment modalities.

In broad terms a pharmacological agent can cause weight loss by reducing energy intake or absorption/and by increasing energy expenditure. Current drug treatment of obesity is directed at reducing energy/food intake either by an action on the gastrointestinal system or via an action through the central nervous system control of appetite and feeding.

Selection of Patients

Pharmacological treatments of obesity have had a controversial history and are still regarded with skepticism and suspicion by some medical practitioners. This results from experiences with older agents that turned out to have serious side effects and were withdrawn as a result. Current agents approved for use have been shown to be safe and effective both in weight reduction and in the improvement of comorbidities of obesity. Nevertheless, it is important that doctors who prescribe such drugs are fully familiar with the mode of action and potential risks.

Several sets of guidelines have been developed for the use of drugs in the treatment of obesity. In the UK, The Royal College of Physicians' guidance on the use of anti-obesity drugs suggests that it may be appropriate to consider use of drugs after at least 3 months of supervised diet, exercise, and behavioral management. Exceptionally, this period may be shortened when the clinician judges that drug treatment is justified at an earlier stage due to over-riding medical circumstances. **Table 4** lists the criteria that should be applied to judge the suitability of a patient for drug treatment.

Table 4 Criteria for selecting obese patients suitable for obesity drug treatment

- Drug treatment may be appropriate where diet and exercise have not achieved acceptable weight loss relative to medical risk
- In such patients drug treatment may be appropriate for:
  - those whose BMI is more than 30
  - those with established comorbidities whose BMI is more than 27, if the drug license permits
- Weight-lowering drugs should be targeted at those at high risk from obesity, not obesity alone

The following groups will have priority for drug treatment

- Patients with established comorbidities such as type 2 diabetes, hypertension, and dyslipidemia
- Patients who are physically restricted by their weight either because of breathlessness or arthritis
- Patients considered to be at high risk – for example, those with a family history of overweight or obese parents who died prematurely from CHD or developed type 2 diabetes with complications

The criteria applied to the use of an anti-obesity drug are similar to those applied to the treatment of other relapsing disorders. It is important to avoid offering anti-obesity drug therapy to patients who are seeking a 'quick fix' for their weight problem. The initiation of drug treatment will depend on the clinician's judgement about the risks to an individual from continuing obesity. It may be appropriate after at least 3 months of supervised diet, exercise, and behavioral management, or at a subsequent review, if a patient's BMI is equal to or greater than $30\,kg\,m^{-2}$ and weight loss is less than 10% of the presenting weight. In certain clinical circumstances it may also be appropriate to consider anti-obesity drug treatment for those patients with established comorbidities whose BMI is $27\,kg\,m^{-2}$ or greater if this is permitted by the drug's licence (see **Figure 1**). An anti-obesity drug should not be prescribed for a patient whose BMI is less than that specified in the product licence for the drug – the licence indication does not presently take account of the morbidity from obesity seen in certain populations at a lower BMI.

The experience from the use of anti-obesity drugs during 12–24 month randomized controlled trials indicate that approximately 50% of the actively treated patients respond as judged by 5–10% reduction in body weight maintained over 12 months. The weight loss occurs in the 'responder' group within 12 weeks. This indicates a suitable time period when a response to drug treatment can be identified and a decision taken to continue the medication. Continuing assessment of drug therapy for efficacy and safety is essential. If the drug is efficacious in helping a patient to lose and/or maintain weight loss, and there are no serious side effects, it may be continued.

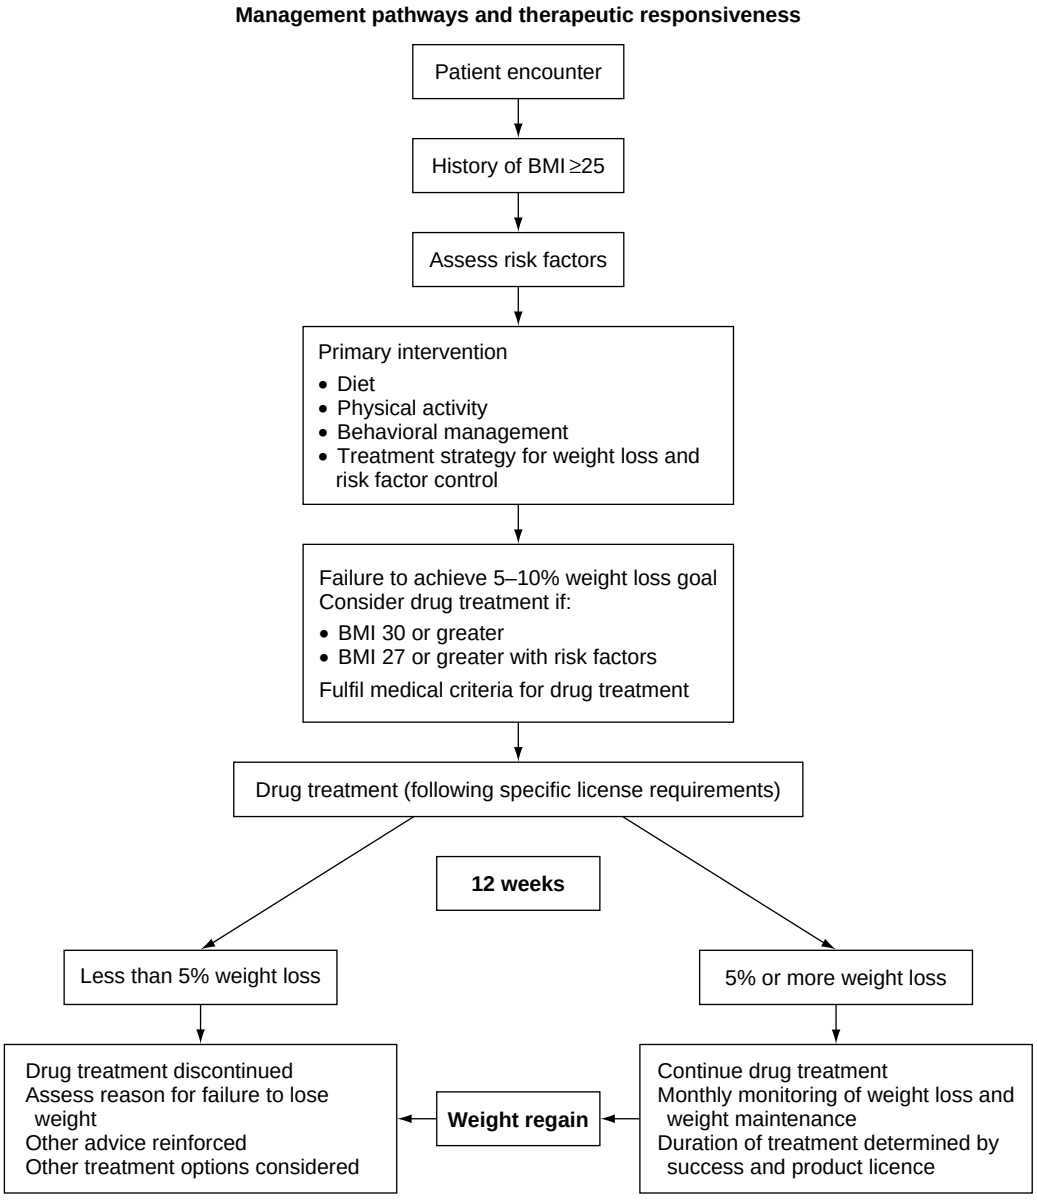

Figure 1 A management pathway for the appropriate prescription of an anti-obesity drug. (Adapted with permission from RCP Guidelines 2003.)

If not, it should be discontinued. Once a weight loss target has been achieved, there should be an opportunity for re-negotiation of a new target, if indicated, and/or long term monitoring with reinforcement.

Types of Drugs

The two categories of anti-obesity medication currently licensed for use in obese subjects are:

1. Those that act on the gastrointestinal system (pancreatic lipase inhibitors) as malabsorption agents to inhibit nutrient absorption.
2. Those that act on the central nervous system primarily to reduce hunger perception.

Drugs acting on the gastrointestinal system

Orlistat Orlistat is a gastric and pancreatic lipase inhibitor that reduces the absorption of dietary fat in a dose-dependent manner. At the therapeutic dose of 120 mg three times a day, it blocks the absorption of about 30% of dietary triacylglycerol resulting in an energy deficit of 850 kJ (200 kcal) day^{-1} for an individual on an average diet of 9240 kJ (2200 kcal) day^{-1} with 40% of calories from fat.

Adverse effects of orlistat are predominantly related to its gastrointestinal action of fat malabsorption and can be associated with a modest reduction in fat-soluble vitamins (A, D, E, and K). However, clinical deficiency has not been reported in clinical trials. Nevertheless, it is recommended that patients taking orlistat receive vitamin supplements. Patients may complain of loose or liquid stool, fecal urgency, anal leakage, and infrequently fecal incontinence due to undigested fat. These adverse effects become less common with longer duration of treatment suggesting that patients learn to avoid high-fat meals to avoid these side effects hence enforcing behavioral change. This may well contribute to the therapeutic effects of orlistat treatment. Orlistat is minimally absorbed (less than 1%) and systemic events are negligible.

Drugs acting on the central nervous system These drugs are commonly referred to as appetite suppressants, which is only one of their actions. Some of these agents have been proven to enhance satiety and slow gastric emptying; and an increase in energy expenditure has also been suggested. They act by increasing the neurotransmitter activity in the brain centers that regulate food intake.

Sibutramine Sibutramine enhances the sensation of satiety after a meal by its central action as a serotonin and/or epinephrine re-uptake inhibitor. Sibutramine is a beta-phenethylamine and is well absorbed following oral administration. It undergoes extensive first pass metabolism in the liver to produce two pharmacologically active metabolites that have long elimination half-lives of 14–16 h.

Side effects commonly reported in clinical trials include dry mouth, constipation, anxiety, rhinitis, and insomnia but these rarely led to withdrawal from the study. The noradrenergic actions of the drug may cause an increase in blood pressure and heart rate in some patients or prevent the expected fall in these parameters with weight loss. It should not be given in patients with uncontrolled hypertension. It should not be given concomitantly with monoamine oxidase inhibitors, nor other centrally acting anorexic drugs, or sympathomimetic agents including cold remedies such as pseudoephedrine.

Phentermine and diethylpropion Published evidence of the use of phentermine and diethylpropion indicates short-term induction of weight loss that is frequently followed by weight regain on cessation of the drug. There are no recently published randomized controlled trials of the drugs demonstrating efficacy beyond 26 weeks. Both drugs remain restricted to 3 month's use in the terms of their product license.

Rimonabant (SR 141716) Rimonabant is a selective central cannaboid (CB1) receptor antagonist. It is an appetite suppressant in advanced development for obesity treatment. The rationale behind this drug is to reduce appetite by blocking cannaboid receptors in the hypothalamus. The central cannaboid (CB1) receptors are believed to play a role in controlling food consumption and the phenomena of dependence/habituation.

Preliminary results from a 2-year international multicenter study confirm its effectiveness in weight reduction, reduction in waist circumference (a marker of the dangerous abdominal obesity), and improvements in lipids and glycemic profiles. The study also confirmed its good safety profile. The side effects reported were mainly mild and transient and most frequently involved nausea, diarrhea, and dizziness.

Rimonabant has potential as a treatment for smoking cessation because the central cannaboid system is also involved in the body's response to tobacco dependence.

Prescribing guidelines for anti-obesity drugs

Anti-obesity drugs should be prescribed in an appropriate clinical setting that includes systems for monitoring and follow-up of progress. The choice of anti-obesity drug is largely dependent on the experience of the prescriber in using one or another agent (see **Table 5**). For the two agents currently recommended for use there are no good clinical studies that have directly compared them or have explored which particular patient will benefit more from one than the other. A drug should not be considered ineffective because weight loss has stopped, provided the lowered weight is maintained.

The Elderly and Children

There is limited information about the use of anti-obesity drugs in patients over the age of 75 years. In such circumstances, the accepted practice is to aim for weight maintenance rather than weight loss. Neither drug is licensed for use in children.

Surgical Treatment for Obesity

Surgical treatment is an appropriate intervention for the management of morbid obesity. Criteria for selection of patients suitable for surgery are listed in **Table 6**.

Table 5 Comparison of actions and indications for use of sibutramine and orlistat

	Sibutramine	*Orlistat*
Mode of action	Promotes satiety Enhancing effect on thermogenesis	Dietary fat malabsorption
Indication	Adjunct to diet in obese patients with BMI $\geq$30 kg m^{-2} without comorbidities or BMI $\geq$27 kg m^{-2} with comorbidities	Adjunct to diet in obese patients with BMI $\geq$30 kg m^{-2} without comorbidities or BMI $\geq$28 kg m^{-2} with comorbidities
Suitable for	Those with uncontrollable appetite Frequent snackers Nocturnal eaters Those with need for immediate weight loss for medical reasons Those without contraindication to its use (specifically cardiac abnormalities or elevated blood pressure, i.e., >145/95 mm Hg) Patients with low HDL cholesterol	Those who have lost at least 2.5 kg through diet and lifestyle modification Patients requiring longer term behavioral changes whose dietary assessment suggests high-fat intake Patients with impaired glucose tolerance Those with elevated LDL cholesterol Chronic malabsorption Cholestasis
Specific contraindication	Tourette syndrome Cardiovascular disease Congestive cardiac failure Hypertension Hyperthyroidism, phaechromocytoma Pregnancy, breastfeeding	Pregnancy, breast feeding
Duration of treatment	Not more than 1 year	Maximum of 2 years

Types of Obesity Surgery

At least 30 surgical techniques have been developed for the treatment of obesity. Superficial cosmetic removal of adipose tissue (liposuction) will not be considered because it has no lasting benefit and it is not regarded as a treatment for obesity. Jaw wiring (intermandibular fixation) can restrict intake of food but it is no longer recommended for surgical treatment of obesity due to a lack of long-term efficacy.

The operative procedures currently used for the surgical treatment of obesity are outlined below.

Gastric restriction Gastric restriction can by achieved by gastroplasty or gastric banding. Gastroplasty techniques involve the fashioning of a proximal pouch of the stomach by vertical stapling and a constrictive band opening, thereby restricting the gastric volume to approximately 15–20 ml that empties into the remainder of the stomach.

Gastric banding involves the external 'pinching off' of the upper part of the stomach with a band usually made of Dacron. A modification of the gastric banding is an inflatable circumgastric band attached to a subcutaneous reservoir that allows access by a hypodermic syringe to inject or withdraw fluid thereby tightening or enlarging the bandwidth. This operation can be performed laparoscopically, significantly improving the perioperative safety of operating for the severely obese patients.

Gastric restriction operations require strict dietary compliance because an intake of high caloric liquids or soft foods are not inhibited by the narrow outlet and may explain a failure to lose weight. The advantage of these techniques is very low operative mortality (<1%) and relative lack of long-term nutritional deficiencies. The reported excess weight loss after 3–5 years is between 40 and 60% but there is a slow regain thereafter.

Table 6 Criteria for patient selection

- BMI $\geq$40 kg m^{-2}
- BMI $\geq$35 kg m^{-2} with serious comorbidity demonstrated to be responsive to weight loss
- Failure to achieve weight loss with conventional means
- Able to lose weight prior to surgery
- Have no evidence of psychiatric disease or maladaptive eating behaviors
- Absence of endocrine disorders that can cause morbid obesity
- Psychological stability:
  - Absence of alcohol and drug abuse
  - Understanding of how surgery achieves weight loss
  - preoperative psychological evaluation for selected patients

Gastric by-pass A 20–30-ml pouch is created by staples and connected to the jejunum transected 50 cm from the ligament of Treitz (Roux-en-Y gastric bypass). It results in weight loss by both restrictive and malabsorptive mechanisms. Published evidence confirms this procedure produces greater weight loss compared to gastric restrictive techniques but more frequent adverse effects including 'dumping' and nutritional deficiency may accompany it. Its operative mortality is approximately 1%.

Biliopancreatic diversion Biliopancreatic diversion includes a gastric resection and diversion of the biliopancreatic juice to the terminal ileum to reduce the absorption of nutrients. In this operation, an entero-entero anastomosis is performed between the proximal limb of the transected jejunum and ileum, 50–100 cm proximal to the ileocecal valve.

Biliopancreatic diversion achieves up to 78% excess weight loss at 5 years. Nutritional deficiencies are relatively common (between 5 and 40% of patients for the longer term). In addition, alterations in bowel movements are frequent with 3–5 motions, commonly offensive, occurring each day.

Efficacy of Surgical Treatment for Obesity

Surgery is usually successful in inducing substantial weight loss in the majority of obese patients. This is achieved primarily by a necessary reduction in calorie intake.

In a review of RCT comparing different treatment strategies of obesity, surgery resulted in greater weight loss (23–28 kg more weight loss at 2 years) with improvement in quality of life and comorbidities.

The Swedish Obese Subjects (SOS) study demonstrated long-term beneficial effects on cardiovascular risk factors. The development of type 2 diabetes mellitus is most favorably influenced with a 14-fold risk reduction in those obese patients undergoing surgical treatment.

A Multidisciplinary Approach to the Management of Overweight and Obesity

Published evidence confirms that patients do better whatever the treatment when seen more frequently and for a greater length of time. Moreover, strategies that involve expertise incorporating dietetic, behavioral, and exercise experts as well as physicians and surgeons are also more successful in sustaining weight loss. This underlines the importance of a multidisciplinary approach. Treatment programs should include a system for regular audit and the provision for change as a result of the findings. Any center that claims to specifically provide expertise in weight management should incorporate the essential elements outlined in Table 7.

Table 7 Essential elements of an appropriate setting for obesity management

- Trained staff directly involved in the running of the weight loss program. These staff (medical, nursing, and other healthcare professionals) should have attended courses on the management of obesity and must be given the opportunity to continue their education
- Printed program for weight management that includes clear advice on diet, behavioral modification technique, physical exercise, and strategies for long-term lifestyle changes. Such a program may include a family and/or group approach
- Suitable equipment, in particular accurate and regularly calibrated weighing scale and stadiometer
- Specific weight-loss goals for patients with energy deficit being achieved by moderating food intake and increasing physical expenditure
- Documentation of individual patients' health risks. This will include BMI, waist circumference, blood pressure, blood lipids, and cigarette smoking and comorbid conditions
- A clearly defined follow-up procedure that involves collaboration between the different settings of care, and provides regular monitoring and documentation of progress, along with details of criteria for judging the success of weight loss. This will allow a weight loss program to be properly supported, medical conditions to be monitored, and problems or issues to be addressed at the earliest opportunity. It is also advisable to have a checklist of possible adverse drug effects, e.g., anxiety, disturbances of sleep, breathlessness, depression, and diarrhea.

Strategies for Weight Loss Maintenance

Preventing regain of fat losses is the major challenge of weight maintenance. A program to enable the individual to maintain their lowered weight must follow any successful weight loss. Published evidence suggests that a combination of dietary and physical activity modifications and reinforcement of behavioral methods are the most effective in the long term. These modifications needs to be integrated and accepted as a way of life and the responsibility for following this must lie with the patient.

Physiological Changes

N Solomons, Center for Studies of Sensory Impairment, Aging and Metabolism (CeSSIAM), Guatemala City, Guatemala

The Aging of the Population and its People

The maximal human life span is about 120 years. Approaching this degree of longevity, however, was not a prominent feature in the evolutionary phases of our species, *Homo sapiens*. The imperative was to survive the various mortal hazards long enough to reproduce and provide initial care for the offspring. The twenty-first century has ushered in an unprecedented longevity. The life expectancy of infants born today in Western Europe or Japan is over 75 years. The most rapidly increasing population segment in the world today is the centenarian. By the year 2020, there will be over 1 billion people over 60 years of age, constituting 13.3% of the global population, and three-quarters of them will be living in developing countries.

Many people are living a long time, but not all of them are healthy and functional throughout their lifespan. Chronic disability and the cost of health

services and custodial care are a growing burden on the economies of developed and developing countries alike. In order to understand the pathological aspects of advancing age, the normative pattern of changes in physiological function in older persons is an essential benchmark.

The Nature of Senescence

Aging has been described as "a series of time-related processes that ultimately bring life to a close," that is, a process of physiological 'wearing out.' Physiology is the basis of human functionality, as well as of our susceptibility to disease. The late gerontologist, Nathan Shock, established the principle of a progressive decline in physiological reserves as a consequence of 'normal' aging, recognizing that the rate of decline differed markedly among the body's organ systems. In fact, one cannot really separate the concept of the physiology of older persons from the physiology of the aging process itself. Similarly, the high prevalence of chronic diseases in older persons challenges our ability to discriminate 'normative' senescence from pathophysiological changes.

The origin of physiological changes in older persons begins within the domain of cellular senescence. The extension to tissue and organ levels originates in what we interpret to be the physiological changes of human aging. Major advances in our cellular and molecular understanding of basic aging processes have been made in recent years.

Cellular Senescence

In most tissues, with the notable exception of neural tissue, healthy cells are replicating cells, which are capable of mobilizing at least 20 enzymes and proteins that must be preassembled to initiate DNA synthesis for cell division. An irreversible state of growth arrest known as replicative senescence is the fundamental basis of cellular aging. Such senescent cells remain viable and metabolically active, but their genomic function and protein expression are distinct from that of normal, proliferating cells. Iron accumulates in senescent cells, possibly contributing to the greater oxidative stress and cellular dysfunction seen in senescent cells. Senescent cells also express proinflammatory enzymes, an internal process that could possibly contribute to the aging process; intercellular adhesion molecules, which are part of the inflammatory response, are overexpressed in association with senescent cells and aging tissue.

Telomeres and Telomerase

Telomeres are small units composed of the tandem DNA repeats and associated proteins, which cap the end of linear chromosomes and are responsible for maintaining chromosome length. They provide stability to the chromosome and protect against DNA loss associated with cellular replication. The mechanism of replicative arrest of senescent cells has been related to changes in the function of telomerase, a nuclear enzyme that synthesizes and maintains the telomeres. Shortening and uncapping of these structures, related to the number of past cell divisions, renders the DNA strand incapable of replication.

Apoptosis

Another factor involved in aging at the cellular level is the orderly 'retirement' of cells. For every cell that divides in, another would somehow have to make space for the extra cell in order to maintain numerical stability in the organ. This is achieved by a process of programed cell death, known as 'apoptosis.' Cell senescence disrupts these apoptotic processes. Necrosis, by contrast, is cell death due to injury or noxious stimuli. Diseases of aging may favor the necrotic process.

Mitochondrial Senescence and Oxidative Stress

The intracellular mitochondria, organelles involved in energy metabolism, are central to the process of cell senescence. They are also involved in regulating thermogenesis, calcium buffering, and integrating apoptosis. With aging, mitochondria become less efficient, in part due to mutations in the cell nucleus, derepressing the expression of proteins that compete with mitochondrial function. This disrupts energy metabolism for the cell and makes the mitochondria more porous, releasing reactive oxygen species into the rest of the cell. The mitochondrial production of reactive oxygen species is inversely proportional to longevity in animals. The oxidative activity also damages the mitochondria themselves. Mitochondria have their own DNA strands, and these accumulate mutations with age. In tissues dependent on progenitor (stem) cells, mitochondrial DNA mutations can disrupt replication.

Free radicals and reactive oxidative species can produce mutations in nuclear material and oxidize proteins and lipids throughout the cells. Aging involves an accumulation of oxidative damage at the cellular level, if not an increase in its intensity as well. The thiol-containing antioxidant mechanisms, typified by glutathione but represented by a number of sulfur-containing species, represent an important buffer against intracellular free radicals, but decline

with age due to downregulation of their synthetic enzymes. Confirming the cellular trend to oxidative stress in aging cells, clinical biomarkers of oxidation and antioxidant mechanisms reveal that systemic oxidative stress increases with aging characterized by lower concentrations of vitamins E and C and carotenes as well as lower activities of Cu-Zn-superoxide dismutase, catalase, and glutathione peroxidase.

Physiological Changes Occurring in Tissues and Organ Systems with Human Aging

Physiology has classically been organized around organ systems. According to this convention, the important features of the age-associated changes are enumerated and synthesized, with implications for human nutrition.

Integumentary Tissues

The integumentary tissues (skin, hair, nails) cover and protect the body. Two of the more classical and reproducible manifestations of aging can be seen in this system. The depigmentation of hair to gray or white is an almost universal aging effect given sufficient survival. Wrinkling of the skin, due to alteration in connective tissue composition, is another consequence of aging; it should be assessed by the changes in skin texture only in the non-sun-exposed regions of the body. Beyond the cosmetic consequences of the aging integumentary tissues, wound healing is a health-relevant consideration. Healing of wounds is slower with increasing age, but the resulting scars have the same tensile strength. Reduced recruitment of vessels of the microvascular is a function of aging.

The skin is an endocrine organ. Vitamin D is produced from the conversion of 7-hydroxy-cholesterol to cholecalciferol in the dermis of the skin. The efficiency of vitamin D decreases with age, such that older persons need a longer exposure to solar radiation to produce a given quantity of the vitamin.

Pulmonary and Respiratory System

Compliance of the chest wall changes with age, which gets stiffer and less compliant. The muscular force of the diaphragm is reduced with advancing years. The combination of these two factors reduces the maximal amount of air that can be moved into and out of the lungs. This diminution in the so-called forced vital capacity (FVC) of the lungs occurs as one gets older. There is less compliance, less recoil, and greater dead space. The original lung capacity, however, is sufficient to allow for sufficient gas exchange throughout life in the absence of underlying pulmonary disease. Nonetheless, the longitudinal Framingham Heart Study found an association between decrease in lung capacity and all-cause mortality.

The hygiene of the respiratory airways is somewhat compromised by a decreasing function of the microcilia of the bronchial epithelial cells. Since this mechanism is used to clear microbial pathogens, it has a direct influence on host defenses. Finally, since the basis of the respiratory system is an exchange of gases (oxygen, carbon dioxide, trace gases) with the bloodstream, any cardiovascular changes involving the right-side chambers of the heart will influence the overall gas-exchange efficiency for the body.

Cardiovascular and Circulatory System

For this system, it is necessary to separate the aging effects on the cardiac muscle and its apparatus from the aging of the vessels of the circulatory system, which transports blood to and from the heart. A characteristic of aging is a diminished resting cardiac output, which can have the combined bases of lower force of the cardiac muscle and a lesser oxygen demand for metabolism with diminished active-cell mass. Aging of the myocardium reduces its capacity for cellular repair and replacement. With aging, elevations of noradrenaline (norepinephrine) associated with downregulation of beta-1 receptors mimics the process of the failing heart. The compliance of the arteries emanating from the heart decreases with age. Stiffening of these vessels produces a progressive rise in the systolic blood pressure.

It is the circulation through smaller blood vessels and the generation of new vessels (neovascularization) that is a major concern with advancing years. The process of angiogenesis, through which new blood vessels are formed, is impaired during aging. The integrity of endothelial cells lining the vessels, the cascade of coagulation factors, and growth factors and neurochemical mediators and their respective receptors are all altered by aging in the neovascularization processes.

Oral Cavity and Alimentary Tract

The digestive tract is subject to functional changes with aging. Beginning in the oral cavity, loosening and loss of teeth is a frequent companion of aging. Saliva secretion decreases leading to relative degrees of xerostomia or dry mouth.

Reduced parietal cell function develops in older persons, but prior *Helicobacter pylori* infections are now thought to be a major cause of hypochlorhydria in later life. An important nutritional consequence of reduced gastric acid secretion is a lesser biological

availability of iron. Since iron stores are generally replete in both men and women in later life, this has little practical nutritional impact. The reduced secretion of gastric intrinsic factor, however, contributes to vitamin B_{12} deficiency, which is an important nutritional problem of older persons.

The capacity of the liver for biliary secretion and the pancreas for digestive enzyme and bicarbonate secretion begins adult life with a >90% excess of the necessary minimum. Secretory function declines with increasing age, but rarely falls below the minimal reserve capacity. The metabolic and detoxifying capacity of the human liver also has a reserve capacity and is not usually compromised by normal aging.

Intestinal motility is reduced with aging as a result of functional changes in the visceral nerves. With decreased transit the residence time of the chyme on the absorptive surfaces is longer, compensating for any senescence in the mucosal uptake itself. The reduction in motility produces the most noticeable and notorious of the manifestations of intestinal health in older persons, namely reduced frequency of defecations.

Musculoskeletal System

Bone mineral content declines with age; this aging process is known as 'osteopenia.' (It should be distinguished from the related pathological process in which bone architecture is altered, producing 'osteoporosis.') From the peak in the third and fourth decades, a 30% average decline in bone mineral density occurs through the ninth decade. In women, there is well-characterized acceleration of the rate of bone mineral loss immediately following the menopause. Decreasing levels of anabolic hormones may be associated with musculoskeletal atrophy and decrease in function that is observed in older women. This change in skeletal mineralization with aging is not associated with any apparent change in vitamin D nutriture as reflected in circulating levels of the vitamin.

The joints of the body undergo changes with the senescence of replacement of the cartilaginous substance, complicated by the pathological effects of cumulative use over the life span.

Recently, increasing attention has been given to the loss of muscle strength and substance with increasing age. Sarcopenia loss of lean body mass skeletal muscle mass replacement by fat mass Decreased creatinine-to-height ratio in normative aging in healthy subjects diminished grip strength is a function of age. [Reduction in muscle mass (sarcopenia obesity) is an important determinant of physical function and metabolic rate.]

Renal and Urogenital System

That renal creatinine and inulin clearance decreases with aging has been demonstrated for decades. These functional changes in filtration are associated with changes in the glomerular structure in the kidney. Circulatory senescence decreases blood flow to the kidneys, which further reduces the efficiency of renal clearance. The reserve capacity of these organs is such, however, that age-associated glomerular decline *per se* does not compromise the net excretion of nitrogenous waste.

Urine flow at the outlet is another aging consideration. The male urogenital system undergoes a characteristic aging change in the hypertrophy of the prostate gland, associated with decreased secretion of prostatic fluid. The anatomical consequence is a constriction in the passage through which urine flows from the bladder.

Gonads and Reproductive System

It has been aptly stated by Harman that: "It is clear that aging results in alterations of endocrine physiology, which in turn appear to contribute to development of the senescent phenotype." Aging is associated with a decrease in pituitary hormone secretions. This decline explains, in part, the reduction in gonadal hormone production with aging. Primary aging of the testes and ovaries themselves accounts for the remainder of the changes. As the ovaries have a finite number of eggs, ovulation can only continue through the number of cycles that correspond to the original store of ova. Menopause ensues with the characteristic cessation of estrogenic hormone secretion. In both sexes, gonadal androgenic hormone production declines with consequent effects on libido.

Endocrine Systems and Metabolism

As stated above, the pituitary gland is the hub of endocrine regulation. Important among the decline stimulation within the axis is that growth hormone (GH) secretion declines with increasing age, a condition termed 'somatopause.' The changes in the growth hormone/insulin-like growth factor axis with aging produce changes in function, metabolism, and body composition analogous to the pathological growth hormone deficiency seen in younger adults. Another change with age is the efficiency with which physical activity stimulates the secretion of GH.

The availability of hormones is not the only variable in endocrine signaling. Cellular and intracellular receptor function is complementary. An attractive explanation for the disordering of hormonal axes is

oxidative damage to cell membranes, compromising the function of receptors.

Basal and resting metabolism and diet-induced thermogenesis are all reduced with increasing age. Changes in body composition, and the replacement of lean tissue with fat and the increasing visceral distribution of fat, as well as decreasing physical activity, influence these metabolic changes of aging. Basal metabolic rate (BMR) declines in aging more than can be attributed to body composition changes and intracellular mitochondrial senescence may explain part of this discrepancy. For practical purposes, the standard oxygen consumption value equivalent to one metabolic equivalent (MET), that is, $3.5\,\mathrm{ml\,min^{-1}\,kg^{-1}}$, is not appropriate for elderly people.

Hematopoietic and Immune System

The formation of new red and white blood cells and platelets is one of the most proliferation-dependent physiological processes of the body. The various classes of circulating white cells are the underpinning of the host defense system, together with tissue macrophages, hepatic proteins, and the alimentary tract's mucosa.

Hematological aging The blood-forming organ is the bone marrow. Aging is associated with fatty infiltration of the marrow spaces in the long bones, but enough marrow remains to support the turnover of erythrocytes and red blood cell lines. The circulating red blood cell mass does not normally change with advancing age, nor does the normative peripheral white cell count or platelet number. As noted, iron stores tend to be abundant in later life; nutritional problems influencing red blood cell production are based on alterations in gastric function (vitamin B_{12} malabsorption), which result in a macrocytic (megaloblastic) anemia.

Immunological aging Circulating phagocytic white blood cells counts do not reduce with aging but aging does influence the innate host defense system. Mucosal barrier functions are influenced by aging of the gut in its interaction with microflora. Although not reduced in number, aged macrophages and neutrophils have blunted intracellular signaling by specific receptors, decreased metabolic functions, and impaired bacterial killing. Production of superoxide anion, chemotaxis, and orderly apoptosis of neutrophils is also disrupted by the disordered signaling. The tumor cell-destroying capacity of natural killer (NK) cells in the elderly is diminished.

More profound changes occur in the adaptive immune functions, which rely on the memory (T cell) lymphocytic cell line. Life-long antigen exposure induces increases in the number of memory T cells, but with enhanced reactivity against self-antigens, priming the individual for autoimmune disease. In healthy adults, IgA concentration increases by $0.2\,\mathrm{g\,l^{-1}}$ per decade throughout life. The T lymphocytes, however, respond more poorly to ongoing antigen assault in later life. Thymic involution associated with neural and hormonal changes of aging is an impediment to T-cell maturation in older persons. The basis of intrinsic function deficits of memory cells, on the other hand, has been ascribed to defective signaling and includes hyporesponsiveness to mitogen-stimulated proliferation and decrease in genetic suppression, allowing increased stimulation of inflammatory cytokines; the balance between pro- and anti-inflammatory cytokines shifts with aging, favoring the inflammatory pole, especially with the greater expression of interleukin 6. This has a negative systemic effect on bone metabolism, as well as dysregulating overall immune function.

Aging of mitochondria in the immune cell lines produces increased intracellular reactive oxygen species burdens. Finally, there is diminished programed death (apoptosis) of immune cells and dysregulation of apoptosis-dependent functions.

Central and Peripheral Nervous System

The integration of all senses and origins of all systemic coordination is a function of the brain and central nervous system. This is the one system in which proliferation of the primary cells (neurons) is not an issue after early childhood, although the supportive, nerve-tending (glial) cells continue to depend on replication and apoptosis for normal function.

Central nervous system The neurons of the brain continue to divide only through to the second year of life. Thereafter, the goal is to preserve the number and health of the cerebral nerve cell mass. Myelination of axons of nerve cells must be maintained throughout life. This is the function of the supporting cells (oligodendrocytes), which over 40 years continue to differentiate into myelin-producing cells. Free radicals pose a threat to these axon-tending cells, whose metabolic demands for producing the brain's cholesterol and maintaining its array of myelin sheaths render them particularly vulnerable to stress.

Positron emission tomography (PET) imaging of the aging brain has revealed and mapped the plethora of changes in blood flow and neurotransmitter metabolism that occurs with advancing years.

Special senses The special senses related directly to the cranial nerves (vision, hearing, taste, and smell) experience age-related change. With respect to vision, the most typical of all biological aging changes is presbyopia, or the loss of accommodation function for the ocular lens with loss of capacity of the associated musculature. The consequence is loss of near-vision, which leads to the need for reading glasses or bifocal spectacles. A more important aging change related to the lens is the opacification that leads to cataract formation. The eye is designed to translate light energy into visual images, but the energy of light, particularly the ultraviolet β rays of solar energy, damages ocular tissue. Thus, there is as a strong environmental component to the disarranging of the laminar stacking of the fibrillar proteins of the lens, which imparts its clear, transparent basis; consumption of diets high in antioxidant vitamins has been associated with the delay in cataract formation.

Age-related hearing loss is a feature of biological aging. It affects the cochlear neural structures and leads to loss of acuity, especially for higher pitched tones. It is speculated that apoptosis of the most vital neural cells drives this hearing loss, based on mutations in the mitochondria due to life-long free-radical stress.

Taste and smell acuity decline with aging, both in sensitivity and in accuracy of recognition. Since these combined senses account for the recognition of flavors, their diminution with age could affect appetite and reduce the enjoyment of meals.

Cognitive function The intellectual, reasoning, and memory functions of the cerebral cortex decline with increasing age. This has been a universal observation in general elderly populations. The debate is whether this is a consequence of neurodegenerative diseases (pathological change) or a biological correlate of aging (senescence). Continued intellectual stimulation has been posited as an approach to retard cognitive decline, and a role for B-complex vitamins and antioxidants has been advanced.

Peripheral nervous system Vibratory perception in the peripheral extremities is the classical index of peripheral nervous decline with aging. Less well appreciated is the effect of aging on pain perception, in which there can be a numbing of sensation or, less commonly, an accentuation of perception. Pain perception from the visceral organs is often dulled, which can have adverse implications for the early detection of organic diseases. All of the peripheral nerve dysfunction can result from the compensatory sprouting of axonal limbs to compensate for the loss of motor neurons. This is well directed at first, but with further aging the synaptic connections are poorly directed and motor function suffers as a consequence.

Drug Metabolism

The metabolism of drugs and pharmacological agents is not the purview of any single organ system. Older persons tend to be prescribed increasing numbers of medications with advancing age. Important changes in drug metabolism occur with aging. Metabolism and disposition of drugs changes with age. This involves age-associated decrease in function of some, but not all, cytochrome P450 enzymes. Among the pharmacokinetic and pharmacodynamic changes that occur with advancing age are reductions in renal and hepatic clearance and an increased effective half-life of lipid-soluble drugs. The older population shows increased sensitivity to some psychotropic drugs and anticoagulants, with the frail elderly being more susceptible than healthy elders.

Synthesis and Conclusion

The number of older people is increasing in all regions and all societies of the world. Advancing age produces senescent changes in cellular function that are reflected in a declining capacity of all physiological systems. The increased prevalence of disease in older populations Aging is a major risk factor for disease but does not necessarily lead to age-related diseases.

All physiological systems are intrinsically interrelated in maintaining the health and function of the organism. Aging is associated with a loss of complexity in the dynamics of many physiological systems. It has been speculated that the basis for the syndrome of frailty in older persons may result from a reduced ability to adapt to internal and external stresses of daily life due to the loss of dynamic coordination among the interrelated physiological systems.

The alterations in physiological functions with aging have important implications for absorbing, retaining, and utilizing nutrients. The extent to which dietary patterns and nutrient intakes are accelerating or retarding the rates of functional decline is a matter of ongoing investigation in gerontological nutrition and physiology.

Nutritional Requirements

N Solomons, Center for Studies of Sensory Impairment, Aging and Metabolism (CeSSIAM), Guatemala City, Guatemala

Human Aging and Nutrition

The World Health Organization defines the 'elderly' as persons of 60 years of age and older. The elderly constitute a rapidly expanding segment of populations in both developed and developing countries. This is the combined result of ever-longer survival and dramatic reductions in fertility rates. Regardless of age, people must respond to their feelings of hunger and thirst by consuming foods and beverages. This eating and drinking behavior also serves to provide the nutrients to nourish the body. The amount of a nutrient that must be ingested and absorbed to maintain an adequate and appropriate body composition varies with age across the life span, depending on basic underlying physiological and metabolic processes specific to the chronological stage of life. The degree to which we retain and conserve, or excrete or degrade, absorbed nutrients is influenced by chronological age and biological aging.

As a consequence of this new demographic reality, attention is being focused belatedly on gerontology and its nutritional biology; this, in turn, is reflected in very recent efforts to refine our knowledge of the amounts of various macro- and micronutrients that the aging body requires (nutrient requirements) and of the amounts that must be consumed in the diet to provide for sufficient uptake of these nutrients (nutrient recommendations).

Successful Aging, Normative Aging, and Frailty

From an epidemiologic and demographic, as well as an economic and humanitarian standpoint, the ideal contribution of life-long nutrition would be to a situation of 'compression of morbidity,' first enunciated by J. Fries. It strives to keep individuals free of chronic illness, functional, and independent until the final moments of their lives, and thus reduces the burden of disability and dependency suffered by individuals, their families, and the society that contributes to their maintenance to a minimum.

A disclaimer has traditionally been appended to the official pronouncements of recommended nutrient intakes; whether they are from national or international expert panels, the prescriptions are meant to apply to 'healthy' individuals. Nutrient needs in disease conditions are considered to be a clinical matter, and are related to the pathologies in question.

When it comes to older persons, the exigency of being 'healthy' becomes immediately problematic. Advanced age is associated with increased susceptibility to chronic and degenerative illnesses. Most persons over 60 years of age have two or three chronic illnesses diagnosed, and are receiving multiple medications. Maintaining a rigid definition of healthy for application of nutrient recommendations in later life would exclude almost everyone from coverage by nutrient-intake standards.

In fact, the older the cohort of individuals examined, the more heterogeneous are individuals of the same chronological age in their physical and cognitive functioning. Over the last two decades, general domains of classifications have come into usage to embrace the heterogeneity of aging populations: successful aging; usual aging; and frailty. Successful aging has been defined as multidimensional, "encompassing the avoidance of disease and disability, the maintenance of high physical and cognitive function, and sustained engagement in social and productive activities." It may involve aspects of resilience and wisdom, as well. Usual aging involves an accumulation of ailments and loss of function that is typical of older persons surviving to later life. Frailty is the far extreme of disability and dependency associated with major physical and cognitive decline in which disease and senescent processes become irreversibly established.

A prominent and optimistic school of thought suggests that exposures to behavioral and environmental

factors that modify risk of disease and dysfunction determine one's position in these alternative outcomes in the aging process. In this view, more optimal nutrient intake, food selection, and life-style choices could reduce the heterogeneity, retaining more individuals in the successfully aged category for most of their life span. Others consider that genetic constitution may be as important in determining the course of aging as any positive or negative influences during our lifetime.

Overview of Specific Factors of Aging Influencing Nutritional Requirements

The discussion of nutrient requirements and recommended dietary intakes of nutrients in older persons has proceeded on both the theoretical and empirical level. Since the peak years for human reproduction occur before advanced middle age, and well before older age begins, the forces of selective reproduction cannot exert themselves for Darwinian selection of traits favoring longevity in the evolution for any traits related to longevity *per se* or physiological sustained function. Hence, there is little evolutionary selection for nutrient requirements to achieve advanced age or for long-term survival. It is more for the preservation of comfort and function for those surviving to advanced age that optimization of nutritional intakes for the elderly would apply, that is for humanitarian and public health importance in the face of the physiological and anatomic changes of senescence.

As early as the 1970s, nutritional scientists advanced the proposition that requirements for different macro- and micronutrients changed with age. A large number of conjectures based on an emerging scientific understanding of senescent physiology have been advanced. It has been suggested that the decreased physical activity and physical conditioning associated with the body composition changes attendant to aging, sets the stage for alterations in requirements in both amounts and relative proportions of protein and the energy-yielding macronutrients. Decreased gastric secretory capacity has a negative influence on the absorption of calcium, iron, and vitamin B_{12}. Changing intestinal motility and digestive function evoked considerations of distinct increases and decreases of nutrients to compensate for the senescence of the intestinal tract, with particular interest in dietary fiber. Attention to compensatory intake for all of the nutrients involved in skeletal mineralization has come to the fore in relation to the recognized tendency to bone mineral loss with advancing age.

The immune and host defense system has been the focus of gerontological nutrition. Increased intakes of both vitamin E and zinc, well above the normally recommended level, have stimulated certain immune functions in studies involving older volunteers. Cognitive function declines with advancing age, and it has even been suggested that adjustment of nutrient intake can favorably affect the retention of memory and cognitive function in older persons. The adequate intake of B-complex vitamins, particularly those related to homocysteine metabolism (vitamin B_{12}, folic acid, vitamin B_6, riboflavin), are associated with mental function in older age. It has also been suggested that older individuals need more *n*-3 fatty acids for preserving cerebral cellular anatomy related to cognition.

Nutrient Intake Recommendations in Later Life

Comprehensive recommendations for macro- and micronutrients with differential attention to older persons have arisen from a collaboration between the US and Canada, and from expert panels serving the United Nations System. Each panel has set out its methodology and definitions and then presented tables of quantitative estimates. The recommendations for persons considered elderly in the respective systems are outlined below.

Definitions Surrounding Recommended Intakes of Nutrients

An important advance in establishing nutrient intake recommendations relates to the semantics. There has been a refining of the operational definitions of terms related to nutrient intakes. Recommended nutrient intakes (RNIs) are set by the agencies of the United Nations (UN) System and are considered to be the intakes of nutrients required to satisfy the requirements of nearly all healthy persons of a given age, sex, and physiological condition, and should be universal for all regions of the globe.

The Food and Nutrition Board of the Institute of Medicine in the US took a new approach in 1997 in which they applied the new dietary reference intakes (DRI) to micro- and macronutrient intakes. This work was undertaken jointly with Canada. It began with an assessment, where possible, of the estimated average requirement (EAR). This is defined as "the average daily nutrient intake level estimated to meet the requirement of half the healthy individuals in a particular life stage and gender group." The EAR is critical for an assessment of the risk of a nutrient deficiency problem at the

population level. The traditional criterion used for decades, the recommended dietary allowance (RDA), is preserved. It is defined in the DRI process as "the average daily nutrient intake level sufficient to meet the nutrient requirement of nearly all (97 to 98 percent) healthy individuals in a particular life stage and gender group." When an EAR cannot be established from which to derive a formal RDA, the DRI process has a 'fall-back' category known as adequate intake (AI); this is defined as "a recommended average daily nutrient intake level based on observed or experimentally determined approximations or estimates of nutrient intake by a group (or groups) of apparently healthy people that are assumed to be adequate." A new classification scheme involving a range of intakes was created specifically for energy, electrolytes, and liquids: the acceptable macronutrient distribution ranges (AMDRs).

For the first time, a specific and well-defined process to delimit levels of excess intake of nutrients and dietary substances was defined by the DRI process as the upper tolerable intake levels (UL). The UL is "the highest average daily nutrient intake level likely to pose no risk of adverse health effects to almost all individuals in the general population." It is considered that as intake increases above the UL, the potential risk of adverse effects increases. To date, the UN System's process has dealt much less explicitly with issues of excessive intake of nutrients and dietary substances.

Established Recommended Intakes for Older Persons

In earlier versions of the RDAs for the US population (up to the 10th edition in 1989), the nutrient recommendations for all healthy adults over 51 years of age were combined as a single value. For the UN System, the age threshold in the early editions was 50 years or older. Concerted efforts to refine our understanding of nutrient requirements for older adults have been made over the past two decades. This allowed the US-Canada DRI process to establish categories for men and women aged 70 years and older. For the WHO/FAO process, a specific estimation for individuals over 65 years has been provided in the 2002 micronutrient recommendations.

Given the magnitude of the theoretical considerations regarding senescence and aging physiology that have been raised by various authors, what is really surprising is the paucity of specific instances in which the recommended intakes of nutrients for men or women in the 'elderly category' are considered to be different from persons in the next youngest age category. Composite tables for men (**Table 1**) and women (**Table 2**) are given for all of the nutrients and dietary substances expressed in the US-Canada DRIs and in the UN system for RNIs.

Macronutrients In the DRI system, a universal, individual protein requirement was established as 0.80 g of good-quality protein per kilogram of body weight per day independent of age. No evidence for altered protein requirements with older age has been found. Moreover, it is recommended that the contribution of protein to total energy intake should not exceed 30%. The US Food and Nutrition Board also established an amino acid pattern in 2002. It specifies the density (mg per g protein) of seven indispensable (essential) amino acids (histidine, isoleucine, leucine, lysine, threonine, tryptophan, and valine) and for two amino acid combinations (methionine + cysteine, phenylalanine + tyrosine). This pattern is universal from age 1 year to the extremes of older age without modification.

It has long been recognized that energy recommendations cannot be made on a group basis, as each individual has his or her own daily energy requirement dependent on the amount of energy one is forced to expend with metabolic reactions, food processing, and physical exertion. In the DRI process, this is recognized in an effort to individualize the estimation of energy intake. Estimated energy requirement (EER) is based on the amount of energy needed to maintain energy balance in relation to one's total energy expenditure. The DRI process for the US and Canada has published general EER equations (multidimensional nomograms) by which a reasonable estimate of an individual energy requirement can be calculated. There are general equations for adult men and women (over 19 years of age), based on consideration of physical activity level, weight, and height. In addition, there is an age term in the general EER, which is attached to a negative (minus sign) term in the equation. This signifies that energy requirements decline as a function of advancing years.

Although dietary fiber is not considered to be an 'essential' nutrient, the DRIs give a recommended level for intake. Curiously, in light of the active discussion of the role of fiber for the elderly in colonic function, the recommendations for intake by men decline from 38 to 30 g per day and in women from 25 to 21 g per day after 50 years. These are continued throughout the 70 year period, as well. This is a consequence of the fiber recommendations being pegged to total average energy intake.

UL, upper tolerable upper intake level; EAR, estimated average requirements; RDA, recommended dietary allowance; AI, adequate intake; AMDR, acceptable macronutrient distribution range; RNI, recommended nutrient intake; PUFA, polyunsaturated fatty acids; RAE, retinol activity equivalents; RE, retinol equivalents; α-TE, alpha-tocopherol.

Water It is recommended in the DRI as an adequate intake (AI) that males over the age of 70 require 2.6 l and females 2.1 l of water per day; this is a decline from the 51–70-year age group, where the daily water intake recommendations were 3.7 l and 2.6 l, respectively. It is further suggested that males and females over 70 years of age derive 81% of their daily water allowance from beverages and 19% as the metabolic water from foods. This is consistent throughout adulthood from age 19 years. Hence, there is no consideration of a higher requirement for water intake with older age. With respect to the electrolytes, no differences in AIs exist across the ages in adulthood.

Micronutrients A number of recommendations (RDAs or AIs) change with advancing age in the DRI system; this is indicated by the bold type in

Table 2 Nutrient intake recommendations for older females

UL, upper tolerable upper intake level; EAR, estimated average requirements; RDA, recommended dietary allowance; AI, adequate intake; AMDR, acceptable macronutrient distribution range; RNI, recommended nutrient intake; PUFA, polyunsaturated fatty acids; RAE, retinol activity equivalents; RE, retinol equivalents; α-TE, alpha-tocopherol.

Tables 1 and **2**. The change in recommendations occurs at either age 50 or 70 years. In women over 50 years, the RDA for dietary iron decreases from 18 mg to 8 mg day^{-1}; there is no change in requirement for the 70 year plus age group. This lower value is the recommendation for adult men of all ages. The fact that the menopause allows women to replete iron stores depleted by an adulthood of monthly menstrual blood loss accounts for this lower RDA in older women.

The senescence of the skeletal system and the reduction of bone mineral content with age is a major nutritional concern in gerontological nutrition. In recent revisions of the recommendations, evidence for the need for increases in both vitamin D and calcium for older persons has led to changes in the estimates of requirements for these nutrients in later life. Within the DRI system the RDA for vitamin D for males and females over 70 years is 15 mg. The

RDA for adults over 50 years is 10 mg and for young adults is 5 mg. Similar increases in vitamin D intake with age are recommended by the FAO/WHO. With respect to calcium, the recommended levels increase from 1000 mg for younger adults to 1200 mg at age 50 and beyond in the DRI system, and from 1000 to 1300 mg in the FAO/WHO standards. These are justified based on the higher propensity for skeletal fractures after 70 years of age associated with epidemiological evidence of widespread vitamin D deficiency in this age group, and evidence showing a reduction in bone loss with daily calcium intakes exceeding 1000 mg after mid-life.

With respect to chromium it is interesting that the estimation for AI declines with advancing age. The AI for persons over 70 in the DRI is the same as that for individuals between 51 and 70, but it is 5 $\mu g\,day^{-1}$ higher for the 19–50 age range. This reduction is tied to the lower energy demands for individuals over 50 years of age.

The upper tolerable upper intake level (UL) for phosphorus in the DRI system is 3000 $mg\,day^{-1}$ for both men and women over 70 years as compared to 4000 $mg\,day^{-1}$ for adults in the 19–70 age group. This lower tolerance is explained by the greater prevalence of impaired renal function in advanced old age.

Magnesium intake recommendations in the FAO/WHO guidelines decline for individuals over 65 years by 30 $mg\,day^{-1}$ compared to those in the 51–65 years age group. An anomalous finding for the magnesium RDA in the DRI system, which applies to all adult age groups, is that the UL for magnesium has been set at 350 mg. This is only 30 mg higher than the 320 mg daily recommended for older women, and is 70 mg lower than the 420 mg daily intake recommended for older men.

Dietary Guidelines for Health, Function, and Disease Prevention

Concomitant to recommendations for daily nutrient intake based on requirements, guidance and orientation for the pattern of selection of nutrient sources among the food groups have emerged as so-called 'dietary guidelines.' They are often accompanied by an icon or emblem, such as a pyramid in the US, a rainbow in Canada, and a Hindu temple in India, each of which expresses the general tenets of the dietary guidelines in a visual manner. A quantitative prescription, or some notion of balance among foods and food groups, is the basis of dietary guidelines; there is also often a proscription for foods considered to be harmful or noxious.

The additional susceptibility of older persons to chronic degenerative diseases makes adherence to these healthful dietary patterns, throughout the periods in the life span preceding the older years, more relevant. Recent epidemiological research has shown that compliance or behavior concordant with healthy eating guidelines are associated with lower later life incidences of certain cancers, cataracts, diabetes, hypertension, stroke, and cardiovascular diseases, as well as overall survival. There is intense interest in whether and how diet and nutrition influence the maintenance of cognitive function with aging.

Robert Russell and colleagues constructed a food guidelines pyramid, which specifically focused on the health of the elderly. Among the elements and tenets that differed from the standard US pyramid are the following recommendations: to drink additional water and liquid; to increase consumption of dietary fiber; and to consider dietary supplements such as calcium and vitamin E. Otherwise, selecting the same requisite serving portions of the specific food groups, and avoiding excess sugar, salt, and separated fats as indicated by the conventional guidelines emblem is recommended for the older population as well.

It is generally conceded that the major benefits for prevention of nontransmissible disease to be derived from adopting a healthful life style and dietary habits will accumulate over a lifetime; hence, beginning such practices at as early an age as possible will yield the greatest benefits. In this context, the application and emphasis of dietary guidelines specifically for the elderly is controversial and as yet unresolved. One school of opinion, one shared by Russell and coworkers, holds the view that the benefits of adhering to dietary guidelines are continuous, and actively protect from metabolic and neoplastic diseases even in the latter stages of the life span. The alternative proposition suggests that long-term survivorship is a manifestation of a superior genetic constitution resistant to chronic diseases. The very fact of survival to advanced age is a suggestion that the survivor's dietary practice will neither prejudice nor further protect health.

Barriers to Meeting Recommended Nutrient Intakes and Healthful Dietary Intake Patterns by Older Persons

The late Professor Doris Calloway, in the early 1970s, commented: "People eat food, not nutrients." This highlights the paradoxes in considering and enumerating the objectives of dietary intake at the level of the

chemical composition, while most members of the general public are uninformed as to the nutrient composition of the foods and beverages in their diets.

Elderly persons face a number of challenges in meeting their recommended nutrient intakes. In the first instance, they are likely to be those with the least sophisticated or available knowledge of the nutrients required and the food sources to provide them. The social, economic, and physiological changes imposing on the lives of persons surviving to advanced age pose logistical problems for their selecting and purchasing a diet. Economic dependency and the limited incomes of older persons may restrict their access to high-quality foods. Social isolation, depression, and impaired mobility, as well as chewing difficulties may limit the variety of items included in the diet with advancing age. In some circumstances, it may be that free-living and independent elders are relatively less able to optimize their nutrient intake and dietary pattern compared to more dependent individuals served or fed in institutional settings.

The exigencies of consuming a healthful diet for the prevention of chronic diseases, emphasizing a plant-based diet rich in whole grains, fruits and vegetables, limits the nutrient selection that would be obtained from an even wider variety of foods and food-groups. Specific essential fatty acids, and certain minerals (calcium, zinc, selenium) and some vitamins are far less nutrient dense in foods of vegetal origin, setting a dilemma between consuming for nutrient adequacy and prevention of degenerative disease.

The widespread fortification of processed foods with micronutrients by the food industry in industrialized nations could mitigate much of the risk of insufficient nutrient intakes. Fortification of foods with iron may be more disadvantageous than beneficial to older persons whose iron reserves for nutritional purposes should normally be amply filled. A higher intake of iron puts a strain on the intestinal regulatory capacity and would tend toward excessive iron storage with any oxidative consequences for health that may result. National programs of fortification of grain flours and cereal products with folic acid for the prevention of neural tube defects in pregnancies are proliferating; mathematical models of how this policy may in fact increase the masking of macrocytic anemias due to vitamin B_{12} deficiency associated with senile gastric atrophy have been generated for European elderly populations.

Future Considerations

The DRI recommendations are specifically derived for the populations of the US and Canada in North America. The RNIs of the UN System are meant to be universal across the entire world. The slight majority of the living elderly are currently to be found in the low-income, largely tropical regions of the world in which 80% of the global population reside; this shift is due to rise rapidly over the next two decades. A number of caveats apply to the estimation of nutrient intake recommendations for the elderly across the world. If the "applies only to healthy individuals" disclaimer were applied to the developing world, then virtually no older people would qualify as eligible for coverage by any nutrient recommendations system. However, rather than abandon the effort for nutrient intake guidance, an attempt should be made to take into account the influences of life-long climatic issues (heat, humidity) and ecological factors (parasites, recurrent infections) on nutrient needs in later life.

Nature versus nurture issues will also continue to be debated with regard to nutrient requirements, especially in later life. Of course, with the recent assembling of the genetic code, the issues of 'nutrigenomics' and 'nutrigenetics' theoretically could soon be brought to bear on understanding individual variation in needs for and tolerances of essential and nonessential nutrients and dietary bioactive substances. The significance of this potential for the already aged person is likely to be limited for two reasons. First, the accumulative effects of nutrient imbalance will already have been established. Second, the economic and intellectual wherewithal to access and execute such individualized prescriptions for nutrient intakes and dietary patterns will likely escape the majority of older persons with limited financial means. Hence, further refinements in recommended intakes for older persons are likely to remain at the level of this segment of the population as a group and will involve establishing evidence that increased intakes of specific nutrients will have health-protective effects or function-enhancing properties, and that the effective upper tolerable levels/limits for certain nutrients in later life are lower than those for younger members of the adult population.

Nutrition-Related Problems

C P G M de Groot and W A van Staveren,
Wageningen University, Wageningen, The Netherlands

The population older than 55 years of age is increasing rapidly throughout the world. In industrialized countries, the proportion of elderly people will increase by approximately 1% per year; in developing countries an increment of approximately 3% per year is expected. The nutritional needs of this population will require increasingly more attention from professionals working in the food industry as well as in health care.

Aging is defined as all physiological changes that occur from conception until old age and ultimately death. In this article, the term is restricted to changes that occur in adulthood, when growth has stopped.

On the one hand, nutrition is considered one of the key determinants in the process of aging. On the other hand, age-related changes take place in body appearance, in functional capacity and in the body's capacity to adapt to physical stress that affects nutritional needs.

It is difficult to distinguish between changes due to old age *per se* and changes that are the consequences of disease. In this article, the effects of aging on body composition, including energy needs and problems of over- and underweight, bone mass, and water balance are discussed. Physiological functions of the digestive system, malabsorption, nutrient drug interactions, and consequences for nutritional requirements are described, together with the high-risk micronutrients and early warning signs for malnutrition.

Changes in Body Composition and Energy Needs

Fat-Free Mass and Energy Needs

One of the truly age-driven phenomena is the loss of muscle mass and strength, called sarcopenia. It is distinct from muscle loss (cachexia) caused by inflammatory disease or from weight loss and attendant muscle wasting caused by starvation or advanced disease. Regardless of major differences between individuals, aging-related changes in body composition with time are universal. In addition to changes in lean tissue, this also holds for changes in fat mass, body water, and bone mass.

Throughout middle age, body mass tends to increase due to an accumulation of fat, preferentially intra-abdominally. Thereafter, usually after 60 years of age, it declines in association with loss of lean tissue. Diminution of physical activity enhances the changes in body composition occurring with aging, which in turn affect physical function. Ultimately, these processes result in a lower requirement for energy.

The total demand for energy is dominated by the energy needed per day to maintain vital functions, the basal metabolic rate (BMR), representing 60–70% of total energy expenditure. Most of the remainder (approximately 25%) is needed to cover the costs of physical activities. The BMR declines with age by up to 5% per decade. It is the decrease in lean tissue with age that determines this decline. One of the most important preventive measures in this process is the maintenance of physical activity. This helps to maintain lean body mass, physical fitness, and the requirement for energy.

Partly as a response to reduced energy needs, the energy intakes of affluent populations decline with age. This decline in food intake involves a decrease

in meal size and a reduction in between-meal snacks. Morley called this physiologic decline in food intake "anorexia of aging." This type of anorexia may be considered partially as a response to reduced energy needs but also partially as a dysregulation of food intake. Roberts *et al*. studied energy regulation in young and older adults by deliberately overfeeding and underfeeding their subjects. After a period of underfeeding, young people compensated by overeating when fed ad libitum. However, the older adults did not compensate. The same holds following a period of overfeeding; the older adults did not compensate with a reduction in food intake when fed ad libitum.

Anorexia of aging places an increasing number of elderly people at risk for malnutrition because the opportunities for providing an adequate dietary nutrient intake are very limited when total food consumption becomes low (e.g., <6.3 MJ (1500 kcal) (**Figure 1**). Current recommendations for daily energy intake are approximately 9 MJ for elderly men and approximately 8 MJ for elderly women. Institutionalized elderly people or the elderly who are sick are especially likely to fail to achieve such intakes.

For health reasons, it is important that elderly people avoid becoming underweight. Although losing weight may be favorable at younger ages and being overweight is a known health risk in adults, there is evidence that low body weight and loss of body weight in the elderly are more strongly associated with risk of mortality (**Figure 2**). This is clearly shown by data from the Survey in Europe on Nutrition and the Elderly, a Concerted Action (SENECA). Weight loss (>5 kg over 4 years) seemed to be predictive for survival. It is even more important to be slightly overweight than underweight for people older than age 70 years. Therefore, except for those who are obese, elderly people should be encouraged to maintain an adequate energy intake. According to the SENECA study, 20–25% of the relatively healthy participants failed to do so: Approximately 8% lost and 16% gained at least 5 kg of body weight over a period of 4 years. When appetite is reduced, an increase in meal frequency may not only help to promote energy intakes but also prevent blood glucose levels from declining steeply.

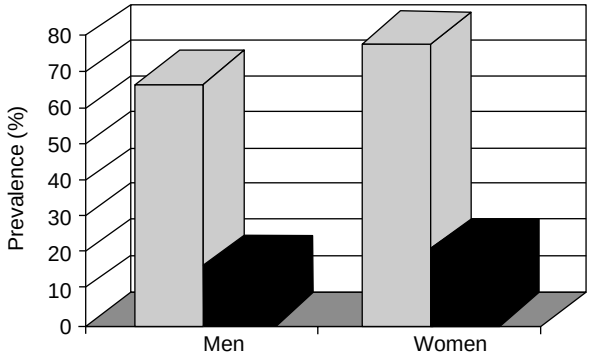

Figure 1 Prevalence of inadequate intake of at least one nutrient among elderly people whose daily energy intake is less than 6.3 MJ (gray bars) and for those whose energy intake exceeds 7 MJ (black bars). Body Water, Dehydration, and Medication

Because lean tissue has a high water content, there is a decrease in total body water—especially extracellular water—with advancing age from 80% at birth to 60–70% after age 70 years. In addition, older people experience diminished sensation of thirst, and urinary concentrating ability declines as a function of age. Thus, older people have an increased risk of dehydration, particularly when diuretic or laxative medicines are used or in the presence of some diseases common in old age, such as diarrhea, renal disease, and infection with fever. Because water is essential to all biological functions, fluid intakes during old age should be at least 1700 ml per day. In the body, water acts as a dilutent for water-soluble drugs. Given the decrease in body water with age, older people may need lower dosages of water-soluble drugs than younger adults to achieve the desired therapeutic effect and to avoid drug toxicity.

Bone Mass and Nutritional Factors

Throughout life, bone mass changes, with a maximum (peak bone mass) achieved by age 25–30 years and bone loss occurring after the fourth decade. Higher calcium intakes in childhood and early adulthood result in a 3–8% greater bone mass later in life, thereby improving the key factor in the osteoporotic process and the age-associated risk of fractures. In women, there is a perimenopausal increase in the rate of bone loss that persists after menopause following a decline in oestrogen production (**Figure 3**).

Factors other than age and sex that are associated with low bone mass include low body weight, smoking, alcohol consumption, reduced physical activity, low calcium absorption, and secondary risk factors such as the use of steroids. Although there is still uncertainty about the quantitative role of nutritional factors in the pathogenesis of osteoporosis, preventive measures include adequate calcium intakes (probably even in old age) and exposure to sunlight to ensure vitamin D adequacy and/or dietary supplementation with vitamin D. Restricted sunlight exposure, reduced capacity of the skin to produce vitamin D, and low vitamin D intake make elderly people prone to vitamin D deficiency.

Nutritionally Related Problems and the Digestive System

Taste

The number of taste buds varies widely from person to person but does not decline with age. Taste perception and the perceived flavor of foods decrease, but this is affected by many factors, including diminishing smell, age-related changes in the olfactory system, the integration of the central nervous system, medication, oral hygiene, and nutrition (**Figure 4**). Inadequate intakes of zinc, copper, nickel, and some vitamins have been associated with decreased perception of flavor of food.

Stomach

Atrophic gastritis is common in elderly people, resulting in hypochlorhydria and reduced gastric secretion. There is no consensus whether atrophic gastritis and the decrease in gastric acid secretion are normal processes of aging or a result of *Helicobacter pylori* infection. Independent of the cause, lack of gastric acid may interfere with the optimal absorption of nutrients. In the case of vitamin B_{12}, this may have clinical consequences. The mechanism for the reduced absorption of vitamin B_{12} is not clear, but protein-bound colabamin absorption is reduced in the elderly with atrophic gastritis or hypochlorhydria and this situation can be reversed with free vitamin B_{12} (the crystalline form) administration. Again, the prevalence of vitamin B_{12} deficiency is higher in *H. pylori* infection and eradication of this bacteria may correct vitamin B_{12} levels.

Small Intestine

Transit time is not changed in the elderly; however, their slower gut motility may cause stasis, with

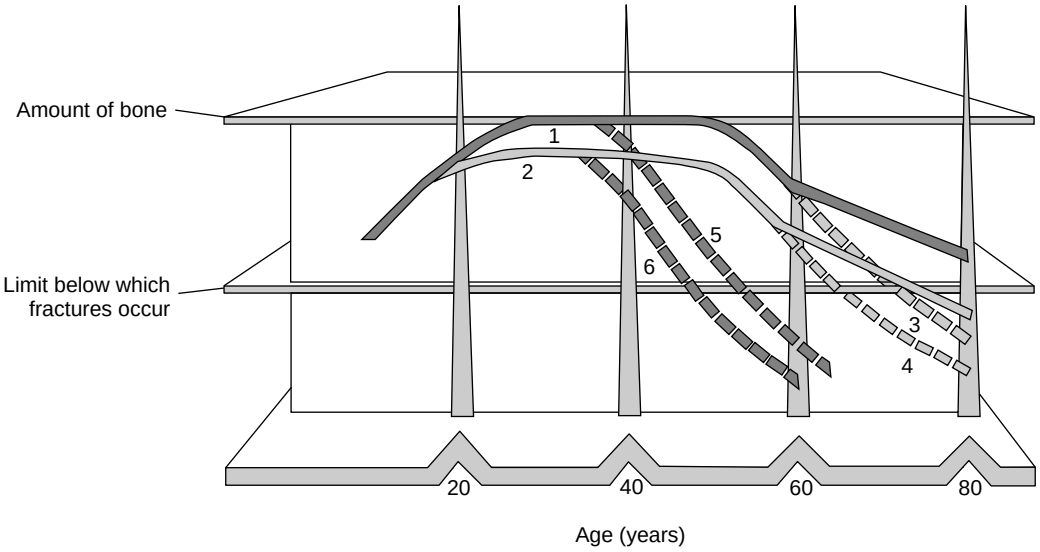

Figure 3 Rate of bone loss: 1, bone mass change in women with a high initial amount of bone and an average loss after menopause; 2, bone mass change in women with a low initial amount of bone and an average loss after menopause; 3 and 4, bone mass change in women with high losses after menopause; 5 and 6, bone mass change in women with an early menopause or after surgical removal of ovaries. First fractures occur approximately 10 years after menopause.

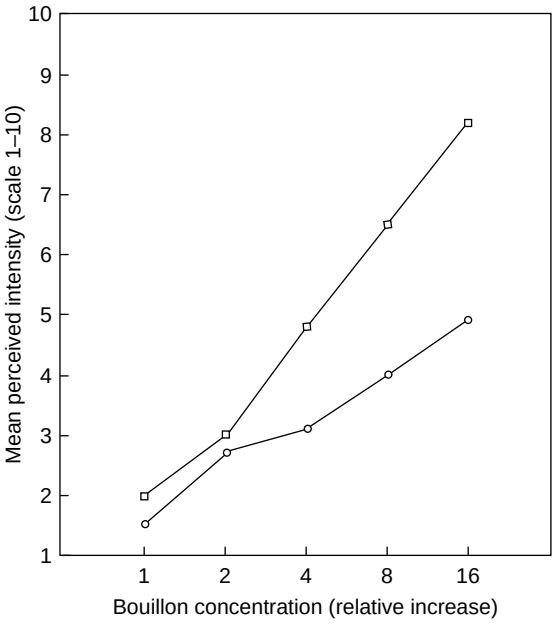

Figure 4 Mean responses of perceived intensity of bouillon flavor judged by a group of 23 elderly subjects (circles) and 32 young subjects (squares). (From Graaf C, Polet P and van Staveren WA (1994) Sensory and pleasantness of food flavors in elderly subjects. *Journal of Gerontology: Psychological Sciences* **94**: 93–99.)

bacterial overgrowth and malabsorption. The latter also may be caused by a reduced mucosal surface due to poor oxygenation of the tips of the villi as a result of a decreased blood supply from a low cardiac output. Decreased absorption is most frequently observed for electrolytes, lactose, vitamin D, and calcium. Absorption of digested food takes place by diffusion and by active transport across membranes. Adequate fluid must be available for absorption to proceed. The dehydrated state of the aged can reduce the capacity of the gut to absorb digested food.

Colon

The mucosal and muscle layers of the colon may atrophy, resulting in weakening of the muscle wall. Reduced motility of the colon allows prolonged exposure of feces to water absorption and drying. Reduced bulk results in further reduction of the stimulus to muscle contraction and will lead to constipation. This may be enhanced by a diet lacking dietary fiber, little physical activity, and poor tone of abdominal muscles.

Liver

Liver reserves of vitamins A, D, and B_{12} are unlikely to be diminished. Protein synthesis and especially the synthesis of vitamin K-dependent factors are reduced. However, it is not clear if this affects vitamin K requirements.

Gastrointestinal System

Elderly people are more prone to nutritional deficiencies that cause significant functionally deleterious consequences. The gastrointestinal system has been identified as an important cause of these problems. However, the mild functional and anatomic age-related changes do not seem to explain the incidence of malnutrition in the elderly. Rather, the lower functional reserve may accelerate nutritional problems under pathological challenge.

Nutrient and Drug Interactions

Many elderly people use drugs. In Europe, 83% of 'apparently healthy' people in the previously mentioned SENECA study use an average of two types of drugs, with antihypertensives (33%), analgesics (31%), diuretics (24%), sleeping pills (18%), and psychotropic drugs (17%) taken most often. Many drugs taken by the elderly can interfere with nutritional status. The possible effects include suppression or stimulation of appetite and impaired nutrient absorption and metabolism. For example, lisdiuretics can have adverse effects on calcium metabolism, salicylates can increase the need for vitamin C, and some types of antihypertensives act as antagonists of vitamin B_6. Negative consequences of laxatives, often taken by the elderly, include interference with nutrient absorption. Dietary interventions may help to reduce the intake of drugs. There is evidence that moderate sodium restriction prevents or delays the development of hypertension. Also, limiting alcohol intake provides protection because approximately 10% of cases of hypertension in men have been attributed to alcohol. Culinary skills become important to ensure that elderly people continue to find eating enjoyable, especially because increases in olfactory and taste thresholds occur with aging (**Figure 4**).

Risks for Malnutrition

Elderly people most at risk of developing malnutrition are those who eat little because of poverty, disability resulting from chronic geriatric disease, or a combination of these factors. Malnutrition is found in elderly people living in their homes if they are indigent, isolated, or homebound because of their own disability or the serious illness of their partner. Ten main risk factors for noninstitutionalized elderly can easily be identified and acted on by nonmedical personnel (**Table 1**). It must be understood that each risk in **Table 1** is only a potential

Table 1 Early warning signs for malnourishment

Medical and physiological factors
Recent unintended weight change of approximately >5% in the preceding month
Disease, polypharmacy or long-term medication
Immobility
High alcohol consumption
Psychological factors
Bereavement and/or depression or loneliness
Mental confusion
Poor nutrional knowledge
Socioenvironmental factors
Lack of sunlight
Low budget for food
Missed meals or snacks

danger sign; each has to be considered in relation to others. It should be stressed, however, that malnutrition is much more common in the elderly in long-term care, especially those who are unable to feed themselves.

Recommended Nutrient Intakes and High-Risk Nutrients in the Elderly

Recommended nutrient intakes for the elderly and very old may be set with different objectives. The values may serve either diagnostic or prescriptive purposes. Today, gerontologists and nutritionists are interested in the amount of nutrient that it takes to prevent a chronic disease from occurring rather than the amount of nutrient it takes to prevent a deficiency state. Most countries have their own set of requirements and age specificity may differ. In **Table 2** values are given as published by the Institute of Medicine (USA and Canada) for the oldest age group, mostly 70 years and older. The values should be accepted cautiously, with the proviso that change may be desirable when new information on nutritional needs of the elderly becomes available; for elderly patients who belong to particular disease groups, including mental diseases; for elderly people using specific drugs; and for elderly

Table 2 Recommended daily allowances (RDA) and observed problems for selected food components

Component	*RDA*[a]	*Problems*
Energy (MJ)		
Men	9–11	Low energy intake (<6.3 MJ) is highly correlated with insufficient micronutrient supply.
Women	8–10	
Protein (g/kg body weight)	0.8	Protein turnover may be lower than in young adults, which indicates lower requirement. However, the efficiency of protein synthesis is decreased.
Vitamin A (μg)		
Men	900	Risk of toxicity from megadoses in supplements.
Women	700	
Vitamin D (μg)	15	Requirement is increased in old age owing to insufficient synthesis with little or no exposure to UV light.
Thiamin (mg)		
Men	1.2	Special attention in those who eat little and elderly with alcoholic problems.
Women	1.1	
Riboflavin mg		
Men	1.3	Those consuming few animal products, especially milk, may be at risk.
Women	1.1	
Vitamin B_6 (mg)		
Men	1.7	Requirement may be higher when using antihypertensive drug hydralazine.
Women	1.5	
Folate (μg)	400	Extra attention for patients with atrophic gastritis and patients using a number of medicines.
Vitamin B_{12} (μg)	2.4	Vegans and patients with hypochlorhydria and atrophic gastritis have high risk; some drugs may interact.
Vitamin C (mg)		
Men	90	Increased requirements for patients using salicytes. Be alert for low vitamin C supply when using cooked meals from catering services and insufficient supply of fresh fruits.
Women	75	
Calcium (mg)	1.2	High-risk groups include elderly people using little or no milk and milk products and patients using lisdiuretica and some other drugs.
Iron (mg)	8	With reduction in lean body mass, iron requirement may be decreased. However, occult blood loss may increase requirement.
Iodine (μg)	150	Supply often inadequate; in some places enriched products (salt) should be used.
Water (ml)	1500–2000	Attention to fluid intake is necessary.

[a]Values derived from recent reports of the Institute of Medicine's Food and Nutrition Board (1999–2002), except RDAs for energy and water. The latter data are derived from the Expert Group Nutrition and the Elderly, The Netherlands (1995).

people using specific diets that may reduce the absorption of some nutrients.

Dietary Guidelines

Dietary surveys do not indicate that dietary guidelines for the elderly should be totally different from those for younger adults. Emphases in the program, however, should be different. Nutrition education programs for the elderly should give priority to drinking habits and to promoting the consumption of foods that are good sources of calcium, zinc, magnesium, potassium, folate, and vitamin B_6. Thus, recommendations should focus on the importance of daily consumption of (green) vegetables, fruit, wholegrain products and fortified cereals, and (low-fat) milk and milk products, and they should emphasize the nutritional value of fish and legumes. Because greater variety is associated with higher nutrient intakes in the elderly, the recommendation to eat a wide variety of foods is also important. Studies have emphasized that a healthy diet as well as other lifestyles, such as being moderately physically active and not smoking, are still important at an older age.

The Use of Dietary Supplements

The few studies on dietary supplementation among elderly people suggest that, as for younger adults, those elderly who need supplements do not use them, whereas the elderly consuming a diet with a high nutrient density use supplements. Food supplements include specially formulated preparations containing vitamins, minerals, and protein or a combination of these and other ingredients. Unnecessary use of supplements should be discouraged because consumption of megadose levels (amounts exceeding 10 times the recommended daily allowance) of various nutrients may cause adverse health effects. However, there are situations in which supplements have a role to play. For example, vitamin D would be indicated for the housebound elderly, and vitamin B_{12}, folate, potassium, or other nutrients may be a necessary supplement in disease conditions or when certain drugs are used that influence nutrient absorption, utilization, or excretion. In addition, suitable supplementation provides a means for improving the nutritional status of malnourished elderly or preventing nutritional deficiencies in people who are at risk.

Nutritional Management of Geriatric Patients

M-M G Wilson and J E Morley, St Louis University, St Louis, MO, USA

Undernutrition

Overwhelming evidence implicates undernutrition as a major index of increased mortality in older adults. Undernourished elders admitted to acute facilities are more likely to develop complications, resulting in increased length of stay and healthcare costs. Rehabilitative efforts are less rewarding as patients often fail to return to baseline functional status and are more likely to require long-term placement or emergency readmission.

Free-living older persons with suboptimal nutritional status are at increased risk of dependence on care givers as a result of compromised activities of daily living. Additionally, convincing evidence exists linking undernutrition with an increased incidence of frailty, gait instability, falls, hip factures, immune dysfunction, delayed wound healing, and decreased cognitive function. Nevertheless, nutritional

assessment and dietary management are often overlooked when health professionals evaluate geriatric patients.

As many as one-third of older adults in the US may be undernourished However, early clinical detection and appropriate intervention occur in less than one-tenth of cases. Health-care providers must remain astutely aware that geriatric health maintenance mandates efficient nutritional evaluation, surveillance, and prompt intervention.

Diagnosis and Evaluation of Undernutrition

Anthropometry

Several anthropometric indices have been proffered for the evaluation of undernutrition in older adults. These include:

- body weight less than 80% of the ideal body weight for height and age;
- weight loss exceeding 10% of baseline weight in the preceding 6 months; or
- body mass index less than 17.

Erroneously, the normative references for most of these criteria are younger subjects.

Within the older population the usefulness of this index is hampered by the lack of age-adjusted reference values. Reference values applicable in younger adults are not suitable for use in older persons as sarcopenia, age-related skin changes, and vertebral osteoporosis with height loss confound such norms. Within the older population, intentional weight loss resulting from dietary restriction should not discourage comprehensive nutritional assessment, as recent evidence indicates that both voluntary and involuntary weight loss in older persons portend similar adverse health outcomes.

Calculation of the body mass index (BMI) is considered to be one of the most objective anthropometric indices, as it permits correction of body weight for height. The BMI, calculated by dividing the weight in kilograms by the height in meters squared, is based on the proven premise that weight in the younger adult increases proportionately with height. However, this concept is false in older persons as height is significantly affected by age-related changes. Loss of height with aging occurs secondary to shortening of the axial skeleton due to age-related osteoporosis, degenerative disc changes, vertebral thinning, and kyphoscoliosis. Furthermore, using height as an anthropometric index is impractical in nonambulant and bed-bound persons. Nevertheless, clinical use of the BMI in the older population has been preserved by the development of adapted nomograms. Such nomograms are based on the determination of BMI using surrogate parameters of height adapted from the appendicular skeleton, which is relatively unaffected by age-related osseous changes. These parameters include total arm length, arm span, erect forearm length, and knee to floor height.

Skin fold thickness measurements are also used as anthropometric indices of total body fat in younger adults. However, the precise relationship between skin fold thickness and total body fat is unpredictable, as is the response of subcutaneous fat to undernutrition. Furthermore, in the older adult, the accuracy of this technique is confounded by age-related qualitative and quantitative changes in body fat. Altered compressibility of body fat has also been shown to occur with aging, rendering skin fold thickness measurements unreliable for use in older adults. Measurement of mid-arm circumference is another frequently used anthropometric index. However, several factors influence muscle bulk including exercise, disease, and genetic factors. In the older person this index is of doubtful clinical utility.

Several factors confound the use of anthropometric indices, underscoring the importance of serial measurements. These allow for quantification of response to intervention and also enhance accuracy of data interpretation by utilizing intrasubject comparison. More accurate methods of body composition analysis are available but are unlikely to be suitable for routine clinical use. These include computerized tomography, bioelectrical impedance, nuclear magnetic resonance imaging, *in vivo* neutron activation analysis, dual energy X-ray absorptiometry (DEXA) and direct photon absorptiometry (DPA). Because of alterations in body water with aging, the value of bioelectrical impedance is questionable. The DEXA technique is excellent but the migration of body fat to the abdomen with aging may result in an underestimation of body fat in older persons. DPA is based on analysis of tissue attenuation of photons transmitted at two different energy levels. This technique permits measurement of different tissue compartments. Both fat mass and fat-free mass can be measured using this technique. Currently, these methods are used almost exclusively for research purposes. Most of these emerging techniques are very expensive and have not been validated for use in clinical settings. Therefore, for practical clinical purposes, the most cost-effective nutritional parameter of proven clinical utility in older adults remains serial body weight measurements.

Biochemistry

Hypoalbuminemia is often erroneously used as an index of undernutrition. However, the diagnostic specificity of this index is poor. Serum albumin levels are determined by a complex interplay between nutritional intake, total body albumin distribution, and several pathological changes that alter the biosynthetic and catabolic rates of albumin. In the acutely ill or stressed older person, cytokine release suppresses albumin and prealbumin synthesis. Additionally, the release of catabolic counter-regulatory hormones in stressful situations reduces albumin synthesis even further. Direct downregulation of albumin gene expression also occurs in situations of acute stress. Paradoxically, undernutrition itself may result in a compensatory reduction in albumin catabolism, yielding inappropriately high albumin levels. Although serum albumin is a poor index of undernutrition, hypoalbuminemia is linked with frailty, excess comorbidity and increased mortality in older adults. Thus, the clinical relevance of hypoalbuminemia lies in the identification of a high-risk subset of older persons in whom early and aggressive nutritional intervention is crucial.

Several other biochemical indices are used as nutritional markers. However, like albumin, they lack diagnostic specificity and have relatively long half-lives, which limit their value in the serial evaluation of undernutrition. Insulin-like growth factor 1 is considered to have the greatest positive predictive value as it has been shown to correlate well with nutritional status even during periods of acute stress. Added advantages of this index are a relatively short half-life of 2–6 h and a rapid response to fasting and refeeding. Nonetheless, routine use of this assay in the evaluation of undernutrition is precluded by cost. Overall, for practical clinical purposes, the use of biochemical markers in routine nutritional geriatric management is costineffective and unreliable.

Hematology

Anemia of chronic disease resulting directly from undernutrition is a recognized clinical entity. Studies have identified reduced erythropoiesis and alterations of erythrocyte function in undernourished persons that respond to nutritional repletion. Iron and folate deficiency anemias may also result from inadequate micronutrient intake in undernourished persons.

Measurement of the total lymphocyte count (TLC) is helpful mainly in the stratification of the severity of undernutrition. A TLC of less than $1200 \times 10^6 1^{-1}$ indicates mild undernutrition while counts less than $800 \times 10^6 1^{-1}$ are usually found in severely undernourished persons.

Recognizing Causative Factors of Undernutrition

Age-related physiological reduction in appetite, 'anorexia of aging,' is well documented. Several factors have been implicated in the genesis of this phenomenon. Evidence suggests that the decrease in lean body mass, energy expenditure, and metabolic rate that occurs with advancing age may partially account for the reduction of food intake in healthy older persons. Age-related reduction in olfactory and gustatory receptor sensitivity may compromise the hedonic qualities of meals, further reducing the desire to eat. Similarly, age-related alterations in hormonal and neurotransmitter-mediated function may also play a role in suppressing food intake. Animal studies suggest that aging results in a reduction in the opioid feeding drive and an increase in the satiating effect of cholecystokinin. This may lead to the ingestion of smaller meals and prolonged periods of satiety between meals. More recently ghrelin, a hunger-inducing peptide hormone, has been shown to decrease with age. Similarly, older hypogonadal men have inappropriately high levels of leptin, a satiation-inducing peptide hormone.

The occurrence of a variety of pathological factors superimposed on the background of age-related physiological changes may further compromise nutritional status in the older adult (**Table 1**). Existing data suggest that as many as one-third of undernourished older persons suffer from untreated depression. Neuro-vegetative symptoms in depressed older persons often result in anorexia, social withdrawal, reduced motivation, and decreased activity, all of which can compromise nutritional intake. The use of appropriate antidepressants very often reverses these symptoms, resulting in an increase in food intake and restoration of adequate nutritional status. Choice of antidepressants is crucial in the management of depressed, older undernourished persons. The popularity of selective serotonin reuptake inhibitors in younger persons has led to their increasing use in the older population. However, in older persons the efficacy of such agents in improving mood may be marred by adverse gastrointestinal effects, such as nausea, vomiting, and diarrhea, which may further compromise nutritional status. Thus, where such agents are used, careful monitoring of nutritional status is mandatory. Mirtazapine is a useful antidepressant that is unrelated to selective serotonin

Table 1 Common and uncommon causes of undernutrition in older persons

Reduced food intake
Anorexia
Ill-fitting dentures
Periodontal disease
Oropharyngeal disease
Orofacial dyskinesias
Psychosocial factors
Depression
Eating disorders
Bereavement
Social isolation
Low financial income
Physical/mental disability

Substance abuse

reuptake inhibitors, tricyclics, or monoamine oxidase inhibitors (MAOI). Mirtazapine belongs to the piperazino-azepine group of compounds. Available evidence suggests that Mirtazapine has an additional orexigenic and anti-emetic effect, which may increase energy consumption. Electroconvulsive therapy is a viable option in depressed persons with severe anorexia. Evidence exists in support of the efficacy of this treatment modality in restoring appetite following failure of pharmacological agents.

Minor dysphoric changes may adversely affect nutritional status and warrant intervention. Over 30% of older community-dwelling persons live alone, usually as a result of bereavement or migration of younger family members. Meals are often eaten alone and the lack of social interaction during meal preparation and consumption can compromise the recreational and hedonic aspects of dining. Consequently, such elders are poorly motivated to prepare and eat meals. Particular attention should be paid to the recreational aspects of mealtimes, and older persons should be encouraged to socialize during meals. This can be accomplished in a variety of ways. Participation in dining clubs, where available, should be encouraged. Arrangements can also be made for older persons to dine at senior citizens' centers. Ambulant senior citizens should be encouraged to eat out, if this is preferred.

Effective nutritional intervention mandates due consideration of financial and socioeconomic factors. Approximately one-third of the older population live below the poverty line and many experience difficulty with the purchase of food items necessary to ensure a balanced diet. Inadequate transportation, limited mobility, and poorly accessible shopping facilities may be added limiting factors. Social and community agency services should be considered where relevant, and an attempt should be made to provide appropriate assistance.

A wide variety of prescribed drugs can cause anorexia, nausea, and other symptoms of gastrointestinal distress in older persons, rendering medication review an important component of nutritional management. Digoxin, theophylline, and nonsteroidal anti-inflammatory agents are frequent culprits in this regard. Enquiry must also be made into the use and tolerance of self-prescribed medication. Offending drugs, once identified, must be discontinued. Iatrogenesis also contributes to undernutrition by way of therapeutic diets. Low-cholesterol and low-salt diets are often prescribed to older persons on the basis of data extrapolated from younger persons. There is currently little evidence to suggest that these diets are of any benefit to older persons when used as primary prevention strategies. Available data actually indicate increased mortality in older adults with low-cholesterol levels. Evidence suggests that hypocholesterolemia may reflect increased cytokine expression in acutely ill and frail older adults. Thus, restrictive diets in older persons should be discouraged, as they often reduce palatability and consequently discourage food intake. Health professionals should also make enquiries regarding self-prescribed diets. Studies indicate that the older population is more susceptible to food fads and advertised commercial diets, which are often unbalanced and of dubious benefit. Prolonged ingestion of such diets can result in marked undernutrition.

A wide variety of medical illnesses require focused therapeutic intervention in order to maintain or restore adequate nutritional status. Degenerative and

neurological diseases can significantly impair mobility and physical function. The use of adapted appliances and cutlery in such cases may improve manual dexterity and preserve the ability to self-feed. In older persons with severely impaired function, who are unable to cook, meal delivery services ('meals on wheels') may be an acceptable alternative to home-cooked meals. Tooth loss is another important risk factor for undernutrition. Periodontal disease and edentulism are highly prevalent among the geriatric population and can impair masticatory ability. Older persons who have lost teeth, experience pain on mastication, or receive inadequate dental care should be carefully screened and offered appropriate therapy. The use of dentures may improve food intake. However, where dentures are poorly tolerated, alteration in the consistency of meals is helpful. Dysphagia occurs commonly in older persons with degenerative and vascular neurological conditions such as dementia, Parkinsonism, and cerebrovascular disease. A bedside swallowing evaluation should be an integral component of nutritional evaluation, followed by a modified barium swallow with fluoroscopy in cases where significant dysphagia is identified. In most cases oral food intake will remain possible, with appropriate modifications regarding swallowing technique, feeding precautions, and food consistency.

Health professionals often wrongly assume that older adults possess adequate knowledge of basic dietetic practice and nutritional studies. There is evidence to suggest that the nutritional attitudes and knowledge of undernourished older persons may be inadequate, particularly with regard to food preparation. Dietary education and counseling are crucial components of nutritional intervention in undernourished older persons who retain the responsibility for preparing their own meals. Such counseling should be targeted towards identifying deficits in basic dietary knowledge and the correction of poor nutritional practices.

Nutritional Assessment Tools

Arrays of nutritional screening tools have been developed to facilitate the identification of older persons at risk for undernutrition. The Nutrition Screening Initiative (NSI) in the US stemmed from a collaborative effort between family physicians, dietitians, and the National Council of Aging. This is a three-tiered tool formulated to assist in the detection of older persons at risk for nutritional compromise and subsequent direction of such persons toward the appropriate level of care. The first level of screening is designed to be initiated by the patient or primary care giver. Persons identified to have an increased risk of undernutrition are then referred for evaluation by healthcare or social services personnel. This constitutes the second level of screening. The identification of factors that may warrant medical intervention will prompt referral to a physician for further evaluation. The NSI is of proven value as an epidemiological tool and serves to increase the awareness of patients and care givers to undernutrition. However, its usefulness within orthodox settings may be hampered by the number of personnel and services required, which may constitute a significant drain on available resources. Added drawbacks to the use of this tool for the individual patient are the lack of professional supervision at initiation and reliance on patient compliance in adhering to the specified clinical pathway protocol.

The Mini Nutritional Assessment (MNA) is a comprehensive and simple tool designed to evaluate the nutritional status of older persons. This is the first well-validated nutritional screening instrument and is recommended for use in people aged over 75 years. Cross-validation indicates that nutritional assessment using this tool will accurately evaluate and categorize nutritional status in about 75% of older persons without the need for further biochemical tests or clinical assessment. The MNA scoring system permits the stratification of older adults into three categories: well-nourished, at risk of undernutrition, and undernourished. An advantage of the MNA is that it can easily be used by a wide range of health professionals in a variety of clinical settings that cater for both free-living and institutionalized older persons. Several other tools are of practical value in the clinical setting. Morley has developed a useful screening tool known by the acronym SCALES (**Table 2**). This uses basic biochemical and anthropometric indices to identify older adults at risk of undernutrition, and can be readily incorporated into serial evaluation of the older person in

Table 2 SCALES: screening tool for the early detection of patients at risk of protein-energy undernutrition

Parameter	*Score 1 point*	*Score 2 points*
Sadness	GDS 10–15	GDS >15
Cholesterol	<4.65 mmol l^{-1} (180 mg dl^{-1})	<4.14 mmol l^{-1} (1660 mg dl^{-1})
Albumin	<40 g l^{-1} (4 g dl^{-1})	<35 g l^{-1} (3.5 g dl^{-1})
Loss of weight	<1 kg (2 lb) in 1 month	<2.7 kg (6 lb) in 6 months
Eating problems	Cognitive impairment or physical limitations	Cognitive impairment and physical limitations
Shopping problems	Inability to shop or prepare a meal	

Patients scoring over 3 are at risk. GDS, geriatric depression score.

Table 3 MEALS ON WHEELS: common causes of undernutrition in older persons

Medication (e.g., digoxin, theophylline, psychotropic drugs)
Emotional (depression)
Anorexia, alcoholism
Late-life paranoia
Swallowing disorders
Oral and dental disease
No money (absolute or relative poverty)
Wandering (dementia, behavioral disorders)
Hyperthyroidism, hyperparathyroidism
Entry problems (malabsorption)
Eating problems
Low-salt or low-cholesterol diets
Shopping and food preparation problems

different clinical settings. The simple mnemonic MEALS ON WHEELS, also devised by Morley, may prove useful in prompting consideration of the risk factors and common causes of nutritional compromise (**Table 3**).

More recently, the Council of Nutrition Appetite Questionnaire has been validated for the evaluation of appetite in older adults. A unique feature of this appetite assessment tool is the ability to predict significant weight loss (**Table 4**).

Table 4 The Council of Nutrition Appetite Questionnaire

1. My appetite is:
1. very poor
2. poor
3. average
4. good
5. very good

2. When I eat:
1. I feel full after eating only a few mouthfuls
2. I feel full after eating about a third of a meal
3. I feel full after eating over half a meal
4. I feel full after eating most of the meal
5. I hardly ever feel full

3. I feel hungry:
1. rarely
2. occasionally
3. some of the time
4. most of the time
5. all of the time

4. Food tastes:
1. very bad
2. bad
3. average
4. good
5. very good

5. Compared to when I was younger, food tastes:
1. much worse
2. worse
3. just as good
4. better
5. much better

6. Normally I eat:
1. less than one meal a day
2. one meal a day
3. two meals a day
4. three meals a day
5. more than three meals a day

7. I feel sick or nauseated when I eat:
1. most times
2. often
3. sometimes
4. rarely
5. never

8. Most of the time my mood is:
1. very sad
2. sad
3. neither sad nor happy
4. happy
5. very happy

Instructions: Complete the questionnaire by circling the correct answers and then tally the results based upon the following numerical scale: A = 1, B = 2, C = 3, D = 4, E = 5. The sum of the scores for the individual items constitutes the CNAQ score. Scoring: If the CNAQ score is less than 28, there is an increased risk of significant weight loss over the next 6 months.

Oral Nutritional Repletion

Appropriate treatment of the underlying causes of undernutrition should be accompanied by oral nutritional supplementation in persons who are able to eat. Objective quantitative baseline assessment of food intake is mandatory. This is best achieved by the maintenance of a food diary, in which the patient records all food items consumed over a 72-h period. Review of the food diary also permits evaluation of food preferences and eating patterns. The goal of nutritional supplementation should be the consumption of the recommended daily allowance of macronutrients and micronutrients. Several predictive equations have been derived for the purpose of determining the optimal energy intake for each individual. However, it remains unclear as to what extent corrections have been made for age-related physiological changes in nutritional requirements and energy expenditure. The Benedict-Harris equation is perhaps the best known and most frequently applied. Using this equation, the required daily energy intake in kilocalories is derived as follows:

- Men: $66 + 13.7W + 5H - 6.8A$
- Women: $665 + 9.6W + 1.8H - 4.7A$

where W is the weight in kilograms, H is the height in centimeters, and A is the age in years. Upward adjustment is required by factors ranging from 1 to 1.5, to compensate for increased activity or pathologically stressful conditions.

For practical clinical purposes, a total daily energy intake of $147\,kJ\,kg^{-1}$ ($35\,kcal\,kg^{-1}$) achieves

efficient nutritional repletion. Recent dietary guidelines emphasize an overall healthy and balanced dietary pattern that includes a wide variety of fruits, vegetables, and grain products. Specifically, at least 5 daily servings of fruits and vegetables and 6 daily servings of grain products, including whole grains. Low-fat dairy products, fish, legumes, poultry, and lean meats are encouraged. Guidelines also suggest at least two servings of fish per week.

The current recommended daily allowance for protein is at least $1\,g\,kg^{-1}$ body weight. However, acutely stressful or hypercatabolic conditions mandate an increase in protein intake to about $1.5\,g\,kg^{-1}$. Generally, compliance with these dietary guidelines achieves the dual purpose of ensuring optimal macronutrient and micronutrient intake. This obviates the need for the routine prescription of pharmacological multivitamin preparations in undernourished persons, unless specific signs of micronutrient deficiency are evident.

Nutritional supplementation with regular or fortified natural food items is the ideal mode of nutritional repletion. This possesses the advantages of familiarity, palatability, and cost-effectiveness. Where the patient is reluctant or unable to consume the required total energy intake in natural food items, commercially formulated nutritional supplements are a reasonable alternative. The choice of preparation should be based on palatability and patient preference unless underlying medical conditions such as lactose or gluten intolerance have to be considered. Patients with malabsorption syndromes should be given hydrolyzed preparations to enhance nutrient absorption. Regardless of the preparation used, an attempt should be made to vary flavors, as age-related sensory-specific satiety may limit intake if only one flavor is used. Erroneously, nutritional supplements are often administered with meals. Recent evidence indicates that liquid supplements are more effective in increasing daily energy intake when administered at least 1 h before meals. Data shows that when supplements are administered with meals, a suppressant effect on food consumption is evident. Thus, older adults on nutritional supplements should receive these between meals to maximize net energy intake. Ultimately, in persons with severe undernutrition, the focus should be on energy intake and patient food preference, not on optimal proportions of macronutrient and micronutrient intake. Frequently, efforts to ensure a balanced diet necessitate the use of food items that may compromise palatability and result in a counterproductive reduction in food intake.

Enteral Tube Feeding

Enteral or parenteral modes of nutrient delivery are often used in people who are unable to eat or swallow. In the presence of a functioning gastrointestinal tract, enteral feeding is more appropriate due to the lower incidence of complications, more efficient nutrient utilization, increased cost-effectiveness, and greater ease of administration. Additionally, small bowel hypoplasia and alterations in gastrointestinal secretions may result from prolonged parenteral nutrition. Nasogastric and nasoenteric tubes should be reserved for short-term nutritional support in persons who may be able to resume oral feeding within 14 days, in order to avoid the significant morbidity associated with the use of nasal tubes. In persons in whom prolonged enteral intake is anticipated, gastrostomy or jejunostomy tubes may be considered.

In patients who retain normal gastrointestinal absorptive function, regular meals may be puréed and delivered through large-bore feeding tubes. A variety of polymeric enteral feeding formulas are also available; these are of relatively low viscosity, rendering them particularly suitable for delivery through small-bore tubes, which are usually more comfortable and aesthetically pleasing. In persons with malabsorption, hydrolyzed predigested formulae are available. Specific formulations also exist for people with special nutritional requirements due to diseases such as diabetes mellitus or renal or respiratory failure.

In older people, large volume bolus tube feedings may be associated with a greater risk of aspiration. Thus, where possible, continuous infusions of feeds are preferred. In order to further reduce the risk of aspiration pneumonia, it is recommended that the patient is positioned in a 30° head-up incline during feedings. Feeds may be infused over a 24-h period or over 14–18 h with a nocturnal break. The latter infusion schedule is often advocated on the grounds that it mimics normal eating patterns more closely. In addition, the absence of a nocturnal feed-free period has been shown to obliterate the physiological diurnal variation in insulin, cortisol, and glucagons secretion. Maximal nutrient utilization is also encouraged by daytime feed infusions as gastric emptying occurs more rapidly during the day. Continuous infusion of enteral tube feeds should be initiated at a rate of $30\,ml\,h^{-1}$ using half-strength feeds. If tolerated, full-strength feeds may then be introduced at the same rate and increased by $25\,ml\,h^{-1}$ every 8–12 h until the recommended daily energy intake is achieved. Despite the popularity of enteral tube feeding, emerging evidence

indicates that the medical risks of percutaneous endoscopic gastrostomy (PEG) tube feeding may outweigh the risks. Studies in older adults with dementia fail to demonstrate any reduction in comorbidity or mortality with PEG feeding. Similarly, available data fails to demonstrate any significant improvement in functional status, nutritional status, or quality of life with this method of feeding. Thus, health providers should set realistic goals for patients and family members who opt for PEG feeding. Ultimately, the indications and benefits of PEG tube placement are more likely to be based on personal psychosocial, cultural, or ethical preferences.

Parenteral Nutritional Repletion

In the older person with a nonfunctioning gastrointestinal tract, parenteral nutrition may be unavoidable. All patients receiving parenteral nutrition must be monitored closely for adverse effects. For short-term intravenous nutritional repletion, peripheral parenteral nutrition may be used. Low osmolality nutritional preparations, with a low risk of toxicity to soft tissue, are best suited for this purpose. There is a paucity of data regarding the safety and efficacy of most peripheral parenteral nutritional products for periods exceeding 14 days. Thus, where longer periods of intravenous feeding are required, total parenteral nutrition through a large central vein is indicated. Standard total parenteral formulations comprising 25% dextrose, 5% amino acids, electrolytes, and trace elements in optimal amounts are suitable for use in most patients. During prolonged parenteral nutrition, lipid emulsion supplements should be added to prevent deficiency of essential fatty acids.

Pharmacological Management of Undernutrition

Older patients with a poor response to treatment of underlying causes and nutritional supplementation may benefit from orexigenic agents (**Table 5**).

Table 5 Orexigenic agents

Megesterol acetate
Mirtazapine
Dronabinol (delta-9-tetrahydrocannabinol)
Corticosteroids
Loxiglumide (Cholecystokinin antagonist)
Oxoglutarate
Anabolic agents (testosterone, anadrol)
Oxandrin
Growth hormone
Cyproheptadine

Megestrol acetate is a synthetic progestogen approved for use by the Food and Drug Administration (FDA) as an orexigenic agent in patients with Acquired Immune Deficiency Syndrome (AIDS) and cancer-related anorexia and cachexia. Recent evidence indicates that megesterol acetate is also an effective orexigenic agent in geriatric patients. Thromboembolic disease and adrenal suppression are rare complications, but patients should be monitored closely for these events.

Dronabinol (delta-9-tetrahydrocannabinol), the active ingredient of *Cannabis sativa*, is another FDA-approved orexigenic agent for use in patients with Acquired Immune Deficiency Syndrome (AIDS). Dronabinol is also an effective orexigenic and antiemetic in patients receiving cancer chemotherapy. Additional evidence indicates that dronabinol induces weight gain in persons with dementia, although research has yet to determine whether weight gain in such patients is due to increased energy intake or reduced agitation with improved behavior and consequently decreased energy expenditure. Side effects of dronabinol in older adults include delirium, euphoria, and increased somnolence. The latter two qualities may favor the use of dronabinol as an orexigenic agent in palliative care.

One third of depressed older adults manifest with weight loss. Effective antidepressant therapy should result in weight gain in this subset of patients. Notably, the choice of antidepressant therapy may influence body weight reuptake. Selective serotonin (5-hydroxytryptamine, 5-HT) inhibitors, such as fluoxetine, can cause significant weight loss at the onset of therapy. Evidence in younger adults suggests that this is a transient phenomenon with baseline body weight being restored as treatment progresses. However, age-related changes in energy regulation and adaptation to chronic disease may delay or prevent return to baseline body weight in older patients. Mirtazapine has proved useful in the management of depressed patients with weight loss. Mirtazapine is a well-tolerated and effective antidepressant that inhibits presynaptic $alpha_2$ adrenergic receptors and postsynaptic 5-HT2 and 5-HT3 receptors. Mirtazapine has been shown to induce an earlier increase in appetite and subsequent weight gain in older depressed persons with weight loss.

Several agents previously touted as effective orexigenic agents, such as human growth hormone, have fallen out of favor. The administration of human growth hormone to healthy older adults has been shown to increase muscle bulk. However, significant side effects such as carpal tunnel syndrome,

gynecomastia and hypoglycemia were noted; furthermore, the increase in muscle bulk failed to produce a parallel increase in muscle strength. Inadequate data regarding the safety and efficacy of growth hormone administration precludes routine clinical use. Similarly, the role of insulin-like growth factor (IGF-I) in the management of undernutrition is questionable. Although the data suggest that exogenously administered IGF-I may enhance nitrogen retention, gluconeogenesis, and maintenance of normal gastrointestinal function, evidence-based outcome studies are lacking.

Abundant data exist regarding the role of anabolic steroids in the management of undernutrition. However, current evidence supports the restriction of testosterone therapy as an orexigenic agent to hypogonadal undernourished men. As a general rule, pharmacological treatment should be considered second-line therapy and reserved for patients who have failed to respond to nonpharmacological measures.

Managing Undernutrition in the Community Setting

With increasing emphasis on home healthcare, the number of community-dwelling persons requiring alternative modes of feeding has increased. Special consideration and appropriate modification of therapeutic regimens may be required in such cases to ease the care giver or personal burden.

If enteral tube feeding is provided at home, continuous infusion may limit the patient's mobility and functional independence. This method also has the disadvantage of requiring immediate access to technical support, in the event of mechanical failure of the infusion pump. Thus, care givers and patients may find intermittent bolus feeding a more convenient and less daunting task. To minimize the aspiration risk, intermittent bolus feeds should be administered, where possible, with the patient in a seated position. Patients should also be encouraged to remain seated for at least 1 h after feeds. Some active older people resent the social inconvenience and embarrassment of tube feeding during daytime hours, and may prefer overnight enteral infusions of hypercaloric feeds. Hypercaloric feeds contain twice the amount of equal volumes of regular enteral feeds, thereby permitting the provision of adequate nutritional support over shorter periods.

Parenteral nutrition within the home is fraught with all the hazards of intravenous therapy. Thus, availability of skilled services to monitor such therapy is critical. Additionally, adequate care giver and social support is mandatory for patients receiving this mode of nutritional repletion at home.

Health providers involved in home delivery of enteral and parenteral nutritional therapy will need to develop and implement comprehensive therapeutic programs incorporating skilled nursing and dietary services to ensure safe and effective treatment.

Managing Undernutrition in Long-Term Care Institutions

Therapeutic strategies for managing undernourished institutionalized older adults are similar to those used within the community, though perhaps due to readily available medical supervision, enteral and parenteral modes of feeding are used more often. The comparatively formal structure of the nursing home environment has the added advantage of encouraging closer supervision of therapy and stricter nutritional surveillance.

A major drawback to oral nutritional repletion in institutionalized older persons is the restricted variety of meals. This can usually be circumvented by involving the residents in menu development and, where feasible, granting permission for meals of the residents' choice to be supplied by family or friends. Residents of nursing homes are often less functional than their peers and thus may be more dependent on assistance for their basic activities of daily living. When the ability to self-feed is compromised, it is imperative that all meals are supervised and assistance with feeding rendered where necessary. Many residents are persistent wanderers, and may expend a considerable amount of energy in this exercise. In such patients an appropriate increase in their daily energy intake is required to prevent weight loss. Similar adjustments may be required for residents with persistent involuntary movements or severe agitation.

Long-term care institutions must preserve the social and recreational aspects of meals; all too often, mealtimes are reduced to clinical, sanitized, and isolated events. Within the nursing home environment mealtimes are best managed as a component of recreational therapy. Socialization and the preservation of each resident's dignity should be encouraged during meals. Nursing facilities should also attempt to mimic community resources by making food items available outside scheduled mealtimes, from vending machines and snack carts.

Nutritional surveillance programs are crucial to the success of established intervention strategies within nursing homes. Quality indicators, preferably

employing anthropometric indices, should be defined to monitor the success of intervention strategies. Continuous quality improvement and total quality management programs must also be implemented as critical components of effective nutritional intervention strategies. Finally, the development of nutrition focus groups and the use of interdisciplinary intervention strategies directed at increasing nutritional intake and preventing undernutrition should be encouraged.

Micronutrient Deficiency

In older people at risk of nutritional compromise, micronutrient supplementation deserves special attention, in order to forestall the development of micronutrient deficiency (**Table 6**). The clinical features of established vitamin deficiency are well recognized. The first recourse in the management of micronutrient deficiencies should be the provision of a well-balanced diet. In the presence of a functioning gastrointestinal tract, an adequate diet containing the recommended daily allowance of each micronutrient effectively prevents and corrects deficiency states. However, the failure to consume the required amount of food may warrant the use of oral pharmacological micronutrient supplements. Vitamin B_{12} deficiency may be considered unique in this regard as, traditionally, replacement therapy has been administered parenterally. However, available evidence suggests that food-cobalamin deficiency may be the most common cause of vitamin B_{12} deficiency in older adults. In this condition cobalamin cannot be extracted from ingested food, although free cobalamin is readily absorbed as absorptive function is normal and intrinsic factor is present in adequate quantities. Thus, in persons with vitamin B_{12} deficiency resulting from food-cobalamin deficiency, repletion may be adequately achieved by oral replacement therapy.

There is a rising trend toward dietary supplementation with pharmaceutical preparations containing large doses of vitamins and minerals, based on conclusions drawn from the results of several studies. Available evidence derived from human and animal studies indicates that antioxidant micronutrients, mainly vitamins A, C and E, may play a role in boosting immunity, preventing neoplastic disease, and preventing or retarding the progression of several degenerative diseases, such as atherosclerosis. Vitamins E and C have also been shown to reduce low-density lipoprotein (LDL) cholesterol levels and increase high-density lipoprotein (HDL) levels, in addition to lowering fasting plasma insulin levels and improving insulin efficiency. Epidemiological studies have suggested a protective role for antioxidants such as vitamin C, vitamin E, β-carotene, and glutathione in macular degeneration and cataracts. Nevertheless, evidence derived from other epidemiological studies suggests that antioxidants may lack significant benefit. Studies are ongoing in an attempt to resolve this controversy.

In older adults reduced cutaneous synthesis and enteric absorption of vitamin D increases the risk of vitamin D deficiency. Reduced renal responsiveness to parathormone is an added risk factor. At least $500\,\text{IU}\,\text{day}^{-1}$ of vitamin D are required to prevent significant osteoporosis in postmenopausal women. Institutionalized patients with reduced exposure to sunlight are at higher risk of vitamin D deficiency due to reduced cutaneous synthesis. The role of calcium supplementation in the prevention of osteoporosis is also well accepted. Additional evidence suggests that inadequate dietary calcium consumption may play a role in the genesis of colorectal cancer and hypertension.

Table 6 Vitamins: recommended daily allowances (RDAs) and clinical features of deficiency states

	RDA	*Deficiency states*
Vitamin A	600–700 μg	Decreased immunity to infections, xerophthalmia, night blindness
Niacin	12–16 mg	Pellagra (dermatitis, dementia, diarrhea), glossitis, cheilosis
Pyridoxine	1.6–2 mg	Dermatitis, delirium, peripheral neuropathy, glossitis
Riboflavin	1.1–1.3 mg	Glossitis, cheilosis, normochromic anemia
Thiamin	0.8–0.9 mg	Beriberi, Wernicke's encephalopathy, Korsakoff's psychosis
Cyanocobalamin	5 μg	Megaloblastic anemia, optic atrophy, peripheral neuropathy, subacute combined degeneration of the cord, dementia
Ascorbic acid	40 mg	Hyperkeratosis, petechial hemorrhages, mucosal bleeding, lethargy
Vitamin D	10 μg	Osteomalacia, osteoporosis
Vitamin E	8–10 mg	Peripheral neuropathy, ataxia, hemolytic anemia
Folate	200 μg	Megaloblastic anemia, cognitive dysfunction
Vitamin K	65–80 mg	Spontaneous hemorrhage, hypothrombinemia

NE, niacin equivalent; RE, retinal equivalent.

Currently, the safety of large pharmacological doses of micronutrient supplements in humans remains to be established. In spite of this, a considerable proportion of the older population consumes large doses of these supplements as a primary preventive health measure. The risk of long-term supplementation with high doses of micronutrients, particularly in the presence of age-related changes, cannot be ignored, and few studies have addressed this issue specifically. Due caution must be exercised, even with the use of micronutrients such as vitamin D and calcium where clinical benefits have been clearly established. The complications of overenthusiastic calcium and vitamin D supplementation include hypercalcemia, nephrocalcinosis, milk-alkali syndrome, ectopic calcification, and rebound gastric acidity. Calcium supplementation may also chelate iron compounds and precipitate iron deficiency. With regard to vitamin A, available data have identified an increase in absorption and reduced peripheral clearance of this vitamin in older adults, therapy increasing the risk of vitamin A toxicity. Similarly, older persons on long-term iron therapy, particularly in the absence of proven iron deficiency, are at increased risk for the development of secondary hemochromatosis.

On the basis of existing evidence, the use of pharmacological doses of vitamin and mineral supplements is probably best restricted to low-potency supplements and reserved for persons with established micronutrient deficiency who are unable to eat an adequate diet. Close monitoring of such patients for adverse effects is mandatory.

Obesity

Men aged 55–64 years have the highest prevalence of overweight for males in the US (71.7%). Although the prevalence drops with age, the prevalence of overweight among men and women over 75 years is still considerable (52% and 44%, respectively). At all ages, African Americans have a higher prevalence of overweight and obesity.

With aging there is increasing upper and central body fat distribution. This trend is accelerated in women following menopause. In women aged 55–69 years, central obesity has been demonstrated to be correlated with greater coronary artery disease mortality as well as total mortality. Even with weight loss, the waist to hip ratio remained an important predictor of mortality in elderly women. Leptin is a hormone produced by fat cells. In women, leptin levels rise in middle age in concert with the increase in fat mass and then fall in late old age as fat mass declines. In men, leptin levels increase progressively from 65 years onwards. This may be due to age-related hypogonadism. In older men, testosterone replacement therapy decreased leptin levels.

As food intake declines with aging, obesity in old age is probably due to other factors. All three components of energy output – resting metabolic rate, thermic energy of feeding, and physical activity – decline with aging; thus the pathogenesis of obesity in old age appears to be predominantly due to altered energy output rather than to increased food intake.

While moderate degrees of overweight appear to confer minimal increased mortality in the older population, those above 130% of average body weight have an increased risk of death even at extreme ages. Most of the complications of obesity in older persons are similar to those seen in younger persons. Certain effects of obesity appear more commonly in older persons; for instance, functional decline is more common compared with younger persons. This is often associated with a 'fear of falling.' This syndrome is particularly common in older urban-dwelling adults and may lead to voluntary restriction of physical activity and consequent frailty. The prevalence of diabetes mellitus increases with age, due in part to the increased fat mass in middle age onwards. Obesity markedly increases the prevalence of sleep apnea in older persons. Overweight increases the rate of progression of osteoarthritis and its effects on function. In nursing homes, obesity has been associated with an increase in pressure ulcers. Increasing weight increases claudication in older persons with peripheral vascular disease.

Management of obesity in older persons usually should focus on enhancing functional status and increasing physical activity as opposed to aggressive caloric restriction. Available evidence linking aggressive weight loss in older adults with increased mortality mandates close monitoring during treatment. Surgery for obesity is not appropriate in older adults as the risks of bariatric surgery outweigh the benefits. For similar reasons, the use of thermogenic and anorexic agents should be avoided. Thus, a combination of exercise, healthy eating, and behavior modification is the cornerstone of therapy in older persons. Older obese adults need to be carefully monitored for the development of sarcopenia, visceral protein depletion, and increasing frailty. Due attention should also be given to micronutrient supplementation.

Osteomalacia *see* **Vitamin D**: Rickets and Osteomalacia

OSTEOPOROSIS

K O O'Brien, Johns Hopkins University, Baltimore, MD, USA

Optimal dietary intake is essential for bone health. During childhood and the pubertal growth spurt, nutrients are needed to fully consolidate skeletal mass and to ensure the attainment of a peak bone mass consistent with one's genetic potential. After peak bone mass is obtained, nutrition continues to play an essential role in skeletal health. If intakes of key nutrients are not consumed at required levels, mineral may be lost from bone or essential bone proteins may not be fully functional.

Osteoporosis and osteopenia are substantial public health problems. Low bone mass (osteopenia and osteoporosis) and vitamin D deficiency are currently substantial public health problems. Osteopenia is defined when adult bone mineral density values are 1–2.5 SD below the mean peak value observed in a young adult. If the deficit in bone is more pronounced, and bone mineral density falls 2.5 SD or more below that observed in a young adult, this is defined as osteoporosis. Approximately 200 million people worldwide have osteoporosis. Many more have suboptimal bone mass and are at increased risk of developing this disease. Vitamin D deficiency in adults can also impair bone mineralization and lead to osteomalacia (in adults) or rickets (if evident in pediatric age groups prior to the completion of longitudinal bone growth). Insufficient bone mass and impaired bone mineralization increases the risk of fractures at considerable cost and loss of quality of life. Because bone loss is not fully reversible, the most effective strategies for reducing osteoporosis should focus on prevention, with nutrition playing a key role.

Dietary Intake and Body Mass

A balanced diet is important to promote health and to maintain an appropriate body weight. An

Table 1 Nutritional and lifestyle parameters that may influence bone health

Minerals	*Vitamins/ hormones*	*Lifestyle and environmental factors*	*Dietary components*
Calcium	Vitamin D	Body mass index	Protein

Sodium	Vitamin C	Alcohol intake	Homocysteine
Zinc	Vitamin B_{12}		
Copper	Vitamin B_6		
Iron	Folate		
Boron			
Manganese			
Fluorine			
Potassium			
Silicon			

individual's body weight is one of the strongest determinants of bone mass because of the skeleton's responsiveness to the load that is placed on it. Individuals with small body frames or those who are excessively thin have an increased risk of osteoporosis due to a lower overall skeletal reserve to draw on for calcium needed to offset the annual loss of bone that occurs later in life. At the extreme end of this spectrum, individuals with anorexia nervosa are at risk of osteoporosis because of alterations in hormonal status and amenorrhea in addition to insufficient dietary intake of nutrients required for bone health.

Although higher body weight is typically associated with a greater skeletal mass, obese individuals may sequester nutrients needed for skeletal health, such as vitamin D, in adipose tissue. Bariatric surgery as a treatment for morbidly obese individuals is becoming more common and leads to a loss of both body weight and bone mass. The long-term impact of this surgery on skeletal health is not yet fully elucidated, and it remains unclear if the amount of bone lost following surgery is solely a response to the decrease in body weight or if it is also associated with other adverse consequences of this surgery on bone health.

Although overall caloric intake impacts body weight, many nutrients and dietary components have been studied in relation to their impact on bone health (**Table 1**). Several of these key nutrients and components of the diet and their roles in bone health and skeletal homeostasis are detailed next.

Calcium

Calcium is the most abundant mineral found in bone and comprises approximately 33% of bone mineral. Optimal calcium intakes are essential across the life cycle to meet the daily intrinsic requirements of calcium required for skeletal growth and to offset urinary, dermal, and endogenous fecal calcium losses. When dietary intakes of calcium are not sufficient to maintain circulating calcium concentrations and/or when the losses of calcium from the body are excessive, bone calcium will be resorbed to maintain calcium homeostasis. Because calcium is essential for the structural integrity of bone, deficiencies or inadequate intakes of this mineral will have a detrimental impact on bone mass and quality.

Skeletal mass peaks at approximately age 20–30 years, with much of this gain occurring during the pubertal growth spurt. Nearly 50% of adult bone mass is accumulated during the pubertal growth spurt. Thus, this period of skeletal accretion can be viewed as a window of opportunity to maximize skeletal mass. Calcium supplementation studies in children have found increased bone mass with supplementation, an effect that is most pronounced when implemented during the prepubertal period. It is not clear to what degree calcium supplementation during the pubertal growth spurt results in a net gain in peak bone mass or if it solely influences the tempo at which peak bone mass is achieved. To account for the importance of this nutrient in bone mineralization, the recommended adequate intake of calcium is highest (1300 mg or 2.5 mmol.day) between the ages of 9 and 18 years.

Calcium supplementation has also been found to have beneficial effects on bone health in adults and may have the greatest impact in individuals whose habitual dietary calcium intakes are less than 400 mg (10 mmol)/day. To account for a decreased efficiency of intestinal absorption coupled with increased losses of calcium in older individuals, recommended calcium intakes increase to 1200 mg (30 mmol)/day in those age 50 or older. As discussed in more detail later, due to the prevalence of vitamin D deficiency in the elderly, oral vitamin D supplements up to 800 IU/day may also be required in order for the impact of calcium supplementation to be evident.

Several epidemiological studies have found significant relationships between an individual's lifelong intake of milk and subsequent risk of fracture. The degree to which this effect is a consequence of increased calcium intake or due to other nutritional components of milk and dairy products requires further study.

Despite the importance of calcium in bone mineral acquisition and maintenance, calcium intakes fall below the recommended level for the

majority of age groups, with intake being particularly low for adolescent girls and adult and elderly women. It is often difficult to increase consumption of calcium in certain age groups due to low intakes of dairy products or to other factors, such as lactose intolerance, dieting, or altered appetite and food consumption patterns in groups such as the elderly. To increase the calcium content of the diet, nonfat milk powder yogurt or cheese, can be added to a number of recipes to increase the calcium content of the food without adversely affecting taste. An increasing variety of calcium-fortified food products are now also available. Individuals with lactose intolerance may improve intake of calcium by use of lactose-free dairy products or lactase pills. Increasing calcium intake from dietary versus supplemental sources also increases the intake of many other nutrients needed for bone health, including protein, magnesium, zinc, phosphorus, and vitamin D. For this reason, dietary approaches to increase calcium intake should be promoted over the use of calcium supplements alone. Despite these benefits, in some instances it may be necessary to utilize calcium supplements to achieve recommended intake levels.

Several forms of calcium supplements are commercially available. Existing supplemental forms differ slightly with respect to their relative calcium content per tablet and their absorbability; however, the magnitude of these differences is minor and may not be biologically significant. Caution should be used when relying on natural sources of calcium (such as those prepared from bone meal, limestone, or oyster shells) because these preparations may also contain heavy metals such as lead. Several calcium supplements also contain additional nutrients required for bone health, including vitamins D and K. Because the fraction of calcium absorbed falls as calcium intake increases, little additional benefit per dose is achieved when taking supplemental calcium sources containing more than 500 mg (12.5 mmol) per dose.

Magnesium

More than half of the magnesium found in the body is located in bone. In addition to its presence in bone, magnesium is important in calcium metabolism and bone health because it is required for parathyroid hormone secretion. Parathyroid hormone (PTH) is integral to bone health because it increases the production of the active form of vitamin D (1,25-dihydroxyvitamin D) and plays a role in the tubular reabsorption of calcium and phosphorus.

Although magnesium deficiency is associated with abnormalities in vitamin D metabolism, hypocalcemia, and impaired PTH secretion, epidemiological studies linking magnesium intakes to measures of skeletal health have produced conflicting results. Some studies report significant associations between dietary magnesium intake and bone mineral density, but others have not supported this finding. Relationships between magnesium status and bone mass may be more challenging to elucidate due to the lack of a highly sensitive indicator of magnesium status.

Studies have indicated that typical magnesium intakes in healthy adolescents may not be sufficient to maintain magnesium balance. Data on the impact of magnesium supplementation on bone mass remain controversial. While some studies have found magnesium supplementation to result in positive effects on bone mass, others have reported no significant benefit. Additional studies are needed to clarify these discrepancies and to assess the net effect of magnesium status and supplementation on bone metabolism. Because dietary intakes fall below recommended levels in several age groups and because of the known relationships between magnesium and hormones integral to bone health, increased attention should be focused on optimal magnesium intakes in relation to bone homeostasis.

Zinc and Copper

Zinc and copper play important roles in bone metabolism and bone health in part due to the roles they play as cofactors for various enzymes required for the synthesis or modification of bone matrix constituents. Zinc is a cofactor for a myriad of enzymes in the body, including alkaline phosphatase. Alkaline phosphatase is synthesized by osteoblasts and is essential for bone mineralization. Zinc also plays a role in the osteoblast via its involvement in aminoacyl-tRNA synthetase. Copper is a necessary cofactor for lysyl oxidase, an enzyme involved in collagen cross-linking. Both copper and zinc are found as components of superoxide dismutase, and they may protect bone from oxidative damage. Genetic defects that cause zinc deficiency (acrodermatitis enteropathica) or copper deficiency (Menkes' disease) result in growth retardation, stunting, and impaired bone growth.

Although more research on the roles of zinc and copper in bone health and fracture risk is clearly needed, the importance of these nutrients in skeletal health should be recognized and optimal intakes should be promoted in relation to skeletal homeostasis.

Vitamin D

Vitamin D is particularly important for bone health because of the role it plays in calcium homeostasis.

The active form of vitamin D stimulates the synthesis of calcium binding protein in the intestine to facilitate calcium transport across the intestine. Vitamin D also plays a regulatory role in renal calcium reabsorption and in calcium release from bone.

Vitamin D can be obtained from the diet (although only vitamin D-fortified milk and fatty fish provide substantial amounts) or is made in the skin following exposure to sunlight. Deficiency of this vitamin is increasingly recognized as an issue of concern across all age groups of the US population from neonates to the elderly. This deficiency is due to a combination of inadequate dietary intake (dairy products provide the largest dietary contribution to vitamin D intake) and to inadequate sunlight exposure. Rickets is increasing among exclusively breastfed minority infants in the United States. This is thought to be due to the low vitamin D content of human milk combined with insufficient endogenous dermal synthesis. Vitamin D deficiency in adults results in osteomalacia and secondary hyperparathyroidism, increasing bone resorption and the risk of osteoporosis.

Lack of sufficient endogenous production of vitamin D in the skin is influenced by geographical location (more northern latitudes have a shorter season during which the wavelength needed for vitamin D synthesis is available), increased use of sunscreen and cosmetics and skin care products containing sunscreen (sunscreens with SPF values of 8 or greater block the dermal production of vitamin D), and lifestyle factors that decrease exposure to sunlight.

Studies suggest that the optimal serum concentration of vitamin D may be markedly higher (>30 ng/ml) than that traditionally used to define vitamin D deficiency (<10–15 ng/ml). If these increased levels are eventually accepted as optimal target concentrations, an even greater fraction of the population will have suboptimal status of this vitamin.

Supplementation with vitamin D and calcium has been found to be effective in decreasing fracture incidence. Several studies in older adults have found significant relationships between vitamin D status (as determined by 25-hydroxyvitamin D concentrations) and both musculoskeletal function and risk of sarcopenia. Combined vitamin D and calcium supplementation in the elderly may also decrease the risk of falling. Individuals with low dairy product intake, those living in northern latitudes, or those with inadequate sunlight exposure may need to rely on supplemental sources of vitamin D to maintain circulating concentrations at optimal levels required to promote bone health.

Vitamin K

Many proteins are dependent on vitamin K for the carboxylation of γ-carboxyglutamyl (Gla) residues. Several of these vitamin K-dependent proteins play integral roles in the bone matrix. Osteocalcin, one of the vitamin K-dependent proteins, is the most abundant noncollagenous protein in bone. Osteocalcin contains three Gla residues that require vitamin K for carboxylation. The ability of osteocalcin to bind to the hydroxyapatite fraction of bone is dependent on its degree of carboxylation. Deficiency of vitamin K increases the fraction of undercarboxylated osteocalcin in the circulation. In addition to osteocalcin, other vitamin K-dependent proteins (including matrix Gla protein and protein S) are found in bone and cartilage. Research is needed to elucidate the impact of vitamin K deficiency on risk of osteoporosis and fracture. Because of the known relationship between vitamin K and several crucial bone proteins, optimal status of this vitamin should be achieved to promote skeletal health.

Phosphorus

Phosphorus is another mineral that functions as an integral component of bone. Bone contains 85% of the phosphorus found in the body, and together calcium and phosphorus comprise the major fraction of bone mineral. Although sufficient phosphorus intakes are necessary to support bone mineralization, phosphorus homeostasis can be maintained across a range of intakes and ratios of calcium to phosphorus in the diet.

There is considerable controversy regarding the potential impact of elevated phosphorus intake from soda on bone health. Although concern has focused on the phosphoric acid and phosphorus content of soda in relation to calcium retention, the major impact of these products on bone health may be their displacement of other more nutritive beverages (such as milk) from the diet. Because increased soda consumption may increase the risk of excess weight gain and displace other more nutritive beverages from the diet, excessive soda intakes should be a cause for concern, especially in children and adolescents during the peak period of bone acquisition.

Sodium

Although many components of the diet play direct roles in bone mineralization, nutrients such as sodium are known to influence the retention of other nutrients required for optimal bone health. Sodium is one of the strongest determinants of

urinary calcium excretion. Increased dietary sodium intake elevates urinary calcium losses, with every 2300 mg (100 mmol) increase in dietary sodium increasing the urinary excretion of calcium by approximately 40 mg (1 mmol). Thus, excessive intakes of sodium (such as those that may occur in individuals who consume large amounts of processed food, salt food heavily, or consume foods high in sodium) increase the obligatory losses of calcium from the body. During the growth phase this could potentially limit the amount of calcium that can be utilized for bone mineralization. The long-term impact of variation in sodium intake on bone mass and fracture risk has been difficult to quantify because of a lack of sufficient information on how dietary effects on urinary sodium loss are counterbalanced and because other dietary components may modify this response.

Protein

Protein is essential for the formation of the organic matrix of bone and optimal intakes are required for normal skeletal development and growth. The importance of protein in bone health is well-known; however, there are conflicting reports on the relative impact of extremes of protein intake on bone health. Many proteins are rich in sulfur amino acids. The resulting protein-induced acid load must be buffered before excretion from the body. Calcium is a positive cation and can be utilized to buffer increased dietary acid loads from high protein intakes. On average, for every 1-g increase in dietary protein intake, urinary calcium excretion increases by approximately 1 mg.

Differences in habitual protein intakes have been related to bone mass and risk of fracture. Many studies have reported positive relationships between increased animal protein intake and bone health. Higher animal protein intakes in the elderly have been associated with reduced bone loss. Other research has supported a positive association between higher animal protein intake and both greater bone mineral density and decreased risk of hip fractures. Studies have found that although urinary calcium excretion increases in response to acute increases in protein intake, intestinal calcium absorption also increases by an amount nearly comparable to that lost in urine. Insufficient intakes of protein can adversely impact muscle mass and function. In addition, low dietary protein intake has been associated with reductions in serum insulin-like growth factor-1 (IGF-1) concentrations. IGF-1 plays an essential role in skeletal health via its impact on osteoblast formation and bone growth.

In contrast to the many studies that have found positive relationships between protein intake and bone health, other data suggest that high protein intakes may have a detrimental impact on bone mass and fracture risk and it is likely that extremes of protein intake, both high and low, may have adverse consequences on bone homeostasis. To clarify these conflicting findings, more research is required to address the relative impact of the quantity and type of protein on skeletal health.

Phytoestrogens

Phytoestrogens are dietary components that have a chemical structure similar to that of endogenous estrogens. The primary phytoestrogens in the diet are obtained from soybean isoflavones (including genistein and daizein). These compounds appear to be able to weakly mediate some the genomic and nongenomic effects of estrogen and may function as agonists or antagonists, depending on the tissue and type of estrogen receptor involved. To date, supplemental sources of these compounds have not been found to decrease fracture risk. Additional clinical trials will assist in determining the long-term impact of phytoestrogens on bone health and fracture risk.

Homocysteine

For some time, it has been known that individuals with a genetic defect in homocysteine metabolism (homocystinuria) have an increased risk of early onset osteoporosis. However, only recently has attention focused on the potential impact of circulating homocysteine concentrations on bone health among the general population. This interest is based on studies that have reported significant relationships between serum homocysteine concentrations and increased risk of fracture in adults. The strength of the relationship observed is substantial and is similar to the relationship found between serum homocysteine concentrations and cardiovascular disease. The mechanisms responsible for the impact of homocysteine concentrations on fracture risk are not known. Increased homocysteine concentrations could possibly interfere with normal collagen production, but studies have not found a significant relationship between serum homocysteine concentrations and bone mineral density, and the impact of elevated homocysteine concentrations on bone health may be indirect. Further research will assist in identifying the mechanisms and relationships between homocysteine and bone health and the degree to which this relationship is influenced by

folate, vitamin B_{12}, and vitamin B_6 status. Because of the other known adverse consequences of elevated serum homocysteine concentrations, additional incentive to monitor and promote reductions in this amino acid in relation to bone health is warranted.

Other Lifestyle Factors

Other lifestyle choices, such as smoking, alcohol abuse, and physical activity, also impact overall bone health. Excessive alcohol intake is a risk factor for low bone mass. This finding may be a consequence of poor dietary quality in chronic alcoholics and may also be related to adverse effects of excessive alcohol intake on osteoblast function. Cigarette smoking also adversely impacts bone health. Smokers may be leaner, and female smokers may experience an earlier menopause and have lower postmenopausal estrogen levels. Smoking may also have adverse effects on bone cells either directly or indirectly through an increase in oxidative stress.

Exercise is known to positively influence bone mass. During exercise, the strain placed on bone stimulates local bone responses to positively influence the balance in bone remodeling. Many studies have found positive associations between exercise and bone mass at a number of sites, especially the hip and the spine. The impact of exercise on bone mass is related to the intensity of the exercise and is associated with the degree to which it increases the habitual physical activity level of the individual. The impact of exercise on bone mass is also influenced by diet and may be most efficacious when calcium intake is optimal. Exercise not only impacts bone mass but also influences muscle strength, muscle mass, balance, and coordination. These improvements in muscle strength may also lead to improvements in posture, balance, flexibility, coordination, and gait stability that decrease the risk of falls.

Nutrient–Gene Interactions

Optimal nutrition is needed to supply the necessary substrates for bone; however, other parameters also influence the impact of a given nutrient on bone health. A substantial amount of bone mineral acquisition (up to 80%) is genetically determined. An individual's ability to utilize a given nutrient intake is influenced by his or her genetic makeup.

Many candidate genes have been associated or linked with the risk of osteoporosis or fracture, including genes coding for hormones (PTH), receptors (including PTH, vitamin D, estrogen, glucocorticoid, and calcitonin receptors), cytokines and growth factors (including IGF-1, transforming growth factor-β, epidermal growth factor, interleukin-4, and interleukin-6), and bone matrix proteins (such as osteocalcin, collagen type 1 (α1 and α2), and collagen type 11 (α1)). Although many of these genes have obvious roles in bone metabolism, other candidate genes (such as those coding for apolipoprotein E and methylenetetrahydrofolate reductase) have less obvious relationships to bone mass.

Several studies have found interactions between genotype, nutrient level, and environmental factors. For instance, the impact of exercise on bone can be influenced by the habitual dietary calcium intake and the individual's genotype (such as the vitamin D receptor genotype). Further research on the genetic control of bone mineral acquisition and loss will be invaluable in targeting groups at risk for low bone mass and may eventually be useful in setting genotype-specific intakes of bone-related nutrients to maximize skeletal health throughout the life cycle.

Best Practices to Prevent Osteoporosis

In summary, several practices can be adopted to assist in the prevention of osteoporosis. From a nutritional standpoint an emphasis should be made on adequate intakes of calcium, vitamin D and a balanced diet that meets the requirements of other essential bone-related minerals and nutrients (detailed in **Table 1**). A healthy body weight should be achieved and maintained throughout the life cycle. Age-appropriate physical activity and exercise programs should be promoted to maintain fitness, muscle strength and weight bearing activities. Lifestyle habits that adversely impact bone health, including smoking and excessive alcohol intake, should be avoided. Individuals with risk factors known to increase the risk of low bone mass should discuss these concerns with their physician to identify the need for bone density screening. Appropriate screening will allow for the initiation of medical interventions to maintain or build existing bone mass and reduce the subsequent risk of fragility related fractures. Attention to bone health and adoption of bone healthy habits should be initiated during childhood and maintained throughout the lifecycle to promote lifelong attainment of skeletal health.

P

PANTOTHENIC ACID

C J Bates, MRC Human Nutrition Research, Cambridge, UK

Absorption, Transport and Storage, Status Measurement

A considerable proportion of the pantothenic acid (vitamin B_5, see **Figure 1**) that is present in food eaten by animals or humans exists as derivatives such as coenzyme A (CoA) and acyl carrier protein (ACP). Compared with the crystalline vitamin, only about half of the vitamin in food is thought to be absorbed. The pantothenic acid in its derivatives in food is largely released as free pantothenic acid or pantetheine by pancreatic enzymes, and is then absorbed along the entire length of the small intestine by a combination of active transport and passive diffusion, of which the active transport process seems to predominate at physiological intakes. This active transport process is dependent on sodium, energy and pH and is saturable: the K_m is *c.* 17 μM and V_{max} is *c.* 1000 pmol cm^{-2} h^{-1}, with minor variations among species. The transport pathway is shared by biotin in colonic epithelial cells, and it appears to be regulated by an intracellular protein kinase C-mediated pathway. Calmodulin is also implicated in cellular pantothenic acid transport pathways.

In mice, it was found that usual dietary pantothenate levels did not affect the rate of absorption of a standard pantothenate dose, i.e., there was no evidence for feedback adaptation of the absorption pathway to low or high intakes, and it is assumed that the same is true in other species, including humans. However, there is some evidence from rat studies that the extent of secretion of enzymes degrading CoA into the gut lumen may partially limit the availability of pantothenic acid from CoA.

In humans, studies of urinary excretion of pantothenic acid after oral intakes of either free pantothenic acid or of the pantothenic acid present in food have indicated a relative availability of *c.* 50% from the food-borne vitamin. Urinary excretion of pantothenate was *c.* 0.8 mg day^{-1} when a pantothenate-deficient diet was eaten, rising to 40–60 mg day^{-1} at a high daily intake of 100 mg day^{-1}. At intermediate intakes, in the range 2.8–12.8 mg day^{-1}, the urinary excretion rate varied between 4 and 6 mg day^{-1}. Excretion of less than 1 mg day^{-1} is considered low. Urinary excretion rates reflect recent intakes perhaps more closely than most other biochemical indices.

The contribution of the gut flora to the available pantothenate for humans is unknown, but there is some evidence that bacterial synthesis of the vitamin may be important in animals, especially ruminants, since severe deficiency can only be achieved by using antibiotics or antagonists. Clinical conditions such as ulcers or colitis can adversely affect pantothenate status and excretion rates, and dietary fiber may affect its absorption.

After a dose of ^{14}C-labeled pantothenate, about 40% of the dose appears in muscle tissue and about 10% in the liver, with smaller amounts occurring elsewhere. The differential affinities of the various different tissues determines their individual contents of the coenzyme derivatives, CoA and ACP, since there is no other major store of the vitamin anywhere in the body. Most organs, including placenta, exhibit evidence of a unidirectional active transport process for the intracellular accumulation of pantothenate, which is dependent on sodium, energy, and pH. In placenta (and probably elsewhere) this transport process is also shared by biotin and by some of its analogs, which can exhibit competitive inhibition. The only tissues that have been shown to differ with respect to transport mechanisms are red cells and the central nervous system.

The uptake and efflux of pantothenate into and out of red blood cells is unaffected by sodium, energy, or pH. Red cells contain pantothenate, 4-phosphopantothenate, and pantetheine, but they do not contain mitochondria, or carry out CoA-dependent processes. The function of the pantothenate derivatives found in red cells is unknown, but their formation clearly results in higher concentrations of total pantothenate in red cells than in plasma, and red cell (or whole blood) total pantothenate is considered a better status index, and is more predictably related to

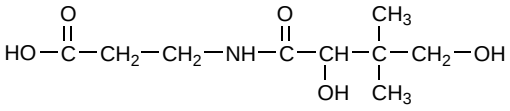

Figure 1 Structure of pantothenic acid.

intake, than is serum or plasma pantothenate. A concentration less than $1\,\mu mol\,l^{-1}$ of pantothenate in whole blood is considered low; the normal range is $1.6–2.7\,\mu mol\,l^{-1}$. Pantothenate in serum appears to be a very short-term marker and it is not well correlated with changes in intake or status.

Concentrations in body fluids are traditionally measured by microbiological assay using *Lactobacillus plantarum*. If CoA is present, enzymatic hydrolysis is needed to liberate free pantothenic acid for the microbiological assay. Other assay methods reported include gas chromatography (after conversion to a volatile derivative), radioimmunoassay (RIA), or enzyme-linked immunoabsorbent assay (ELISA).

Unlike several other B vitamin precursors of cofactors, pantothenate is not entirely converted to coenzyme forms inside the cell, and metabolic 'trapping' is therefore less dominant than it is for some other B vitamins. There is some evidence that the free pantothenate in tissues is more closely related to dietary pantothenate than the coenzyme forms are; the latter are relatively protected during periods of dietary deficiency or of low intakes. Uptake of pantothenate from plasma into most tissues is proportional to the plasma concentration because the active transport process is nowhere near saturated at typical plasma concentrations of *c*. 10^{-6} M.

Pantothenate is required for the hepatic acetylation of drugs by its presence in acetyl CoA, and it has been shown that pantothenate deficiency can impair this process; moreover, 20–60% of human populations are slow acetylators, varying with their ethnic grouping. Whether this function can be used to develop a functional test for pantothenate status is an intriguing but unresolved question.

Metabolism and Turnover

The primary role of pantothenic acid is in acyl group activation for lipid metabolism, involving thiol acylation of CoA or of ACP, both of which contain 4-phosphopantotheine, the active group of which is β-mercaptoethylamine. CoA is essential for oxidation of fatty acids, pyruvate and α-oxogutarate, for metabolism of sterols, and for acetylation of other molecules, so as to modulate their transport characteristics or functions. Acyl carrier protein, which is synthesized from apo-ACP and coenzyme A, is involved specifically in fatty acid synthesis. Its role is to activate acetyl, malonyl, and intermediate chain fatty acyl groups during their anabolism by the biotin-dependent fatty acid synthase complex (i.e., acyl-CoA: malonyl-CoA-acyl transferase (decarboxylating, oxoacyl and enoyl-reducing, and thioester-hydrolyzing), EC 2.3.1.85).

The organ with the highest concentration of pantothenate is liver, followed by adrenal cortex, because of the requirement for steroid hormone metabolism in these tissues. Ninety-five per cent of the CoA within each tissue is found in the mitochondria. However, the initial stages of activation of pantothenate and conversion to CoA occur in the cytosol. It was originally believed that the final stages of CoA synthesis must occur within the mitochondria, but later evidence indicated that transport across the mitochondrial membrane is, after all, possible. β-oxidation within the peroxisomes is also CoA-dependent, and is downregulated by pantothenate deficiency.

The pathways of conversion of pantothenic acid to CoA and to ACP are summarized in **Figure 2**. There are three ATP-requiring reactions and one CTP-requiring reaction in the synthesis of CoA. The rate of CoA synthesis is under close metabolic control by energy-yielding substrates, such as glucose and free fatty acids (via CoA and acyl CoA) at the initial activation step, which is catalyzed by pantothenate kinase (ATP: pantothenate 4-phosphotransferase, EC 2.7.1.33). This feedback control is thought to be a mechanism for conservation of cofactor requirements. There are also direct and indirect effects of insulin, corticosteroids, and glucagon, which result in important changes in tissue distribution, uptake, etc. in persons with diabetes. The mechanisms involved here are complex and not yet fully understood; however insulin represses and glucagon induces the enzyme.

A rare genetic disease, Hallervorden-Spatz syndrome, has recently been shown to result from deficiency of pantothenate kinase, and is now alternatively known as pantothenate kinase-associated neurodegeneration (PKAN). Dystonia, involuntary movements, and spasticity occur, and although there is no cure, some palliative treatment is possible.

In genetically normal people, fasting results in a reduction of fatty acid synthase activity with loss of the coenzyme of ACP, which thus achieves the desired objective of a shift away from fatty acid synthesis, towards breakdown. This interconversion of apo-ACP and holo-ACP is thus a very important process for the short-term regulation of fatty acid synthesis.

Deficiency of sulfur amino acids can result in reduced CoA synthesis; likewise copper overload can (by interfering with sulfur amino acid function) also reduce CoA synthesis.

Excretion of free pantothenate in the urine is the primary excretion route in humans; in other mammals

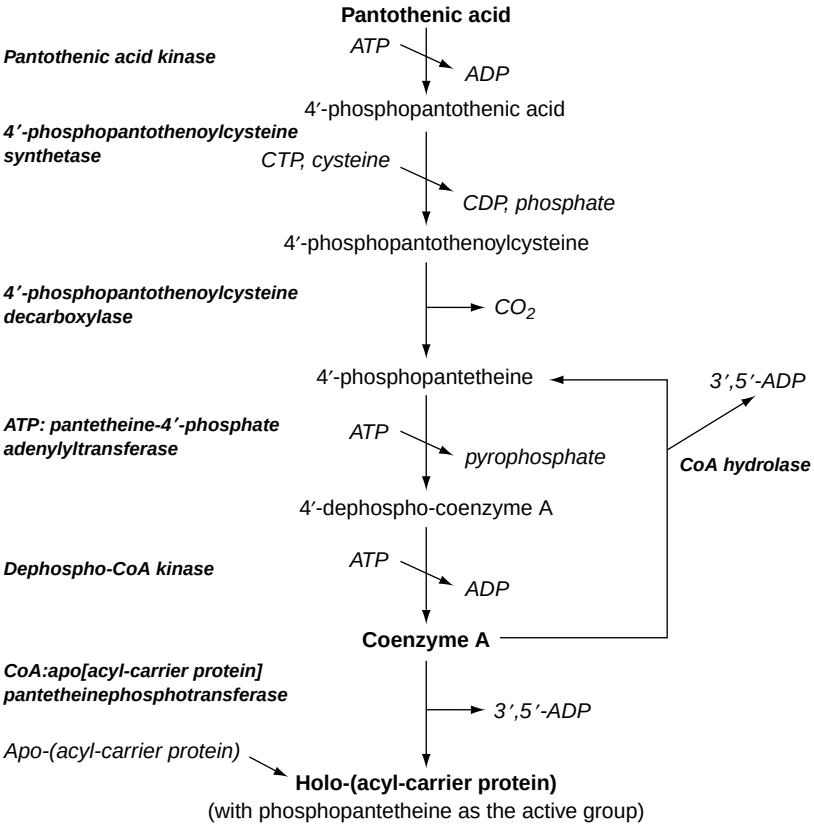

Figure 2 Synthetic pathway between pantothenic acid, coenzyme A, and acyl carrier protein.

the glucuronide or glucoside may be excreted. There is little evidence of degradation to simpler products, and pantothenic acid appears to be very efficiently conserved in animals. Some bacteria can cleave it to yield pantoic acid and β-alanine. A potentially useful breakdown product of CoA is taurine, formed via cysteamine. This amino acid is an essential nutrient for some carnivorous animals such as cats.

When dietary intakes are low, the majority of the circulating vitamin, which is filtered in the kidney tubules, is absorbed by the same type of sodium-dependent active transport process that also occurs at most other sites in the body. Retention of a test dose of pantothenate is, as expected, greater in partially depleted subjects, than in saturated ones. Secretion into breast milk is proportional to intake and to blood levels of the vitamin; therefore, dietary supplements taken by the lactating mother generally increase the breast milk content of the vitamin.

Metabolic Function and Essentiality

As noted above, the biochemical functions, and hence the basis for the dietary requirement of pantothenic acid, arise entirely from its occurrence as an essential component of CoA and of ACP, which cannot be synthesized *de novo* in mammals from simpler precursors.

In addition to the now well-established roles of CoA in the degradation and synthesis of fatty acids, sterols, and other compounds synthesized from isoprenoid precursors, there are also a number of acetylation and long-chain fatty acylation processes which seem to require CoA as part of their essential biological catalytic sites, and which are still being explored today. The acetylation of amino sugars, and some other basic reactions of acetyl-CoA and succinyl-CoA in intermediary metabolism, have been known since the 1980s. However, the addition of acetyl or fatty acyl groups to certain proteins in order to modify and control their specific and essential properties is a more recent discovery. The first category of these modifications comprises the acetylation of the N-terminal amino acid in certain proteins, which occurs in at least half of all the known proteins that are found in higher organisms. The specific amino acids that are recipients of these acetyl groups are most commonly methionine, alanine, or serine. The purposes of this terminal acetylation process are not entirely clear and may be multiple, including modifications of function

(e.g., of hormone function), of binding and site recognition, of tertiary peptide structure, and of eventual susceptibility to degradation. Another possible site of protein acetylation is the side chain of certain internal lysine residues, whose side chain ε-amino group may become acetylated in some proteins, notably the basic histone proteins of the cell nucleus, and the α-tubulin proteins of the cytoplasmic microtubules, which help to determine cell shape and motility. Its essential role in the synthesis of α-tubulin appears to be a particularly important one.

Proteins can also be modified by acylation with certain long-chain fatty acids, notably the 16-carbon saturated fatty acid, palmitic acid, and the 14-carbon saturated fatty acid, myristic acid. Although structurally very similar to each other, these two fatty acids seek entirely different protein locations for acylation and also have quite different functions. They have recently been explored with particular emphasis on viral and yeast proteins, although proteins in higher animals, in organs such as lung and brain, can also become acylated with palmityl moieties. Palmitoyl CoA is also required for the transport of residues through the Golgi apparatus during protein secretion. It is believed that these protein acylations may enable and control specific protein interactions, especially in relation to cell membranes, and proteins that are palmitoylated are generally also found to be associated with the plasma membrane. Signal transduction (e.g., of the human β_2-adrenergic receptor) is one process that appears to be controlled by palmitoylation, and other palmitoylated proteins possess some structural importance, for example in the case of the protein–lipid complex of brain myelin. Clearly, these subtle protein modifications, all of which depend on CoA and hence on pantothenic acid, have a wide-ranging significance for many biological processes, which is still being actively explored.

Pantothenic acid is essential for all mammalian species so far studied, namely humans, bovines, pigs, dogs, cats, and rodents, as well as for poultry and fish. Pantothenate deficiency signs in animals are relatively nonspecific and vary among species. Deficiency in young animals results in impaired growth, and requirement estimates based on maximum growth rates are between 8 and 15 mg per kg diet. Rats that are maintained on a diet low in pantothenate exhibit reduced growth, scaly dermatitis, alopecia, hair discoloration and loss, porphyrin-caked whiskers, sex organ disruption, congenital malformations, and adrenal necrosis. Deficient chicks are affected by abnormal feather development, locomotor and thymus involution, neurological symptoms including convulsions, and hypoglycemia. Pigs exhibit intestinal problems and abnormalities of dorsal root ganglion cells, and several species suffer nerve demyelination. Fish exhibit fused gill lamellae, clumping of mitochondria, and kidney lesions. Signs specific for pantothenate depletion are not well characterized for humans. A syndrome that included 'burning feet' has been described in tropical prisoner-of-war camps during World War II, and it was said to respond to pantothenic acid supplements; however this was likely to have been a more complex deficiency. A competitive analog of pantothenate, ω-methyl pantothenate, interferes with the activation of pantothenic acid; it also produces burning feet symptoms, Reye-like syndrome, cardiac instability, gastrointestinal disturbance, dizziness, paraesthesia, depression, fatigue, insomnia, muscular weakness, loss of immune (antibody) function, insensitivity to adrenocorticotrophic hormone, and increased sensitivity to insulin. Large doses of pantothenate can reverse these changes. One of the earliest functional changes observed in mildly deficient rats was an increase in serum triacylglycerols and free fatty acids, presumably resulting from the impairment in β-oxidation. Paradoxically, CoA levels are relatively resistant to dietary pantothenate deficiency; however there are some inter-organ shifts in pantothenate in certain metabolic states.

As noted above, CoA is required for Golgi function, involved in protein transport. Pantothenate deficiency can therefore cause reductions in the amounts of some secreted proteins. Other metabolic responses to deficiency include a reduction in urinary 17-ketosteroids, a reduction in serum cholesterol, a reduction in drug acetylation, a general reduction in immune response, and an increase in upper respiratory tract infection.

Recently, some studies of wound healing and fibroblast growth have indicated that both pantothenic acid and ascorbic acid are involved in trace element distribution in the skin and scars of experimental animals, and that pantothenic acid can improve skin and colon wound healing in rabbits. It is not yet known whether these observations are relevant to wound healing in humans.

Requirements

In the UK, National Food Survey records suggest that during recent decades mean adult daily pantothenate intakes have been consistently in the range of 4–6 mg. Since there is little evidence for the magnitude of minimum requirements in humans, the UK committee responsible for the revision of dietary reference values in 1991 suggested that intakes in the range 3–7 mg day^{-1} can be considered as adequate (although no specific values for the reference nutrient intake, estimated average

requirement or lower reference nutrient intake for pantothenate were set). The US adequate intake (AI) for pantothenic acid is currently set at 5 mg day^{-1} for adults; 4 mg day^{-1} for children aged 9–13 years; 3 mg day^{-1} for 4–8 years, and 2 mg day^{-1} for 1–3 years. There was insufficient evidence to set an estimated average requirement (EAR), a recommended daily allowance (RDA), or a tolerable upper intake level (UL).

There are few studies in communities where intakes are likely to be low; indeed, pantothenic acid is so widely distributed in human foods that it is unlikely that any natural diets with a very low content will be encountered. Some variations in status among communities have been described, but these do not define requirements. In a group of adolescents in the USA, daily pantothenate intakes were around 4 mg; total blood pantothenate was in the 'normal' range of *c.* 350–400 ng ml^{-1}, and intakes were correlated with red cell pantothenate ($r = 0.38$) and with urinary pantothenate ($r = 0.60$), both $P < 0.001$. In adults, these correlations were less strong.

During pregnancy and lactation there is some evidence that requirements may increase. As for most water-soluble vitamins, maternal blood levels do decrease significantly on normal diets during pregnancy, and the mean daily output of the vitamin in breast milk in the US is of the order of 2–6 mg. The adequate intake (AI) in the USA is 6 mg day^{-1} during pregnancy and 7 mg day^{-1} during lactation. It has been suggested that infant formulas should contain at least 2 mg pantothenate per liter and the AI for infants is 1.7 mg day^{-1} from birth to 6 months and 1.8 mg day^{-1} from 7 to 12 months of age.

Dietary Sources and High Intakes

Pantothenate is widely distributed in food; rich sources include animal tissues, especially liver, and yeast, with moderate amounts occurring in whole grain cereals and legumes (see **Table 1**). It is fairly stable during cooking and storage, although some destruction occurs at high temperatures and at pH values below 5 or above 7. Highly processed foods have lower contents than fresh foods. Commercial vitamin supplements containing pantothenate usually contain the calcium salt, which is crystalline and more stable than the acid.

Synthesis by gut flora in humans is suspected but not yet proven; the rarity of diet-induced deficiency has been attributed to contributions from gut flora sources.

There is some evidence that pantothenic acid supplements may be beneficial for treatment of rheumatoid arthritis and for enhancement of athletic performance, specifically in running. Pantethine, the disulfide dimer of pantetheine, may have cholesterol-lowering properties. The mechanisms of these reported effects are unclear and they require further investigation and verification. A homolog of pantothenate, pantoyl γ-aminobutyrate (hopanthenate), which can act as a pantothenate antagonist, has been used to enhance cognitive function, especially in Alzheimer's disease. It acts on GABA receptors to enhance acetylcholine release and cholinergic function at key sites in the brain.

There is little or no evidence for any toxicity at high intakes: at daily intakes around 10 g there may be mild diarrhea and gastrointestinal disturbance, but no other symptoms have been described. Pantothenate has been prescribed for various chronic disorders, but is not known to be useful in high doses.

Table 1 Pantothenate content of selected foods

Food	*mg per 100 g wet wt*	*mg per MJ*
Meat, offal, and fish		
Stewed minced beef	0.36	0.41
Grilled pork chop	1.22	1.58

PARASITISM

P G Lunn, University of Cambridge, Cambridge, UK

Introduction

In common with all other animals, human beings are susceptible to a range of parasitic organisms. The most important and commonest of these have been with man for countless years and have become so well adapted that in most cases man is their major if not only host. Although parasitic infections occur throughout the world, it is in the wet tropics and subtropics where they are found at their greatest prevalence and intensity. Most developing countries are also located in these areas and the consequent poverty, poor hygiene, and inadequate sanitation augment the favorable environmental conditions to enhance proliferation of these organisms. Only those that are known to interfere with host nutritional status will be discussed in this article.

Parasitic infections of the gastrointestinal tract are among the commonest diseases in the world (**Table 1**) and in most developing countries there has been little improvement in prevalence rates for many years. Indeed in some cases, e.g., schistosomiasis, local prevalence has been increasing with expanding irrigation schemes. Their association with poverty ensures that these diseases occur in areas where poor child growth and malnutrition are common and where there are persistent health problems. While there is no doubt that severe infections of any parasite can result in severe illness or even death of the host, such cases are rare even in areas of high prevalence and the norm is for low to moderate parasite numbers, which result in few, if any overt clinical symptoms. Nevertheless, by causing subtle reductions in appetite, digestion and absorption; by increasing chronic inflammation, and by inducing

Table 1 Estimated world prevalence of parasites important to human nutrition

	Approx. prevalence (millions)
Helminth parasites	
Ascaris lumbricoides (roundworm)	1500
Necator americanus and *Ancyclostoma duodenale* (hookworms)	1300
Trichuris trichiura (whipworm)	1100
Schistosoma haematobium, S. japonicum, and *S. mansoni*	200
Strongyloides stercoralis and *S. fülleborni*	200
Protozoal parasites	
Giardia intestinalis	200 symptomatic cases, total much higher
Entamoeba histolytica	400 but may be much higher
Cryptosporidium spp.	?

Data from Crompton, DWT (1999) How much human helminthiasis is there in the world? *Journal of Parasitology* **85**: 397–403; Olsen BE, Olson ME, and Wallis PM (2002) *Giardia: The Cosmopolitan Parasite*. nutrient loss, particularly of iron and protein, it is believed that such low-level but long-term infections contribute to the persistently poor nutritional state of many, especially children, in the developing world.

The most important parasites of man are from two main groups: the helminth worms and protozoans. Although several hundred different species have been described, the vast majority of infections are caused by relatively few.

Mechanisms of Parasite–Host Nutrition Interactions

Gastrointestinal parasites interfere with the nutrition of their host by one or more of the following mechanisms (**Figure 1**).

Loss of Appetite, Anorexia

Loss of appetite is a common feature in many illnesses and not only those involving the gastrointestinal tract. It is now thought that much of the appetite loss in disease is mediated by one or more cytokines released by lymphocytes as part of the body's response to tissue damage or invasion. Additionally, however, parasitized individuals often complain of symptoms such as nausea, abdominal pain, flatulence, and distension and discomfort, while the protozoal infections are associated with vomiting, diarrhea, or dysentery, all of which can be expected to reduce appetite.

Maldigestion and Malabsorption

Several GI parasites are well placed to interfere with these processes so it is not surprising that maldigestion and/or malabsorption of fat, protein, and carbohydrate as well as many of the micronutrients has been reported during infection. Structural damage to the mucosa of the intestine, such as the flattening or thickening of villi, or villus atrophy, will reduce the absorptive surface area. Damage to the cells diminishes their absorptive properties and limits active transport processes, while accelerated replacement of damaged cells may result in immature mucosal cells with reduced enzymatic and transport capacity. Food that is not fully digested and absorbed in the small intestine will enter the large bowel where excessive colonic fermentation may result in diarrhea.

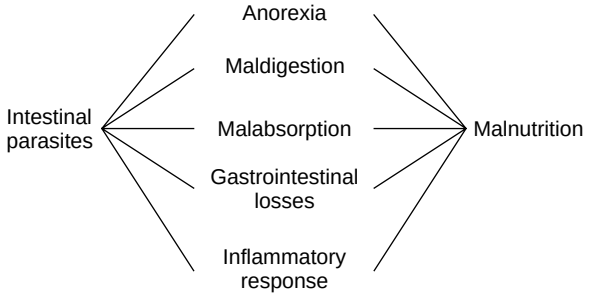

Figure 1 Mechanisms of parasite–host nutrition interactions.

Nutrient Losses

Accelerated loss of nutrients from the body is probably the most important mechanism by which parasitic infections compromise the nutritional status of their host. Nutrient losses arise both directly and indirectly.

Direct losses occur during the feeding of the blood-sucking and tissue-invading parasites. Blood and tissue ingested by the worms forms part of the loss but the lesions caused by feeding and burrowing activity continue to ooze blood and tissue fluids after the parasites have moved on. Similarly, the passage of schistosome eggs through the tissues of the bladder or intestine is often accompanied by tissue damage and blood loss. Increased turnover and accelerated shedding of parasite-damaged enterocytes into the lumen of the GI tract is another mechanism of increased nutrient loss. Even though some of the nutrients lost into the lumen may be reabsorbed, the process is far from complete. Vomiting or diarrhea causes loss of electrolytes and important trace elements such as zinc.

Indirect losses arise from stimulation of the host's immunological and inflammatory mechanisms that are mobilized to combat the infection and repair tissue damage. Localized inflammation at the site of the parasite activity, often accompanied by lymphocytic infiltration of tissues cause further damage to the mucosa, augmenting maldigestion, malabsorption, and nutrient losses as more damaged cells are shed. Activation of the systemic inflammatory system, i.e., the acute phase response, is a general reaction of the body to pathogen invasion or tissue damage. It results in a widespread cytokine-mediated catabolic response. Growth slows or ceases, muscle tissue is broken down to provide substrates for gluconeogenesis and the repair of damaged cells, and a negative nitrogen balance ensues. Anorexia occurs and there are increased losses of amino acids, minerals, and vitamins in the urine and feces.

Competition for Nutrients

Competition for nutrients is generally unlikely owing to the considerable difference in biomass of the host and parasite. However, the tapeworm, *Diphyllobothrium latum*, does compete for vitamin B_{12} taken in the diet. The worm concentrates large amounts of this vitamin in its own tissues, depriving the host and in some cases leading to megaloblastic anemia.

Parasite Epidemiology and Impact on Host Nutrition

Clinical Studies

Much of our knowledge of the impact of parasitism on host nutrition (**Table 2**) comes from hospital studies of heavily parasitized patients. Irrespective of the organism involved, nutritional status and anthropometric indices of such severely ill patients are invariably poor on admission but quickly improve following treatment. Such data must however be interpreted with caution. In developing countries, malnourished individuals admitted to hospital rarely suffer from a single parasitic infection; viral and bacterial pathogens and other parasitoses are frequently present as are frank dietary deficiencies. Patients are routinely dosed with wide-range antibiotics and anthelmintics and given high-quality rehabilitation diets, so, in general, neither the cause of their symptoms nor the basis for recovery can be established with certainty.

Helminth Parasites

Ascaris lumbricoides (**roundworm**) About 73% of all infections by this worm are estimated to occur in Asia with many countries having prevalence rates greater than 50%. In some rural areas over 90%

Table 2 Parasite interference with host nutrition

Parasite	*Symptom*	*Nutritional effect*
Ascaris lumbricoides	Anorexia and abdominal pain	Growth retardation, weight loss
	Malabsorption syndrome	Reduced fat and nitrogen uptake
		Reduced vitamin A status
	Lactose intolerance	Growth retardation, weight loss
	Acute-phase response	Growth retardation, weight loss
Hookworm	Anorexia and abdominal pain	Growth retardation, weight loss
	Diarrhea	Growth retardation, weight loss
	Blood loss	Iron deficiency, anemia
	Protein-losing enteropathy	Hypoalbuminemia, edema
Schistosoma spp.	Anorexia	Growth retardation, weight loss
	Diarrhea	Growth retardation, weight loss
	Blood loss	Iron deficiency, anemia
	Plasma protein loss	Hypoalbuminemia
	Acute-phase response	Growth retardation, weight loss
Trichuris trichiura	Anorexia	Growth retardation, weight loss
	Abdominal pain and vomiting	Growth retardation, weight loss
	Diarrhea and dysentery	Loss of trace elements, e.g., zinc
		Growth retardation, weight loss
	Blood loss	Iron deficiency, anemia
	Plasma protein loss	Hypoalbuminemia, edema
	Acute phase response	Growth retardation, weight loss
Strongyloides spp.	Anorexia	Growth retardation, weight loss
	Abdominal pain and vomiting	Growth retardation, weight loss
	Malabsorption syndrome	Reduced fat absorption
	Protein-losing enteropathy	Hypoalbuminemia, edema
	Acute-phase response	Growth retardation, weight loss
Giardia intestinalis	Anorexia	Growth retardation, weight loss
	Diarrhea and vomiting	Loss of trace elements
	Malabsorption syndrome	Reduced fat absorption
		Reduced vitamin A status
	Mucosal disruption	Lowered disaccharidase activity
		General maldigestion
	Acute-phase response	Growth retardation, weight loss
Cryptosporidium spp.	Anorexia	Growth retardation, weight loss
	Abdominal pain	Growth retardation, weight loss
	Diarrhea and vomiting	Loss of trace elements
	Mucosal disruption	Lowered disaccharidase activity
		General malabsorption
	Acute-phase response	Growth retardation, weight loss
Entamoeba histolytica	Diarrhea and dysentery	Fluid and electrolyte loss
		Electrolyte imbalance
		Loss of trace elements
	Acute-phase response	Growth retardation, weight loss

of children harbor the infection. It is less prevalent in Africa (about 12% of all cases) and in central and southern America (about 8% of all cases). It is uncommon but still present in some rural areas of Europe and southeastern parts of the US. Adult *A. lumbricoides* live in the lumen of the upper part, i.e., the jejunum, of the small intestine. The worms live for some 12–20 months and females grow to 20–35 cm in length and 3–6 mm in diameter. An adult female discharges 200 000–240 000 eggs per day into the lumen and these pass out of the body in the feces. Infection occurs by oral ingestion of eggs from fecally contaminated food, water, hands, kitchen utensils, or play things. Both the prevalence and intensity of infection with *A. lumbricoides* increase rapidly during early childhood and although prevalence often remains high throughout life, intensity of infection tends to peak in the 5–15 years age range.

Despite the large size of these worms, mild to moderate infections are generally well tolerated with few, if any, overt symptoms. Clinical studies give inconsistent results. Although anorexia, abnormal mucosal histology, decreased absorption of fat and carbohydrate, reduced lactase activity, decreased transit time, reduced nitrogen retention, reduced vitamin A absorption, and lower vitamin A status have all been reported, they are by no means present in all cases. These abnormalities are in keeping with a stimulation of the host's immune and inflammatory mechanisms and it seems likely that occurrence of these symptoms depends on whether such mechanisms have been initiated. Why the immune and inflammatory response should be initiated in some cases of *A. lumbricoides* infection but not others is not known, but it may be at least partly due to genetics.

Hookworms Although 13 different human hookworm parasites have been listed, only two species, *Necator americanus* and *Ancyclostoma duodenale*, are responsible for virtually all cases of hookworm disease in humans. The two worms are similar in appearance, feeding pattern, and life history. Man is their only known host. *Necator americanus* is the only species seen in North America and it predominates in central and southern America, central Africa, southern India, Indonesia, and the South Pacific. *Ancyclostoma duodenale* is found in Mediterranean Europe, the Middle East, North Africa, Pakistan, Iran, and northern India. Both species occur in parts of Brazil, India and Africa, throughout Southeast Asia, Indonesia and the Pacific islands.

Adult worms live in the upper part of the small intestine and eggs are discharged into the lumen. Up to 10 000 (*N. americanus*) or 25 000 (*A. duodenale*) eggs per day can be produced and are passed out in the feces. Eggs hatch within 48 h and the larvae are free living for 2–3 weeks but then must reach a host or die. Adult female *A. duodenale* are 10–13 mm in length, *N. americanus* 9–11 mm, and the males about 2 mm shorter. *Necator americanus* can live for up to 5 years.

Both prevalence and intensity of infection increase with age in childhood up to about 10–15 years, and then remain constant during adulthood. High prevalence is associated with inadequate or unhygienic disposal of feces, which contaminates the soil. Lack of footwear, a common state in developing countries, allows feet to come in contact with infective larvae.

Loss of blood, particularly of its iron content, is the most important pathological feature of hookworm infection. Iron deficiency anemia is one of the commonest deficiency diseases in the world and there is no doubt that hookworms contribute significantly to the estimated two billion individuals who suffer from this problem. Through its feeding activity, each *N. americanus* worm causes the loss of about 0.03 ml of blood per day, while the larger *A. duodenale* accounts for approximately 0.15 ml per day. Part of this loss is blood ingested by the worm, but each time the worm moves to a new site, perhaps up to six times per day, the lesions continue to ooze blood into the lumen.

Daily blood loss from an individual passing 2000 eggs per gram of feces has been estimated at 4.3 ml (containing 2.0 mg of iron) and 8.9 ml (4.2 mg of iron) for *N. americanus* and *A. duodenale*, respectively. Although the intestine will reabsorb approximately 35% of this iron, daily losses will be 1.3 and 2.7 mg of iron, respectively. Assuming that only 10% of dietary iron is absorbed, an increased dietary intake of 13 mg and 27 mg, respectively, is required to make good these losses. As most diets contain only 15–20 mg of iron per day and some 10–15 mg of this is needed to cover daily metabolic requirements, intake would need to at least double to replace the loss from even this moderate hookworm load. In developing countries this is rarely possible, so without iron supplements, iron stores are soon depleted and iron deficiency anemia ensues. In lighter infections, subclinical iron deficiency is shown by low plasma ferritin and iron concentration, low transferrin saturation, and elevated erythrocyte protoporhyrin content.

Protein is also lost into the lumen of the small intestine during hookworm disease. Estimates of plasma loss vary considerably and values over 100 ml (containing 6–7 g of protein) per day have

been recorded, although much of this may be reabsorbed. Nevertheless, moderate to heavy hookworm infections are associated with hypoalbuminemia, hypoproteinemia, edema, and kwashiorkor, especially in areas where the protein content of the diet is low.

Schistosomes The three commonest species responsible for disease are *Schistosoma haematobium, S. mansoni*, and *S. japonica*, with some individuals in Africa harboring two species. Urinary schistosomiasis, found mainly in Africa and some eastern Mediterranean countries, is caused by *S. haematobium*. Infection with either *S. mansoni* (found in Africa, the Middle East, parts of South America, and the Caribbean) or *S. japonica* (occurs in China, the Philippines, and Indonesia) results in intestinal schistosomiasis. These worms live in blood vessels: *S. haematobium* in the vesicle venules of the urinary bladder with the other two species infecting the mesenteric veins adjacent to the intestines. Adults live in male/female pairs and damage is caused by passage of eggs through the tissues into either the bladder (*S. haematobium*) or the gut lumen. Eggs leave the body in the urine or feces. If they reach fresh water, they hatch to produce miracidia, which must find a suitable snail host. After entering the snail, the parasites multiply by asexual reproduction, eventually producing free-swimming cercaria that are infective to man. Infection is by skin penetration during contact with fresh water containing cercaria. Egg production starts some 2–3 weeks after infection. The parasite lives for 3–8 years. The prevalence of this parasite in many developing countries is increasing as irrigation schemes allow the intermediary snail hosts to extend their range.

Iron deficiency anemia associated with blood loss occurs in both urinary and intestinal schistosomiasis. Although blood loss can be severe in heavy *S. haematobium* infection, in a study of nonhospitalized children with low to moderate infection, iron losses ranged from 120 to 500 $\mu g\,day^{-1}$, increasing with rising egg count. This is less than losses due to hookworm, but dietary iron consumption would need to increase by about a third to compensate. In areas where iron status is poor, the extra burden due to *S. haematobium* will undoubtedly contribute to the onset of anemia. Intestinal schistosomiasis caused by *S. mansoni* can also result in iron deficiency but it is generally less severe than that seen in hookworm disease. Little data is available for *S. japonicum* infection, but its effect appears to be similar to *S. mansoni*.

The poor nutritional status of infected individuals may be related to anorexia, diarrhea, and activation of the inflammatory mechanisms of the host. Blood cytokine concentrations are raised in schistosomiasis causing growth faltering and weight loss.

Trichuris *trichiuris* (whipworm) This helminth is widespread throughout the tropics and subtropics. Most cases of infection (63% of the worldwide total) occur in Asia, with 11% in Africa and 14% in the Americas; however, a few cases are still seen in the US, Western Europe, and Japan.

Man is the principal host of the parasite, which lives in the large intestine. Adults are 3–5 cm in length and are whip shaped; the long thin anterior end is embedded in the mucosa, with the thicker posterior end in the lumen. Worms feed on mucosal cells but may also ingest red and white blood cells. Eggs leave the host in feces and embryonate in the soil. Infection occurs by oral ingestion of embryonated eggs on fecally contaminated food, hands, or utensils. They hatch in the small intestine and larvae develop in the villi before moving down to the large intestine. Egg production starts 30–90 days after ingestion.

In some rural areas the prevalence can exceed 90% and although prevalence remains high throughout life, peak intensity usually occurs between the ages of 5 and 15 years.

This helminth causes loss of blood and iron from the large intestine of its host by its burrowing and feeding activities. More than 3000 worms have been found in heavy *T. trichiuris* infection and such individuals do have marked iron deficiency anemia. However, in the majority, where worm counts rarely exceed 100, the infection is usually asymptomatic. Plasma protein loss can also be substantial in heavy infections but although plasma albumin values are frequently reduced, hypoproteinemic edema is rare.

Heavy infections are characterized by persistent dysentery, abdominal pain, nausea, vomiting, and tenesmus leading to rectal prolapse. Appetite is reduced and raised plasma cytokines and acute-phase proteins indicate activation of host immune and inflammatory mechanisms. Loss of nutrients including zinc and other trace elements in the persistent dysentery and vomiting may further lower nutritional status.

Strongyloides stercoralis This worm has a worldwide distribution but is found predominantly in the tropics. Prevalence rates are uncertain as detection of the larvae by direct fecal examination (the method usually employed) gives a considerable underestimate. Prevalence rates of up to 85% have been reported but are uncommon. In parts of Africa,

a closely related worm, *Strongyloides fülleborni* is often more common than *S. stercoralis*.

Adult worms are about 2.7 mm in length and are usually found in the duodenum and upper jejunum. Eggs are passed into the lumen but most hatch while still in the GI tract. Although the majority of larvae pass out in the feces, some penetrate the wall of the intestine and reinfect the host, a situation known as autoinfection. Larvae passed with the feces live in the soil and grow into adults of both sexes. Eggs are laid and larvae hatch within 1–2 weeks. They metamorphose to an infective stage when they must either locate a host or die. Infection is usually by skin penetration. Because of the autoinfection process, infection with this parasite can last indefinitely and severe disease can suddenly appear many years after an individual has left an endemic area.

The impact of this worm on nutritional status has not been clearly defined. Heavily infected subjects have a severe small intestinal illness with anorexia, abdominal pain, nausea, diarrhea, and vomiting. There is some evidence for a malabsorption syndrome, steatorrhea is often present, but it is not seen in all cases. A substantial protein-losing enteropathy can occur, resulting in severe hypoalbuminemia and kwashiorkor-like oedema. Protein loss arises from a combination of the burrowing activity of the worms and a local inflammatory reaction from the host. The little information on *S. fülleborni* infection suggests it has a similar impact on host nutrition.

Special features of helminth parasites Helminth infections all exhibit certain characteristic features by which they differ from most other infective organisms:

1. In contrast to most infective organisms, most helminths cannot reproduce within the host; each worm has to gain individual access to the host, usually by ingestion or skin penetration.
2. Intensity of infection shows an overdisperse distribution; it is usual for 20% of an infected population to harbor 80% of the parasites. Thus, a large majority of individuals will have only light infections and show few if any symptoms.
3. Some individuals appear to be predisposed to have heavy worm burdens; they quickly reacquire a heavy load after eradication of their original infection. Household and family clustering of high parasite loads is also seen. Clearly such differences might be explained on the basis of increased exposure of individuals and family groups due to particularly unhygienic living conditions or greater occupational risk. However, increased host genetic susceptibility has recently been demonstrated to account for between 21 and 44% of the observed variance in infection intensity.
4. Infection by several different parasites at the same time (polyparasitism) is extremely common in many areas.
5. Re-infection following deworming occurs very quickly because of considerable contamination of the environment by the large numbers of eggs produced by the parasites. In a study in Myanmar, preinfection prevalence of *A. lumbricoides* was reached only 6–8 months after deworming.

Protozoal Parasites

***Giardia intestinalis* (= *lamblia*)** This organism is a common parasite of the human gastrointestinal tract and is found in all parts of the world. Although its prevalence is greatest in developing countries where hygiene facilities are poor, outbreaks of giardiasis continue to occur in many developed countries. It has a simple life history. The trophozoite (the active form in the intestine) lives in the duodenum and jejunum of the host where it attaches to the enterocytes by means of a ventral disk. It reproduces rapidly by mitotic division and in heavy infections can cover large areas of the mucosa. Some trophozoites encyst; a protective wall forms around the organism, and the cysts pass out in the feces. Cysts are directly infective and after ingestion by a new host, the organisms emerge to establish a new infection. Disease can follow the ingestion of as few as 10 cysts which, given moist conditions, are viable for several months.

In developed countries, most infections can be traced to contaminated water, but direct person-to-person transmission has been documented. In developing countries, poverty-related unsanitary conditions and inadequate disposal of feces promote oro-fecal spread of the parasite, but contaminated water is also likely to be important. The large number of cyst-producing individuals with asymptomatic infection constitutes a reservoir of *G. intestinalis*. In addition, some animals are known to harbor *Giardia* and may be a source of human giardiasis.

Infection with *G. intestinalis* can be associated with a wide range of symptoms: from mild, self-limiting watery diarrhea to persistent foul-smelling diarrhea with vomiting, abdominal pain and distension, and a severe malabsorption syndrome. However, many infected individuals (from 20 to 84% of infected cases) remain asymptomatic. It is not clear why the parasite can cause such a range of degrees of illness.

The nutritional impact varies with both the severity and duration of the symptoms. In the early stages, anorexia is of major importance, but if the disease persists, intestinal aspects compound the situation. In at least 50% of symptomatic patients there is malabsorption of fat, carbohydrates, protein, and micronutrients (particularly vitamin A) associated with structural and functional abnormalities in the small intestine. Damage to the mucosa can range from little to subtotal villus atrophy, but most subjects have mild villus shortening and increased crypt depth. The abnormalities are associated with a reduction in disaccharidases, notably lactase activity and in lowered intraluminal concentrations of the hydrolytic enzymes trypsin, chymotrypsin, and lipase. The small intestinal barrier function is compromised, allowing translocation of potentially antigenic macromolecules into the body with consequent stimulation of the immune and inflammatory mechanisms resulting in growth retardation. Little is known about the nutritional effects of nonsymptomatic giardiasis.

***Cryptosporidium parvum and* other *Cryptosporidium* species** These organisms have only been recognized as human parasites since 1976. They have a worldwide distribution but in developed countries they generally causes a self-limiting disease, which occurs most commonly in child institutions and in people working with animals. However, water-borne outbreaks have occurred in which large numbers of people have become infected. Cryptosporidiosis is much more prevalent in developing countries where it is mainly a disease of children. The parasites live in the upper part of the small intestine, attached to the mucosal cells from which they feed.

Both sexual and asexual reproduction occurs in the host and cysts are produced, most of which pass out in the feces. However, some excyst while passing through the gastrointestinal (GI) tract resulting in autoinfection that can prolong the disease long after the original source of infection has been eliminated. Infection is by ingestion of cysts in fecally contaminated food, water, or utensils, or from unhygienic contact with infected persons. Continued exposure is facilitated by the many infected individuals who remain asymptomatic while passing cysts. *Cryptosporidium* spp., including *parvum*, also occur in many animals and can be transmitted to humans.

Most infected individuals remain asymptomatic, but in others, acute or chronic diarrhea associated with vomiting, abdominal pain, dehydration, and fever can occur. Immunocompromised and previously malnourished cases tend to have more severe and prolonged disease.

The nutritional impact of the infection depends on the severity and duration of the infection but growth retardation and lowered nutritional indices occur in asymptomatic cases as well as those with symptoms. Structural damage to the mucosa of the small intestine is seen, with shortened and fused villi and lengthening of the crypts due to accelerated cell division to replace damaged cells. Surface area is greatly reduced and the immature enterocytes have lower enzymatic and transport activity than mature cells. The resulting maldigestion, malabsorption, and stimulation of the host immune and inflammatory mechanisms are likely to account for the adverse nutritional effects. In children, growth remains poor for many months after infection has resolved. The nutritional status of asymptomatic individuals appears to be compromised by less extreme expression of these same mechanisms.

Entamoeba histolytica This ameba has a very wide distribution but is most commonly found in developing countries where lack of hygienic facilities exacerbate fecal contamination of water, food, and hands. The organism is exclusive to humans; there are no animal hosts. These parasites generally infect the large intestine where they can cause severe disease by invading mucosal tissues.

The life cycle is simple: adult amebae reproduce asexually forming substantial colonies and in some cases cause ulcerative lesions in the mucosa. Some organisms encyst and pass out with the feces. Following ingestion of the cysts by another host, the amebae emerge when the cyst reaches the large bowel. The organism can also invade other organs, notably the liver, resulting in a life-threatening illness.

Although this parasite can cause life-threatening diarrhea and dysentery in some, most infected individuals remain free of symptoms. In others, persistent diarrhea can continue for months, interspersed with periods of apparently normal bowel function. As the parasite is most commonly found in the large intestine, there is little interference with food digestion and absorption and its main effect on nutrition seems to be due to loss of trace elements and electrolytes in watery stools. In more severe cases, blood is also lost in this way but amounts are small. Infection is associated with inflammation of the large bowel (colitis) indicating that host immune and inflammatory mechanisms have been stimulated and this may account for reports of hypoalbuminemia.

Community and Intervention Studies

Iron Deficiency and Iron Deficiency Anemia

A close relationship between the level of hookworm infection and severity of anemia has been observed in many cross-sectional field studies. Similar, though generally less severe, levels of anemia have been associated with intensity of schistosome species and *T. trichiura* disease. The cause and effect relationship suggested by this data has been confirmed by longitudinal investigations of iron status following anthelmintic administration. Community studies in Kenya, India, and Papua New Guinea have recorded substantial increases (up to $6\,g l^{-1}$) in hemoglobin concentration between 4 and 8 weeks after treatment for hookworm. These marked improvements were seen even when parasite loads were not completely eliminated. Effective treatment of severe *Schistosoma and T. trichiura* infections also results in much improved iron status.

Growth and Protein-Energy Malnutrition

Although clinical studies confirm that these parasites have the potential to interfere with growth and nutritional status, evidence that they are a major cause of the widespread stunting and protein-energy malnutrition seen in developing countries is not as conclusive as may be expected. This may be because most infected individuals in a community will have only low to moderate parasite loads and whether a particular disease is important in precipitating malnutrition on a community or public health scale will depend on whether or not such low level infections impact on nutritional status. Information has come from two types of study: (1) cross-sectional surveys; and (2) longitudinal, placebo controlled intervention studies in which nutritional improvements are sought following the use of antiparasite drugs.

A large number of cross-sectional community studies have associated parasitic infection with growth deficits and poor anthropometric indices. Schistosomiasis has long been associated with poor growth, and an extreme condition, schistosomiasis dwarfism, in which physical and sexual development were severely retarded was reported to be quite common in China until the 1950s. Most recent studies of mild to moderate infection with all three schistosome species confirm an association with poor nutritional status that is more marked in girls, but the degree of impairment is variable between different regions and at best can only explain a small part of the total nutritional deficit of the subjects. Hookworm infection is similarly associated with poor appetite, slower growth, and lowered nutritional indices, all of which become more marked with increasing severity of iron deficiency anemia. Iron supplementation of hookworm-infected children has been reported to improve appetite and growth performance as well as iron status, suggesting that the lowered nutritional status may be secondary to iron deficiency rather than a direct effect of the parasite. Growth retardation seen in moderate to heavy *T. trichiura* infection may be similarly explained, although heavier burdens of this worm frequently cause dysentery, which can result in loss of essential trace elements such as zinc.

The impact of the protozoal parasites *Giardia* and *Crytosporidium* on nutritional status has been less well studied, but infection appears to be associated with persistent diarrheal disease and prolonged growth faltering even after apparent elimination of the parasites. Moreover, these parasites, unlike the helminths, are very common in children during the first 2 years of life when growth is at its greatest. Growth-retarding infections at this time of life, particularly in developing countries, appear to compromise growth throughout the whole growth period, thus the impact of these parasites on nutritional status may be far greater than currently appreciated. This is certainly an area requiring more research.

The results of these cross-sectional studies have been reinforced by longitudinal community-wide studies of nutritional improvement following reduction or eradication of parasite burden with anthelmintic drugs. The results of such studies have, however, been less than convincing. Successful treatment of heavily poly-parasitized Kenyan children harboring hookworm, *A. lumbricoides* and *T. trichiura,* with albendazole resulted in improvements in weight, arm circumference, and skinfold thickness and was associated with increased appetite and fitness. Statistical analysis of this data implicated hookworm as being the most important in compromising nutritional status. Weight gain above placebo-treated counterparts averaged 1.3 kg per 6 months, and added about 3% points to a weight-for-age of approximately 80%. However, similar studies in many parts of the world in subjects with lower intestinal helminth burdens have reported only small improvements, whereas others found no change at all in nutritional status indices following successful deworming. Treatment of schistosomiasis in Kenyan, Brazilian, and Filipino children showed only small improvements in nutritional status, e.g., in Kenya, the per cent weight-for-age only increased from 72.9 to 74.9% following eradication with praziquantel. A recent meta-analysis of these studies concluded that deworming did improve nutritional status, but that the effect was small.

Overall, both community and intervention studies do suggest that elimination of GI parasites would improve growth and anthropometric status of children in developing countries but that such improvement would be limited. This contrasts with the very substantial improvement in iron status and iron deficiency anemia that follows effective treatment of organisms causing blood loss.

Treatment and Prognosis

Table 3 shows the drugs most commonly used in treatment of these parasitic infections. Anthelmintic drugs have improved dramatically during the last 20 years and are now highly effective; in most cases a single course of treatment will result in parasite eradication. However, immunocompromised hosts, including malnourished children, may require more extensive courses of therapy to completely eliminate the infection. This is particularly the case in the treatment of cryptosporidiosis. Iron supplements are usually provided where blood loss has resulted in iron deficiency anemia.

Recovery from infection is usually complete and rapid as most parasites do not cause lasting damage to their host. Schistosomiasis is the exception and can result in permanent granuloma formation in several tissues, particularly the liver and spleen, which may become life threatening.

Prevention

Although drugs are now available to eradicate infections, unless the home environment changes, most individuals will soon become reinfected. The transmission of all the parasites discussed occurs most commonly through close contact between the host and infected human feces, either orally or by skin penetration. The basic requirement for prevention is an efficient and hygienic mode of disposal of feces, improved facilities in the home, for example clean running water, concrete floor to the home, plus a knowledge of basic hygiene. Use of footwear and avoidance of contact with water likely to contain schistosome cercaria would help. For the foreseeable future, however, such control measures are quite unrealistic in most developing countries and the alternative may be the large-scale, nation-wide use of anthelmintics to regularly deworm all individuals in endemic areas. School-based regular treatment programmes can be effective. Safe, effective, and relatively cheap drugs are now available and their use in this way could substantially reduce the level of helminth disease throughout the developing world. Such programs can be expected to result in a marked reduction in the prevalence and severity of iron deficiency anemia but in most situations, to have a relatively small impact on child growth, stunting, and incidence of protein-energy malnutrition.

Table 3 Drugs of choice for parasitic infections

Infection	*Drug*
Ascariasis	Mebendazole, albendazole, pyrantel pamoate
Hookworm infection	Mebendazole, albendazole
Schistosomiasis	Praziquantel, metrifonate, niridazole, oltipraz
Trichuriasis	Mebendazole, albendazole
Strongyloidiasis	Thiobendazole, ivermectin
Giardiasis	Metronidazole, tinidazole, secnidazole, furazolidone, albendazole
Cryptosporidiosis	Nitazoxanide, spiramycin, clindamycin,
Amebiasis	Metronidazole, secnidazole, paromomycin, nitazoxanide

PELLAGRA

C J Bates, MRC Human Nutrition Research, Cambridge, UK

History of Pellagra: Recognition, Causes, and Treatment

The following historical summary is based mainly on Carpenter's excellent compendium of key pellagra-related publications published in 1981. Pellagra (meaning 'rough' or 'raw' skin) was common in western Europe (e.g., France and Italy) and especially the southern United States until the early decades of the twentieth century. It has been estimated that it claimed approximately half a million lives between the early eighteenth century and 1930, with as many as 10 000 deaths in the United States in 1929 alone. The typical signs and symptoms of human pellagra are summarized in **Table 1**.

The characteristic signs and symptoms of pellagra were given the name 'mal de la rosa' in 1720 by doctors working in the Asturia region of Spain, and it was very common in Italy at the end of the eighteenth century. As early as 1810, one European description concluded that the disease was neither contagious nor hereditary but was probably caused by a poor diet, especially diets in which grain such as corn (i.e., sweet corn) was the principal staple. The concept of a 'protein' deficiency, as distinct from the characteristic body-wasting calorie deficiency of common famines, was proposed in approximately 1850, and a good hospital diet was shown to have positive curative effects. As early as 1860, however, one observer commented that poor Mexican peasants whose diet was mainly corn based did not exhibit pellagra, and he attributed this to their practices of roasting the corn with lime and of preventing mould growth.

Table 1 Signs and symptoms of niacin deficiency in man and animals

Human deficiency[a]
Loss of appetite and weight
Dermatosis (hyperpigmentation, hyperkeratosis, desquamation of the epidermis, especially where frequently exposed to strong sunlight)
Anorexia
Achlorhydria
Angular stomatitis, cheilosis, magenta tongue
Diarrhea
Anemia
Neuropathy (headache, dizziness, tremor, neurosis, apathy)
Death in severe and prolonged cases
Blacktongue in dogs and cats
Pustules in mouth and excessive salivation, darkening and necrosis of tongue
Diarrhea
Pigs
Neurological lesions affecting ganglion cells; histopathology of nerves
Anemia
Degeneration of intestinal mucosa and diarrhea
Rats
Reduced growth rate
Alopecia
Damage to peripheral nerves (cells and axons)
Birds (e.g., chickens and ducks)[b]
Inflammation of the upper gastrointestinal tract
Dermatitis
Diarrhea
Poor growth of feathers; bowed and weakened legs

[a]All animal species lose appetite and weight when deficient, but the characteristic skin lesions that are observed in human pellagra are rarely seen in other species. Some deficiency symptoms have been produced in other primates (e.g., monkeys).
[b]Ruminants are usually resistant to pellagra, except when forced to produce high quantities of milk or lean tissue.

For the next approximately 50 years, the 'toxin' theory of pellagra causation held sway, and there were government-backed campaigns in Europe to prevent mould growth (in Italy) and to reduce the population's reliance on corn as a staple (in France). In Europe, the prevalence of pellagra was clearly declining sharply (by the beginning of the twentieth century) just as it was beginning to emerge as a major new scourge in the southern United States. A plethora of conflicting hypotheses in the United States included poor sanitation, infection, insect-borne disease, and toxins from bacteria or moulds, but the largely correct 'poor diet' hypothesis was completely ignored until Joseph Goldberger, during the period from 1914 until his death in 1929, carried out classical and definitive controlled feeding studies, both in human convicts and in an animal model, causing 'blacktongue,' a corn diet-induced condition that could be induced in dogs (**Table 2**). Although the exact relationship of the diseases that Goldberger described, and then produced in his animal model, to classical human pellagra remains controversial, the most important outcome of his studies was that pellagra was now seen not as an infectious disease but as primarily a diet-related one, and it was recognized that it and similar diseases could unequivocally be induced by monotonous, poor-quality diets. Families who kept a cow were relatively protected.

Funk's newly formulated hypothesis about essential 'vitamines' and Gowland Hopkins' concept of 'accessory food factors', both of which were emerging at about the same time as Goldberger's studies, set the scene for a focused hunt for a specific organic substance that would be present in the 'curative' diets and which might thereby be identified as the elusive 'pellagra-preventive' (PP) that was thought to be present in the preventative and curative foods. Goldberger classified a range of foods according to their PP properties and found that dried yeast and a water-soluble extract from yeast were both curative, even in small quantities. During the 1930s, following the elucidation of the role of the pyridine nucleotides in food energy metabolism and release, the central roles of nicotinic acid and nicotinamide were elucidated and were equated with the curative PP factor present in the curative food extracts. The term 'niacin' was then coined because 'nicotinic acid' appeared to be etymologically associated with tobacco and was therefore considered to be unsuitable as the name for an essential dietary factor.

Complex Causation

Although pellagra in dogs and humans usually responds well to supplements of pure niacin, there are several further strands to the story that complicate the idea that all the characteristics and manifestations of pellagra can be explained as the result of a simple dietary deficiency of a single water-soluble factor (i.e., vitamin) identified as the molecule niacin. First, it soon became clear that the total niacin content of different foods, as measured by chemical analysis, was not necessarily a good guide to their pellagra-producing or preventing properties. During the 1940s, it was shown that in rats (which respond to pellagragenic diets by a reduced growth rate but not by skin lesions) high dietary tryptophan levels could substantially reduce the requirement for dietary niacin. Tryptophan was then shown to be equally effective in humans in reducing the pellagragenic properties of poor diets.

Table 2 History of the recognition of pellagra, and its probable causes, in human populations

1. A poorly understood disease (dermatitis, gastrointestinal and mental signs/symptoms) appeared first in Europe in the eighteenth and nineteenth centuries and then in the southern United States in the 1910s and was named 'pellagra' (= raw/rough skin).
2. Favored causal hypotheses (USA) initially included infection, mouldy grain and insects.
3. In 1914–1916, Joseph Goldberger disproved the infection hypothesis by self-experimentation and then producing pellagra in prisoners fed mainly corn diets.
4. In the 1920s, he developed the "blacktongue" model of pellagra in dogs, with corn diets.
5. In the 1930s, nicotinic acid was isolated as a pure water-soluble compound ('vitamin') of known structure from yeast and liver extracts, able to cure pellagra and blacktongue.
6. In the mid-twentieth century, niacin was shown to be bound as an unavailable part of the large chemical complex 'niacytin' in corn. Heating in alkaline environment (e.g., Mexican tortillas) can liberate this bound niacin.
7. Intermediary metabolism studies revealed that niacin can be produced from tryptophan in the body. Pellagragenic diets are therefore low in tryptophan as well as niacin. The concept of 'niacin equivalents,' usually [mg niacin plus one-sixtieth of mg tryptophan] in food, developed. Human requirements are estimated.
8. The Indian cereal 'jowar' shown to be pellagragenic. Some, but not all, studies have implicated its high leucine content.
9. Niacin and riboflavin deficiencies often coexist; therefore, the signs and symptoms of 'pellagra-like' disease are often attributable to multiple vitamin deficiencies, of which niacin and riboflavin are usually the most important.
10. Certain inborn errors of metabolism (genetic defects) or iatrogenic effects of drugs can mimic pellagra signs, symptoms, and metabolic defects.

Soon after this, the complex metabolic pathway linking tryptophan to niacin and to the pyridine nucleotide coenzymes was elucidated. Between 34 and 86 mg tryptophan in human diets is now considered to be equivalent to 1 mg niacin, with a mean conversion ratio of 60 mg tryptophan per 1 mg niacin used universally to calculate the niacin equivalents (NE) value of any diet. This is recognised to be a much better index of the anti-pellagra potency of a diet than its niacin content *per se*.

However, this was only one part of the complex etiology of pellagra. The causes of the signs of pellagra in human populations, and indeed also in Goldberger's experimental studies, were and are likely to be a complex mixture of B vitamin deficiencies, of which niacin and tryptophan content are indeed the dominant effectors, but riboflavin is also an important component, followed sometimes by thiamin, vitamin B_6, and possibly vitamin B_{12} and some other nutrients including zinc and iron. The antivitamin effects of certain toxins, especially mould toxins, cannot be ruled out, and several bacterial, fungal, and other toxins have been shown to be capable of depleting cellular levels of NAD(P). In addition, and perhaps most important for corn and the other grain diets, the niacin present in corn and other grains is often chemically bound into a macromolecular complex that is sometimes called niacytin, from which the niacin cannot readily be released by digestive enzymes in the gastrointestinal tract but which requires heat and alkali treatment during food preparation (as in the preparation of Mexican tortillas, which involves lime and heat treatment) so as to make it adequately bioavailable.

In India, the millet-type cereal called 'jowar' is frequently associated with pellagra signs and symptoms, even though it is apparently a reasonably good source of available niacin and tryptophan. Studies have suggested an association with its high leucine content, which may impair the conversion of tryptophan to niacin coenzymes. However, the aetiology of this association remains controversial and unresolved. Balance studies in humans have failed to show a consistent effect of either leucine or vitamin B_6 supplementation on the excretion of the metabolites of tryptophan, which is a sensitive test for imbalanced tryptophan conversion pathways.

Oestrogenic hormones can affect the conversion of tryptophan to niacin coenzymes, and this is thought to be the causal basis for the observation that women (except during pregnancy) seem to be considerably more susceptible to pellagra than men.

Several commonly used drugs also have anti-niacin (iatrogenic) effects in man. Perhaps the most important is isoniazid, which is commonly used in the treatment of tuberculosis. It inhibits kynureninase activity (an enzyme in the tryptophan conversion pathway) by inactivating the enzyme's essential cofactor, pyridoxal phosphate, derived from vitamin B_6. There are several other metabolic interconnections between niacin and vitamin B_6, such that any interference with vitamin B_6 metabolism is likely to affect niacin economy as well. Since up to 60% of Asian Indians are genetically slow acetylators (i.e., deactivators) of isoniazid, the use of this drug in Indians is especially apt to cause pellagra symptoms. The anti-Parkinsonism drugs Carbidopa and Benseride can also cause pellagra symptoms, and in people taking these, there is a reduced rate of excretion of the niacin metabolite *N*-methylnicotinamide. Another niacin antagonist is *N*-acetyl pyridine, which can cause neurological symptoms and histological damage to the hippocampus in some animals.

There are also several inborn errors of metabolism that can result in pellagra-like symptoms in man. Although none of these are very common, the best known is Hartnup's disease, an autosomal recessive condition in which the cellular transport of tryptophan (and other neutral amino acids) is impaired so that tryptophan is rapidly lost in the urine through failure of renal tubular reabsorption. Patients respond well to supplementation with niacin or with tryptophan peptides but not to free tryptophan, which cannot be well absorbed and retained. Other inborn errors of tryptophan economy that can result in pellagra include the vitamin B_6-responsive condition xanthurenic aciduria, hydroxykynurenuria, tryptophanuria (i.e., tryptophan dioxygenase deficiency), and another linked to an increased activity of the enzyme picolinate carboxylase. All these conditions are rare but informative inborn errors of metabolism affecting the tryptophan–niacin metabolic pathway. Tumors of the enterochromaffin cells, which synthesise excessive amounts of 5-hydroxytryptophan and 5-hydroxytryptamine, can also result in pellagra since hyperactivity of this pathway can result in the diversion of tryptophan away from the alternative pathway that converts it to the niacin coenzymes.

High-Risk Groups in Present-Day Society

Today, the most high-risk group for development of pellagra signs and symptoms in Western society is chronic alcoholics, whose diets are often poor, and in addition are subject to liver damage from alcohol abuse and its cellular toxicity. Certain forms of psychosis, including depression and schizophrenia, are associated with abnormalities of the tryptophan metabolism pathways, including those involved in the formation of 5-hydroxytryptamine (serotonin)

and 5-hydroxytryptophan in the central nervous system. Some of these may benefit from modulation of these pathways by drugs and/or supplements. People with AIDS may exhibit some impairment of NAD production, which may in turn respond to niacin supplements as a support treatment, and high-dose nicotinic has been used as one of many alternative treatments for people with cardiovascular disease. In the developing world, pellagra is most commonly encountered in certain African countries (e.g., refugees in Malawi) and areas of India and China.

Biochemical Status Assays: Recommended Intakes

The detection of subclinical niacin deficiency and the confirmation of a clinical deficiency require the objective measurement of biochemical status (and, if possible, of dietary intake, which is usually a more time-consuming task) in order to provide confirmatory evidence, especially because the typical clinical signs and symptoms of pellagra are not entirely specific and pathognomic. Biochemical status estimates can be used to characterize a population, particularly any high-risk subgroups, and to monitor the efficacy of any anti-pellagra interventions. For most micronutrients, robust, specific, and sensitive blood component status assays have been developed. However, for niacin the only promising blood-based assay, namely of intracellular pyridine nucleotide (NAD(P)) concentrations, has not been developed into a definitive and generally accepted biochemical status assay with well-defined normal ranges and a demonstrated association between low concentrations and clinical deficiency signs and symptoms. It has been suggested that a ratio of NAD to NADP below 1.0 in erythrocytes may provide evidence of niacin deficiency, but this requires confirmation.

The practical measurement of niacin status has mainly depended on urinary assays of the excretory products of niacin metabolism, namely N^1-methyl nicotinamide (NMN), N^1-methyl-2-pyridone-5-carboxamide (2-pyridone), and N^1-methyl-4-pyridone-3-carboxamide (4-pyridone), which can be quantitatively estimated by high-performance liquid chromatography separation followed by UV absorption–detection. The Interdepartmental Committee on Nutrition for National Defense has selected as the preferred principal index of niacin status an NMN excretion rate of 5.8 μmol (0.8 mg) per day in 24 h urine samples as defining the junction between biochemical deficiency and sufficiency. If only casual (spot) urine samples are available, then the ratio of NMN to 2-pyridone may provide a useful alternative index, and one study suggested that <8.8 μmol of the combined excretion of NMN plus 2-pyridone can be considered as defining borderline adequacy, corresponding to a niacin intake in the region of 6 mg NE/day. The average adult NE requirement has been estimated from depletion–repletion studies to be approximately 5.5 mg NE/1000 kcal food energy/day, and thus with a 20% allowance for individual variation to cover the needs of the majority of healthy individuals, an RNI (UK) of approx. 6.6 mg NE/1000 kcal (4200 kjoule) food energy/day translates into the broad ranges of UK RNI values that are shown in **Table 3**. In the USA, the basis for the calculation is

Table 3 Reference and recommended intakes of niacin equivalents[a]

Age group	*United Kingdom*[b]		*United States*[c]
	LRNI (mg niacin equivalents/day)	*RNI*	*RDA (mg niacin equivalents/day)*
0–6 months	2	3	2
6–12 months	3–4	4–5	4
12 months–13 years	5–10	8–15	6–12
Adult	8–12	13–18	14–16
Lactation	10	15	17

[a]One niacin equivalent (mg NE) is equivalent to 1 mg niacin or one-sixtieth of the tryptophan consumed. Since the mean energy intake increases with age, and differs between the sexes after puberty, there is a corresponding difference in the absolute values for each population group. This table provides only a simplified summary of the published values.

[b]UK values are calculated on the basis of an LRNI (Lower Reference Nutrient Intake) of 4.4 mg NE/1000 kcal food energy and an RNI (Reference Nutrient Intake) of 6.6 mg NE/1000 kcal, both of which are constant for all population groups. The LRNI is intended to cover the needs of the lower 2.5% of a healthy population, whereas the RNI is intended to cover 97.5% of a healthy population.
Source: Department of Health (1991) *Report on Health and Social Subjects No. 41. Dietary Reference Values for Food Energy and Nutrients for the United Kingdom*. London: HMSO.

[c]The US RDA values are intended to cover the needs of 97.5% of a healthy population and are set 30% above the Estimated Average Requirements. Source: Food and Nutrition Board (1998) *Dietary Reference Intakes for Thiamin, Riboflavin, Niacin, Vitamin B_6, Folate, Vitamin B_{12}, Pantothenic Acid, Biotin and Choline*. Washington, DC: National Academy Press.

now somewhat different, but nevertheless, the US RDA ranges shown in **Table 3** are generally similar to the UK RNIs.

Glossary

Niacin Combination of nicotinamide and nicotinic acid.

Niacin equivalents (NE) mg niacin plus one-sixtieth of mg tryptophan in a defined quantity (e.g., mg/100 g or mg/d) of food or diet.

Niacytin A macromolecular complex of niacin found in some cereals, notably maize (sweet corn), which is poorly bioavailable but liberates niacin on heating with alkali. Mexican tortillas are cooked by heating maize flour with lime, which liberates the niacin in a bioavailable form.

Jowar An Indian cereal (staple) that is associated with high pellagra risk and is rich in the amino acid leucine, but which contains only a marginally adequate amount of niacin + tryptophan.

Isoniazid A drug used in the treatment of tuberculosis that antagonizes vitamin B_6 and is associated with pellagra symptoms, especially in Asian Indians.

Carbidopa, Benseride Anti-Parkinsonism drugs that can cause pellagra-like symptoms.

***N*-acetyl-pyridine** A niacin antagonist, studied in animals.

NAD, NADH, NADP, NADPH The pyridine nucleotide coenzymes containing niacin that are involved in many essential hydrogen transfer reactions of intermediary metabolism, namely nicotinamide adenine dinucleotide (oxidized and reduced forms) and nicotinamide adenine dinucleotide phosphate (oxidized and reduced forms).

NMN N^1-methyl nicotinamide, a degradation product of niacin found in the urine.
2-pyridone, N^1-methyl-2-pyridone-4-carboxamide, another degradation product of niacin, is also found in the urine.

RDA Recommended Dietary Amount of a named nutrient, being the daily amount needed to cover the needs of the majority, usually 97.5% (i.e., mean plus 2 standard deviations) of the members of a healthy population of each defined age group and sex in the USA. RNI (Reference Nutrient Intake) is the UK equivalent of the RDA. (EAR: Estimated Average Requirement; LRNI: Lower Reference Nutrient Intake (UK only), which is the amount need to cover only that 2.5% of the population with the lowest requirements for the named nutrient).

Pellagra A human disease that is often equated with a clinical niacin deficiency but may have more complex causes.

Hartnup's disease A genetic disease of humans that exhibits some features similar to those of pellagra but that results from an impaired membrane transport of tryptophan.

Blacktongue Induced niacin deficiency disease in dogs, an animal model for human pellagra.

Units Niacin or niacin equivalents in food are usually expressed as milligrams per 100 g, usually of wet weight of food. Concentrations of analytes in tissues, blood, or urine are usually expressed in SI units (e.g., μmol/l or $\mu mol\,l^{-1}$).

PHOSPHORUS

J J B Anderson, University of North Carolina, Chapel Hill, NC, USA

The consumption of a diet sufficient in phosphorus, in the form of phosphate salts or organophosphate molecules, is critical for the support of human metabolic functions. Too much phosphorus, in relation to too little dietary calcium, may contribute to bone loss, and too little phosphorus along with too little dietary calcium may not adequately maintain bone mass, especially in the elderly. Therefore, under normal dietary conditions, dietary phosphorus is used for numerous functions without any concern; it is only when too much or too little phosphorus is ingested that skeletal problems may arise. Certainly, elderly subjects need to consume sufficient amounts of phosphorus, like calcium, to maintain bone mass and density, but too much phosphorus may contribute to inappropriate elevations of parathyroid hormone (PTH) and bone loss. It is not clear where most elderly subjects fall along this continuum of intake patterns. This article discusses the mechanisms by which phosphate ions impact on calcium and also on bone tissue.

Calcium–Phosphate Interrelationships

Although phosphorus in the form of phosphate ions is essential for numerous body functions, its metabolism is intricately linked to that of calcium because of the actions of calcium-regulating hormones, such as PTH and 1,25-dihydroxyvitamin D, on bone, the gut, and the kidneys. Adequate phosphorus and calcium intakes are needed not only for skeletal growth and maintenance but also for many cellular roles, such as energy production (i.e., adenosine triphosphate (ATP)). Phosphate ions are incorporated in many organic molecules, including phospholipids, creatine phosphate, nucleotides, nucleic acids, and ATP.

Dietary Sources of Phosphorus

Animal products, including meats, fish, poultry, eggs, milk, cheese, and yogurt, are especially rich in phosphorus, as phosphates, but good amounts of phosphorus can be obtained from cereal grains and many vegetables, including legumes. Because of the abundance of phosphorus in the food supply, deficiency is highly unlikely except perhaps late in life when some elderly individuals consume little food. An extremely rare deficiency disease, phosphate rickets, in infants has been reported to result from inadequate phosphorus intake.

In the United States, mean phosphorus intakes approximate 1200–1500 mg per day in adult males and 900–1200 in adult females. In addition, phosphate additives used in food processing and cola beverages are also consumed, but the quantities are not required by food labeling laws to be given on the label so that the actual additional amounts consumed can only be estimated. Phosphate additives used by the food industry may be found in baked goods, meats, cheeses, and other dairy products.

Table 1 Calcium and phosphorus composition of common foods

Food category	*Phosphorus mg/serving*	*Calcium mg/serving*	*Ca:P ratio (wt:wt)*
Milk, eggs, and dairy			
Cheddar cheese, 1 oz.	145	204	1.4
Mozzarella cheese-part skim, 1 oz.	131	183	1.4
Vanilla ice milk, 1 cup	161	218	1.4
Lowfat yogurt, 1 cup	353	448	1.3
Skim milk, 8 oz.	247	301	1.2
Skim milk-Lactose reduced, 8 oz.	247	302	1.2
Vanilla ice cream, 1 cup	139	169	1.2
Vanilla soft-serve ice cream, 1 cup	199	225	1.1
Egg substitute, frozen, 1/4 cup	43	44	1.1
Chocolate pudding, 5 oz.	114	128	1.1
Processed American cheese, 1 oz.	211	175	0.8
Lowfat cottage cheese, 1 cup	300	200	0.7
Processed cheese spread, 1 oz.	257	129	0.5
Instant chocolate pudding, 5 oz.	340	147	0.4
Soy milk, 8 oz.	120	10	0.1

A conservative estimate is that most adults in the United States consume an extra 200–350 mg of phosphorus each day from these sources and cola beverages. Therefore, the total phosphorus intakes for men and women are increased accordingly. Because the typical daily calcium intake of males is 600–800 mg and that of females is 500–650 mg, the Ca:P ratios decrease from approximately 0.5–0.6 to less than 0.5 when the additive phosphates are included. As shown later, a chronically low Ca:P dietary ratio may contribute to a modest nutritional secondary hyperparathyroidism, which is considered less important in humans than in cats. **Table 1** provides representative values of calcium and phosphorus in selected foods and the calculated Ca:P ratios. Only dairy foods (except eggs), a few fruits, and a few vegetables have Ca:P ratios that exceed 1.0.

Recommended intakes of phosphorus have been set for adults in the United States at 900 mg per day for men and 700 mg per day for women.

Intestinal Absorption of Phosphates

Because phosphate ions are readily absorbed by the small intestine (i.e., at efficiencies of 65–75% in adults and even higher in children), a prompt increase in serum inorganic phosphate (Pi) concentration follows within an hour after ingestion of a meal begins. (Calcium ions or Ca^{2+} are much more slowly absorbed.) The increased serum Pi ($HPO_4^{=}$) concentration then depresses the serum calcium ion concentration, which in turn stimulates the parathyroid glands to synthesize and secrete PTH. PTH acts on bone and the kidneys to correct the modest decline in Ca^{2+} and homeostatically return it to the set level. Reports suggest that an elevation of serum Pi ionic concentration directly influences PTH secretion independently of hypocalcemia. These meal-associated fluctuations in Pi and Ca^{2+} are part of normal physiological adjustments that occur typically three or more times a day.

Pi ions are thought to be absorbed primarily by transcellular mechanisms that involve cotransport with cations, especially sodium (Na^{+}). These rapid mechanisms account for the uptake of Pi ions in blood within 1 h after ingestion of a meal. The blood concentration of Pi is less tightly regulated than the serum calcium concentration. Wider fluctuations in serum Pi concentrations reflect both dietary intakes and cellular releases of inorganic phosphates.

Most Pi absorption by the small intestine occurs independently of the hormonal form of vitamin D. The reported role of 1,25-dihydroxyvitamin D in intestinal Pi transcellular absorption is somewhat unclear because of the normally rapid influx of Pi ions after a meal, but this hormone may enhance the late or slower uptake of Pi ions. Paracellular passive absorption of Pi ions may also occur, but the evidence for this is limited.

Phosphate Homeostatic Mechanisms

The blood concentrations of Pi ions are higher early in life and then decline gradually until late life. The normal range for adults is 2.7–4.5 mg/dl (0.87–1.45 mmol/l). The percentage distributions of the blood fractions of phosphorus compared to those

Table 2 Approximate percentage (%) distributions of calcium and phosphate in blood

Serum fraction	*Calcium*	*Phosphate*
Ionic	50–55%	55–60%
Protein-Bound	45–50	10–13
Complexed	0.3–0.6	30–35

of calcium are given in **Table 2**. The homeostatic control of this narrow concentration range of Pi is maintained by several hormones, including PTH, $1,25(OH)_2$ vitamin D, calcitonin, insulin, glucagon, and others, but the control is never as rigorous as that of serum calcium. In contrast to calcium balance, which is primarily regulated in the small intestine by $1,25(OH)_2$ vitamin D, Pi balance is mainly regulated by the phosphaturic effect of PTH on the kidney, primarily the proximal convoluted tubule. In this sense, Pi regulation is less critical than that of calcium, which may result from the presence of multiple stores of this ion distributed throughout the body (i.e., bone, blood, and intracellular compartments).

A major regulator of Pi is PTH, whose role has been fairly well uncovered. PTH increases bone resorption of Pi (and calcium ions), it blocks renal tubular Pi reabsorption following glomerular filtration (whereas PTH favors calcium reabsorption), and it enhances intestinal Pi absorption (and calcium absorption) via the vitamin D hormone, $1,25(OH)_2$ vitamin D. Other hormones have more modest effects on serum Pi concentration.

Functional Roles of Phosphates

Several major roles of Pi ions have been briefly noted (i.e., intracellular phosphate groups for cellular energetics and biochemical molecules as well as for the skeleton and teeth (structures)). Other important functions also exist. For example, in bone tissue phosphates are critical components of hydroxyapatite crystals, and they are also considered triggers for mineralization after phosphorylation of type 1 collagen in forming bone. Serum phosphates, $HPO_4^{=}$ and $H_2PO_4^{-}$, also provide buffering capacity that helps regulate blood pH and also cellular pH.

Considerable cellular regulation occurs through the phosphorylation or dephosphorylation of Pi ions under the control of phosphatase enzymes, including protein kinases. These cell regulatory roles of Pi ions coexist with regulatory functions involving calcium ions, but Pi ions are much more widely distributed within cells and cell organelles than Ca ions.

Insulin affects Pi ions by increasing their intracellular uptake, although temporarily, for the prompt phosphorylation of glucose. Insulin may also influence the use of Pi ions when insulin-like growth factor-1 acts to increase tissue growth or other functions. Because of the broad uses of Pi ions in structural components, energetics, nucleic acids, cell regulation, and buffering, there is an overall generalization that these versatile yet critical ions support life.

Phosphate in Health and Disease

Phosphate balance in adults is almost always zero, in contrast to calcium balance, which is usually negative, because of the effective action of PTH on renal tubules to block Pi reabsorption. In late life, however, intestinal phosphate absorption decreases and the serum phosphate concentration declines. These physiological decrements may contribute to disease, especially to increased bone loss and osteopenia or more severe osteoporosis. Typically, these changes in Pi balance are also accompanied by similar changes in calcium balance. Too little dietary phosphorus and too little dietary calcium may be determinants of low bone mass and density and, hence, increased bone fragility. The usual scenario invoked to explain osteoporosis in old age, however, is that too little dietary calcium in the presence of adequate dietary phosphorus stimulates PTH release and bone loss (**Figure 1**).

Three human conditions that involve abnormal Pi homeostasis need explanation.

Aging and Renal Function

The serum concentration of Pi increases with a physiological decline in renal function associated with aging (but not renal disease per se). Healthy individuals excrete approximately 67% of their absorbed phosphate via the urine and the remainder via the gut as endogenous secretions. As the glomerular filtration capacity of the kidneys declines, the serum Pi concentration increases and more Pi is retained by the body. PTH secretions increase but the typical serum PTH concentrations, although elevated, remain within the upper limits of the normal range, at least for a decade or so. Thereafter, however, serum Pi and PTH both continue to climb as renal function declines and increased rates of bone turnover lead to measurable bone loss. This situation probably affects millions in the United States each year as they enter the 50s and proceed into the 60s; many of these individuals are overweight or obese and have the metabolic syndrome, which

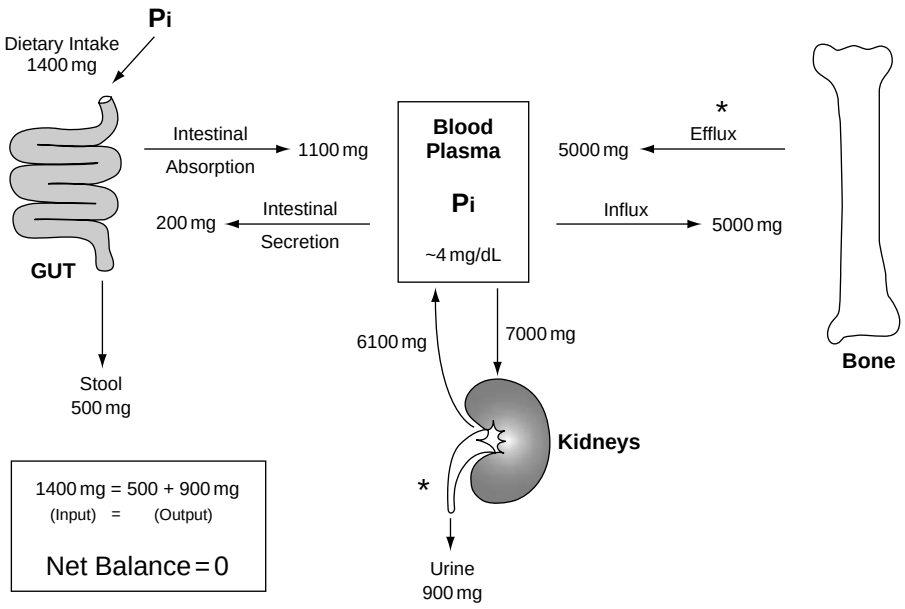

Figure 1 Phosphorus homeostasis and balance. The intestine, kidneys, and bone are organs involved in phosphate homeostasis. Fluxes of phosphate ions between blood and these organs are shown. Note the high fluxes in and out of bone each day. To convert phosphorus values from g to mmol, multiply by 32.29; from mg/dl to mmol/l, multiply by 0.3229. *Steps enhanced by parathyroid hormone. (Adapted with permission from Anderson JJB, Sell ML, Garner SC, and Calvo MS (2001) Phosphorus. In: Bowman BA and Russell R (eds.) *Present Knowledge in Nutrition*, 8th edn, p. 282. Washington, DC: International Life Sciences Institute Press.)

may negatively impact renal function. As the syndrome worsens, many of these individuals will progress to chronic renal failure and renal secondary hyperparathyroidism.

Nutritional Secondary Hyperparathyroidism

This mild condition has not been fully assessed in any longitudinal studies lasting as long as 1 year. The initiating event is a chronic low-calcium and high-phosphorus intake (low Ca:high P ratio) that leads to a chronic elevation of serum PTH. Elevations in PTH stimulate osteoclastic bone resorption and declines in bone mass and density. This condition has only been studied experimentally using human subjects for 28 days, but the chronic increases in PTH and vitamin D hormone suggest that even a lowering of the Ca:Pi ratio below 0.5—in this study to ~0.25—resulted in adverse effects. Longer term studies are needed to determine if bone losses occur under this chronic dietary regimen.

Renal Secondary Hyperparathyroidism

The true secondary hyperparathyroidism of chronic renal failure (CRF) has been extremely difficult to treat by clinicians because of high Pi and PTH concentrations in this condition. Traditional treatment includes the use of binders (chemical) to prevent Pi absorption from the small intestine. In recent years, a calcium-sensing receptor (CaR) in the parathyroid glands has been identified and drugs are being developed that will trick the CaR into thinking that serum calcium is normal rather than depressed, thereby reducing PTH secretion. A reduction in PTH then helps in the conservation of bone tissue since bone loss is such a severe problem in CRF patients.

Conclusions

The general view of dietary phosphorus, supplied in foods as phosphates, is that too much relative to calcium skews the Ca:P ratio to much less than 0.5. Another view, however, has been emerging that suggests that many elderly subjects, especially women, have very low phosphorus intakes in addition to low calcium intakes and that they may benefit from increased consumption of both calcium and phosphate from foods and supplements. In dietary trials designed to reduce fractures of elderly women and men, especially nonvertebral fractures, calcium plus vitamin D has been the treatment, but at least one trial that used calcium phosphate plus vitamin D has shown significant reduction in fractures over 18 and 36 months of follow-up. Further studies are needed to target the role of phosphate ions in reducing fractures among the elderly.

PHYTOCHEMICALS

Contents

Classification and Occurrence

A Cassidy, School of Medicine, University of East Anglia, Norwich, UK

There is a considerable body of evidence to suggest that populations that consume diets rich in fruits and vegetables, whole-grain cereals, and complex carbohydrates have a reduced risk of a range of chronic diseases. This has led to the suggestion that the diversity of substances found in food, particularly plant-derived or plant-based foods, may underlie the protective effects that are attributed to diets high in fruits and vegetables and other plant foods. Although fruits and vegetables are rich sources of micronutrients and dietary fiber, they

also contain a wide variety of secondary metabolites, which provide the plant with color, flavor, and antimicrobial and insecticide properties. Many of these substances have been attributed a wide array of properties but have yet to be recognized as nutrients in the conventional sense. Many of these potentially protective plant compounds, termed phytochemicals, are receiving increasing attention. Phytochemicals, also known as phytonutrients, are plant-based compounds that exert numerous physiological functions in mammalian systems. Many of them are ubiquitous throughout the plant and as a result are present in our daily diet. Among the most important classes are the flavonoids, which are classified based on their chemical and structural characteristics. This article focuses on the different classes of phytochemicals and their relationships to human diseases.

Phytochemicals: General

Plants synthesize a wide array of compounds that play key roles in protecting plants against herbivores and microbial infection and as attractants for pollinators and seed-dispersing animals, allelopathic agents, UV protectants, and signal molecules in the formation of nitrogen-fixing root nodules in legumes. Although they have long been ignored from a nutritional perspective, the function of these compounds and their relative importance to human health are gaining significant interest.

Phytochemicals comprise a wide group of structurally diverse plant compounds, which are predominantly associated with the cell wall and widely dispersed throughout the plant kingdom. They are secondary plant metabolites, characterized by having at least one aromatic ring with one or more hydroxyl groups attached. The nature and distribution of these compounds can vary depending on the plant tissue, but they are mainly synthesized from carbohydrates via the shikimate and phenylpropanoid pathways. They range in chemical complexity from simple phenolic acids, such as caffeic acid, to complex high-molecular-weight compounds, such as the tannins, and they can be classified according to the number and arrangement of their carbon atoms. In plants, they are commonly found conjugated to sugars and organic acids and can be classified into two groups, flavonoids and nonflavonoids. The most researched group of compounds to date is the flavonoids, and this article focuses on this group.

Flavonoids

Flavonoids constitute a large class of phytochemicals that are widely distributed in the plant kingdom, are present in high concentrations in the epidermis of leaves and skin of fruits, and have important and varied roles as secondary metabolites. More than 8000 varieties of flavonoids have been identified, many of which are responsible for the colors of fruits and flower. They are found in fruits, vegetables, tea, wine, grains, roots, stems, and flowers and are thus regularly consumed by humans. Although it has been widely known for centuries that derivatives of plant origin possess a broad spectrum of biological activities, it was first suggested that flavonoids may be important for human health in the 1930s when it was observed that a fraction from lemon juice could decrease the permeability of arteries and partially prevent symptoms in scorbutic pigs. At the time, it was suggested that these compounds should be defined as a new class of vitamins, vitamin P, and the substance responsible for the effects was identified as the flavonoid rutin. However, the data were not generally accepted and the term vitamin P was abandoned in the 1950s. There was renewed interest in flavonoids when a potentially protective role for flavonoids in relation to heart disease in humans was reported. Since that time, there has been a surge of interest in the potential role of flavonoids in human health, with research suggesting antioxidant effects, hormonal actions, antiinfectious actions, cancer-preventative effects, the ability to induce chemical defense enzymes, and actions on blood clotting and the vascular system. However, concrete evidence that they positively influence human health is lacking, and adverse effects have also been reported for some polyphenols. The main subclasses of flavonoids are flavones, flavonols, flavan-3-ols, isoflavones, flavanones, and anthocyanidins (**Figure 1** and **Table 1**).

Other flavonoid groups that are thought to be less important from a dietary perspective are the dihydroflavones, flavan-3,4-diols, coumarins, chalcones, dihydrochalcones, and aurones. The basic flavonoid skeleton can have numerous constituents; hydroxyl groups are usually present at the 4-, 5-, and 7- positions. Sugars are very common, and the majority of flavonoids exist naturally as glycosides. The presence of both sugars and hydroxyl groups increases water solubility, but other constituents, such as methyl or isopentyl groups, render flavonoids lipophilic.

Although many thousands of different flavonoids exist, they can be classified into different subclasses. The main subclasses that are important from a human health perspective are the flavones,

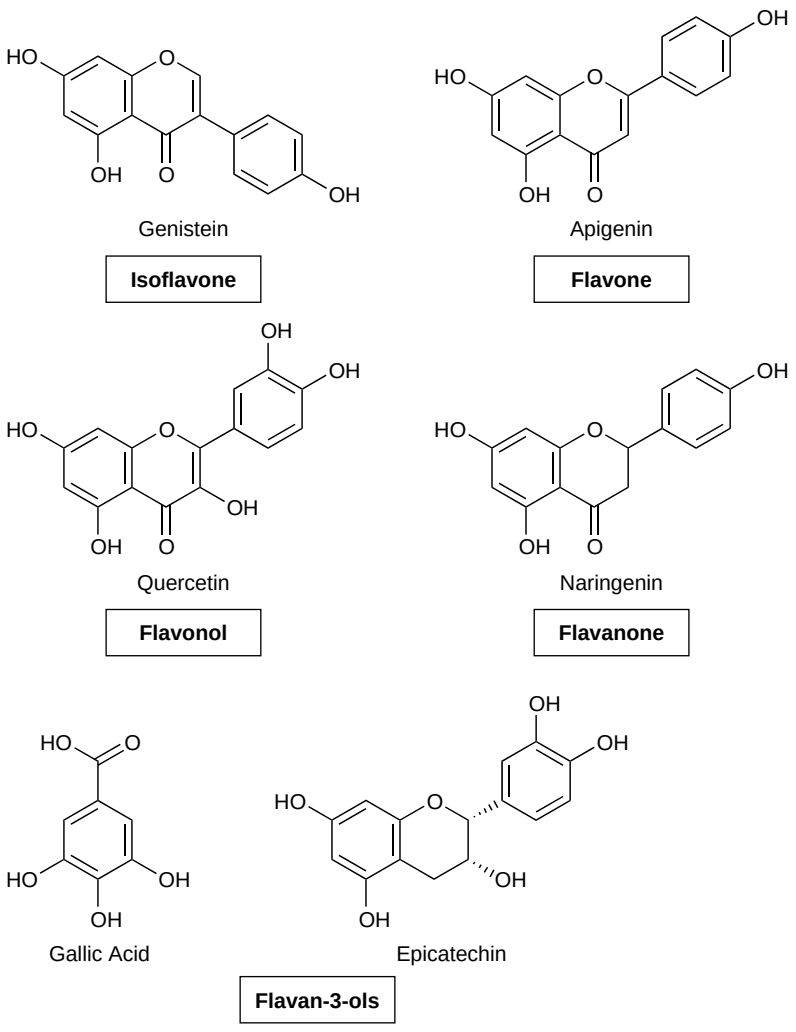

Figure 1 Structures of the major subclasses of flavonoids.

flavonols, flavan-3-ols, isoflavones, flavanones, and anthocyanidins (**Figure 1**).

Flavonols

These are arguably the most widespread of the flavonoids because they are dispersed throughout the plant kingdom. The distribution and structural variations of flavonols are extensive and have been well documented. Extensive information on the different flavonols present in commonly consumed fruits, vegetables, and drinks is available; however, there is wide variability in the levels present in specific foods, in part due to seasonal changes and varietal differences. The most common flavonols are kaempferol, quercetin, isorhamnetin, and myricetin.

Flavones

Flavones have a close structural relationship to the flavonols, but unlike flavonols they are not widely distributed in plants. The only significant occurrences in plants are in celery, parsley, and a few other herbs, and they predominantly occur as 7-*O*-glycosides (e.g., luteolin and apigenin). In addition, polymethoxylated flavones have been found in citrus fruits (e.g., nobiletin and tangeretin).

Flavan-3-ols

Flavan-3-ols, often referred to as flavanols, are the most complex class of the flavonoids because they range from simple monomers (catechin and its isomer epicatechin) to the oligomeric and polymeric proanthocyanidins, which are also known as condensed tannins. Proanthocyanidins can occur as polymers of up to 50 units, and when hydroxylated they can form gallocatechins or undergo esterification to form gallic acid. Red wine contains oligometric proanthocyanidins derived mainly from the seeds of black grapes. Green tea is also a rich source of

Table 1 Principal dietary sources of flavonoids

Flavonoid	*Compound*	*Food source*
Flavonol	Quercetin, kempferol, myricetin	Onion, apple, broccoli, tea, olives, kale, cranberry, lettuce, beans (green, yellow)
Flavone	Luteolin, apigenin	Olives, celery
Flavan-3-ol	Catechin, epicatechin	Tea, red wine, apple
Flavanone	Naringenin, hesperidin	Citrus fruit
Anthocyanidins	Cyanidin, delphinidin, malvidin, petunidin	Grapes, cherries
Chalcones, dihydrochalcones		Heavily hopped beer, tomatoes (with skins), cider, apple juice
Isoflavone	Genistein, daidzein	Soy

Information from Hollman PC, Katan MB (1997) Absorption, metabolism and health effects of dietary flavonoids in man. Biomed Pharmacother **51**(8): 305–10.
Scalbert A, Williamson G (2000) Dietary intake and bioavailability of Polyphenols. *J Nutr* **130** (8S Suppl): 2073S–85S.

flavan-3-ols, principally epigallocatechin, epigallocatechin gallate, and epicatechin gallate. However, during fermentation of tea leaves the levels of catechins decline and thus the main components of black tea are high-molecular-weight thearubigins, whose structures are derived from flavonoids but are unknown. The catechins are widespread, but the main sources in the diet come from tea, wine, and chocolate.

Anthocyanins

Anthocyanins are widespread in nature, predominantly in fruits and flower tissues, in which they are responsible for the red, blue, and purple colors. They are also found in leaves, stems, seeds, and root tissue. In plants, they protect against excessive light by shading leaf mesophyll cells. Additionally, they play an important role in attracting pollinating insects. The most common anthocyanins are pelargonidin, cyanidin, delphinidin, peonidin, petunidin, and malvidin, which are predominantly present in plants as sugar conjugates.

Flavanones

The flavanones are the first flavonoid products of the flavonoid biosynthetic pathway. They are characterized by the presence of a chiral center at C2 and the absence of the C2–C3 bond. The flavanone structure is highly reactive, and they have been reported to undergo hydroxylation, glycosylation, and O-methylation reactions. Flavanones are present in high levels in citrus fruits, with the most common glycoside known as hesperidin (hesperetin-7-*o*-rutinoside), which is present in citrus peel. Interestingly, flavanone rutinosides are tasteless, whereas the flavanone neohesperidoside conjugates (e.g., neohesperidin) from bitter orange and naringenin (naringenin-7-*o*-neohesperidoside) from grapefruit peel have an intensely bitter taste.

Isoflavones

Isoflavones are flavonoids, but they are also called phytoestrogens because of their oestrogenic activity. Structurally, they exhibit a similarity to mammalian oestrogens and bind to oestrogen receptors α and β. Apart from basic structural similarities, the key to their estrogenic effect is the presence of the hydroxyl groups on the A and B rings. They are classified as oestrogen agonists but also as oestrogen antagonists since they compete with oestrogen for their receptor. They have also been demonstrated to exert effects that are independent of the oestrogen receptor.

Current Estimates of Intake

Diets rich in plant-derived foods can provide more than 1 g of phenolic compounds per day, although there are major international and interindividual differences in exposure. Flavonols, flavones, and flavan-3-ols constitute the three major subclasses of flavonoids, and a significant amount of information on the content of selected flavonoids from these subclasses in fruits and vegetables has been obtained using high-performance liquid chromatography techniques. The other subclasses are flavanones, anthocyanidins, and isoflavones.

Given the differences in dietary intake, particularly for fruits and vegetables, between populations, it is not surprising that the relationships between the predominant flavonoids and their sources will vary between populations, nor is it unexpected that there will be wide inter- and intraindividual variations in intake of the individual subclasses of the flavonoids. Flavonol intake was estimated to be highest in a Japanese population group (64 mg/day) and lowest in Finland (6 mg/day). International comparisons of dietary sources also reflect this variation, but only a few sources of flavonoids are responsible for most of the intake. Red wine was the main source of the flavonol quercetin in Italy, tea was the main source in Japan and The Netherlands, and onions were the most significant contributor to intake in Greece, the United States, and the former Yugoslavia (**Table 1**).

Table 2 Estimated dietary intake of flavonoid subclasses in different countries

Flavonoid subgroup	*Estimated intake (mg/day)*			
	Denmark	*Holland*	*Finland*	*Japan*
Flavonol	1.5–8.6	1–17	1.1–7	16.4
Flavone	1–2	2	No data	0.3
Flavan-3-ol	45	50	8.3	40
Flavanone	7.1–9.3	No data	8.3–28.3	No data
Isoflavone	<1	No data	No data	50
Anthocyanidins	6–60	No data	No data	No data

The estimated daily intake of flavonoids, including catechins and anthocyanins, is >50 mg for all the countries presented in **Table 2**, and realistically intake is probably higher than 100 mg/day if data on all flavonoid groups were available. If this intake is compare to daily intakes of other dietary antioxidants, such as vitamin C (80 mg/day), vitamin E (8.5 mg/day), and β-carotene (1.9 mg/day), it is clear that flavonoid intakes exceed or are at least comparable to those of other established antioxidants, indicating that these compounds constitute an important part of dietary intake of antioxidants.

Absorption and Metabolism of Flavonoids

The flavonols and flavones are generally present in plants in the form of glycosides and as such are water-soluble. Thus, some of the flavonol glycosides may be absorbed intact in the small intestine or hydrolyzed by mucosal enzymes and absorbed as aglycones. However, those that pass through the small intestine unabsorbed or reenter the gut from the bile become available for bacterial metabolism in the colon.

The colon contains numerous microorganisms and as a result it has significant capacity for catalytic and hydrolytic reactions. These colonic bacteria produce enzymes that are capable of stripping flavonoid conjugates of their sugar moieties, enabling free aglycones to be absorbed. The enzymes produced by colonic bacteria can also break down the flavonoids into simple compounds, resulting in the production of a range of derivatives, some of which may be more biologically active than the parent compound. This is an important area for future research because the metabolism of flavonoids is influenced by intestinal microflora and these metabolic reactions may result in deactivation of bioactive compounds or activation of previously inactive compounds. It is therefore critical to identify the bacteria involved in these transformation reactions and define their relative importance and occurrence in the human gut to gain a better understanding of the transformation processes.

Other key body compartments that are important in defining the metabolism of flavonoids are the liver and, to a lesser extent, the small intestine and kidney, in which the biotransformation enzymes are located. Flavonols and flavan-3-ols are primarily metabolized in the colon and liver.

The evidence for absorption of intact flavonoid glycosides is weak. Recent data showing β-glucosidase activity in the small intestine, together with the absence of intact glycosides in plasma and urine, strongly suggest that only free flavonoid aglycones are being absorbed. In addition, data also indicate that there is a more rapid and efficient absorption of flavonoids originating from glucosides than from other glycosides or free aglycones. This suggests that dietary sources containing high levels of glucose-bound flavonoids are more likely to have potential health benefits than foods containing other flavonoid glycosides.

Bioavailability of Flavonoids

Critical to a food's 'nutritional' value is whether the 'nutrient' or compound is provided in a bioavailable form from the food. Flavonoids therefore may have to be absorbed from the large intestine if they are to exert a potential health effect. Early data from animal studies suggested that flavonoids were only absorbed to a limited degree because gut microflora preferentially destroyed the heterocyclic rings of the compounds before absorption occurred in the small intestine. However, an increasing number of studies suggest that the bioavailability of flavonoids is greater than was previously recognized, although increases in the concentrations of flavonoids and its associated metabolites in plasma and urine do not necessarily mean that they have significant effects *in vivo*. There are few data on their intracellular location and mechanism of action. Thus, a key area for future research will be to clarify the absorption, bioavailability, and metabolism of a range of flavonoid compounds.

Potential Mechanisms of Action

The effect of flavonoids on enzymatic, biological, and physiological processes has been extensively studied, but few studies have attempted to determine the actual compound or metabolite responsible for the observed effects. Much of the *in vitro* data assume that the biological activity originates

from the flavonoid ingested, without taking into consideration the biotransformations that may occur following ingestion and metabolism, as it is well established that following ingestion they are transformed into a range of structurally distinct compounds.

In interpreting the mechanistic data, it is also important to remember that little attention has been paid to the physiological relevance of the concentration used in the *in vitro* model systems. Thus, in some instances biological effects have been shown at concentrations that are unachievable *in vivo*; therefore, the biological relevance of these mechanisms to humans is questionable.

Since flavonoids are complex groups of compounds with variable structures and activities, it is unlikely that they exert their biological effects by common mechanisms. However, since it is also now established that the pathophysiological processes leading to the development of cardiovascular disease and cancer are complex, this means that there are many potential sites and stages at which bioactive plant compounds present in food could act to potentially reduce the formation of cancerous cells or the atherosclerotic plaque in cardiovascular disease. Elucidating the underlying mechanisms of how flavonoids work is a key aim for nutrition research.

In vitro experimental systems suggest that flavonoids can scavenge oxygen-derived free radicals; exert antiinflammatory, antiallergic, and antiviral effects; and have anticarcinogenic properties.

Potential Health Effects

There is substantial epidemiological evidence that populations that consume diets rich in plant foods have a reduced risk of cardiovascular disease and various cancers, and the potential role of bioactive compounds in plants in this association is gaining significant attention within nutrition research. Identification of the role of flavonoids in the primary mechanisms that may protect against cellular damage may yield clues to slowing aspects of the aging process and postpone age-related diseases.

Most research on flavonoids and health has focused on quercetin due to its antioxidant potency and potential role in cardiovascular disease. However, the diverse and broad nature of flavonoids means that subclasses other than the flavonols may be more important to human health since they appear to be more bioavailable and thus have a greater potential to protect against the various mechanisms involved in aging and disease development.

Cardiovascular Health

The stimulus for much of the research on the role of flavonoids in human health was derived from epidemiological studies, particularly a study suggesting that dietary flavonoids may protect against cardiovascular disease. During the past decade, a significant amount of research has examined the effect of flavonoids in foods and pure flavonoid compounds at various stages in the atherosclerosis process.

A significant proportion of the research on flavonoids has concentrated on their antioxidant actions, and their capacity to act as antioxidants remains their best described biological property to date. Their antioxidant ability is well established *in vitro*, and *in vivo* animal data also suggest that consumption of compounds such as rutin or red wine extracts, tea, or fruit juice lowers oxidative products such as protein carbonyls, DNA damage markers, and malonaldehyde levels in blood and a range of tissues.

The flavones and catechins appear to be the most powerful flavonoids at protecting the body against reactive oxygen species. Although the mechanisms and sequence of events by which free radicals interfere with cellular functions are not fully understood, one of the most important events may be lipid peroxidation, which results in cellular damage. Flavonoids may prevent such cellular damage by several different mechanisms, including direct scavenging of free radicals such as superoxides and peroxynitrite, inhibition of nitric oxide, or antiinflammatory effects.

Cancer

The specific mechanisms by which individual dietary components can alter the cancer process remain poorly understood. However, mechanisms underlying the carcinogenesis process are understood sufficiently so that model systems to evaluate the ability of a specific compound to inhibit or promote processes that may prevent or delay cancer development can be predicted. Phytochemcials can act at a variety of sites relevant to the development of the cancer cells. They may inhibit carcinogen activation, induce hepatic detoxification pathways, exert antioxidant effects/metal chelation properties, enhance immune response, induce apoptosis, and alter hormonal environment.

From a mechanistic perspective, evidence suggests that flavonoids have the potential to alter the cancer

development process by several different mechanisms. These include inhibition of the metabolic activation of carcinogens by modifying the expression of specific phase I and II enzymes, acting as antioxidants, inhibiting protein kinase C, interfering with expression of the mutated *ras* oncogene, and influencing other redox-regulated aspects of cell proliferation.

In addition to *in vitro* data, it is also well established that certain flavonoids can protect against chemically induced and spontaneously formed tumors in animal models. However, despite the significant amount of experimental evidence indicating that specific flavonoids have potent anticarcinogenic effects, the available epidemiological data are contradictory. Some ecological, cohort, and case–control studies suggest that tea consumption lowers the risk of developing cancer, whereas other investigations have failed to find such an association. The inconclusive nature may relate to poor information on dietary intake of flavonoids.

Safety

Although flavonoids may have potential health effects, the function of many of these compounds in the plant is to discourage attack by fungal parasites, herbivores, and pathogens. As a result, it is not surprising than many are toxic and mutagenic in cell culture systems, and excessive consumption by animals or humans may cause adverse metabolic reactions. However, the concentrations used in cell culture experiments in general tend to exceed the levels that are achievable *in vivo* following dietary consumption. Results of recent studies using β-carotene supplements should reinforce the need to proceed with caution in using flavonoid supplements, where levels could easily exceed doses obtained from normal dietary intake. For the majority of the identified phytochemicals, there are limited data on the 'safe level' of intake or optimal level of intake for health benefits, and it is critical that these margins be more clearly defined in future research.

Conclusions

There is increasing evidence that flavonoids may be protective against a number of age-related disorders. Data suggest that diets high in flavonoids may not only reduce the risk of cardiovascular disease and cancer but also, by protecting against cellular damage, may slow aspects of the aging process and improve quality of life by postponing age-related diseases. There is still much to be uncovered about their bioavailability, metabolism, mode of action, and optimal doses or, indeed, the actual compounds responsible for the health effect. Research has focused on foods as well as individual components of food to help us further our knowledge. Given the limited information to date, there are no recommended dietary intakes for phytochemicals, but people should consume a wide variety of foods that incorporate the various phytochemicals to maximize disease prevention. Further research is required to define optimal doses for potential health effects and to define safe levels of intakes for many of these phytochemicals. Many of these compounds should be viewed as pharmaceutical compounds because although they occur naturally, they still require the same levels of proof of efficacy and safety in use as synthetic pharmaceutical agents.

Epidemiological Factors

H Wiseman, King's College London, London, UK

There is considerable interest in the role that dietary phytochemicals may play in the protection of human health. This article considers the epidemiological evidence for the health protective effects of phytochemicals such as flavonoids, phytoestrogens, glucosinolates, and their derivatives and allium organosulfur compounds, particularly against cancer and heart disease. Possible health benefits of the soya isoflavone phytoestrogens to brain (especially cognitive function) and bone health are also considered together with the importance of their metabolism by the gut microflora (conversion of daidzein to equol) (**Table 1**). The possible mechanisms of action of these phytochemicals and others of related interest are also considered.

Epidemiological Sources of Evidence Indicating Potential Health Benefits of Phytochemicals

Flavonoids

Flavonoids are a group of more than 4000 polyphenolic compounds found in many plant foods. This group includes the flavonols such as quercetin, flavanols (or catechins, including catechin, epicatechin, epigallocatechin, and epigallocatechin gallate), flavones such as apigenin, and flavanones and anthocyanadins.

Until recently, the extent of absorption and bioavailability of flavonoids was somewhat unclear. Studies with ileostomy patients have shown that humans can absorb significant amounts of quercetin and that glycosides can be absorbed from the small intestine. Absorption of quercetin glucosides was 52%, absorption of pure quercetin was 24%, and that of quercetin rutinoside was 17%. This shows that not only can the glycone form of quercetin be absorbed but also absorption of the glucoside was greater than that of both the aglycone and the rutinoside, showing absorption to be enhanced by conjugation with glucose.

Epidemiological evidence suggests that dietary flavonoids, such as the quercetin, kaempferol, myricetin, apigenin, and luteolin found in tea, apples, onions, and red wine (usually as glycoside derivatives of the parent aglycones), may help to protect against coronary heart disease (CHD). The main epidemiological evidence comes from the Zutphen Elderly study and the Seven Countries Study. In the Zutphen Elderly study (805 men aged 65–84 years), the mean baseline flavonoid intake was 25.9 mg daily and the major sources of intake were tea (61%), onions (13%), and apples (10%). Flavonoid intake, which was analyzed in tertiles, was significantly inversely associated with mortality from CHD, and the relative risk of CHD in the highest versus lowest tertile of flavonoid intake ($\geq$28.6 vs $<$18.3 mg/day) was 0.42 (95% confidence interval, 0.20–0.88).

The Zutphen Elderly study thus suggests that regular flavonoid consumption, as part of the food matrix, may reduce the risk of death from CHD in elderly men. This study also provides evidence for flavonoid-mediated protection against stroke.

Table 1 Overview of epidemiological data relating to the role of soybean products in breast cancer risk

Study	*Soybean product*	*Findings*	*Estimate of relative risk*
Case–control[a]	Soybean protein	↓ Risk	0.43
	Soybean:total protein	↓ Risk	0.29
Case–control	Soybean	Not significant	[b]
Prospective	Miso soup	↓ Risk	0.46
Prospective	Miso soup	↓ Risk[c]	[b]
	Tofu	↓ Risk[c]	[b]

[a]Premenopausal women only.
[b]Could not be calculated.
[c]Decreased risk was only found to be significant for the baseline period 1971–1975.
Adapted from Messina MJ, Persky V, Setchell KDR and Barnes S (1994) Soy intake and cancer risk: A review of the *in vitro* and *in vivo* data. *Nutrition and Cancer* **21**: 113–131.

Dietary flavonoids (particularly quercetin) were inversely associated with stroke incidence. The relative risk of the highest versus the lowest quartile of flavonoid was 0.27 (95% confidence interval, 0.11–0.70). Black tea contributed approximately 70% to flavonoid intake and the relative risk for a daily consumption of 4.7 cups or more of tea versus less than 2.6 cups of tea was 0.31 (95% confidence interval, 0.12–0.84). This study also found that intake of catechins, whether from tea or other sources (e.g., chocolate), may reduce the risk of ischemic heart disease but not stroke. In the Rotterdam study (a large population-based study of men and women aged 55 or older), an inverse association was found between tea and flavonoid (quercetin, kaempferol, and myricetin) intakes and the incidence of myocardial infarction.

In 16 cohorts of the Seven Countries Study, the average long-term intake of flavonoids was inversely associated with mortality from CHD (**Table 2**). Surprisingly, flavonoid intake, did not appear to be an important determinant of cancer mortality in this study. This is in contrast to the anticarcinogenic effects observed in animal models and in human cancer cells *in vitro*. An inverse association between tea consumption and the incidence of some cancers has been reported in a prospective cohort study of 35 369 postmenopausal women. Inverse associations with increasing frequency of tea drinking were seen for cancers of the digestive tract and the urinary tract. The relative risk for women who reported drinking $\geq$2 cups (474 ml) of tea per day compared to those who never or only occasionally drank tea was 0.68 (95% confidence interval, 0.47–0.98) for digestive tract cancers and 0.4 (95% confidence interval, 0.16–0.98) for urinary tract cancers. Another epidemiological study reported a reduced risk of gastric cancer from drinking 10 cups or more daily of green tea. Tea, especially green tea, is particularly rich in catechins, such as epicatechin, epigallocatechin, and epigallocatechin gallate, in addition to flavonols such as quercetin.

The association between flavonoid intake and chronic diseases has been studied in Finland in 10 054 men and women. The incidence of cerebrovascular disease was lower at higher kaempferol, naringinin, and hesperetin intakes. Asthma incidence was lower at higher quercetin, naringinin, and hesperetin intakes. Men with high quercetin intakes had a lower lung cancer incidence, and men with higher myricetin intakes had a lower prostate cancer risk.

Flavonol and flavone intakes have been studied in the United States in health professionals (37 886 men and 78 886 women) using a semiquantitiative food frequency questionnaire. Of the flavonols and flavones investigated, quercetin contributed 76% in men and 73% in women. The mean flavonol and flavone intake was 20–22 mg/day, and onions, tea, and apples contributed the greatest amounts of flavonols and flavones. This information should prove useful in the investigation of the role of flavonoids in disease prevention.

Phytoestrogens

Phytoestrogens are phytochemicals found in a number of edible plants. The highest levels of dietary intakes of phytoestrogens are found in countries with a low incidence of hormone-dependent cancers. The main phytoestrogens in the human diet are the isoflavonoids and the lignans. Isoflavonoids include the isoflavones genistein, daidzein, and glycitein and occur mainly (as glycosides of the parent aglycone) in soybeans (*Glycine max*), a wide range of soy products, and to a lesser extent in other legumes. The main source of plant lignans are various seeds, such as linseed (secoisolariciresinol), sesame seed

Table 2 Data from the Seven Countries Study: Flavonoid (flavonol and flavone) intakes of middle-aged men in various countries in approximately 1960 and contribution of different foods to total flavonoid intake

Country	*Flavonol and flavone intake (mg/day)*	*Quercetin intake (mg/day)*	*Tea (%)*	*Fruit and vegetables (%)*	*Red wine (%)*

(matairesinol), and various grains (matairesinol and secisolariciresinol).

The incidence of breast and prostate cancer is much higher in Western countries than in Far Eastern ones, where there is an abundance of dietary phytoestrogens. Populations in the Far East have been consuming soyabean for centuries. In contrast, Western cultures and diets have only started to adopt soy foods much more recently. Western-style soy foods are produced by modern processing techniques in large soybean-processing plants. Traditional soy foods, made from soybeans, include both nonfermented and fermented foods. The nonfermented soy foods include soy milk and the soy milk product tofu and also whole-fat soy flour, soy nuts, whole dry beans, and fresh green soybeans. Traditional fermented soy foods include soy sauce, tempeh, natto, miso, and fermented tofu and soy milk products. Soy milk is the name given to the aqueous extract derived from whole soybeans. A cup of soy milk is thought to contain approximately 40 mg of isoflavones. In soybeans, textured vegetable protein, and tofu (soybean curd), there are high levels of the conjugated isoflavones called daidzin and genistin. In contrast, in the fermented soybean products such as miso, nearly all the isoflavones are present in their unconjugated forms called genistein and daidzein.

After ingestion, the glycones daidzin and genistin are hydrolyzed by gut bacterial glucosidases and by mammalian intestinal lactase phlorizin hydrolase to release the aglycones genistein and daidzein. These may be absorbed or further metabolized. Although most studies suggest that the bioavailabilities of genistein and daidzein are similar, some indicate greater bioavailability for genistein. Daidzein can be metabolized by the gut microflora to form the isoflavan equol (oestrogenic and more potent antioxidant than daidzein) or *O*-desmethylangolensin (*O*-DMA; nonoestrogenic), whereas genistein is metabolized to the nonoestrogenic *p*-ethyl phenol. In studies, only approximately 35% of subjects are able to convert daidzein to equol. Interindividual variation in the ability to metabolize daidzein to equol could thus influence the potential health protective effects of soya isoflavones. Equol is produced in greater amounts by subjects who consume diets that are low in fat and high in carbohydrate and fiber. Developmental changes in isoflavone metabolism occur, and although isoflavone absorption and the ability to convert daidzein to *O*-DMA develop early in infancy, equol production appears much later.

The lignan phytoestrogen precursors matairesinol and secisolariciresinol are present in foods as glycosides and are converted by gut bacteria to the two main mammalian lignans enterolactone and enterodiol, respectively, which are weakly oestrogenic. Matairesinol undergoes dehydroxylation and demethylation directly to enterolactone, whereas secisolariciresinol is converted to enterodiol, which can then be oxidized to enterolactone. After absorption, enterolactone and enterodiol are converted to their β-glucuronides and eventually excreted in urine.

In humans, omniverous subjects usually have quite low levels of isoflavonoid excretion. The Japanese (males and females) have the highest levels of isoflavonoid excretion in subjects following macrobiotic, vegan, and lactovegetarian diets. Urinary lignan excretion is higher in Finland compared to the United States and Japan. In assessing exposure to the protective effects of phytoestrogens, urinary excretion rates should be considered in combination with actual plasma levels. In some Japanese men, the plasma biologically active sulfate + free lignan fraction was similar or even higher than in Finnish men.

Urinary excretion of phytoestrogens can be used as a measure of intake and thus possible exposure and possible protection against cancer. Low urinary excretion of enterolactone in breast cancer patients was found in an epidemiological case–control study in Australia. Prospective studies from Finland and Sweden have shown low plasma concentrations of enterolactone to be associated with a high risk of breast cancer. However, the Swedish study also found a greatly increased risk of breast cancer in the highest quintile of enterolactone concentrations. A plasma enterolactone concentration of 30–80 nmol/l is therefore probably protective against breast cancer. Production of equol is associated with a decreased risk of breast cancer, and production of large amounts of equol is associated with an increased ratio of 2-hydroxyestrone to 16α-hydroxestrone in urine and this has been suggested to decrease breast cancer risk.

Japanese women and women of Japanese origin living in Hawaii but who consume a diet similar to the traditional Japanese diet (rich in soy products) have a low breast cancer incidence and mortality. Women in the Far East who have low rates of breast cancer are thought to consume approximately 30–50 times more soy products than women in the United States. A case–control study in Singapore found that premenopausal women who consumed 55 g of soy per day had a 50% reduced risk of breast cancer compared to women who infrequently consumed soy foods. A high intake of miso soup has been associated with a reduced risk of breast cancer in Japanese women. In prospective trials, a trend toward an inverse association between intake of tofu and

subsequent risk of breast cancer and an inverse association between intake of miso soup and development of breast cancer have been found. However, a large prospective study in Japan did not show any effect of soy consumption on breast cancer risk, although this may be because dietary intake was studied in adult women rather than in children or adolescents. A number of studies in rodents have indicated that a protective effect of a soy isoflavone-rich diet may occur only if soya is consumed before puberty or during adolescence. Soy, if consumed throughout life, appears to protect against breast cancer, particularly if consumed before and during adolescence. Soy isoflavones may decrease breast cancer risk by influencing the menstrual cycle and endogenous sex hormone concentrations. In some but not all studies, increased concentrations of sex hormone binding globulin leading to lower free sex hormone concentrations and a longer menstrual cycle were observed.

A trend toward protective effects against prostate cancer of tofu but not miso has been shown in a large group (approximately 8000) of men of Japanese ancestry in Hawaii followed for 20 years. The latency period for prostate cancer appears to be lengthened in these men, who have a low mortality from prostate cancer. However, the incidence of *in situ* prostate cancer in autopsy studies is similar to that of men in Western countries. The consumption of soy isoflavones by these men may be responsible for this long latency period. This probably means that they die of other causes, including old age, before the prostate cancer can develop to a life-threatening stage. The three most recent studies all suggest that soy intake does protect against prostate cancer. Two studies showed that reduced risk is related to consumption of soy foods and one was a prospective study that showed that consumption of soy milk more than once a day was protective against prostate cancer.

Although soy and isoflavonoids appear not to protect against colon cancer, lignans or lignan-rich foods can protect against colon cancer development in animal models. There is also increasing evidence for cardioprotective effects, bone protective effects, and possibly cognitive benefits of phytoestrogens, and these are under investigation. A lower incidence of heart disease has been reported in populations consuming large amounts of soy products, often in combination with oily fish consumption, which also has cardioprotective benefits. Increased bone mineral density has been found in epidemiological studies in women with high dietary intakes of soy isoflavones. The incidence of dementia has been reported to be lower in Asian countries, particularly Japan, where consumption of soy isoflavones is high. Although one epidemiological study found an association between high intakes of tofu and cognitive impairment, other factors, including age and education, may explain this possible increased risk among tofu consumers.

Brassica Glucosinolates and Their Derivatives

Glucosinolates (previously known as thioglucosides) are sulfur-containing phytochemicals found in cruciferous or brassica vegetables, such as broccoli, cabbage, kale, cauliflower, and Brussels sprouts. Although approximately 100 different glucosinolates are found in the plant kingdom, only approximately 10 are found in brassica vegetables. They are also found in other plant foods. Degradation products of glucosinolates include other organosulfur compounds, such as the isothiocyanates and dithiothiols. Glucosinolate degradation products also include indoles.

Epidemiological data suggest that the relatively high content of glucosinolates and related compounds may be responsible for the observed protective effects of brassica vegetables in the majority of the 87 case–control studies and 7 cohort studies that have been carried out on the association between brassica consumption and cancer risk (**Tables 3–5**). In the case–control studies, 67% of studies showed an inverse association between consumption of brassica vegetables and risk of cancer at various sites. If individual brassica vegetables are considered, then the values for the number of studies that showed an inverse association between consumption of brassica vegetables and risk of cancer at various sites are as follows: broccoli, 56%; Brussels sprouts, 29%; cabbage, 70%; and cauliflower, 67%. The cohort studies showed inverse associations between broccoli consumption and the risk of all types of cancer taken together; between the consumption of brassicas and risk of stomach cancer and the occurrence of second primary cancers; and between the consumption of cabbage, cauliflower, and broccoli and the risk of lung cancer. Overall, it appears that a high consumption of brassica vegetables is associated with a decreased risk of cancer. The associations were most consistent for stomach, lung, rectal, and colon cancer. The epidemiological literature also provides some support for the hypothesis that high intakes of brassica vegetables can reduce risk of prostate cancer. Further epidemiological research is required to separate the cancer protective effects of brassica vegetables from those of vegetables in general.

Allium Organosulfur Compounds

There is increasing epidemiological evidence that other organosulfur compounds in addition to those derived from glucosinolates can protect against

cancer. Allium species such as garlic (*Allium sativum*) and onions (*Allium cepa*) are a rich source of organosulfur compounds, such as the diallyl sulfides. There is epidemiological evidence from the Netherlands Cohort Study (120 852 men and women 55–69 years of age) for a strong inverse association between onion consumption and incidence of stomach carcinoma. However, the consumption of leeks and the use of garlic supplements were not associated with stomach carcinoma risk. The relative risk for stomach carcinoma in the highest onion consumption category ($\geq$0.5 onions/day) was 0.50 (95% confidence interval, 0.26–0.95) compared to the lowest consumption category (no onions/day). However, this study did not support an inverse association between the consumption of onions and leeks and the use of garlic supplements and the incidence of male and female colon and rectal carcinoma. There is only limited epidemiological evidence concerning the beneficial influence of garlic organosulfur compounds on cardiovascular disease.

Potential Importance of Flavonoids to Human Health: Molecular Mechanisms of Action

Flavonoids possess a broad spectrum of biological actions ranging from anticarcinogenic to antiinflammatory, cardioprotective, immune-modulatory, and

antiviral. The mechanisms by which flavonoids cause these effects may include induction of the activity of some important enzymes while inhibiting the activity of others. Modulation of membrane function, including the activity of membrane-bound enzymes, through a protective membrane antioxidant action is likely to be of prime importance.

Membrane function is understood to be of vital importance to many cellular processes, including the role of membrane enzymes and receptors in cell growth and signalling. Membrane function may be influenced by dietary components directly by altering membrane fluidity or indirectly by protection against the free radical-mediated process of membrane lipid peroxidation. This can arise from oxidative stress and result in oxidative membrane damage. Flavonoids such as quercetin and myrecetin have been widely found to inhibit membrane lipid peroxidation. Flavonoids inhibit lipid peroxidation *in vitro* by acting as chain-breaking antioxidants: They donate a hydrogen atom to lipid radicals, thus terminating the chain reaction of lipid peroxidation. Additionally, flavonoids can act as metal chelating agents. Furthermore, kaempferol-3-*O*-galactoside protected mice against bromobenzene-induced hepatic lipid peroxidation. The relative potencies of flavonoids as antioxidants is governed by a set of structure–function relationships: In general, optimum antioxidant activity is associated with multiple phenolic groups, a double bond in C2–C3 of the C ring, a carbonyl group at C4 of the C ring, and free C3 (C ring) and C5 (A ring) hydroxy groups. It is of related interest that consumption of 300 ml of either black or green tea greatly increased plasma antioxidant capacity in 10 volunteers. This suggests that normal levels of tea consumption could provide sufficient flavonoids to achieve a potentially health protective effect.

There is increasing evidence for the role of free radicals in the oxidative DNA damage implicated in carcinogenesis. The ability of flavonoids to act as antioxidants may contribute to the anticancer effects observed in animal models and human cells in culture *in vitro*, which could potentially be important to human health despite the current lack of epidemiological evidence and the finding that consumption of flavonoids in onions and black tea (providing 91 mg/day of quercetin for 2 weeks) by young healthy male and female subjects had no effect on oxidative DNA base damage in leucocytes. Quercetin has been shown to have growth inhibitory effects *in vitro* on breast cancer cells, colon cancer cells, squamous cell carcinoma cell lines, acute lymphoid and myeloid leukemia cell lines, and a lymphoblastoid cell line. These effects appear to be mediated *via* binding to cellular type 2 oestrogen binding sites. Furthermore, when the ability of two citrus flavonoids, hesperetin and naringenin (found in grapefruit mainly as its glycosylated form naringin), and three noncitrus flavonoids to inhibit the proliferation and growth of a human breast cancer cell line was investigated, the concentrations required to achieve 50% inhibition ranged from 5.9 to 56 μg/ml. The effectiveness of the citrus flavonoids was enhanced by using them in combination with quercetin, which is widely distributed in other foods. Quercetin fed to rats in the diet at levels of 2% or 5% inhibited the incidence and multiplicity of chemical carcinogen-induced mammary tumors. Mammary tumorigenesis in rats was delayed in the groups given orange juice (rich in citrus flavonoids together with other phytochemicals and nutrients) or fed the naringin-supplemented diet compared with the other groups. A number of the phenolic compounds of green tea, including the catechins, have been shown to inhibit tumour formation in rats induced by *N*-methyl-*N*′-nitro-*N*-nitrosoguanidine and also mutation induced by aflatoxin and benz(*a*)pyrene.

Quercetin has been shown to inhibit the activity of two enzymes that play an important role in mammary cell growth and development, tyrosine protein kinase activity and phosphoinositide phosphorylation, and it also inhibits protein kinase C, which is vital in the regulation of cellular proliferation. Blockade of the tyrosine kinase activity of the EGR receptor leading to growth inhibition and apoptosis in pancreatic tumor cells have been reported for quercetin and luteolin. Furthermore, inhibition of

tumor growth through cell cycle arrest and induction of apoptosis by quercetin are thought to be functionally related to activation of the tumor supressor protein p53. In addition, quercetin has been shown to regulate the growth of endometrial cancer cells (Ishikawa cell line) via suppression of EGF and the cell cycle protein, cyclin D1. A further mechanism for the antiproliferative action of quercetin may be via perturbation of microtubule functions such as polymerization through the binding of quercetin to tubulin, which induces conformational changes.

A number of mechanisms have been proposed for the protection by flavonoids against CHD, including antioxidant activity. Oxidative damage to low-density lipoprotein (LDL) (particularly to the apoprotein B molecule) is considered to be an important stage in the development of atherosclerosis: It is a prerequisite for macrophage uptake and cellular accumulation of cholesterol leading to the formation of the atheromal fatty streak. Flavonoids such as quercetin are effective inhibitors of *in vitro* oxidative modification of LDL by macrophages or copper ions. Although consumption of flavonoids in onions and black tea (providing 91 mg/day of quercetin for 2 weeks) by young healthy male and female subjects had no effect on plasma F_2-isoprostane concentrations (a biomarker of *in vivo* lipid peroxidation) or on resistance of LDL to copper–ion-induced oxidation, flavonoids in red wine have been reported to protect LDL against oxidative damage. The antioxidant properties of flavonoids may contribute to the reduced risk of CHD in wine drinkers, the so-called French paradox. Resveratrol, another phenolic phytochemical found in wine, has been shown to protect LDL against oxidative damage and appears to protect against cancer in animal models. Further studies on this interesting compound are clearly warranted.

Quercetin displays potent antithrombotic effects: It inhibits thrombin and ADP-induced platelet aggregation *in vitro*, and this may be through inhibition of phospholipase C activity rather than through inhibition of thromboxane synthesis. Flavonoid binding to platelet membranes may inhibit the interaction of activated platelets with vascular endothelium. In addition, quercetin elicits coronary vasorelaxation that is endothelium independent. The antioxidant activity of flavonoids may also prevent the damaging action of lipid peroxides generated by activated platelets on endothelial nitric oxide and prostacyclin, which both inhibit platelet aggregation and have vasodilatory activity.

The activity of flavonoids as inhibitors of the viral enzyme reverse transcriptase also suggests that they may be beneficial in the control of retroviral infections such as AIDS.

Possible adverse effects on human health should also be considered. Quercetin was reported to induce bladder cancer in rats when administered in the diet at a level of 2%. These results were not confirmed in another study, however, which used quercetin at levels reaching 10%. It should be noted that under certain *in vitro* conditions flavonoids and other phenols can act as prooxidants and cause DNA damage. However, phenols have complex pro- and antioxidant effects *in vitro*, depending on the assay system used, and it is often difficult to predict their net effect *in vivo*. For example, many synthetic and dietary polyphenols (including quercetin, catechin, gallic acid ester, and caffeic acid ester) can protect mammalian cells from the cytotoxicity induced by peroxides such as hydrogen peroxide. Although tea is a good source of flavonoids, phenolic compounds including tannins and also polyphenols and phenol monomers are good inhibitors of iron absorption, which could contribute to the nutritional problem of iron deficiency. In general, it is unlikely that sufficiently toxic quantities of any particular flavonoid could be consumed from the diet, which contains many diverse varieties of flavonoids in varying quantities.

Potential Importance of Phytoestrogens to Human Health: Molecular Mechanisms of Action

The probable beneficial effects of phytoestrogens against breast cancer are likely to be mediated via numerous mechanisms. However, it has not been fully established whether the protective effects of soya and cereals result from their phytoestrogen content or from some other effect.

Many studies utilising breast cells in culture such as the oestrogen-sensitive MCF-7 cell line show that phytoestrogens (genistein was used in most of studies) stimulate tumor growth at low concentrations while inhibiting growth at higher concentrations. Genistein is a potent and specific *in vitro* inhibitor of tyrosine kinase action in the autophosphorylation of the epidermal growth factor (EGF) receptor and is thus frequently used as a pharmacological tool. The EGF receptor is overexpressed in many cancers, particularly those with the greatest ability for metastasis, and it has therefore often been assumed that some of the anticancer effects of genistein are mediated *via* inhibition of tyrosine kinase activity. However, this is likely to be an oversimplification of the true *in vivo* situation.

Although genistein is a much better ligand for oestrogen receptor β (ERβ) than for the ERα (20-fold higher binding affinity), it can also act as an oestrogen agonist via both ERα and ERβ in some test systems. Mechanisms other than those involving oestrogen receptors are likely to be involved in the inhibition of cell proliferation by genistein because genistein inhibits both the EGF-stimulated and the 17β-oestradiol-stimulated growth of MCF-7 cells. Although studies have shown that exposure to genistein can reduce the tyrosine phosphorylation of cell proteins in whole cell lysates, studies using cultured human breast and prostate cancer cells have not confirmed that genistein has a direct effect on the autophosphorylation of the EGF receptor. Many other mechanisms of anticancer action for isoflavones and genistein in particular have been suggested, including inhibition of DNA topoisomerases, cell cycle progression, angiogenesis, tumor invasiveness, and enzymes involved in oestrogen biosynthesis. They also include effects on the expression of DNA transcription factors c-*fos* and c-*jun*, on reactive oxygen species, on oxidative membrane damage and oxidative damage *in vivo*, and on the negative growth factor, transforming growth factor-β (TGF-β).

Although cholesterol lowering is probably the best documented cardioprotective effect of soya, vascular protection is also likely to contribute and may be mediated via a number of mechanisms. Soya isoflavones are likely to contribute to the cardioprotective benefits of soya.

ERβ is the predominant ER isoform expressed in the rat, mouse, and human vascular wall. In the rat carotid injury model, following endothelial denudation of rat carotid artery, ERα is expressed at a low level, whereas the expression of ERβ increases by greater that 40-fold and treatment of ovariectomized female rats with genistein provides a similar dose-dependent vasculoprotective effect in this model to that observed with 17β-oestradiol. However, studies in ERβ knockout mice have shown that ERβ is not required for oestrogen-mediated inhibition of the response to vascular injury and suggest that either of the two known oestrogen receptors (or another unidentified one) is sufficient to protect against vascular injury.

Vascular protection could also be conferred by the ability of genistein to inhibit proliferation of vascular endothelial cells and smooth muscle cells and to increase levels of TGF-β. TGF-β helps maintain normal vessel wall structure and promotes smooth muscle cell differentiation while preventing their migration and proliferation. Genistein has been shown to increase TGF-β secretion by cells in culture, and increased TGF-β production may be a mediator of some of the cardioprotective effects of soya isoflavones.

Antioxidant action is one of the mechanisms that may contribute to the vascular protective effects of soya isoflavones. Antioxidant properties have been reported for isoflavones both *in vitro* and *in vivo*. In a randomized crossover study of young healthy male and female subjects consuming diets that were rich in soy that was high (56 mg total isoflavones/day: 35 mg genistein and 21 mg daidzein) or low in isoflavones (2 mg total isoflavones/day), each for 2 weeks, plasma F_2-isoprostane concentrations were significantly lower after the high-isoflavone dietary treatment than after the low-isoflavone dietary treatment. The lag time for copper–ion-induced LDL oxidation was significantly longer.

Increased resistance to LDL oxidation has also been reported in a 12-week single open-group dietary intervention with soy foods (60 mg total isoflavones/day) in normal postmenopausal women. A randomized crossover study in hyperlipidemic male and female subjects consuming soya-based breakfast cereals (168 mg total isoflavones/day) and control breakfast cereals, each for 3 weeks, reported decreased oxidized LDL (total conjugated diene content) following consumption of the soy-based breakfast cereal compared to the control.

Effects of soya isoflavones on arterial function, including flow-mediated endothelium-dependent vasodilation (reflecting endothelial function) and systemic arterial compliance (reflecting arterial elasticity), may contribute to vascular protection and these have been measured in a number of studies. A randomized double-blind study administering either soy protein isolate (118 mg total isoflavones/day) or cesin placebo for 3 months to healthy male and postmenopausal subjects (50–75 years of age) showed a significant improvement in peripheral pulse wave velocity (reflecting peripheral vascular resistance and one component, together with systemic arterial compliance, of vascular function) but worsened flow-mediated vasodilation in men and had no significant effect on the flow-mediated vasodilation in postmenopausal women.

Some beneficial effects following dietary intervention with soy isoflavones have been observed on bone health, and the mechanism is likely to be via an oestrogenic action, particularly because ERβ is highly expressed in bone, although this requires further investigation. Consumption by postmenopausal women (6-month parallel group design) of soy protein (40 g/day providing either 56 mg isoflavones/day or 90 mg isoflavones/day) compared to caesin and nonfat dry milk (40 g/day) produced significant increases in bone mineral content (BMC)

and bone mineral density (BMD) in the lumbar spine (but not in any other parts of the body) only in the higher isoflavone (90 mg/day) group compared to the control group. In a long-term study, consumption by postmenopausal women (2-year parallel group design) of isoflavone-rich soy milk (500 ml/day providing 76 mg isoflavones/day) compared to isoflavone-poor soy milk control (providing 1 mg isoflavones/day) resulted in no decline in BMC and BMD in the treatment group compared to significant losses in the control group. The ability to produce equol was associated with a better response to the treatment.

Some beneficial effects following dietary intervention with soy isoflavones have been observed on the cognitive function aspect of brain health, and the mechanism is likely to be via an oestrogenic action, particularly because ERβ, in addition to ERα, is expressed in brain. Although other mechanisms may contribute, they remain to be elucidated. Consumption by young healthy male and female subjects (parallel group design) of a high-soy diet (100 mg isoflavones/day for 10 weeks) compared to a low-soy diet (0.5 mg isoflavones/day) resulted in improved cognitive function, including significantly improved short-term and long-term memory and mental flexibility. These improvements were found in males and females. Consumption by postmenopausal women (parallel group design, placebo controlled) of a dietary supplement (soy extract containing 60 mg isoflavones/day for 12 weeks) resulted in improved cognitive function, particularly improved long-term memory.

Phytoestrogens can cause infertility in some animals and thus concerns have been raised over their consumption by human infants. The isoflavones found in a subterranean clover species (in Western Australia) have been identified as the agents responsible for an infertility syndrome in sheep. No reproductive abnormalities have been found in peripubertal rhesus monkeys or in people living in countries where soy consumption is high. Indeed, the finding that dietary isoflavones are excreted into breast milk by soy-consuming mothers suggests that in cultures in which consumption of soy products is the norm, breast-fed infants are exposed to high levels without any adverse effects. Isoflavone exposure soon after birth at a critical developmental period through breast feeding may protect against cancer and may be more important to the observation of lower cancer rates in populations in the Far East than adult dietary exposure to isoflavones. Although some controversy exists as to whether soy-based infant formulas containing isoflavones pose a health risk, a review of studies on the use of soy milk in infants suggests that there is no real basis for concern. Toxicity from isoflavones may arise from their action as alternative substrates for the enzyme thyroid peroxidase, and people in Southeast Asia would be protected by the dietary inclusion of iodine-rich seaweed products.

Potential Importance of Glucosinolate Derivatives and Related Compounds to Human Health: Molecular Mechanisms of Action

There may be some important health protective effects of glucosinolate derivatives and related compounds. The hydrolytic products of some glucosinolates have been shown to display anticancer properties. Glucosinolates are hydrolyzed following exposure to the endogenous plant enzyme myrosinase (also found in the gut microflora) to form isothiocyanates. Isothiocyanates are biologically active compounds with anticancer properties and are more bioavailable than glucosinolates.

A metabolite of glucobrassicin (3-indoylmethylglucosinolate), indole-3-carbinol has been shown to inhibit the growth of human tumors of the breast and ovary. Furthermore, indole-3-carbinol may modulate the oestrogen hydroxylation pathway such that a less potent form of oestradiol is produced, thus conferring protection against oestrogen-related cancers.

Consumption of Brussels sprouts (300 g/day of cooked sprouts) for 1 week has been shown to increase rectal glutathione *S*-transferase -α and -π isoenzyme levels. Enhanced levels of these detoxification enzymes may partly explain the epidemiological association between a high intake of glucosinolates in cruciferous vegetables and a decreased risk of colorectal cancer. It is likely that genetic polymorphisms and associated functional variations in biotransformation enzymes, particularly in glutathione *S*-transferases, will alter the cancer preventative effects of cruciferous vegetables.

Compounds including the isolated glucosinolate sinigrin and aqueous extracts of cooked and autolyzed Brussels sprouts (rich in glucosinolate degradation products) decreased hydrogen peroxide-induced DNA stand breaks in human lymphocytes and thus exerted a DNA-protective effect. Oral adminiatration of sinigrin has been shown to induce apoptosis and suppress aberant crypt foci in the colonic mucosa of rats treated with 1,2-dimethylhydrazine. Similar effects were observed with oral administration of freshly prepared Brussels sprout juice, rich in glucosinolate breakdown products including isothiocyanates.

Isothiocyanates can prevent the formation of chemical carcinogen-induced tumors of the liver, lung, mammary gland, stomach, and oesophagus in animal models. The anticarcinogenic effects of isothiocyanates may be mediated by a combination of mechanisms, including inhibition of carcinogen activation by cytochromes P450: This could be achieved by both direct inhibition of enzyme catalytic activity and downregulation of enzyme levels and induction of phase 2 enzymes such as glutathione transferases and NAD(P)H:quinone reductase (these detoxify any remaining DNA-attacking electrophilic metabolites generated by phase 1 enzymes). Dietary glucosinolates and their breakdown products have been tested as anticarcinogens in terms of their ability to induce the anticarcinogenic phase 2 enzyme marker quinone reductase in murine Hep a1c1c7 cells, and the relative activities observed were found to be dependent on the nature of the side chain of the parent glucosinolate.

Phenethyl isothiocyanate protects mice against nitrosoamine-induced lung tumorigenesis. It also modulates the activity of phase 1 and phase 2 xenobiotic-metabolizing enzymes, resulting in the inhibition of the oxidative activation of a number of chemical carcinogens.

The isothiocyanate sulforophane is a particularly potent inducer of detoxification enzymes. A novel isothiocyanate-enriched broccoli has been developed that has an enhanced ability to induce phase 2 detoxification enzymes in mammalian cells compared to standard commercial broccoli.

Undesirable goitrogenic effects have been identified for isothiocyanates and other hydrolytic products of glucosinolates. Furthermore, in contrast to the anticancer effects of brassica vegetables discussed previously, a number of genotoxic effects have also been demonstrated in bacterial and mammalian cells. In bacterial assays (induction of point mutations in *Salmonella* TA98 and TA100 and repairable DNA damage in *Escherichia coli* K-12), juices from eight brassica vegetables tested caused genotoxic effects in the absence of metabolic activation. The order of potency was Brussels sprouts > white cabbage > cauliflower > green cabbage > kohlrabi > broccoli > turnip > black raddish. In mammalian cells, structural chromosome aberrations were observed with some of the juices, with the most potent being Brussels sprouts and white cabbage, and genotoxic effects were accompanied by decreased cell viability. The isothiocyanate-containing fraction (and other breakdown products of glucosinolates) of these brassica juices was found to contain 70–80% of the total genotoxic activity of the juices. The flavonoid- and other phenolic-containing fraction had a much weaker effect. In related studies, the isothiocyanates, allyl isothiocyanate and phenethyl isothiocyanate, were found to be more than 1000-fold more cytotoxic in a Chinese hamster ovary cell line than their parent glucosinolates (sinigrin and gluconasturtiin, respectively). Phenethyl isothiocyanate also induced genotoxic effects (chromosome aberrations and sister chromatid exchanges).

More data are required before an overall recommendation can be made regarding the likely beneficial or otherwise influences of glucosinolates (and their derivatives) on human health.

S-Methyl Cysteine Sulfoxide

S-methyl cysteine sulfoxide is another sulfur-containing phytochemical found in all brassica vegetables, in addition to glucosinolates. Both *S*-methyl cysteine sulfoxide and methyl methane thiosulfinate (its main metabolite) can block genotoxicity, induced by chemicals, in mice. *S*-methyl cysteine sulfoxide is thus likely to contribute to the observed ability of brassica vegetables to protect against cancer in both human and animal studies. It is of interest that a hydrolytic product of *S*-methyl cysteine sulfoxide was linked in the 1960s to the severe hemolytic anemia or kale poisoning observed in cattle in Europe in the 1930s.

Potential Importance of Other Phytochemicals to Human Health: Molecular Mechanisms of Action

Allium Organosulfur Compounds

Allium organosulfur compounds may be phyotchemicals of importance to human health by acting as antioxidants, thus protecting against free radical-mediated damage to important cellular targets such as DNA and membranes implicated in cancer and neurodegenerative diseases and aging. Protection against oxidative damage to LDL and cellular membranes could also protect against cardiovascular disease. Aged garlic extract (AGE) inhibits lipid peroxidation and the oxidative modification of LDL, reduces ischemic/reperfusion injury, and enhances the activity of the cellular antioxidant enzymes superoxide dismutase, catalase, and glutathione peroxidase. AGE also inhibits the activation of the oxidant-induced transcription factor NF-κB. Investigation of the major organosulfur compounds in AGE identified highly bioavailable water-soluble organosulfur compounds with antioxidant activity, such as *S*-allylcysteine and *S*-allylmeracptocysteine.

Organosulfur compounds such as diallyl sulfide may also protect against cancer by modulation of carcinogen metabolism, and this may involve altered

ratios of phase 1 and phase 2 drug-metabolizing enzymes. Various garlic preparations including aged garlic extract have been shown to inhibit the formation of nitrosamine-type carcinogens in the stomach, enhance the excretion of carcinogen metabolites, and inhibit the activation of polyarene carcinogens. Inhibitory effects of organosulfur compounds on the growth of cancer cells *in vitro*, including human breast cancer cells and melanoma cells, have been observed. Modulation of cancer cell surface antigens, associated with cancer cell invasiveness, has been observed, and in some cases cancer cell differentiation can be induced. AGE can reduce the appearance of mammary tumors in rats treated with the powerful carcinogen dimethyl benz(*a*)anthracene (DMBA), which is activated by oxidation by cytochromes P450 to form the DNA binding form of DMBA diol epoxide, resulting in DNA legions and cancer initiation. The antibacterial activity of these allium compounds may also prevent bacterial conversion of nitrate to nitrite in the stomach. This may reduce the amount of nitrite available for reacting with secondary amines to form the nitrosamines likely to be carcinogenic particularly in the stomach.

Allium organosulfur compounds appear to possess a range of potentially cardioprotective effects. In one study, 432 cardiac patients were divided into a control group (210) and a garlic-supplemented group (222), and garlic feeding was found to reduce mortality by 50% in the second year and by approximately 66% in the third year. Furthermore, the rate of reinfarction was reduced by 30 and 60% in the second and third year, respectively. It should be noted that only a small number of patients in both groups experienced the end event of death or myocardial infarction, and a much larger scale study is needed. AGE lowers cholesterol and triglycerides in laboratory animals and can reduce blood clotting tendencies. It has been suggested that garlic supplementation at a level of 10–15 g of cooked garlic daily could lower serum cholesterol by 5–8% in hypercholestrolemic individuals. However, there may be more important cardioprotective effects of garlic. In animal studies, AGE suppressed the levels of plasma thromboxane B_2 and platelet factor levels, which are important factors in platelet aggregation and thrombosis. In rats, frequent low doses (50 mg/kg) of aqueous extracts of garlic or onions (onion was less potent) produced significant antithromotic activity (lowering of thromboxane B_2) without toxic side effects.

Aqueous extracts of raw garlic also inhibited cyclooxygenase activity in rabbit platelets, again contributing to an antithrombotic effect. In addition, AGE and *S*-allyl cysteine and *S*-allyl mercaptocysteine have antiplatelet adhesion effects. Platelet adhesion to the endothelial surface is involved in atherosclerosis initiation. Furthermore, *S*-allyl mercaptocysteine inhibits the proliferation of rat aortal smooth muscle cells, another important atherosclerotic process. Indeed, this antiproliferative effect on smooth muscle cells may be indicative of a possible antiangiogenic ability in relation to prevention of tumor growth and metastasis.

Saponins

Saponins are another steroidal phytochemical of interest that may, in addition to isoflavone phytoestrogens, contribute to the health protective effects of soya products. Soyabeans have a high saponin content and soyabean saponins have been shown to have a growth inhibitory effect on human carcinoma cell *in vitro*, probably by interacting with the cell membrane and increasing membrane permeability. The proposed anticarcinogenic mechanisms of saponins include normalization of carcinogen-induced cell proliferation, direct cytotoxicity, bile acid binding, and immune-modulating effects. Of particular interest is the finding that saponins actively interact with cell membrane components: They possess surface active characteristics because of the amphiphillic nature of their chemical structure. Thus, they can act to alter cell membrane permeability and cellular function. Soybean saponins have been reported to inhibit hydrogen peroxide damage to mouse fibroblast cells and thus may protect human health through antioxidant-mediated mechanisms.

Saponins from ginseng root (*Panax ginseng C.A. Mey.*) may also be important. Antioxidant effects have been reported for total ginseng saponins and its individual saponins (ginsenosides Rb1, Rb2, Rc, and Rd; others include Re and Rg1). Furthermore, ginsenosides Rb1 and Rb2 protected cultured rat myocardiocytes against superoxide radicals, and the mechanism for this may involve induction of genes responsible for antioxidant defences rather than radical scavenging. Ginsenosides stimulate endogenous production of nitric oxide in rat kidney, and this may contribute to the observed antinephritic action of these compounds and suggest a protective role in the kidney. Furthermore, it has been suggested that the observed cardioprotective effects of ginsenosides in animal models may be mediated by nitric oxide release. In addition, ginsenoside enhanced release of nitric oxide from endothelial cells, particularly from perivascular nitric oxidergic nerves in the corpus cavernosum of animal models, may partly account for the reported aphrodisiac effects of ginseng. Also, ginsenosides have been shown to have beneficial effects on inferior human

sperm motility and progression. It is of interest that regulation of lipid metabolism by ginseng has been reported, and although the mechanism of action remains unclear, it is likely that the peroxisome proliferator-activated receptor-α is involved.

Other Phytochemicals of Interest

A wide range of other phytochemicals may have important beneficial effects on human health if consumed in sufficient amount to be efficacious. In many cases, their full spectrum of molecular actions remains to be elucidated. Nevertheless, the following phytochemicals and their main botanical sources are deemed worthy of mention.

The phytochemicals dihydrophthalic acid, ligustilide, butylidene, phthalide, and *n*-valerophenone-*O*-carboxylic acid have been isolated from Angelica root (*Angelica sinensis*). They are likely to contribute to the observed circulatory modulating effects of Angelica root, including increasing coronary flow, modulation of myocardial muscular contraction, and antithrombotic effects.

Phytochemicals extracted from licorice (*Glycyrrhiza glabra L.*) include glycyrrhetic acid, glycyrrhizic acid (the sweet principle of licorice), and an active saponin glycyrrhizin (a 3-*O*-diglucuronide of glycyrrhetic acid). In rats, dietary supplementation with 3% licorice elevated liver glutathione transferase activity, suggesting a potential detoxification and anticancer effect of these phytochemicals because glutathione transferase catalyses the formation of glutathione conjugates of toxic substances for elimination from the body. Antibacterial, antiviral, antioxidant, and antiinflammatory effects have also been reported for these compounds. Indeed, glycyrrhizin has been reported to inhibit HIV replication in cultures of peripheral blood mononuclear cells taken from HIV-seropositive patients.

Phytochemicals found in ginkgo (*G. biloba*) leaves, including ginkgolic acid, hydroginkgolic acid, ginkgol, bilobol, ginon, ginkgotoxin, ginkgolides (A–C), and a number of flavonoids common to other plants, such as kaempferol, quercetin, and rutin, are currently attracting attention for their possible effects on circulation, particularly cerebral circulation, and this may improve brain function and cognition. Indeed, ginkgo, ginseng, and a combination of the two extracts have been found to improve different aspects of cognition in healthy young volunteers. A number of studies have reported that extracts of ginkgo leaves enhanced brain circulation, increased the tolerance of the brain to hypoxia, and improved cerebral hemodynamics. It has been suggested that these effects are mediated via calcium ion flux over smooth cell membranes and via stimulation of catecholamine release. In addition, protection against free radical-mediated retinal injury has been reported; thus, other antioxidant-mediated protective effects on human health are also possible. Damage to mitochondrial DNA could play a role in neurodegenerative diseases such as Alzheimer's disease and Parkinson's disease. There is limited evidence for significant improvements in CHD patients following treatment with a daily dose equivalent to 12 mg total ginkgetin. Ginkgolide B-activated inhibition of glucocorticoid production has been reported and is likely to result from specific transcriptional suppression of the adrenal peripheral-type benzodiazepine receptor gene in rats. This suggests that ginkgolide B may be useful pharmacologically to control excess glucocorticoid formation.

POTASSIUM

L J Appel, Johns Hopkins University, Baltimore, MD, USA

The major intracellular cation in the body is potassium, which is maintained at a concentration of approximately 145 mmol/l of intracellular fluid but at much lower concentrations in the plasma and interstitial fluid (3.8–5 mmol/l of extracellular fluid). The high intracellular concentration of potassium is maintained via the activity of the Na^+/K^+-ATPase pump. Because this enzyme is stimulated by insulin, alterations in the plasma concentration of insulin can affect cellular influx of potassium and thus plasma concentration of potassium. Relatively small changes in the concentration of extracellular potassium greatly affect the extracellular/intracellular potassium ratio and thereby affect nerve transmission, muscle contraction, and vascular tone.

In unprocessed foods, potassium occurs mainly in association with bicarbonate-generating precursors such as citrate and, to a lesser extent, with phosphate. In processed foods to which potassium is added and in supplements, the form of potassium is potassium chloride. In healthy people, approximately 85% of dietary potassium is absorbed. Most potassium (approximately 77–90%) is excreted in urine, whereas the remainder is excreted mainly in feces, with much smaller amounts excreted in sweat. Because most potassium that is filtered by the glomerulus of the kidney is reabsorbed (70–80%) in the proximal tubule, only a small amount of filtered potassium reaches the distal tubule. The majority of potassium in urine results from secretion of potassium into the cortical collecting duct, a secretion regulated by a number of factors including the hormone aldosterone. An elevated plasma concentration of potassium stimulates the adrenal cortex to release aldosterone, which in turn increases secretion of potassium in the cortical collecting duct.

Acid–Base Considerations

A diet rich in potassium from fruits and vegetables favorably affects acid–base metabolism because these foods are also rich in precursors of bicarbonate. Acting as a buffer, the bicarbonate-yielding organic anions found in fruits and vegetables neutralize noncarbonic acids generated from meats and other high-protein foods. In the setting of an inadequate intake of bicarbonate precursors, excess acid in the blood titrates bone buffer. As a result, bone becomes demineralized and calcium is released. Urinary calcium excretion increases. This state has been termed a 'low-grade metabolic acidosis.' Increased bone breakdown and

calcium-containing kidney stones are adverse clinical consequences of excess diet-derived acids. Diets rich in potassium with its bicarbonate precursors might prevent kidney stones and bone loss. In processed foods to which potassium is added and in potassium supplements, the conjugate anion is typically chloride, which cannot act as a buffer.

Adverse Effects of Insufficient Potassium

Severe potassium deficiency, which most commonly results from diuretic-induced potassium losses, is characterized by a serum potassium concentration of less than 3.5 mmol/l. The adverse consequences of hypokalemia are cardiac arrhythmias, muscle weakness, and glucose intolerance. Moderate potassium deficiency, which commonly results from an inadequate dietary intake of potassium, occurs without hypokalemia and is characterized by increased blood pressure, increased salt sensitivity, an increased risk of kidney stones, and increased bone turnover. An inadequate intake of dietary potassium may also increase the risk of stroke and perhaps other cardiovascular diseases.

Kidney Stones and Bone Demineralization

Because of its effects on acid–base balance, an increased dietary potassium intake might have favorable effects on kidney stone formation. In one large observational study of women (**Figure 1**), there was a progressive inverse relationship between greater intake of potassium and incident kidney stones. At a median potassium intake of 4.7 g/day (119 mmol/day), the risk of developing a kidney stone was 35% less compared to that for women with an intake of <2.0 g/day (52 mmol/day). In the one available trial, an intake of approximately 3.6–4.7 g/day (92–120 mmol/day) of potassium in the form of potassium citrate reduced the risk of recurrent kidney stones.

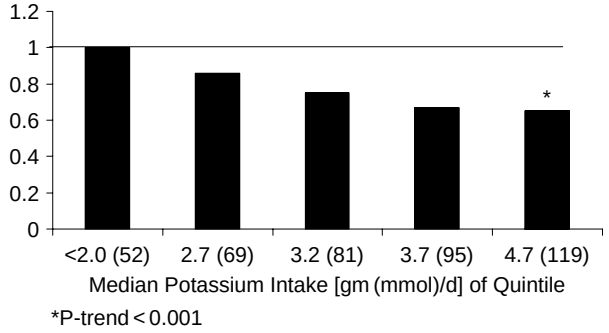

Figure 1 Relative risk of kidney stones during 12 years of follow-up by quintile of potassium intake in 91 731 women. (Data from Curhan GC, Willett WC, Speizer FE, Spiegelman D, and Stampfer MJ (1997) Comparison of dietary calcium with supplemental calcium and other nutrients as factors affecting the risk of kidney stones in women. *Annals of Internal Medicine* **126**: 497–504.)

Epidemiologic studies have consistently documented that increased potassium intake is associated with greater bone mineral density. In trials, supplemental potassium bicarbonate reduced bone turnover as manifest by less urinary calcium excretion and by biochemical evidence of greater bone formation and reduced bone resorption. However, no trial has tested the effect of increased potassium or diets rich in potassium on bone mineral density or clinical outcomes related to osteoporosis.

Elevated Blood Pressure

High levels of potassium intake are associated with reduced blood pressure. Observational data have been reasonably consistent in documenting this inverse relationship, whereas data from individual trials have been less consistent. However, three meta-analyses of these trials have each documented a significant inverse relationship between potassium intake and blood pressure in nonhypertensive and hypertensive individuals. In one meta-analysis, average net systolic/diastolic blood pressure reductions associated with a net increase in urinary potassium excretion of 2 g/day (50 mmol/day) were 4.4/2.4 mmHg. Typically, greater blood pressure reductions from potassium occur in African Americans compared to non-African Americans. Most of the trials that tested the effects of potassium on blood pressure used pill supplements, typically potassium chloride.

A high potassium intake has been shown to blunt the rise in blood pressure in response to increased salt intake. The term 'salt-sensitive blood pressure' applies to those individuals or subgroups who experience the greatest reduction in blood pressure when salt intake is reduced. One metabolic study of 38 healthy, nonhypertensive men (24 African Americans and 14 non-African Americans) investigated the effect of potassium supplementation on the pressor effect of salt loading (5.7 g/day of sodium (250 mmol)). Before potassium was supplemented, 79% of the African American men and 26% of the non-African American men were termed 'salt sensitive,' as defined by a salt-induced increase in mean arterial pressure of at least 3 mmHg. There was a progressive reduction in the frequency of salt sensitivity as the dose of potassium was increased. In the African Americans with severe salt sensitivity, increasing dietary potassium to 4.7 g/day (120 mmol/day) reduced the frequency of salt sensitivity to 20%, the same percentage as that observed in non-African American subjects when their potassium intake was increased to only 2.7 g/day (70 mmol/day).

Other studies indicate that potassium has greater blood pressure lowering in the context of a higher salt intake and lesser blood pressure reduction in the setting of a lower salt intake. Conversely, the blood pressure reduction from a reduced salt intake is greatest when potassium intake is low. These data are consistent with subadditive effects of reduced salt intake and increased potassium intake on blood pressure.

Cardiovascular Disease

The beneficial effects of potassium on blood pressure should reduce the occurrence of blood pressure-related cardiovascular disease. Potassium may also have protective effects that are independent of blood pressure reduction. This possibility has been tested in experimental studies conducted in rodents. In a series of animal models, the addition of either potassium chloride or potassium citrate markedly reduced mortality from stroke. Interestingly, these reductions occurred when blood pressure was held constant. Such data indicate that potassium has both blood pressure-dependent and blood pressure-independent properties that are cardioprotective.

In many, but not all, epidemiologic studies, an inverse relationship between dietary potassium intake and subsequent stroke-associated morbidity and mortality has been noted. A few observational studies have also shown an inverse association between potassium intake and coronary heart disease. In a 12-year follow-up of 859 men and women enrolled in the Rancho Bernardo Study, a significant inverse relationship between potassium intake and subsequent risk of stroke-related mortality was documented. Similarly, during the course of 8 years of follow-up in 43 738 US men in the Health Professionals Follow-Up Study, there was a significant inverse relationship between baseline potassium intake and stroke after adjustment for established cardiovascular disease risk factors, including blood pressure and caloric intake (**Figure 2**). In this study, a median potassium intake of 4.3 g/day (110 mmol/day) was associated with a 41% reduced risk of stroke in comparison to those with a median intake of 2.4 g/day (61 mmol/day). Consistent with these studies are other observational studies that have repeatedly documented a reduced risk of stroke from an increased intake of fruits and vegetables.

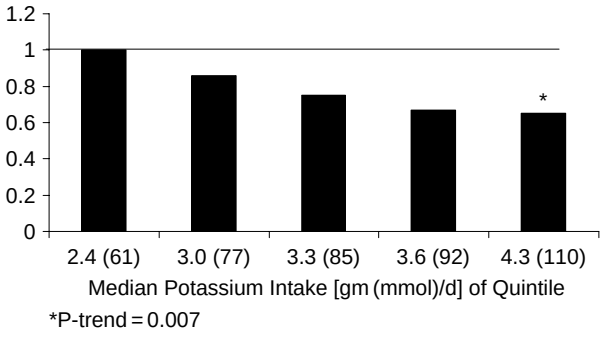

Figure 2 Relative risk of ischemic stroke by quintile of potassium intake in 43 738 men. (Data, from Ascherio A, Rimm EB, Hernan MA *et al.* (1998) Intake of potassium, magnesium, calcium, and fiber and risk of stroke among U.S. men. *Circulation* **98**: 1198–1204.)

Adverse Effects of Excess Potassium Intake

In the generally healthy population with normal kidney function, a high potassium intake from foods poses no risk because excess potassium is readily excreted in the urine. In contrast, supplemental potassium can lead to acute toxicity in healthy individuals. Also, in individuals whose urinary potassium excretion is impaire a potassium intake less than 4.7 g/day (120 mmol/day) is appropriate because of adverse cardiac effects (arrhythmias) from hyperkalemia. Drugs that commonly impair potassium excretion are angiotensin converting enzyme inhibitors, angiotensin receptor blockers, and potassium-sparing diuretics. Common medical conditions associated with impaired potassium excretion are diabetes, chronic renal insufficiency, end stage renal disease, severe heart failure, and adrenal insufficiency. Elderly individuals are at increased risk of hyperkalemia because they often have one or more of these conditions or take one or more of the medications that impair potassium excretion.

Recommended Potassium Intake, Current Intake, and Dietary Sources

On the basis of available data, an Institute of Medicine committee set an Adequate Intake for potassium at 4.7 g/day (120 mmol/day) for adults. This level of dietary intake should maintain lower blood pressure levels, reduce the adverse effects of salt on blood pressure, reduce the risk of kidney stones, and possibly decrease bone loss. Current dietary intake of potassium is considerably lower than this level.

Humans evolved on a diet that was rich in potassium and bicarbonate precursors and low in salt. However, contemporary Western-style diets have the opposite pattern—that is, relatively low content of potassium and high content of salt. Based on intake data from the Third National Health and Nutrition Examination Survey (NHANES-III,1988–1994), the

percentage of men and women who consumed equal to or more than 4.7 g/day (120 mmol/day) was less than 10 and 1%, respectively. Median intake of potassium in the United States ranged from 2.8 to 3.3 g/day (72 to 84 mmol/day) for adult men and 2.2 to 2.4 g/day (56 to 61 mmol/day) for adult women. The median potassium intake of non-African Americans exceeded that of African Americans. Because African Americans have a relatively low intake of potassium and a high prevalence of elevated blood pressure and salt sensitivity, this subgroup would especially benefit from an increased potassium intake.

Dietary intake surveys typically do not include estimates from salt substitutes and supplements. However, less than 10% of those surveyed in NHANES-III reported using salt substitutes or a reduced-sodium salt. Because a high dietary intake of potassium can be achieved through diet rather than pills and because potassium derived from foods also comes with bicarbonate precursors, as well as a variety of other nutrients, the preferred strategy to achieve the recommended potassium intake is to consume foods rather than supplements.

Dietary sources of potassium, as well as bicarbonate precursors, are fresh fruits, fruit juices, dried fruits, and vegetables. Although meat, milk, and cereal products contain potassium, their content of bicarbonate precursors does not sufficiently balance the amount of acid-forming precursors, such as sulfur amino acids, found in higher protein foods. The typical content of potassium-rich foods is displayed in **Table 1**. Salt substitutes currently available in the marketplace range from 0.4 to 2.8 g/teaspoon (11–72 mmol/teaspoon) of potassium, all as potassium chloride.

Table 1 Foods rich in potassium

Food	*Portion size*	*Potassium content, g (meq)*
Beans		
Cooked dried beans	1/2 cup	0.4 (10.7)
Lima beans	5/8 cup	0.4 (10.8)
Fruit		
Apple	1 medium	0.1 (2.8)
Apricots	3 medium	0.3 (7.2)
Banana	6 in.	0.4 (9.5)
Cantaloupe	1/4 medium	0.3 (6.4)
Dates	10 pitted	0.6 (16.6)
Orange	1 small	0.3 (7.7)
Peach	1 medium	0.2 (5.2)
Prunes, dried	10 medium	0.7 (17.8)
Raisins	1 tablespoon	0.1 (2.0)
Watermelon	1 slice	0.6 (15.4)
Fruit juices		
Grapefruit	1 cup	0.4 (10.4)
Orange	1 cup	0.5 (12.4)
Pineapple	1 cup	0.4 (9.2)
Tomato	1 cup	0.5 (13.7)
Vegetables		
Corn	1 ear	0.2 (5.0)
Potato		
– White	1 boiled	0.3 (7.3)
– Sweet	1 boiled	0.3 (7.7)
Tomato	1 medium	0.4 (9.4)
Squash, winter	1/2 cup boiled	0.5 (11.9)
Meats		
Hamburger	1 patty	0.4 (9.8)
Rib roast	2 slices	0.4 (11.2)
Fish (e.g., haddock)	1 medium fillet	0.3 (8.0)
Milk		
Skim milk	8 oz.	0.3 (8.5)
Whole milk	8 oz.	0.4 (9.0)

Conclusion

Potassium is an essential nutrient that is required for normal cellular function. Although humans evolved on diets rich in potassium, contemporary diets are quite low in potassium. An increased intake of potassium from foods should prevent many of the adverse effects of inadequate potassium intake, which are higher blood pressure levels, greater salt sensitivity, increased risk of kidney stones, and possibly increased bone loss. An inadequate potassium level may also increase the risk of stroke. In view of the high prevalence of elevated blood pressure, stroke, and conditions related to bone demineralization (i.e., osteoporosis and kidney stones) in the general population, individuals should strive to increase their consumption of potassium-rich foods, particularly fruits and vegetables.

Role of Placenta in Nutrient Transfer

P Haggarty, Rowett Research Institute, Aberdeen, UK

Introduction

The main nutritional role of the placenta is to provide the correct mix of nutrients in sufficient quantities to support fetal growth and development throughout pregnancy. It has to do this whilst coping with wide variations in maternal nutrient intake between pregnancies and temporal variations within a pregnancy. The effective barrier to nutrients within the placenta is a single layer of cells called the syncytiotrophoblast, which close to term is around 4 μm thick with a total exchangeable surface area of around 10–15 m^2. This membrane represents a nutritional 'bottleneck' where competition for nutrient transporters and metabolic selectivity allows the placenta to regulate the nutrient mix within the fetal circulation to one best suited to fetal development. In addition to its role as a simple nutrient transporter the placenta also acts as an extra fetal organ for many metabolic transformations with the feto-placental unit working as a metabolic whole. Adaptive mechanisms within the placenta allow the mother to meet the nutrient demands of the growing fetus whist consuming apparently poor diets during pregnancy. The fetus itself plays an active role in regulating key aspects of placental metabolism and nutrient transfer function to meet its own nutrient requirements.

Under normal circumstances the nutrient transfer capacity of the human placenta exceeds the fetal requirement and a considerable proportion of transport function would have to be lost before it became limiting for fetal growth. Although relatively rare, intrauterine growth restriction resulting from uteroplacental insufficiency does occur. However, this is a complicated syndrome in which almost all aspects of placental and fetal metabolism are altered and it may not simply be due to a limitation of placental nutrient transfer capacity.

Fetal Nutrient Requirements

Prenatal development can usefully be divided into two periods: the embryonic period, which covers the

first 8 weeks of life, and the fetal period, which lasts from the 9th week of gestation until term. During the latter period the fetus is entirely dependent on the placenta for its supply of nutrients. The fetus has an absolute requirement for the same essential nutrients as the adult but the adequacy of supply is particularly critical during *in utero* life when all the structures of the body are being established. In addition, because of the particularly high demand for some strictly nonessential nutrients these may be considered as 'conditionally essential' if the rate of utilization exceeds the fetal capacity for *de novo* synthesis.

The placenta has to maintain the supply of all nutrients at a rate adequate to allow unrestricted fetal growth. It also has to provide an appropriate mix of nutrients to meet the needs of the fetus at the different stages of pregnancy. For example, in the first two-thirds of pregnancy the fetus deposits mainly protein, while in late gestation fat takes over as the dominant form of deposition (**Figure 1**).

The availability of individual nutrients to the fetus depends not only on the maternal dietary intake but also on the function of the placenta and the many physiological and biochemical adaptations that occur during pregnancy (**Figure 2**). An understanding of placental function and its interaction with diet is essential to the setting of appropriate dietary guidelines for pregnancy.

The Human Placenta

The human placenta is a hemochorial, villous type where the maternal blood enters the intervillous space via the spiral arteries and flows directly around the terminal villi of the fetal circulation without any intervening maternal vessel wall. The surface area available for exchange gradually increases throughout pregnancy until it reaches around 10–15 m^2 in the last trimester (**Figure 1**). The nature of the exchangeable surface of the placenta also changes throughout gestation with the mature intermediate villi appearing towards the end of the second trimester and the terminal villi, which represent the main site of feto-maternal exchange, appearing a few weeks later. The rate of fetal blood delivery to the placenta (umbilical flow) also changes markedly during pregnancy and is approximately linearly related to fetal weight, and hence the fetal nutrient requirement, throughout gestation (**Figure 1**).

Anatomically, the human placenta is a large structure typically weighing around half a kilogram. However, its physical bulk belies the flimsy nature of the separation between the maternal and fetal

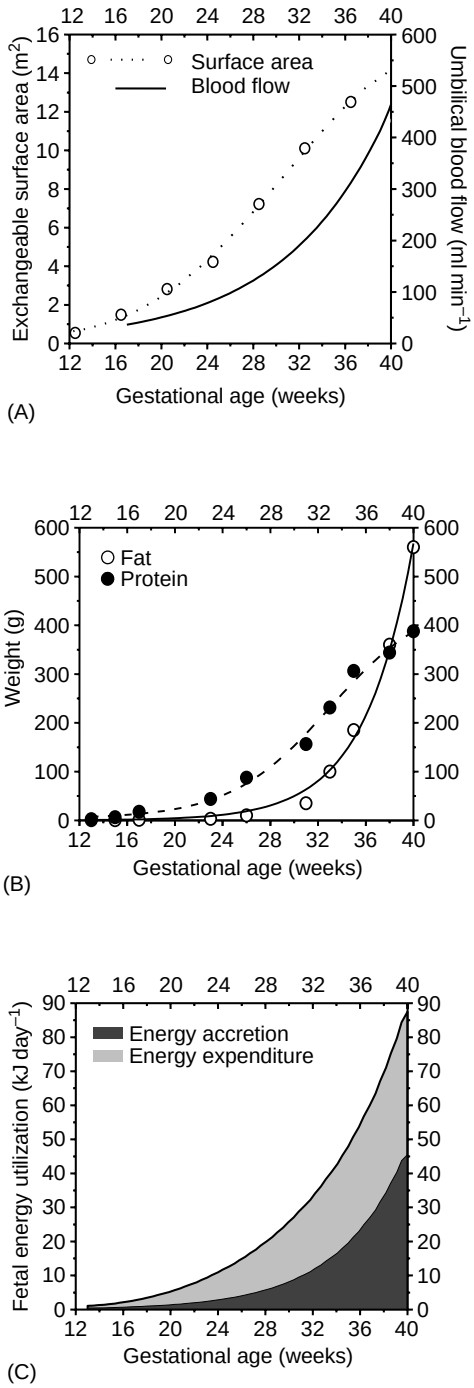

Figure 1 Changes with gestational age in placental exchangeable surface area and umbilical blood flow (A), accretion of fat and protein in the fetus (B), and the components of fetal energy requirements (C). Figure 2 Nutrient exchanges between the maternal circulation, placenta, and fetus.

circulations, which consists of only two cell layers; the syncytiotrophoblast and the capillary endothelium. The endothelium allows the passage of nutrients through pores within the interendothelial cleft and therefore is not a significant barrier to nutrient passage. The effective barrier between the maternal and fetal circulation is provided by a thin trophoblastic cover in the form of a syncytium (a tissue in which the cytoplasm of constituent cells is continuous), known as the syncytiotrophoblast. Between 10 weeks and term the thickness of the villous trophoblast falls from around 10 μm to 4 μm and the overall maternofetal diffusion distance from 40 μm to 5 μm. Any substance crossing between the maternal and fetal circulation has to pass though this barrier, which consists of two membranes: the micovillous membrane (MVM) facing the maternal blood and the basal membrane (BM) facing the fetal blood. The surface area of the maternal-facing MVM is around 5–6 times that of the fetal-facing BM. There are other cell types and structures within the placenta, such as maternal myometrium and decidua, connective tissue, Hofbauer cells, and persisting cytotrophoblast cells, which contribute to the metabolic activity and nutrient requirements of the placenta but which are not thought to be significant barriers to transport.

Methods Used to Study Placental Function

Direct measurement of placental nutrient transport function in human pregnancy is practically and ethically extremely difficult to achieve. All of the available techniques have drawbacks and involve a trade-off between physiological relevance and the quality of the information derived. There is a very small number of reports of studies where stable isotope-labeled amino acids and fatty acids have been administered to the mother and their appearance measured in the cord blood. These studies have the potential to provide information on dynamic placental nutrient transfer rates *in vivo* but their interpretation is severely constrained by the number of sequential cord blood samples that can be taken, and the conclusions have therefore been necessarily tentative. Placental function is often inferred by measurements of concentration differences in the maternal and fetal circulations. The most sophisticated of these involve measurements of arterio-venous differences across the umbilical cord at Caesarean section before the cord is cut but such studies are therefore only carried out in very late gestation. Cord blood levels may also be measured following delivery or, more informatively, at earlier stages of development using the invasive method of cordocentesis. However, an important disadvantage of any 'snapshot' of cord blood nutrient concentrations is that these are the net result of both placental delivery and fetal utilization.

Because of the problems with interpretation of results from *in vivo* studies a number of *in vitro* approaches have been developed. These include the dually perfused placenta, which retains the cellular structure and metabolic activity of the syncytiotrophoblast and the placental vascular structure but allows the nutrient composition of the maternal and fetal circulation to be controlled and transfer rates to be measured dynamically using isotopic tracers. The problems with this *ex vivo* technique are that the placenta tends to be very mature, the efficiency of perfusion cannot be assumed to exactly mimic the *in vivo* situation, and the composition of the maternal and fetal perfusates are not truly physiological. More detailed but less physiologically relevant to absolute rates of transfer are vesicles formed from the syncytiotrophoblast, which are particularly well suited to the study of nutrient transport mechanisms under highly controlled conditions. The most reductionist methodology involved the identification and characterization of individual transport proteins.

The Mechanisms of Placental Nutrient Transport

The transport of individual nutrients across the placenta generally depends on the same principles

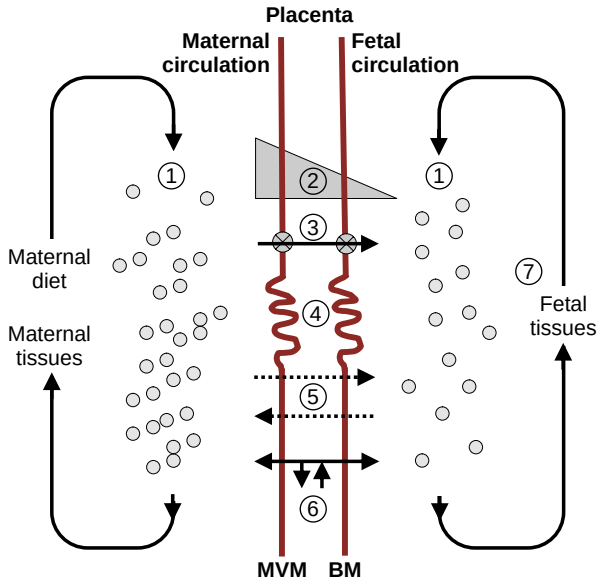

Figure 3 Factors affecting nutrient transfer across the syncytiotrophoblast. These include: (1) maternal and fetal blood flow; (2) the nutrient concentration gradient across the syncytiotrophoblast; (3) the concentration of transport proteins to facilitate or actively transport nutrients; (4) the exchangeable surface area; (5) the rate of diffusion of some nutrients across membranes without the intervention of transport proteins; (6) metabolism (utilization and *de novo* synthesis) within the placenta; and (7) the rate of nutrient utilization by the fetal tissues.

and the presence of the same or similar transport systems to those in the tissues and organs of the adult, although there are some additional factors specific to the placenta (**Figure 3**). In particular, unlike most tissues in the adult where either uptake or export dominate at any given time, the syncytiotrophoblast whose primary function is transport has to do both simultaneously.

The placental transport systems for the macronutrients (carbohydrate, fat, and protein) have been extensively studied. Glucose transport within the placenta appears to be mediated exclusively by the GLUT1 transporter, which has been located on both the MVM and BM. GLUT3 and GLUT4 are also present in the placenta but not in the syncytiotrophoblast itself. They are located on the vascular endothelium and the intravillous stromal cells, respectively. The syncytiotrophoblast also contains a wide range of amino acid transporters: system A, ASC, Asc, B^0, $b^{0,+}$, L, N, Gly, y^+, y^+L and X_{AG} and β. A number of fatty acid-binding proteins are also found in the placenta. Of these proteins FAT/CD36 and FATP have been located to both the MVM and BM but there is also a placenta-specific protein (p-FABPpm), which has been located exclusively on the MVM. This p-FABPpm is similar in size (~40 kDa) to the ubiquitous FABPpm found in most mammalian cells but it has a different amino acid composition.

The driving force that results in the net transfer of nutrients to the fetus is different for different nutrients and this is reflected in their transplacental gradients (**Figure 4**). Where the nutrient concentrations are lower in the cord than maternal blood this has been cited as a reason to supplement the mother but in many cases it is precisely this gradient that drives placental nutrient transfer. Glucose is thought to flow down a concentration gradient from the mother to the fetus and this process of 'facilitated diffusion' is mediated by GLUT1. Unlike glucose the concentration of most amino acids in the fetal circulation is greater than that in the maternal circulation suggesting some form of active transport. For many amino acids the concentration is even higher within the placenta than the fetal circulation and the key gradient generating step for amino acids is the active transport across the MVM. The amino acids can then diffuse down a concentration gradient into the fetal circulation, and to some extent back to the mother. The concentration of water-soluble vitamins and lactate in the fetal circulation also exceeds that in the maternal circulation.

Like glucose, the fats and fat-soluble vitamins also flow down a concentration gradient from the mother to the fetus mediated by the various fatty acid transport proteins. However, unlike glucose or the amino acids, fat-soluble compounds can also cross the syncytiotrophoblast, and all other membranes for that matter, by simple diffusion and partition without the intervention of a carrier protein. The role of the fatty acid-binding proteins appears to be to improve the efficiency of this process. The key factor in understanding the driving force for the placental transfer of fat-soluble nutrients is that these compounds are only sparingly soluble in water (13 μM for C18:0 at 37 °C) and have to be transported in the plasma in hydrophobic binding sites on carrier proteins. The partition of fats between the maternal and fetal circulations is largely determined by the relative abundance of available hydrophobic binding sites within those compartments. Since only NEFA are thought to cross membranes it is the NEFA concentration gradient that is most relevant to the transplacental flow of fatty acids. The concentration of NEFA in the maternal plasma at term is around 3 times that in the fetal circulation but the concentration of its primary carrier protein, albumin, is actually 10–20% higher in the fetal circulation. This results in a ratio of NEFA to albumin on the fetal side of the placenta of around a quarter of that on the

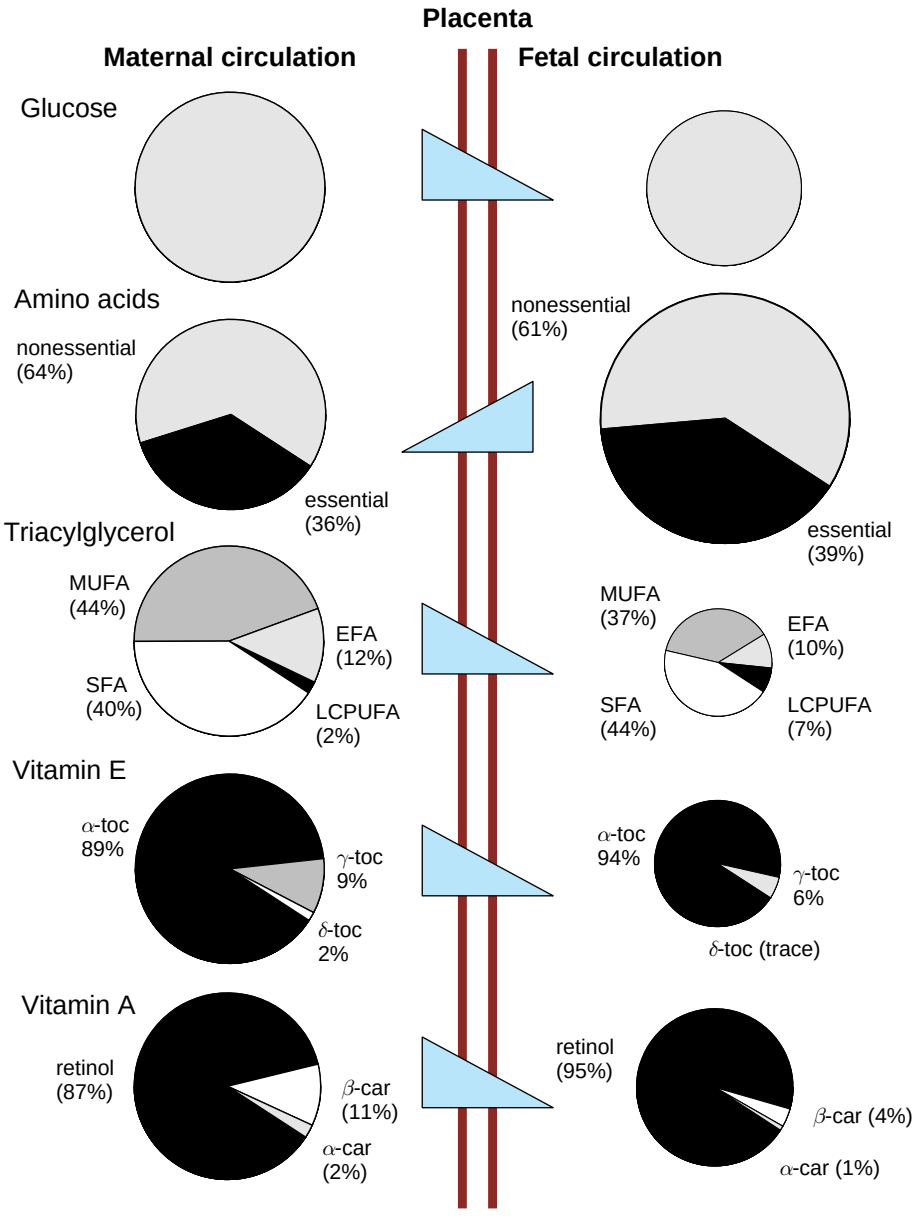

Figure 4 The relative concentration of nutrients in the maternal and fetal circulations. The concentration differences for each nutrient class are represented by the area of the circle in the fetal circulation relative to the maternal circulation. Apart from glucose the relative concentrations of individual nutrients within the nutrient groups are shown as segments of the circle. For triglyceride the fractions are saturated (SFA) monounsaturated (MUFA), essential (EFA), and long-chain polyunsaturated fatty acids (LCPUFA). For vitamin E the fractions are α-tocopherol (α-toc), γ-tocopherol (γ-toc), and δ-tocopherol (δ-toc). For vitamin A the abbreviated fractions are β-carotene (β-car) and α-carotene (α-car). (Reproduced with permission from: Berghaus TM, Demmelmair H, and Koletzko B (1998) Fatty acid composition of lipid classes in maternal and cord plasma at birth. *European Journal of Pediatrics* **157**: 763–768; Kiely M, Cogan PF, Kearney PJ and Morrissey PA (1999) Concentrations of tocopherols and carotenoids in maternal and cord blood plasma. *European Journal of Clinical Nutrition* **53**: 711–715; Cetin I., Marconi AM, Bozzetti P, Sereni LP, Corbetta C, Pardi G, and Battaglia FC (1988) Umbilical amino acid concentrations in appropriate and small for gestational age infants: a biochemical difference present *in utero*. *American Journal of Obstetrics and Gynecology* **158**: 120–126; Bozzetti P, Ferrari MM, Marconi AM, Ferrazzi E, Pardi G, Makowski EL, and Battaglia FC (1988) The relationship of maternal and fetal glucose concentrations in the human from midgestation until term. *Metabolism* **37**: 358–363.)

maternal side at term. The fat-soluble vitamins (A, E, and D) are also present in the fetal circulation in lower concentrations than in the maternal circulation. These materno-fetal concentration differences for the macronutrients develop gradually throughout gestation.

It is less easy to generalize about the transplacental gradient for minerals as some are at a

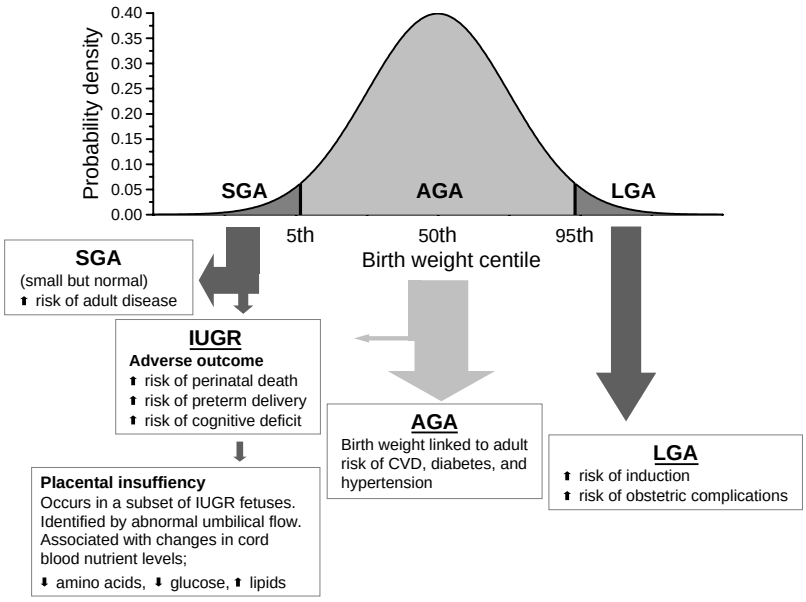

Figure 5 The normal distribution of birth weights and relative risks associated with babies that are small for gestational age (SGA), appropriate for gestational age (AGA), large for gestational age (LGA) and those subjected to intrauterine growth retardation (IUGR), and the relationship to placental insufficiency.

lower concentration in the fetal circulation (Se, Cu, Ba), some are higher (Ca, Zn, Be, Rb), and some are about the same (Co, Mg, Mo, Sn, Bi, Cd, Cs, La, Li, Pb). Iron is particularly important during pregnancy and its concentration in the fetal venous blood leaving the placenta is almost 3 times that of the maternal serum. Iron is transported in the serum on the transport protein transferrin and, like the fats and fat-soluble vitamins, its rate of transfer may be influenced by the availability of free binding sites.

Placental Selectivity

One of the key functions of placental nutrient transport is to maintain the most appropriate balance of nutrients in the fetal circulation and the balance of nutrients transferred by the placenta may be as important as the overall transfer capacity in influencing the pattern of fetal growth. Nutrients such as the fatty acids and amino acids occur in many forms yet they are translocated across membranes by a relatively small number of transporter molecules. This nutritional 'bottleneck' results in competition for transfer and the possibility of placental selectivity. An example of the resulting change in nutrient quality can be seen in the increase in the relative proportion of the essential to nonessential amino acids in the fetal circulation compared to the maternal circulation (**Figure 4**). The same is true of the fat-soluble vitamins where the relative concentration of the most biologically active form is increased in the fetal circulation. In the case of the fatty acids it is the long-chain polyunsaturated fatty acids (LCPUFA) such as arachidonic acid (20:4 n-6; AA) and docosahexaenoic acid (22:6 n-3; DHA) that perform most of the essential functions in the fetus. Although the overall concentration of the lipid classes are greatly reduced in the fetal circulation the critical LCPUFA make up a greater proportion of total fatty acid in the fetal circulation. In the case of the fatty acids the placenta has multiple mechanisms including preferential binding of LCPUFA by p-FABPpm, selective uptake by the syncytiotrophoblast, intracellular metabolic channeling of individual fatty acids, and selective export to the fetal circulation, which allow it to preferentially deliver DHA and AA to the fetal circulation.

Placental Metabolic Activity

Although the barrier between the maternal and fetal circulation is effectively only one cell thick, the placenta is a substantial organ made up of many cell types. It is extremely active metabolically and has its own requirement for nutrients and this is consistent with the observations that the surface area of the maternal-facing membrane (MVM) is around 5 times greater than that of the fetal-facing membrane (BM), that the concentration of expression of GLUT1 is greater on the MVM, that the MVM contains additional fatty acid binding

proteins that are not present on the BM, and that the amino acid transporters act to produce the maximum amino acid gradient across the MVM. The metabolic transformations within the placenta are intimately linked to fetal metabolism and represent another way in which the placenta can regulate nutrient transport availability within the fetal circulation.

In late pregnancy the overall contribution of fat to whole body oxidation is reduced and this is thought to result from the preferential utilization of carbohydrate and amino acids such as glutamate as an energy source in the feto-placental unit and the sparing of fatty acids to maximize fetal accretion of the critical LCPUFA in particular. The interrelationships between the placenta and fetus are particularly complex for the amino acids. The placenta is a net user of serine, glutamate, leucine, isoleucine, and valine and there is significant interconversion of alanine, pyruvate, and lactate between the placenta and fetal tissues. The concentration of lactate in the fetal circulation is considerably greater than that in the maternal circulation and a considerable proportion of the glucose taken up by the placenta is converted into lactate prior to export into the fetal circulation for use by the fetus. The placenta takes up serine from both the maternal and fetal circulation, converting this into glycine and exporting it into the fetal circulation for oxidation by the fetal liver and there is significant cycling of glutamate and glutamine between the placenta and fetal liver. This partition of the various segments of metabolic pathways between the placenta and fetal tissues is a general phenomenon and in many respects the feto-placental unit can be considered as a metabolic whole with the placenta acting as an extra fetal organ in addition to its role as a simple nutrient transporter. Metabolic activity in the feto-placental unit is also responsive to nutrient supply and fetal demand. For example, AA is an important precursor of the prostacyclins, prostaglandins, thromboxanes, and leukotrienes, which play key roles in pregnancy. When the maternal circulation of AA is low there is net uptake from the fetal circulation to maintain placental synthesis of these compounds.

Placental Buffering of Maternal Dietary Intake

In cases where the increased demand for nutrients during pregnancy is not met by the diet alone the shortfall may be made up from the maternal stores and the placenta may play a role in orchestrating some of the maternal nutritional adaptations in pregnancy. For example, placentally derived leptin is a potent stimulator of lipolysis and there is evidence that the rate of export into the maternal circulation is controlled to allow the placenta to modulate its own substrate supply in response to the fetal demand for fats. The various homeostatic mechanisms within the placenta and their interaction with maternal physiological adaptations during pregnancy act to ensure a constant supply of substrate to the fetus, free of large diurnal fluctuations corresponding to the timing of maternal meals, and to protect the fetus against a transiently poor intake during critical periods of fetal growth. These adaptations help the mother to meet the full fetal requirement for nutrients such as LCPUFA and iron whilst consuming apparently poor diets.

Placental Insufficiency and Fetal Growth

Potentially the most important public health issue relating to pregnancy is the epidemiological association between birth weight and adult disease susceptibility (cardiovascular disease, diabetes, and hypertension). The highest risk is associated with the lowest birth weight but, because of the nature of the normal distribution, in terms of the numbers potentially affected in adult life, it is the small variations in the normal birth weight range that have the largest public health implications. A causal connection between birth weight and adult disease has been proposed in the 'fetal origins' hypothesis, which is that fetal undernutrition in middle to late gestation leads to disproportionate fetal growth and programs later disease susceptibility. The close association between birth weight and placental weight has led to speculation that the placenta may limit fetal growth within the normal weight range. However, the available evidence suggests that the capacity of the human placenta to transport macronutrients exceeds the fetal requirement and that a considerable proportion of transport function would have to be lost before it became limiting for fetal growth.

True intrauterine growth restriction (IUGR) resulting from utero-placental insufficiency is a serious pathology that is associated with a greatly increased risk of adverse outcomes including perinatal mortality and morbidity, impaired mental, visual and aural development, autism, and cerebral palsy. IUGR is often detected indirectly by measuring abnormal umbilical artery flow velocity waveforms and/or abnormal fetal heart rate. The abnormal waveforms are thought to result from increased vascular resistance associated with abnormal arteriolar tree and villi branching and a reduction in the

villous capillary tree. Pregnancies in which these abnormalities are observed are also associated with fetal hypoxia and reduced concentrations of glucose and amino acids in the fetal circulation and reduced activity of the system A amino acid transporter within the placenta. However, *in vitro* studies have shown that the hypoglycemia observed in some IUGR fetuses is not caused by a decreased glucose transport capacity within the placenta (expression and activity of GLUT1) and IUGR fetuses are actually hypertriglyceridemic compared to their appropriately grown counterparts. The fetal blood concentrations of the trace elements are also either normal or elevated in IUGR. Thus, while it is possible that the placenta from IUGR fetuses may limit the supply of amino acids there is no evidence that placental delivery is the first limiting factor in the supply of glucose, lipids, or trace elements. IUGR is a complicated syndrome in which almost all aspects of placental and fetal metabolism are altered and many researchers have emphasized the primary importance of the fetal hypoxia and its effects on fetal metabolism rather than a simple limitation of placental nutrient transfer capacity.

There is considerable uncertainty about the magnitude of the problem of IUGR. The lowest 5% of weight-for-gestational-age babies (defined according to well-nourished fetal growth centile charts) are referred to as small for gestational age (SGA) but babies in this range need not be growth retarded but may be naturally small and have no increased risk of adverse outcome. A further complication is that a baby born within the normal birth weight range could have suffered growth retardation *in utero* if its genetic potential was for a higher birth weight. The true incidence of IUGR resulting from uteroplacental insufficiency is therefore unknown but if it is defined in relation to umbilical flow or fetal heart rate abnormalities then it is only a fraction of even those in the lowest 5% of weight-for-gestational-age that are affected by uteroplacental insufficiency. At the other end of the spectrum babies that are large-for-gestational-age (LGA) are at higher risk of adverse obstetric outcomes and early developmental problems but there is no evidence that LGA or macrosomic babies are produced as a result of a primary alteration in the placenta.

The Role of the Fetus

The nutrient composition of the human diet varies enormously among populations yet the healthy human newborn is essentially the same the world over. The available evidence points to extensive homeostatic mechanisms at work within the placenta to ameliorate some of the variation in the quality of the maternal diet by regulating the mix of nutrients to the developing fetus. However, these mechanisms can only operate on the nutrients already available in the maternal circulation. The maternal diet and maternal circulating concentrations of many nutrients are major determinants of the concentrations in the fetal circulation and the fetus clearly has the ability to cope with relatively large variations in nutrient availability in the cord blood. The fetus also plays an active role in regulating placental nutrient transfer. The rate of placental nutrient transport is directly influenced by the transplacental concentration gradient, which is in turn largely determined by the rate of uptake by the fetal tissues. Another major determinant of placental nutrient transfer is the umbilical blood flow, which is approximately linearly related to the fetal weight, and hence the fetal nutrient requirement, throughout gestation. Finally, the most intimate connection between the fetus and the placenta is the way in which different parts of metabolic pathways and cycles are distributed between the placenta and fetal tissues, mainly the fetal liver. Thus, whilst the placenta has to provide the correct mix of nutrients in sufficient quantities to support fetal growth and development throughout pregnancy it is the fetus itself that ultimately regulates many key aspects of placental nutrient transfer function.

Nutrient Requirements

L H Allen, University of California at Davis, Davis, CA, USA

Providing pregnant women with their nutrient needs is a public health priority in both wealthier and poorer countries, although the local resources to attain this objective may vary widely. The inability to meet nutrient requirements during pregnancy can have serious and often long-term adverse effects on development during the fetal and postpartum period and on maternal health. Most of the research that provides information on nutrient requirements during pregnancy has been conducted in industrialized countries, although trials in developing countries have been important in revealing the adverse effects of maternal nutrition and the benefits of nutrient interventions. In general, even in wealthier countries there is an unacceptably high rate of pregnancy complications that may be prevented by improved maternal nutrition, including anemia, low birth weight, birth defects, and preeclampsia. The situation is far worse in poorer regions of the world, however.

The most recent and best described recommended intakes of nutrients during pregnancy are those of the Institute of Medicine, developed for the United States and Canada, and these are the main set presented in this article (**Table 1**). The recommendations for the United Kingdom were published in 1992 and are discussed here when recommendations differ substantially from those of the Institute of Medicine. Many other countries have their own sets of recommendations, as do organizations such as the Food and Agriculture Organization/World Health Organization and the European Economic Community.

The set of Dietary Reference Intake (DRI) recommendations developed by the Institute of Medicine includes several values. The Estimated Average Requirement (EAR) is the intake required to meet the nutrient needs of 50% of a population group (e.g., pregnant women). It is an important value for two reasons. First, it is the value used to estimate the prevalence of inadequate intakes of a nutrient in a population group; the percentage of a group consuming less than the EAR of a nutrient is the percentage with an inadequate intake. For energy, the Estimated Energy Requirement is equivalent to the EAR. Second, the Recommended Dietary Allowance (RDA) is calculated by adding two standard deviations (usually unknown but assumed to be 20%) to the EAR. The RDA should meet the requirements of 97.5% of a population group. The Tolerable Upper Level (UL) for a nutrient is the intake above which there is a risk of adverse effects.

Table 1 shows the RDA for nonpregnant women and the EAR, RDA, and UL for pregnant women.

Energy

Maternal energy requirements increase during pregnancy due to higher basal energy expenditure as well as energy deposition in maternal and fetal tissues. Basal metabolism of the mother is higher due to the increased work by the lungs and heart and because of the metabolism of the fetus and uterus. A longitudinal study by Butte *et al.* found that basal metabolic rate increased by 10.7 ± 5.4 kcal per week of gestation, mostly in the second and third trimesters. On average, the fetus requires approximately 168 kcal/day. The substantial variability in basal energy expenditure among individual women is caused mainly by differences in fat-free mass (including maternal skeletal muscle mass and fetal tissue). The cumulative increase in basal energy expenditure during pregnancy is positively correlated with maternal fatness and weight gain. Energy requirements for the thermic effect of feeding are not different from those of nonpregnant women, nor is there much change in the total energy cost of activity. Although the increasing body weight of the mother means that the energy cost of each activity is higher, the net effect is cancelled out by the fact that after approximately 25 weeks of gestation

Table 1 Recommended Dietary Allowances (RDAs) for nonpregnant and pregnant women and Estimated Average Requirements (EARs) and Upper Limits of nutrients for pregnant women[a]

[a]Dietary Reference Intakes published by the Institute of Medicine, National Academy Press, for the United States and Canada (http://www.nap.edu).
[b]Values are RDAs except for vitamins D and K, pantothenic acid, biotin, choline, calcium, chromium, fluoride, and manganese, where value is an Adequate Intake (AI).

women tend to become less active. The longitudinal study by Butte *et al*. suggests that energy expenditure in physical activity decreases by approximately 100–200 kcal/day in women with a low or normal body mass index prior to pregnancy and by an average of more than 400 kcal/day in those with a high body mass index ($>26\,kg/m^2$).

In deriving the recommendations for the United States and Canada, the Estimated Energy Requirement (EER) during pregnancy is accepted to be the sum of the Total Energy Expenditure (TEE) of the nonpregnant woman, measured using a doubly labeled water technique, plus an estimated median change in TEE of 8 kcal/week, plus 180 kcal/day to cover energy deposited in maternal and fetal tissues. In the first trimester of pregnancy, TEE changes little and weight gain is small, so the energy requirement is increased only during the second and third trimesters. There is no RDA or UL because energy intakes greater than the EER would lead to undesirable weight gain.

The EER for pregnancy is as follows:

Trimester 1: nonpregnant EER + 0 kcal

Trimester 2: nonpregnant EER + 160 kcal (based on 8 kcal/week × 20 weeks) + 180 kcal

Trimester 3: nonpregnant EER + 272 kcal (based on 8 kcal/week × 34 weeks) + 180 kcal

Note that these formulae present average requirements in trimesters 1 and 2. If a more precise estimate of requirements is needed at a specific stage of

gestation, instead of the mean increment of 160 kcal in trimester 1 and 272 kcal in trimester 2, the actual weeks of gestation can be multiplied by 8 kcal per week.

The UK recommendation is for an additional 200 kcal (0.8 MJ)/day above the prepregnant EAR but only in the last trimester. The recommendation is lower than that in the United States and Canada, in part because of the observation that the actual increase in energy intake during pregnancy is usually small.

Protein

The turnover of body protein is higher after approximately 13 weeks of pregnancy, and the mother adjusts by losing less nitrogen as urea even during the first trimester. A woman who gains 12.5 kg of body weight has deposited 925 g of protein, the fetus gains 440 g, the uterus 166 g, expanded maternal blood volume contains 81 g, the placenta 100 g, and the increment in extracellular fluid 135 g. The mother probably stores some additional protein in her body, presumably in muscle. The EAR for all age groups is 0.88 g/kg/day protein or 21 g of additional protein/day. The RDA is 1.1 g protein/kg/day or 25 g/day.

One-third of the 925 g total protein deposition during the 40 weeks of pregnancy occurs in the second trimester and two-thirds in the third trimester. By the end of the third trimester, the US–Canada recommendations assume that an additional consumption of 17 g protein/day is required to meet the needs for protein deposition, and since about half of this occurs during the second trimester this amounts to 8 g/day. It is also assumed that no additional protein is needed in trimester 1, but for the last two trimesters consumption of an additional 21 g/day (a total of 1.1 g/kg/day) is recommended. Recommended protein intakes for UK women are that an additional 6 g should be consumed during all three trimesters.

No UL has been set for protein, including for pregnancy, in the US–Canada recommendations due to lack of data on harmful effects. However, some earlier studies noted adverse pregnancy outcomes when high-protein supplements were given to relatively well-nourished pregnant women, so caution in this regard is certainly warranted.

Vitamins

Folic Acid

Maternal folate requirements increase markedly during pregnancy due to the utilization of the vitamin in cell division in the mother and fetus, single-carbon transfer reactions, and deposition in the fetus. Approximately a decade ago, research including randomized controlled trials finally proved that the risk of women giving birth to an infant with a neural tube defect (NTD) was significantly reduced if they consumed folic acid supplements prior to conception through approximately the first 4–6 weeks of pregnancy—during the time of neural tube closure. Some women are at greater risk of producing an infant with this birth defect, especially when their folate intake is rather low. Because such women are unaware of this risk unless they have had a previous NTD delivery, the recommendation is that all women who are capable of becoming pregnant consume at least 400 μg of folic acid daily from supplements, fortified food, or both in addition to consuming food folate from a varied diet.

In pregnancy, the recommendation is for all women to consume an additional 200 μg dietary folate equivalents daily (approximately 100 μg of folic acid as a supplement, which is more than twice as bioavailable as folate in food) in addition to the RDA for the nonpregnant woman of 400 μg/day. This amount was shown to prevent plasma homocysteine from becoming elevated during pregnancy and to maintain normal folate concentration in red blood cells. The UL of 1000 μg/day, the same as for nonpregnant women, is set to avoid potential exacerbation of vitamin B_{12} deficiency.

In the United Kingdom, the recommendation is substantially lower—an intake of 100 μg folate daily in addition to the recommendation of 200 μg/day for the nonpregnant, nonlactating woman. The UK committee's recommendation was based on the assumption that 100 μg/day will maintain plasma and erythrocyte folate concentrations at least at the level of those of nonpregnant women. Prevention of NTDs was not discussed, probably in part because the results of folic acid intervention trials were not clear at the time the recommendations were set.

In addition to its importance for lowering risk of NTDs in the periconceptional period, there is evidence that adequate folate status, which is important for maintaining normal plasma homocysteine concentrations, lowers the risk of other delivery problems and birth defects, including preeclampsia, preterm delivery, very low birth weight, club foot, and placental abruption. In the United States, Canada, and many other countries (more than 20 in Latin America alone), wheat flour is fortified with folic acid to ensure adequate folate status for pregnant women.

Other B Vitamins

Several B vitamin deficiencies cause homocysteinemia, notably folic acid, vitamin B_{12}, riboflavin, and vitamin B_6. Importantly, homocysteinemia is associated with adverse pregnancy outcomes. In a large retrospective study in Norway, for example, women in the highest 25% of plasma homocysteine concentrations had significantly more placental abruption, stillbirths, very low-birth-weight and preterm infants, preeclampsia, club foot, and NTDs in their offspring compared to women with values in the lowest 25%. Supplementation with folic acid up to 500–600 μg/day lowers plasma homocysteine, but few studies have been done on the other B vitamins. Of these, it is most difficult for poor women to obtain their dietary vitamin B_{12} requirement because this vitamin in found only in animal source foods, such as meat and dairy products.

The recommended intakes of most B vitamins and choline are increased above nonpregnant values as shown in **Table 1** The increases are based on evidence for higher maternal requirements (in the case of thiamin, riboflavin, niacin, and vitamin B_6) and for fetal and placental deposition of the vitamin (thiamin, riboflavin, niacin, vitamin B_6, vitamin B_{12}, and choline). UL values, the same as for nonpregnant women, have been set for niacin when consumed as nicotinic acid in supplements based on a 'flushing' reaction and for choline based on cholinergic reactions and a fishy body odor.

Vitamin A

The increment in vitamin A requirements during pregnancy is based on the amount of the vitamin that is found in fetal liver at birth. The liver content is assumed to be 36 μg, mostly accumulated during the last 3 months of gestation. Using an estimated 70% absorption of the vitamin from the maternal diet, the EAR is 50 μg above the requirement for the nonpregnant woman, whereas the RDA is 20% higher (60 μg).

In wealthier regions of the world, vitamin A deficiency during pregnancy is rare. Rather, there is more concern about the potentially adverse effects of consuming excessive amounts of the vitamin. Based on the potential for retinol excess to cause birth defects (malformations), especially if high doses are consumed early in pregnancy, a UL of 3000 μg/day is set for all women who may become pregnant as well as those who are pregnant. This intake is unlikely to be achieved with natural food, although it would be possible if large amounts of liver, foods fortified with the vitamin, or supplements were consumed. One situation in which this restrictive UL becomes important is in the context of developing countries where high-dose vitamin A supplements are provided to postpartum women and their infants as part of the Expanded Program on Immunization, National Vitamin A Days, or similar programs. It is accepted that it is only safe to provide these high-dose supplements to the mother during the first 6 weeks postpartum, in case she becomes pregnant again.

Nevertheless, it is important to provide pregnant women with their recommended intake of the vitamin because one major study in Nepal showed a 40% reduction in infection-related maternal mortality by supplementing the women with approximately their RDA as retinol per week. Supplementation with β-carotene reduced mortality by 49%, and it is a nontoxic alternative. Additional trials to confirm the benefits of maternal supplementation with the vitamin in deficient populations are ongoing.

Vitamin D

In the form of 25(OH) cholecalciferol, vitamin D is transferred from the mother to the fetus in relatively small amounts that do not appear to cause maternal depletion. Those women who obtain adequate exposure to ultraviolet light do not need higher amounts during pregnancy. However, if usual intake declines below 150 IU (3.8 μg)/day at high latitudes (where there is little ultraviolet radiation in the winter, such as in France), evidence of low maternal 25(OH) cholecalciferol and infant depletion has been observed at delivery.

The recommendation for both adolescent and adult women is to continue to consume the amount recommended as adequate (the Adequate Intake (AI)) for nonpregnant women, 5 μg (200 IU/day). The UL of 50 μg (2000 IU/day) is the same as before pregnancy, based on prevention of high serum calcium concentrations. In the United Kingdom, the recommended intake is higher at 10 μg/day, which is probably appropriate based on its generally more northern latitude (thus less ultraviolet radiation) and lower synthesis of the vitamin in skin.

Vitamin C (Ascorbic Acid)

The EAR for nonpregnant women is based on the intake that attains the maximum neutrophil concentration of ascorbic acid. Maternal plasma vitamin C concentrations decline during pregnancy, probably as a result of normal hemodilution. Oxidized ascorbic acid is transferred from the maternal circulation to the fetus, where it is retained in the reduced form. Although vitamin C deficiency in pregnancy is rare

in most situations, it has been associated with premature rupture of the membranes, increased risk of infections, preterm birth, and eclampsia. Smokers have lower levels of ascorbic acid in their serum and amniotic fluid. Based on the amount known to prevent infants from developing scurvy, the EAR is increased by 10 mg/day to 66 mg/day for those 14–18 years old and to 70 mg/day for adult women, and the RDA is 80 and 85 mg/day for these groups, respectively. The recommended intake is also increased by 10 mg/day in the United Kingdom. Women who smoke more than 20 cigarettes per day and regular aspirin users may require twice as much, as may heavy users of alcohol and street drugs. The UL of 2000 mg/day is based on prevention of diarrhea and gastrointestinal disturbances that occur with high intakes.

Vitamin E

There is no increase in the recommended intake of vitamin E during pregnancy, so the RDA remains at 15 mg of α-tocopherol/day for all ages. There have been no reports of deficiency of vitamin E during pregnancy nor any evidence of benefit from maternal supplementation. The UL is 1000 μg/day of any form of the vitamin taken as a supplement, extrapolated from data showing that high levels cause hemorrhaging in rats.

Minerals

Calcium

It has become recognized relatively recently that changes in maternal calciotropic hormones and calcium metabolism (i.e., increased intestinal absorption and reduced urinary excretion) enable the fetus to be supplied with adequate amounts of this mineral, and that little change in maternal intake is needed. There is no correlation between the number of pregnancies a woman has and her risk of bone fracture, so the maternal skeleton does not serve as the calcium reservoir for the fetus. Thus, for the United States and Canada there is no increase in recommended calcium intakes for pregnancy and the AI recommendation remains at 1300 mg/day for women aged 14–18 years and 1000 mg/day for the 18- to 51-year-old group. In the United Kingdom, the recommendation is also that no increase in intake is required during pregnancy, although the level of intake for nonpregnant, nonlactating women is considerably lower at 700 mg/day.

In a series of 14 randomized, controlled calcium intervention studies in different countries, increasing calcium intake in the range of 375–2000 mg/day reduced maternal blood pressure and the risk of pregnancy-induced hypertension and preeclampsia by 30–40%, with a greater effect in populations that consumed diets relatively low in calcium. The multicenter Calcium for Preeclampsia Prevention trial on 4589 pregnant women in the United States found no such benefits of a 2000 mg/day supplement, presumably because of reasonably high usual intakes of the mineral. It is possible that women at higher risk of pregnancy-induced hypertension, such as those with very low calcium intakes or adolescents, may benefit from calcium supplementation.

The UL for calcium in pregnancy is the same as that for the nonpregnant woman, 2500 mg/day. This safe level is set based on documented cases of 'milk-alkali syndrome,' in which there is high blood calcium, renal failure, and sometimes metabolic alkalosis as a result of chronic consumption of high calcium intakes.

Phosphorus

The efficiency of phosphorus absorption increases by 15% during pregnancy. The term infant contains approximately 17 g of phosphorus at birth, mostly in bone and water. The physiological adaptations of the mother that increase calcium retention also help to supply the fetus with more phosphorus. There is no evidence that the EAR needs to increase over that recommended for the nonpregnant women, so the RDA for women aged 14–18 years is 1250 mg/day and for those aged 19–50 years it is 700 mg/day. Based on the need to avoid high serum phosphorus concentrations, and the fact that phosphorus absorption is more efficient in pregnancy, the UL is set at 3500 mg/day, slightly lower than the 4000 mg/day for nonpregnant women.

Magnesium

It is assumed that the gain in fat-free mass in pregnancy (7.5 kg) is associated with a greater deposition of magnesium. If this tissue contains 470 mg/kg, after adjustment for a bioavailability of 40%, the EAR is an increase of 35 mg/day for pregnant women of all ages, and the RDA is 10% higher than this; for women aged 14–18 years, the EAR and RDA respectively are 335 and 400 mg; for those aged 19–30 years, these values are 290 and 350 mg; and for those 31–50 years, they are 300 and 360 mg. In the United Kingdom, there is no increment for magnesium in pregnancy based on the assumption that phosphorus metabolism becomes more efficient to meet fetal needs.

The UL for magnesium in pregnancy is set at 350 mg/day taken as a supplement, based on the potential for higher doses of magnesium salts to cause an osmotic diarrhea.

Iron

Incremental iron requirements for the mother and fetus are relatively well established, although how these requirements should be met is more controversial. It is generally accepted that the mother needs to absorb an additional 6 mg/day to supply the amount retained by the fetus (300 mg) and placenta (60 mg) and that used to synthesize additional maternal erythrocytes (450 mg) and replace blood loss during delivery (200 mg). Some iron is saved by the lack of menstruation in pregnancy. The fetus obtains iron from the placenta in a process that involves iron transfer from maternal transferrin to transferrin receptors on the placenta, endocytosis of holotransferrin, and release of iron into the fetal circulation. Maternal iron absorption and transfer to the fetus increases during the second and third trimesters. This process is upregulated if the mother is iron deficient, although in recent years it has become apparent that maternal iron deficiency does reduce the amount of fetal iron stored at birth and available to the fetus during the first months of life.

The EAR for pregnancy is set at 23 mg/day for adolescents and 22 mg/day for adult women, and the RDA is 27 mg/day for both groups. Although the requirement is mainly in the last trimester, it is important to build iron stores early and to avoid high doses later, so the higher intake recommendation is distributed throughout pregnancy. The UL is the same as that for the nonpregnant woman and is based on the need to avoid gastrointestinal distress.

It has been calculated that the maternal diet can supply enough iron to meet these increased needs during pregnancy, especially if maternal iron stores are adequate at conception. For this reason, the United Kingdom does not recommend that iron intake be increased during pregnancy, except when there is evidence of iron deficiency anemia. Iron deficiency anemia is a relatively common occurrence during pregnancy, especially in the following situations: Maternal iron status is poor at conception, and maternal diet is low in absorbable iron including heme iron from meat, fish, and poultry. The World Health Organization estimates that approximately 18% of women in industrialized countries and 35–75% of those in developing countries develop iron deficiency anemia during pregnancy. In the United States, the Centers for Disease Control and Prevention reports that anemia affects 10% of low-income women in the first trimester, 14% in the second, and 33% in the last, with a much higher proportion of women becoming iron depleted by term. Accepted cut points for adequate hemoglobin concentration are 110 g/l in trimesters 1 and 3 and 105 g/l in trimester 2 due to midpregnancy hemodilution.

In most countries, iron supplements are recommended routinely for all pregnant women. Benefits clearly include reduction of anemia risk, improved maternal and iron status that can persist through the early postpartum period, and possibly some protection against low birth weight. The amount recommended has been reduced from former levels of 60–120 mg to 30 mg for nonanemic women and 60 mg for anemic women. The World Health Organization recommends 60 mg/day plus 400 μg folic acid, starting as soon as pregnancy is confirmed, but recognizes that 30 mg/day may be as effective as 60 mg/day. The folic acid recommendation was originally set based on older studies showing development of folate deficiency anemia in women. Although the risk of this anemia is probably low on a global scale, folic acid supplementation is recognized to have other potential benefits. Some countries still recommend iron supplementation only when pregnant women become anemic. There has also been considerable controversy concerning the best time to start supplementation.

Zinc

The estimated additional zinc required for pregnancy is approximately 100 mg, equivalent to 5–7% of the mother's body zinc, part of which is obtained through more efficient intestinal zinc absorption. Approximately half of this is deposited in the fetus. The EAR for pregnant women is based on an additional requirement of 2.7 mg/day during the last 10 weeks of gestation. The UL is based on evidence of impaired copper status at high intakes, as for nonpregnant women. No increment is recommended for pregnancy in the UK report, based on the assumption that needs can be met through adjustments in maternal zinc metabolism.

Zinc plays critical roles in cell division, hormone metabolism, protein and carbohydrate metabolism, and immunocompetence. Because zinc deficiency in pregnant animals causes birth defects and fetal growth retardation, there has been considerable effort to determine the effects of human zinc status on pregnancy outcome, especially in developing countries, where zinc intakes

are often inadequate. In an analysis of 12 randomized, controlled intervention trials, only 2 (1 in India and 1 in the United States) found that zinc supplementation increased birth weight and reduced preterm delivery risk, whereas 6 found no effect. In the United States study, a positive effect was found in low-income, obese African American women with below average plasma zinc concentrations. Trials in Peru and Bangladesh showed no such benefits. In general, however, meeting recommended zinc intakes is more difficult but more critical for women whose diets are low in animal source foods and higher in fiber. High intakes (supplements) of iron and calcium may also impair zinc absorption and therefore increase requirements.

Iodine

In the many countries with endemic iodine deficiency, which include parts of the United States, Canada, and substantial areas of Europe and many other industrialized and developing countries, there is clear potential for the harmful effects of this deficiency to emerge during pregnancy. The most damaging effect of iodine deficiency is on the brain of the fetus since iodine is required for thyroid hormone, which in turn affects myelination and function of the developing central nervous system. The clinical expression of severe maternal iodine deficiency during pregnancy is cretinism, including severe mental retardation, deaf mutism, short stature, and spasticity. Injections of iodized oil before midpregnancy have markedly reduced cretinism and neonatal mortality in areas of severe iodine deficiency. In most countries, Universal Salt Iodization has reduced the prevalence of cretinism substantially, but milder indications of maternal deficiency persist even in Western Europe, including countries such as Belgium.

The EAR for pregnancy is set at 150 μg/day and the RDA at 160 μg/day for the United States and Canada based on the amount needed to prevent increased thyroid size in previously deficient women. The UL is 1100 μg/day, the same as for nonpregnant, nonlacting women, and it is based on the need to avoid elevated thyroid-stimulating hormone concentrations.

Trace Elements: Copper, Selenium, Chromium, Fluoride, Manganese, and Molybdenum

Copper is required for the function of many enzymes, primarily oxidases. In pregnancy, an increased intake of this mineral is recommended to cover deposition of approximately 18 mg/day, most of which is in fetal liver. The UL (10 000 μg/day) is the same as for nonpregnant women, based on the need to prevent the liver damage that occurs with high intakes.

Recommended intakes of selenium for adults are based on the criterion of maximizing plasma glutathione peroxidase activity. Based on an estimated selenium content of the fetus of 1000 μg, across pregnancy this would require that an additional 4 μg/day be consumed. The EAR is therefore increased from 45 to 49 μg/day and the RDA from 55 to 60 μg/day. The UL is determined on the basis of hair loss and brittle nails, which occur at higher levels of intake, and is the same as that set for nonpregnant women. An intake of 60 mg/day is also recommended throughout pregnancy in the United Kingdom, which is the same as the prepregnancy value for that population.

Chromium is required for normal insulin metabolism. There are no data from which to derive a recommendation for pregnancy, so an increase of 5 μg/day is recommended (as an AI) based on the additional weight and tissue chromium gained in pregnancy. No UL was set due to lack of documented adverse effects in humans.

For fluoride, there is no evidence that increasing the AI in pregnancy above that for the nonpregnant woman would benefit fetal tooth or bone content or afford protection against later tooth decay in the child. The UL is set at 10 mg/day to avoid fluorosis (discoloration of tooth enamel, joint pain, and skeletal abnormalities).

Manganese is required for bone formation and the normal metabolism of amino acids, lipids, and carbohydrates. The AI for pregnancy, estimated from the manganese content of maternal weight gain, is 2 mg/day. The UL is based on avoidance of elevated blood manganese and neurotoxicity, and it is not increased for pregnancy.

Recommended molybdenum intakes, based on the mineral's role as a cofactor for several enzymes, increase by 16 mg/day in pregnancy to cover the increment in fetal and maternal weight. The UL is derived from adverse reproductive effects seen in animals.

Water and Electrolytes

The US–Canada recommended intake of water for pregnant women is based on median intake from a large national survey in the United States. The AI of 3 l/day is anticipated to come from foods (0.7 l) and beverages (2.3 l). No UL was set because individuals stop drinking once their intake is adequate.

The AI for sodium in pregnancy is 1500 mg/day based on an intake level to cover daily losses, provide adequate intakes of other nutrients, and maintain normal function. The UL of 2300 mg/day is based on the adverse effects of higher intakes on blood pressure in susceptible members of the population.

The AI for potassium in pregnancy (4.7 g/day) is set at a level that will lower blood pressure, reduce the extent of salt sensitivity, and minimize the risk of kidney stones. There is no evidence that adverse effects of potassium are seen with high intakes from food and no UL was set, but potassium supplements can cause high blood potassium in some chronic diseases, such as renal disease and type 1 diabetes.

Summary

In the US–Canada recommendations, the recommended intakes are increased for most, but not all, nutrients during pregnancy. However, the recommendations are often based on less than ideal experimental data, in part due to the difficulty of conducting experiments on pregnant women.

For most nutrients, it is likely that some population groups may have higher requirements than those recommended in **Table 1**, notably women bearing more than one fetus or adolescents (see the Institute of Medicine volumes for specific recommendations for this age group). In order to meet the recommended nutrient increases, dietary quality often needs to be improved during pregnancy. It is often advised that pregnant women should also take iron supplements and/or a multiple vitamin–mineral supplement. The specific benefits of supplementation in pregnancy, optimal timing, and optimal doses are still somewhat controversial and the subject of ongoing research. Currently, some countries recommend routine supplementation for all pregnant women, whereas others recommend supplementation only when there is evidence of anemia, other nutritional deficiencies, a poor diet, or other problems such as drug or alcohol abuse.

Energy Requirements and Metabolic Adaptations

G R Goldberg, MRC Human Nutrition Research, Cambridge, UK

The subject of energy metabolism in human pregnancy has received extensive consideration for more than 60 years, dating back to early work that assessed the contribution of fetal metabolism to the overall energy costs of pregnancy. Since then, the emphasis of much work has been on separating and quantifying the different components of gestational energy needs and on establishing appropriate recommendations for the energy requirements of pregnant women, with the intention to quantify average amounts. Deviations from average values were mostly regarded as undesirable biological or measurement noise that needed to be

overcome by studying large samples of women to get a more precise estimate of the mean values. These inter-individual variations in the metabolic responses to pregnancy are increasingly recognized as biologically significant 'plasticity' that has true adaptive value in enabling women to carry a pregnancy to term under a wide range of nutritional conditions. The shorter and longer term consequences of such adaptations are being explored as part of fetal and infant origins of adult disease hypotheses.

Extra Energy Costs of Pregnancy

The question of how much extra dietary energy a pregnant woman needs is closely linked to the question of the amount of weight she should gain during pregnancy. This in turn is linked to her age and to her prepregnant body mass index as a proxy for energy status.

Hytten and Leitch's theoretical estimations of the overall energy costs of human pregnancy published more than 30 years ago have subsequently been experimentally validated as reasonable average values, and they have been adopted by many national and international bodies as a partial basis for developing recommended energy intakes in pregnancy. The costs can be divided into three main components: the energy deposited as new tissue in the conceptus, the energy deposited as fat, and the energy required to maintain this new tissue.

Tissue Deposition

Weight gain during pregnancy consists of the fetus, placenta, and amniotic fluid (the products of conception) and the extra growth of several maternal tissues. The deposition of fat in pregnancy is presumed to help meet the extra energy demands of lactation. The total energy deposited as new tissue, excluding maternal fat, averages approximately 49 MJ (11 700 kcal). If an average maternal fat gain of 2.6 kg is assumed, then the estimate of the total energy deposited as new tissue during an average pregnancy is approximately 174 MJ (41 600 kcal) (**Table 1**).

Maintenance Energy Costs of Pregnancy

Because of the increase in tissue mass, the body's oxygen consumption also increases during pregnancy. Estimates suggest that the increase in oxygen consumption is equivalent to an extra 187 (45), 414 (100), 620 (148), and 951 (230) kJ/day (kcal) at 0–10, 10–20, 20–30, and 30–40 weeks of gestation, respectively. The total maintenance cost for an average human pregnancy is approximately 150 MJ (35 800 kcal) (**Table 2**).

Table 2 Increases in oxygen consumption during pregnancy[a]

	ml/min			
	10 weeks	20 weeks	30 weeks	40 weeks
Cardiac output	4.5	6.8	6.8	6.8
Respiration	0.8	1.5	2.3	3.0
Kidneys	7.0	7.0	7.0	7.0

Theoretical Total Metabolic Costs of Pregnancy

Compared to many other mammals, humans have a relatively small and usually single infant, which develops during a long gestation period. The energy stress to the mother is therefore low per unit time. The 49 MJ of energy deposited as the products of conception represents only 4 or 5 days of food intake for the mother. Humans also differ from most other mammals because their large fat stores can help meet some of these costs. The theoretical total metabolic costs (i.e., due to extra tissue and increased metabolism) of pregnancy are approximately 335 MJ (80 000 kcal), or 1.25 MJ/day (300 kcal). This value does not make any allowance for changes (increases or decreases) in energy expended on physical activity. It is assumed that the majority of the energy costs of human pregnancy are met by behavioral adjustments in energy metabolism rather than increased energy intake. This assumption has formed the basis for energy intake recommendations, some of which are summarized in **Table 3**. It should be noted that the 1985 estimates used by WHO/FAO/UNU are under revision. Future recommendations may separate the obligatory costs (e.g., by fixed increments for basal metabolic rate (BMR) and tissue deposition) and differences in physical activity (based on PAL values).

Longitudinal Studies of the Energy Costs of Pregnancy

Fat Deposition

The increase in maternal fat stores is by far the largest contributor to the energy cost of tissue deposition. It is also the most variable. Although the average increase for a well-nourished woman who has an uncomplicated pregnancy and healthy infant is approximately 3 kg, a large number of studies have reported ranges of −2 to 8 kg and standard deviations of 2–4 kg. There is also a wide range in fat deposition between different populations, particularly when those from developed and developing countries are compared. Fat is very energy dense and therefore changes in body fat stores have a large impact on the energy costs of pregnancy. A loss of 2 kg saves approximately 78 MJ (18 600 kcal), whilst a gain of 8 kg costs approximately 312 MJ (74 600 kcal). Women most likely to need an energy reserve to help meet the costs of lactation are often those who are least able to deposit spare energy as fat in pregnancy. Conversely, women who store large amounts of fat during pregnancy are least likely to need to use it during lactation. They are often able to increase food intake and/or decrease physical activity instead.

Table 3 Examples of current recommendations for energy intakes during pregnancy

	Trimester(s)	*Increment, MJ/day (kcal/day)*	*Total for pregnancy, MJ (kcal)*	*Qualifying comments*
FAO/WHO/UNU (1985)	All	1.20 (300)	336 (80 300)	
	All	0.84 (200)	235 (56 150)	For healthy women who reduce activity Energy and protein requirements are undergoing revision (interim report published 2004)
United Kingdom (1991)	3rd	0.80 (190)	74 (17 000)	Underweight women and those not reducing activity may need more
United States and Canada (2002)	1st	Adult EER + 0		For women aged 19–50 years
	2nd	Adult EER + 160 kcal (8 kcal/week × 20 weeks) + 180 kcal		EERs for pregnant adolescents are based on EER for 14- to 18-year-olds
	3rd	Adult EER + 272 kcal (8 kcal/week × 34 weeks) + 180 kcal		EER is based on total energy expenditure in the nonpregnant state; increments for pregnancy are 8 kcal/week for total energy expenditure and 180 kcal/day for tissue deposition

EER, estimated energy requirement.

Studies have shown that excess energy intake during pregnancy results in excess maternal weight (and fat) gain. Postpartum retention of excess fat has implications for the development of obesity and its comorbidities such as type 2 diabetes.

Basal Metabolic Rate

The cumulative increase in BMR can comprise a large part of the total energy costs of pregnancy. Although 150 MJ is a good estimate of the average energy cost of maintenance for a well-nourished woman, there is a very wide range. This has an important influence on the extra daily requirements for individual women. Studies in which BMR has been measured every 6 weeks from prepregnancy to 36 weeks of pregnancy have shown very marked differences. In some women, there is the expected response to pregnancy—an immediate and progressive increase in BMR. In other women, BMR actually decreases or increases only slightly in the early stages of pregnancy and does not increase substantially until late gestation. This offsets the later increase in BMR such that there is actually a slight net saving of energy over the entire gestation period in some of these 'energy-sparing' women. The total net cost of maintenance, estimated as the cumulative area under the curve represented by the rise in a mother's BMR above the prepregnancy baseline metabolic rate, is negative or only very small. Data indicate that this between-subject variability is found in women from both well-nourished and marginally-nourished populations. However, 'energy-sparing' and 'energy-profligate' responses dominate in marginally and well-nourished women, respectively. There is a more than 5-fold range between the most energy-profligate and the most energy-sparing women.

In addition to the wide variability in changes in BMR between individual women, there are also wide variations between different populations. Well-nourished affluent women from developed countries tend to show an energy-profligate increase in BMR. In marginally nourished thinner women from developing countries the increase in BMR is delayed and/or preceded by a decline in early pregnancy. The total maintenance costs of pregnancy in these studies range from +210 MJ (+50 000 kcal) to −45 MJ (−11 000 kcal).

Diet-Induced Thermogenesis

A reduction in diet-induced thermogenesis (DIT) may be a mechanism by which energy is saved during pregnancy. However, when expressed as a proportion of energy intake, DIT remains essentially unaltered during pregnancy and any changes are small and unlikely to be biologically significant.

Energy Cost of Activities

Results from a number of longitudinal studies have shown that the cost of non-weight-bearing activity changes little until very late pregnancy. From approximately 35 weeks, the gross costs (which include changes in BMR) increase by approximately 11% and net costs by approximately 6%. The gross and net costs of weight-bearing exercise (treadmill walking and standardized step testing) remain fairly constant during the first half of pregnancy and then increase progressively by approximately 15–20% at term.

Behavioral Changes in Physical Activity

It has frequently been assumed that a behavioral reduction in the energy expended on physical activity helps to counteract the increases in expenditure due to increased body weight, and in some women this leads to saving of energy that largely meets the costs of pregnancy. However, although relatively small changes in activity patterns can potentially result in significant energy savings, there is little evidence that this occurs to a large extent. A possible reason for this is that affluent women are habitually so sedentary that there is little scope for further reduction. In contrast, in developing countries habitual levels of physical activity are high and there is therefore more potential for behavioral reductions. However, many women are likely to be unable to reduce their physical activity because of the constraints imposed by a subsistence livelihood, where farm work is obligatory for survival.

This topic has been one of considerable debate in recent years, particularly since longitudinal studies that have measured total energy expenditure with doubly labeled water have shown that many women increase the energy expended on physical activity during pregnancy, and that any decreases are not sufficient to counterbalance the energy costs of pregnancy due to tissue (fat) deposition and maintenance energy metabolism. It has been recommended that the data used by the World Health Organization should be revised to take account of changes in energy expended on physical activity and to separate these energy costs from those of maintenance and tissue deposition. The Dietary Reference Intakes for the United States and Canada have already incorporated these changes (**Table 3**).

Between-Country Comparison of the Metabolic Costs of Pregnancy

The average costs across different populations result in a wide range of energy needs from −30 MJ (−7000 kcal) to 523 MJ (125 000 kcal). Studies found that the average costs in the well-nourished groups were similar to the current international assumption of 336 MJ (80 000 kcal). These studies have also shown that the amount of prepregnancy body fat is strongly correlated with both the maintenance costs and the total metabolic costs of pregnancy. The combined costs of maintenance, fat deposition, and conceptus across studies from different countries drawn from emerging and affluent nations show that the energy cost of fat deposition also varies according to the state of affluence and is positively correlated with variations in maintenance requirements.

This flexibility in energy metabolism acts in a protective manner, with undernourished women showing significant energy-sparing adaptive strategies that tend to normalize energy balance. Body fat content is one of the measures of fitness for reproduction; fertility is suppressed in undernourished women. However, future unfavorable conditions cannot be anticipated and pre- or early pregnant fatness may be indicative of overall nutritional status and energy balance during pregnancy.

These relationships suggested the existence of a mechanism that can monitor the mother's prepregnancy energy status and adjust the homeorrhetic changes in maternal metabolism accordingly. The discovery of leptin provides a plausible mechanism by which peripheral energy status can be centrally monitored and may coordinate the metabolic responses to pregnancy. It is clear that in addition to its role in the regulation of adipose tissue, appetite, and metabolic rate, leptin plays a significant role in several components of the reproductive axis. Evidence suggests that it plays a key role in pregnancy, including the modulation of fetal growth.

Individual Variability in the Total Energy Costs of Pregnancy

Because of the marked differences between individuals in the different components of the energy costs of pregnancy (changes in BMR, body fat, and energy expended on physical activity), the total energy costs, and therefore energy requirements, are also variable. Studies of well-nourished women indicate that the total extra energy costs of pregnancy average 418 MJ (100 000 kcal), considerably higher than the estimates in **Table 3**, and there is a large range from 34 to 1200 MJ (8000–287 000 kcal). These values are probably representative of many women in developed countries. They show that it is impossible to prescribe energy intakes for individual women since it cannot be predicted how they will respond metabolically (BMR and fat) or behaviorally (physical activity and food intake) to pregnancy.

Implications of Energy-Sparing Adaptations for Mother and Infant

Human energy metabolism is particularly adaptable during pregnancy, with early/prepregnancy body 'fatness' being a major determinant. The adaptive strategies that maintain energy balance seem to be a coordinated biological system in which energy-sensitive modulations in metabolism help to sustain human pregnancies and protect fetal growth in highly marginal environmental circumstances. However, the existence of such mechanisms should not be misinterpreted as suggesting that maintenance of optimal nutritional status in pregnant women is not a priority because the adaptive mechanisms of the women will cope. It cannot be assumed that pregnant women will have energy-sparing alterations in metabolism and/or that physical activity decreases. Any adaptations that do occur should not be overinterpreted as suggesting that this is the case. The possible long-term detrimental effects must also be considered. The biochemical and physiological processes that are downregulated in the mother causing the suppression in BMR are unknown and there may be long-term consequences to her health and that of her infant.

The associations between maintenance needs, pregnancy weight gain, and prepregnant fatness indicate that a target weight gain of 12.5 kg is associated with maintenance costs of approximately 160 MJ (38 000 kcal). Although individual women or populations may have lower maintenance requirements, these may be associated with inadequate weight gain and low-birth-weight infants. A major determinant of birth weight is maternal weight gain, and the single most important determinant of infant survival is birth weight. Although birth weight is relatively well preserved at different planes of nutrition, weight alone is an inadequate measure of an infant's overall condition at birth. Even subtle nutritional influences on the fetal environment may have long-term consequences.

As mentioned previously, pregnancy weight gain is a critical component of the overall energy costs of pregnancy. The issue of whether pregnancy weight

gain drives, or is driven by, the metabolic changes is interesting, but it is clear that women who consume marginal diets have small weight gains and that women from poorer countries have much lower percentage weight gains despite having lower initial body weights. Extremes of weight gains during pregnancy may have several consequences, which may or may not be mediated directly through an effect on birth weight. Other effects of weight gain may be more subtle and may be mediated through qualitative effects on fetal growth and development at different stages of intrauterine growth. There is a considerable body of evidence that suggests that many chronic adult diseases have their origins in fetal and infant nutrition, which has refocused attention on early life as a critical period in human development.

Weight Gain

L H Allen and J M Graham, University of California at Davis, Davis, CA, USA

During the past 40 years, there have been dramatic changes in the recommendations for optimal maternal weight gain during pregnancy. In the past, it was thought that it was necessary to restrict the diet of many pregnant women in order to reduce the perceived risks associated with higher weight gains. The fetus was thought to be relatively unaffected by this advice. In contrast, the current recommendations in the United States are based on weight changes in pregnancy that have been taken from records and known to be compatible with a healthy pregnancy outcome. The US recommendations have been widely accepted by many other Western countries. Because several maternal factors influence the amount of weight gained in pregnancy, these factors have to be taken into consideration when basing recommendations on actual weight gain. The result has been the development of more realistic weight gain guidelines that are based to some extent on the characteristics of the mother. Additional experience has been gained since these guidelines were developed that encompasses a variety of subpopulations including different ethnic groups and overweight women, and the knowledge gained broadens the scope of these recommendations among modern diverse populations. However, there is still much to be learned about the

determinants of, and variability in, energy requirements and balance of pregnant women.

Pregnancy Weight Gain Recommendations

In 1970, the US National Academy of Sciences published guidelines for weight gain during pregnancy in the report, Maternal Nutrition and the Course of Pregnancy. The recommended pregnancy gain was 24 lb (10.9 kg), with a range of 10–25 lb (9.1–11.4 kg). The report advised health care providers and pregnant women not to restrict weight gain—a practice that had been fairly widespread during the previous decade in order to reduce the perceived risks of labor complications, preeclampsia, and excess weight retention postpartum. In fact, many obstetricians had been recommending gains of only 15–20 lb (6.8–9.1 kg).

Even with the more generous recommendations set in 1970, by the 1980s it had become clear that average gains of women in the United States far exceeded these guidelines. An analysis of data from the National Natality Survey in 1980 showed the average pregnancy weight gain to be 29 lb (13.2 kg), and by the time of the National Maternal Infant Health Survey in 1988 the average had increased to 32 lb (14.5 kg). The range of gain was very wide, from no gain to more than 75 lb (34.1 kg).

Based on this realization, in 1990 the weight gain recommendations were revised completely by a committee established by the Institute of Medicine (IOM) of the National Academy of Sciences. Existing data from a national survey were analyzed to determine the weight gain that was compatible with a normal pregnancy outcome. The latter was defined as the infant being born full term and of normal birth weight and the absence of pregnancy or delivery complications. It became apparent from these analyses that maternal weight-for-height at conception, expressed as body mass index (BMI; weight in kilograms and height in meters squared), was an important predictor of actual weight gain. Thin women (with a low BMI) gained more weight than fatter women. Different weight gain recommendations were therefore developed for women entering pregnancy with different BMIs (**Table 1**). For thinner women (BMI <19.8 or <90% of ideal body weight), recommended gains are 28–40 lb (12.7–18.2 kg); for women with a normal BMI (19.8–25.9), gain should be 25–35 lb (11.4–15.9 kg) or 1 lb (0.45 kg) per week; and for overweight women (BMI >29.0 or >135% ideal body weight), gain should be at least 15 lb (6.8 kg) or 0.7 lb (0.32 kg) per week. New weight gain grids were constructed that showed the recommended gains over the course of pregnancy for each BMI group (**Figure 1**), enabling the adequacy of weight gain to be tracked for individual women. To use the chart, women's height and weight should be measured as near to the time of conception as possible (because pregnancy causes a temporary reduction in height) and used to obtain their BMI from a table. The US recommendations are deemed to be appropriate for women in developed countries worldwide.

Table 1 Recommendations for pregnancy weight gain by body mass index (BMI) at conception

BMI category	*Recommended total gain*	
	Kilograms	*Pounds*
Low (BMI <19.8)	12.8–18.0	28–40
Normal (BMI >19.8–26.0)	11.5–16.0	25–35
High (BMI >26.0–29.0)	7.0–11.5	15–25
Obese (BMI >29.0)	≤6.0	≤13

Modified from Institute of Medicine, Committee on Nutritional Status during Pregnancy and Lactation (1990) Nutrition During Pregnancy. Weight Gain. Nutrient Supplements. Food and Nutrition Board. Washington, DC: National Academy Press.

Pattern of Weight Gain

Relatively little (1–2.5 kg) of the total weight gain during pregnancy occurs during the first trimester, whereas gain in the last two trimesters is relatively linear. Nevertheless, it is important to pay attention to the quality of pregnant women's diets during the first trimester and to ensure that they do not restrict their intake during this time, when there is the

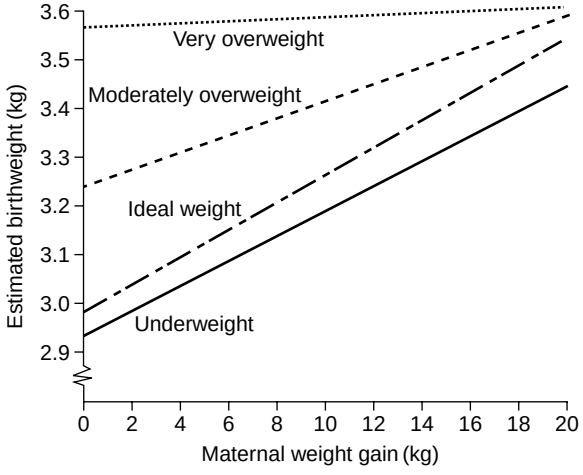

Figure 1 The relationship between maternal pregnancy weight gain and birth weight. (Reproduced with permission from the Institute of Medicine, Committee on Nutritional Status during Pregnancy and Lactation (1990) *Nutrition during Pregnancy. Weight Gain. Nutrient Supplements. Food and Nutrition Board.* Washington, DC: National Academy Press.)

strongest risk of nutrition-related birth defects and spontaneous abortions. In some studies, an association has been noted between low weight gain in the first trimester and increased risk of spontaneous preterm delivery.

Variability in Weight Gain

The BMI-specific target ranges for pregnancy weight gain are relatively narrow, but a very wide range of gain actually occurs. In a California study, for example, only 50% of the mothers who had an uncomplicated pregnancy with a normal birthweight infant gained the recommended 12.5–18 kg, with the remainder gaining more or less. Since a substantial amount of the variation in weight gain is due to physiological variability and prepregnancy BMI, deviation from the recommended range may not necessarily be cause for concern. However, it is especially important to assess the dietary patterns and other behaviors of women whose weight gain is unexpectedly high or low. The IOM *Implementation Guide* for weight gain recommendations provides helpful information on the assessments that should be used.

Maternal Weight Gain and Birth Weight

Inadequate weight gain is associated with poor fetal growth even when the contribution of fetal weight and factors such as length of gestation are taken into consideration. Birth weight is an important determinant of child health and survival; low-birth-weight (<2.5 kg) infants are 40 times more likely to die in the neonatal period. Low weight-for-length at birth may be a risk factor for chronic disease in later life. It has been estimated that in women with a normal prepregnancy BMI, each kilogram of total pregnancy weight gain has an average effect on birth weight of 20 g. In California, women with pregnancy weight gains below recommendations had a 78% higher risk of the infant being born small, whereas women who gained in excess of recommendations were twice as likely to give birth to a large infant.

As noted previously, maternal BMI at conception is strongly inversely related to expected pregnancy weight gain. Nevertheless, heavier women still tend to deliver heavier infants (**Figure 2**) and thinner women tend to have smaller infants. In thinner women, birth weight is more strongly related to pregnancy weight gain. Thus, as is evident from

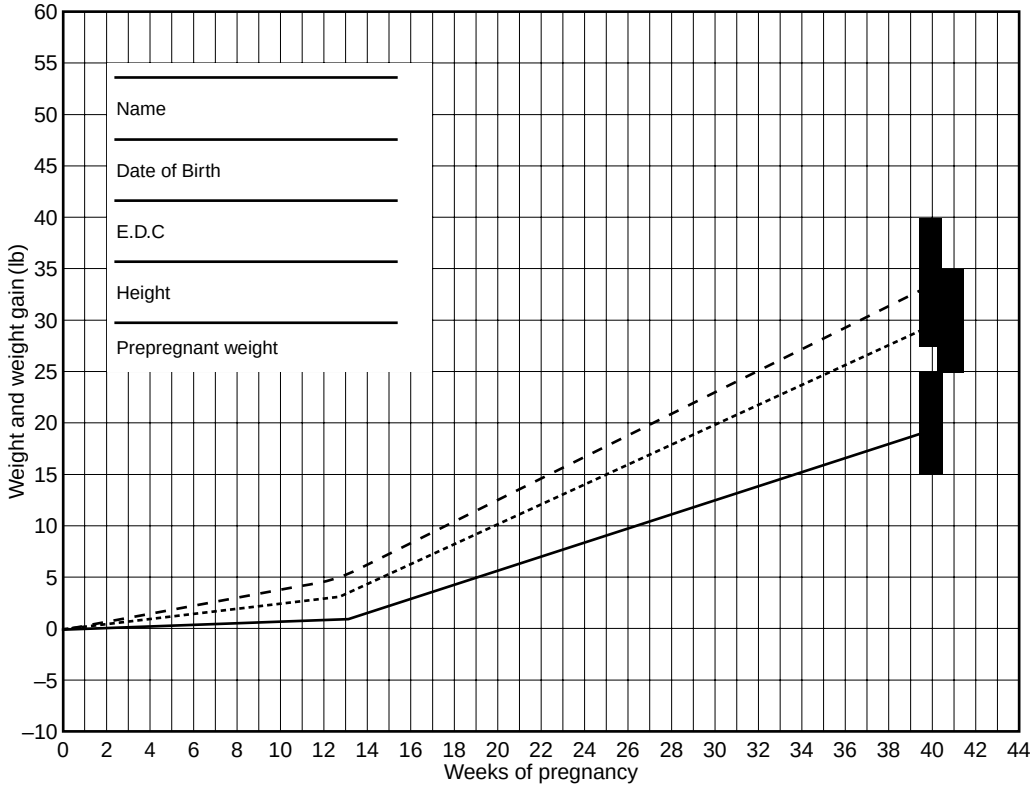

Figure 2 Recommended pregnancy weight gains based on body mass index (BMI) at conception. Dotted line, prepregnancy BMI <19.8 lbs; dashed line, prepregnancy BMI 19.8–26.0 lbs (normal); solid line, prepregnancy BMI >26.0 lbs. (Reproduced with permission from the Institute of Medicine, Committee on Nutritional Status during Pregnancy and Lactation (1992) *Nutrition during Pregnancy and Lactation. An Implementation Guide. Food and Nutrition Board*. Washington, DC: National Academy Press.)

Figure 2, the greatest risk of low birth weight is for thin women with a low pregnancy weight gain. It is crucial that thin women gain adequate amounts of weight. These associations are not explained by other risk factors associated with thinness, such as smoking.

Changes in Body Composition and Maternal Energy Status

It used to be assumed that maternal energy intake during pregnancy was the main determinant of the amount of weight gained. Although our knowledge of this relationship is still inadequate, newer information indicates that other maternal factors, and especially body composition, are more important predictors.

The weight gained during pregnancy can be roughly divided into the weight of the fetus, placenta, and amniotic fluid (a total of approximately 5 kg), maternal gain in the uterus, breasts, blood, and fluid (approximately 4 kg), and maternal fat. The latter component is the most variable, accounting for approximately 70% of the variability in pregnancy weight gain. Although average fat gain in different studies is approximately 2–5 kg, values for individual women range from a loss of several kilograms to a gain of approximately 12 kg. Even in a group of women with normal BMIs at conception, the range of fat gain was 0.5–9.5 kg. Fatter women at conception gained less fat during pregnancy, as would be expected from their lower weight gains. The greater fat gain of thinner women is a potential energy store for the fetus and would afford some protection against maternal malnutrition in late pregnancy—a situation that is not uncommon in some economically disadvantaged countries.

Maternal BMI at conception influences not only the amount of maternal weight and fat gained during pregnancy but also changes in maternal basal metabolic rate (BMR). In studies of well-nourished pregnant women, BMR has been reported to increase by approximately 20–30%. For undernourished women, however, the increment in BMR may be only 20% of that seen in those who are well nourished. In contrast, in a group of well-nourished Californian women weighing 55–116 kg, the BMR of those with higher BMIs was almost twice that of the thinnest women in the group.

Overall, it is clear that heavier women gain less weight and fat during pregnancy and have a larger increase in BMR. It has not been determined how these changes translate into energy requirements for women in the different BMI groups used to predict weight gains. Therefore, a single value for energy requirements is used for all pregnant women regardless of their BMI at conception.

Weight Gain for Special Population Groups

Adolescents

Well-nourished adolescents tend to gain at least as much, if not more, weight than adult women. The relationship between BMI, pregnancy weight gain, and birth weight is probably no different in this group, but to ensure adequate nutrition for those who are still growing, weight gain in the upper range of BMI-specific recommendations is advised. The effects of this recommendation on weight retention postpartum have not been evaluated adequately.

Short Women

Women who are less than 157 cm tall tend to give birth to infants who are large relative to maternal pelvic size, with a subsequently slightly greater risk of a more difficult delivery. These women are therefore advised to gain near the lower end of the weight gain range that is compatible with their BMI.

Ethnic Groups

Black women in the United States tend to gain less weight in pregnancy and to produce lower birthweight infants. The reasons for this are not known, but it could not be explained by differences in gestational age or other factors that were measured. Adequate weight gain in this group is known to be especially important for the prevention of fetal growth retardation. In one study, 18% of nonobese black women who gained less than the IOM recommendations gave birth to low-birth-weight infants compared to 10% whose gain was in the ideal range and 4% who gained more than the recommendations. In obese black women, the low birth weight prevalence was approximately six times higher than that for those who gained less than the recommendations.

Most surveys indicate that Hispanics seem to gain approximately the same amount of weight as Anglo women. In the 1980 National Natality Survey, Hispanic and non-Hispanic white women gained a similar amount of pregnancy weight, but the risk of low birth weight was twice as high in Hispanics. Surveillance of a predominantly Hispanic population indicated that half of the underweight women and one-third of the normal weight women gained the recommended amount of weight, whereas more

than half and three-fourths of overweight and obese women, respectively, had excessive gains. Inadequate weight gain during the third trimester was predictive of preterm birth. Underweight Hispanic women had nearly twice the risk of premature delivery.

The maternal weight gain recommendations have been evaluated in a group of Chinese women with good pregnancy outcomes ($N = 504$) to assess the need for an ethnic-specific recommendation for this group. The BMI categories were used at different levels. The recommended total pregnancy weight gain ranges according to BMI for Chinese women were 13–16.7 kg for BMI <19, 11–16.4 kg for BMI 19–23.5, and 7.1–14.4 kg for BMI >23.5. Women with weight gain in the lowest quartile had twice the risk of having a low-birth-weight infant, and those with excessive weight gain were in need of assisted delivery (either vaginal or cesarean delivery).

Substance Abusers

Cigarette smokers tend to gain less weight during pregnancy and to produce smaller infants. This effect is not explained by a lower food intake of smokers. Alcohol and drug use have similar effects. Simply gaining more weight during pregnancy will not compensate for the adverse effects of these practices on fetal outcome or pregnancy complications.

Multiple Births

Relatively few data are available from national surveys on which to base weight gain recommendations for women with twins. A weight gain of 15.9–20.5 kg or 0.7 kg per week in the second and third trimesters is usually consistent with a healthy pregnancy outcome for these women. No recommendations are available for women carrying more than two fetuses, but it is reasonable to expect that they will increase by 3.5 kg for each additional infant.

Obese and Overweight Women

Obesity during pregnancy is associated with higher morbidity for both the mother and the child. Higher prepregnancy weights have been shown to increase the risk of late (>28 weeks of gestation) fetal deaths. In addition, the prevalence of gestational hypertension increases 3-fold and there is a 3–4 times greater risk of gestational diabetes in obese pregnant women.

Exercising Women

Women who are physically fit at conception appear to be able to continue to exercise during pregnancy without harm to themselves or the fetuses, as long as the activity is not too strenuous or prolonged. In several studies it was observed that exercising women gained 2 or 3 kg less than those who were more sedentary.

Pregnancy Weight Gain and Postpartum Risk of Obesity

On average, well-nourished women retain relatively little weight approximately 1 year postpartum (approximately 0.5–1.5 kg). Delivery is followed by a rapid loss of weight in the subsequent 2 weeks due to fluid loss. This is followed by a slower rate of loss for the next 6 months, so a complete return to preconception weight should not be expected in less time than this. In general, weight still retained at 1 year postpartum is unlikely to be lost without lowering intake and/or increasing physical activity. If weight retention is substantial, it can add to the risk of obesity in the longer term, and obesity is a major public health concern in many countries.

The relatively low average weight retention postpartum obscures the fact that many women do retain an excessive amount of weight. Those who retain most are likely to have gained large amounts of weight during pregnancy. At 10–18 months postpartum, weight retention was 2.5 kg for women who gained more than the IOM recommendation compared to 0.7 kg for white women and 3.2 kg for black women who gained the advised amount. These large racial differences in weight retention have not been explained and certainly may be a risk factor for the higher prevalence of later obesity in this group.

Most women breast-feed their infants exclusively or partially for a relatively short time. There is little difference in weight loss between women who breast-feed and those who do not for periods up to 6 months postpartum. This is presumably due to the greater appetite and energy intake of women who are breast-feeding and perhaps to dieting on the part of non-breast-feeders. One study of women who breast-fed until 12 months postpartum did report a 2-kg greater weight loss compared to women who stopped breast feeding before 3 months. Even more weight was lost by those who breast-fed more often and gave longer feeds.

Women with a high BMI at conception tend to either lose or gain more weight postpartum than those with a normal BMI; approximately one-third end up weighing less than at conception, and one-third weigh substantially more. The reasons for the highly variable weight retention in this group are not known.

Although inadequate intake of nutrients during lactation can lead to maternal nutrient depletion and lower breast milk content of some nutrients and

especially vitamins, breast feeding women who choose to lose weight can do so by exercising and/or reasonable restriction of energy intake. Exercising by jogging, biking, and aerobics for 45 minutes, four or five times per week for 12 weeks did not affect well-nourished mothers' ability to lactate or influence their milk composition. However, it is possible that severe energy deficit in lactation, especially of thinner women, will reduce breast milk volume.

Impact of Supplementation

Numerous investigators have explored the benefits of energy and/or protein supplementation for pregnancy weight gain and other outcomes. However, relatively few trials have randomly assigned these supplements and used control diets. A statistical analysis was conducted of the 10 such studies that met this criterion in 1995. Most, but not all, of these studies were performed in developing countries. A 5-year controlled trial in The Gambia provided daily prenatal dietary supplements (two biscuits) that contained 4250 kJ energy and 22 g protein. This supplement increased pregnancy weight gain and birth weight during the hungry and harvest seasons. There was a significant but very small increase in head circumference and a significant reduction in perinatal mortality.

It was originally thought that timing of supplementation during later gestation would be most likely to increase birth weight. This hypothesis was supported by data from the Dutch famine, during which women in their third trimester had infants with the lowest birth weights. An increase in low birth weight prevalence was also observed in The Gambia when third-trimester gestation overlapped with the hungry season. Nonetheless, research suggests nutrition interventions initiated earlier in pregnancy will have the strongest effect on birth weight. There are enduring advantages to continued supplementation postpartum (during lactation) and into the ensuing pregnancy. A longitudinal study in Guatemala reported a significant increase (approximately 350 g) in birth weight in the second pregnancy when the mother was supplemented during the previous pregnancy and throughout subsequent lactation and the second pregnancy compared to those who were not supplemented during the prior pregnancy. Overall, it is appropriate for supplementation to begin as early in the pregnancy as possible so that both mother and fetus receive the maximum benefits for optimal health and development. However, this advice is tempered by concerns that supplementation of short Asian women may increase their offspring's risk of diabetes in later life.

Safe Diet for Pregnancy

S Stanner, British Nutrition Foundation, London, UK

A balanced diet that contains adequate amounts of all the nutrients needed by a mother and her growing fetus is essential for a healthy pregnancy. Pregnant women also need to be advised about how to reduce their risk of exposure to substances that may be toxic to the fetus during development (teratogenic) and therefore associated with the production of physical defects in the developing embryo (e.g., alcohol and excess vitamin A), as well as other dietary and lifestyle behaviors that could optimize maternal health and reduce the risk of health problems in their children.

The aim of this article is to describe evidence relating to food safety issues during pregnancy, including potential risks to the fetus as a result of prenatal exposure to food pathogens or toxic food components (e.g., heavy metals and dioxins) and the potentially harmful effects of high doses of alcohol, caffeine, and vitamin A.

Food-Borne Infections during Pregnancy

For many years it has been recognized that food-borne antenatal infections may cause death or serious fetal damage. Women may be more susceptible to the effects of infection during pregnancy because of immunological changes leading to suppression of the immune system (most commonly cell-mediated immunity), probably as a result of increases in pregnancy-associated sex steroids, such as oestradiol or progesterone. Among the most common causes of diarrhea during pregnancy are several food- or water-borne pathogens (bacteria, protozoa, or viruses), including salmonella species, *Helicobacter pylori*, *Shigella*, *Escherichia coli*, and cryptosporidium. Hepatitis A is also a food- or water-borne pathogen of concern, particularly in countries where sanitation is poor. In pregnant women, severe vomiting and diarrhea may negatively affect the availability of important nutrients to the growing fetus. For example, impairment of the supply of folate (or the synthetic form, folic acid) during a critical stage of development could increase the risk of associated neural tube defects, such as spina bifida.

Although rare, infection with *Listeria* or *Toxoplasma* during pregnancy is of particular concern because even in a mild form these infections can prove fatal. Listeriosis caused by the consumption of food containing the bacterium *Listeria monocytogenes* leads to flu-like symptoms, such as fever, muscle aches, and sometimes nausea or diarrhea. If the infection spreads to the nervous system, it may also cause headaches, stiff neck, confusion, loss of balance, or convulsions. The bacterium has been found in a variety of raw foods, including unpasteurized (raw) milk, uncooked meats, and vegetables, and in processed foods that become contaminated after processing, such as soft cheeses and cold cuts of meat. According to the Centers for Disease Control and Prevention, pregnant women in the United States are approximately 20 times more likely than other healthy adults to get listeriosis and approximately one-third of listeriosis cases occur during pregnancy. The fetus and newborn are at greatest risk of this infection and its consequences can be severe, leading to miscarriage, stillbirth, and premature delivery or to meningitis in the newborn infant. When infection occurs during pregnancy, antibiotics given promptly to the pregnant woman can often prevent infection of the fetus or newborn, and infants developing the infection can also be treated in the same way.

Toxoplasma gondii is a parasite that can be transmitted to the fetus in utero through transplacental transmission, causing stillbirth, miscarriage, or mental retardation. The parasite has been found in raw, inadequately cooked or cured meat, cat feces, and unwashed raw fruit and vegetables. It has also occasionally been reported in unpasteurized goat milk. In the United Kingdom, toxoplasmosis occurs in approximately 2.5–5.5 in 1000 pregnant women (1750–2850 cases per year), generally causing flu-like symptoms, swollen lymph glands, or muscle aches and pains that last for a few days to several weeks. If a pregnant woman contracts the infection, there is an approximately 30–40% chance of fetal infection (congenital toxoplasmosis). Infants who became infected before birth may develop growth problems, vision and hearing loss, hydrocephalus, brain damage, epilepsy, and other problems. In Europe, congenital toxoplasmosis affects between 1 and 10 in 10 000 newborns, of whom 1 or 2% develop learning difficulties or die and 4–27% develop permanent loss of vision. Both the incidence of placental transmission and the severity of congenital disease depend on gestational age at which maternal seroconversion occurs. Although transmission rates from mother to fetus tend to be low early in pregnancy, fetal disease severity is highest when the fetus is infected early in gestation. Mothers can be tested to determine if they have developed an antibody to the infection. Fetal testing may include ultrasound and testing of amniotic fluid or cord blood. When

Table 1 General guidelines on good hygienic practices in the home

The risk of food poisoning can be minimized by adopting the following practices:

Cleanliness in the kitchen

Keeping all work surfaces scrupulously clean
Washing cooking utensils after coming into contact with raw meat, poultry, or eggs to prevent cross-contamination
Using separate chopping boards for foods that are to be cooked (e.g., raw meat)
Keeping kitchen cloths clean; rinsing crockery in hot water, leaving it to dry, and then wiping it clean with a tea towel
Using kitchen towels to mop up spills rather than a dishcloth
Ensuring waste bins are covered and away from food and keeping pets away from the kitchen

Hygienic food handling

Washing all equipment and work surfaces before and after touching raw food
Washing all foods to be eaten raw thoroughly
Cooking meat thoroughly to an internal temperature of at least 70 °C
Keeping raw and cooked foods separated during preparation and storage
Cooling cooked foods as quickly as possible if they are to be stored in a refrigerator or freezer
Covering foods and not leaving them standing around in the kitchen
Storing food at the correct temperature (<4 °C in the refrigerator or <−18 °C in the freezer)
Storing raw meat, well covered, at the bottom of the refrigerator
Storing eggs in a refrigerator, if possible
Never overloading the refrigerator because this can reduce the circulation of cool air
Keeping foods for as short a time as possible (especially meat and fish) and following storage instructions (i.e., not using beyond the 'use by' or 'best before' date)
Thawing frozen meat thoroughly before cooking
Avoiding reheating food more than once
Reheating foods thoroughly (if this is done in a microwave, the standing times recommended by the manufacturer should be observed to ensure that food attains an even temperature before it is eaten)

Personal hygiene

Washing hands thoroughly before preparing food, after visiting the toilet, and after emptying the trash bin
Never licking fingers or utensils and putting them back into food
Washing hands after blowing or touching the nose while handling food
Keeping nails clean and hair out of food
Wearing a clean apron
Not handling food during periods of illness (e.g., heavy cold, sickness, or diarrhea)
Covering all cuts, spots, and pimples, particularly on the hands, with a waterproof dressing and replacing it often
Washing hands thoroughly after handling cat feces or using rubber gloves

toxoplasmosis is diagnosed during pregnancy, antibiotic treatment can often help reduce the severity of symptoms in the newborn.

The risk of food poisoning can be minimized by ensuring adequate attention to good hygienic practice when preparing, cooking, and storing foods (**Table 1**). Pregnant women should therefore be advised of the need for a high regard for food hygiene and personal cleanliness during this vulnerable time. In addition, there are a few foods that may pose a particular (although small) risk, which should be avoided during pregnancy where possible (**Table 2**).

Alcohol

Excessive Alcohol Consumption during Pregnancy

Chronic alcohol abuse may result in a wide spectrum of secondary disturbances of the absorption and utilisation of many nutrients, including glucose, amino acids, fat, sodium, and some vitamins (especially thiamin, vitamin B_{12}, and folate). The inhibition of folate absorption by alcohol is of particular concern because of the risk of neural tube defects associated with an inadequate supply of this vitamin to the fetus before conception and during the first trimester of pregnancy. Alcohol may also directly impair the placental transfer of nutrients essential for growth

Table 2 Foods to avoid during pregnancy to minimize the risk of food-borne infections

Unpasteurized milk and milk products
Undercooked meats, poultry, eggs, fish (e.g., smoked salmon or trout, sushi), and shellfish (e.g., oysters)
Cook-chill meals and ready-to-eat poultry, unless they have been reheated until very hot
Raw egg or uncooked eggs or foods made from them, such as homemade mayonnaise, soft-whip ice cream, cake mix, mousses, and hollandaise sauce (eggs should be cooked until both the white and yolk are solid)
Unwashed fruit and vegetables
All types of pâté (including vegetable)
Soft, mould-ripened, or blue-veined varieties of cheese (e.g., Brie, Camembert, and Stilton) (foods containing these cheeses that have been properly cooked will be safe to eat)

Table 3 Symptoms of fetal alcohol syndrome (FAS)[a]

Prenatal and postnatal growth retardation
Intrauterine growth retardation, including smaller than normal head circumference, continued growth below the 10th centile, and failure to thrive
Central nervous system involvement
Neurological abnormalities, developmental delay, intellectual impairment, brain malformation, and hearing and visual disabilities
Physical anomalies
Characteristic facial deformity, including short upturned nose, receding forehead, and chin, smaller than normal eye appertures, absent philtrum, and asymmetrical ears

[a]The diagnosis of FAS requires signs in all three of the categories.

(e.g., amino acids), which at critical phases of fetal organogenesis could compound any direct fetotoxic effects of ethanol or acetaldehyde.

Both alcohol and its primary metabolite, acetaldehyde, are teratogenic. Excessive alcohol consumption (>80 g of ethanol or 10 units per day) during pregnancy can result in a child being born with a specific combination of physical and mental disabilities known as fetal alcohol syndrome (FAS). Such fetuses usually survive until birth but are growth retarded and display a characteristic range of clinical features, principally craniofacial abnormalities and neurological damage (**Table 3**).

It is estimated that 1 in 1000 infants worldwide are affected with the full syndrome, whereas 3 in 1000 may exhibit only some features. The damage varies depending on the stage of development at which high doses of alcohol are encountered. The fetus is most vulnerable to organ damage from the time the umbilical cord begins to function (5 weeks) to the completion of organ development (11 weeks). Inhibition of growth and neurobehavioral development occurs in the second and third trimester. Although the facial features of FAS become more subtle with age, growth deficits and central nervous system impairment may be permanent.

FAS is only seen in infants born to women who are excessive drinkers, but it is not an inevitable result of heavy drinking in pregnancy, and even children born to mothers who are active alcoholics may not show it. This differing susceptibility of fetuses to the syndrome is thought to reflect the interplay of genetic factors, social deprivation, nutritional deficiencies, and tobacco and other drug abuse, along with alcohol consumption.

Binge Drinking and Social Alcohol Consumption during Pregnancy

Binge drinking, generally defined as the consumption of alcohol equivalent to five or more standard drinks per occasion, may be particularly harmful because it exposes the fetus to high blood alcohol concentrations over relatively short periods of time and may be associated with repeated withdrawal episodes. Animal studies have demonstrated binge-like exposure to alcohol to be as teratogeneic as long-term exposure throughout gestation, even if the overall alcohol amount consumed by binge drinking is less than intake during more continuous drinking patterns. However, the findings of human studies have been inconsistent, possibly because of the problems of recording binge drinking during pregnancy.

The question of whether moderate or occasional alcohol consumption is safe during pregnancy has been widely debated. Currently, there is little evidence that modest drinking (<10 units per week) has any harmful effects. Although there is general agreement that women should not drink alcohol excessively during pregnancy, a consensus opinion of a safe limit to drink has not been established at any stage of pregnancy, and advice differs between countries. Many studies are confounded by factors such as cigarette smoking, social class, drug abuse, very high levels of caffeine intake, and different cross-country categorization of 'light,' 'moderate,' and 'heavy' drinking. A review of the evidence by the Royal College of Obstetricians and Gynaecologists in the United Kingdom concluded that alcohol consumption of more than 3 drinks per week during the first trimester increases the risk of spontaneous abortion, and consumption of more than 15 units per week can have a small negative effect on birth weight. However, it found no conclusive evidence of adverse effects on fetal growth or IQ at levels of intake less than 15 units per week.

Despite the lack of evidence of detrimental effects on any outcome at low/moderate maternal alcohol consumption, many professional bodies err on the side of caution. The Royal College of Obstetricians and Gynaecologists has suggested that alcohol intake during pregnancy should not exceed 1 unit/day (**Table 4**). The UK Department of Health advises that women who are pregnant or planning a pregnancy should not consume more than 1 or 2 units once or twice a week, and they should avoid

Table 4 Definition of a unit of alcohol

1 unit of alcohol approximately equals 8 g of absolute alcohol, which is equivalent to
1/2 pint of ordinary-strength beer, lager, or cider
1/4 pint of strong beer or lager
1 small glass of wine
1 single measure of spirits
1 small glass of sherry

intoxication. Advice in North America (United States and Canada) is that women should not consume alcohol at all during pregnancy, and there are warnings on products and advertisements. Anecdotally, many pregnant women develop a spontaneous aversion to the taste and/or smell of alcoholic beverages and so may limit their intakes anyway.

Vitamin A

During the period of early development, the supply of preformed vitamin A (retinol) must be carefully managed to ensure that the developing fetus is exposed to neither too little nor too much of the nutrient because either condition can have teratogenic consequences. Adequate vitamin A is required for normal embryonic development, and an insufficient supply during pregnancy can result in malformations in the offspring as well as increased mortality and morbidity during early childhood from infectious diseases, such as diarrhea, measles, and respiratory infections.

Excess vitamin A intake has also been associated with teratogenicity in animals and may represent a risk in humans, particularly within the first trimester of pregnancy. Characteristic features include severe motor deficit malformations of the heart, thymus, face, jaw, ears, palate, and brain. Although adverse effects from dietary sources are very rare, events have occurred with the ingestion of high-dose supplements. Although epidemiological data suggest there is no danger when consumption is less than 3000 RE per day, a threshold for any teratologic effects remains to be established.

In Western countries, where vitamin A deficiency is rare, women who are or might become pregnant are advised against taking vitamin A supplements (including cod liver oil), except on the advice of a doctor or antenatal clinic, and not to consume liver or liver products. In developing countries, vitamin A supplementation programs have resulted in decreased pregnancy-related mortality and lower rates of childhood morbidity and mortality, with benefits clearly outweighing any potential risks. The initiation of such programs in any population should be carefully examined in each case according to the risk–benefit ratio, with the final decision taking into account the estimated vitamin A status of the woman, the availability of vitamin A-rich foods, and whether supplementation can be supervised.

Fish and Pregnancy

Fish is a good source of protein, vitamins, and minerals. In particular, oil-rich fish (e.g., mackerel, salmon, kippers, herrings, trout, sardines, and fresh tuna) contain the long-chain n-3 fatty acids eciosapentenoic acid (EPA) and docosahexenoic acid (DHA), which may confer many health benefits to the developing fetus. For example, DHA is required for nerve and retinal development, and eating oily fish has been found to have a slight beneficial effect on birth weight and length of gestation. However, fish consumption has been positively associated with intakes of certain contaminants, namely mercury, dioxins, and polychlorinated biphenyls (PCBs), and concern has been expressed about the consequences of prenatal exposure to these toxic chemicals on the risk of brain and nervous system abnormalities.

Mercury

Mercury is a metal that is present in the environment from natural and man-made sources (e.g., coal-burning or other industrial pollution). It is converted primarily by microorganisms to a more toxic form, methylmercury, which is bioaccumulated in the aquatic food chain, reaching it highest levels in large, longer living predatory fish. Among humans, the sole source of exposure to methylmercury is the consumption of fish and sea mammals.

Methylmercury is neurotoxic and accumulates in the brain and central nervous system. It inhibits the division and migration of neuronal cells and disrupts the cytoarchitecture of the developing brain. Although a mother may show no signs of neurotoxicity, the developing fetus may be damaged following exposure to methylmercury. The concentration of methylmercury in fetal brain has been shown to be 5–7 times higher than that in maternal blood, and it has been estimated that the fetus is 5–10 times more sensitive to methylmercury exposure than an adult, although the reason for this is unknown.

Disasters in Minamata, Japan, in the 1950s and in Iraq in 1971–1972 demonstrated that acute prenatal exposure may result in severe mental retardation, cerebral palsy, blindness, and deafness. However, whether exposure to lower chronic doses, which may occur if pregnant women consume large amounts of fish, can also lead to adverse neurodevelopmental consequences is less certain. Large, long-term prospective epidemiological studies of high fish-eating populations have not found a consistent pattern of association between exposure and neuropsychological outcomes. Although subtle neuropsychological changes were reported in a study of children in the Faroe Islands study, where exposure was mainly from whale consumption, a similar study in the Seychelles found no adverse effects from fish consumption alone.

The Joint FAO/WHO Committee on Food Additives revised its safety guideline for weekly intake of

methylmercury, known as the provisional tolerable weekly intake (PTWI), to 1.6 μg/kg body weight per week. The UK government's independent expert Committee on Toxicity of Chemicals in Food, Consumer Products, and the Environment (COT) has applied a lower PTWI limit of 0.7 μg/kg body weight per week to women who are pregnant or those intending to become pregnant and to mothers who are breast feeding.

Any public health recommendations to pregnant women regarding fish consumption must recognize the important role that it plays as part of a healthy, balanced diet. Most fish contain trace amounts of methylmercury, but high concentrations of the metal have only been found in large, predatory fish, such as shark, marlin, and swordfish (**Table 5**). If a pregnant or breast feeding mother were to consume one portion of these predatory fish, she would exceed the lower PTWI set by COT and the EPA by 400%. Therefore, as a precaution, pregnant women, breast feeding mothers, and those who intend to become pregnant within the next 12 months are advised to avoid consumption of these types of fish (in the United States, this also includes king mackerel and tilefish). Some samples of tuna have also been found to have higher levels than other species. In the United Kingdom, pregnant women (and those who may become pregnant) are advised to restrict their weekly intake to two 140-g portions of fresh tuna or four 140-g portions of canned tuna.

Dioxins and Polychlorinated Biphenyls

Fish can also contain other organic pollutants, such as PCBs and dioxins. Whereas mercury accumulates in the muscles of larger predatory fish, PCBs and dioxins are found in the fatty tissues of fish. Most human exposure to PCBs and dioxins comes from dietary sources because they accumulate in the lipid fractions of meat, fish, milk and milk products, eggs, grains, and oils.

Table 5 Concentrations of methylmercury in surveyed fish in the United Kingdom

Fish	*Methylmercury (mg/kg)*
Shark	1.52
Swordfish	1.35
Marlin	1.09
Fresh tuna	0.40
Canned tuna	0.19
Herring	0.09
Pink shrimps	0.09
Cod	0.07
Plaice	0.06
Mackerel	0.05
Haddock	0.04
Scallops	0.01

PCBs and dioxins have been linked with increased rates of some cancers in studies of individuals exposed to high amounts through either vocational exposure or accidental environmental contamination. Prenatal exposure to large amounts of these pollutants (e.g., through contaminated fish) has been associated with neurobehavioral alterations in newborn children. Some studies have also suggested that exposure to smaller quantities of PCBs and dioxins in utero may lead to more subtle cognitive and motor developmental delays, although a favorable home environment appears to counteract any effect. However, the difficulty of separating the effects of PCBs and dioxins from potentially confounding factors (e.g., exposure to other contaminants, breast-feeding, smoking, and maternal education) makes it difficult to reach firm conclusions. Further research is also needed to ascertain whether any cognitive changes are temporary or persist into later life.

The potency of dioxins is expressed as toxic equivalents (TEQs), which have been internationally accepted. In the United Kingdom, the tolerable daily intake (TDI) recommended by COT is 2 pg TEQ/kg body weight, which is in line with recommendations of other international and European expert committees. In common with the United States and the European Union, approximately one-third of the UK population may exceed the TDI in their daily diet. The TEQ, therefore, provides a target to reduce dioxins and PCBs in the environment internationally. Since the 1960s, following the prohibition of many dioxins and PCBs by governments, concentrations have been declining in breast milk, which is commonly used to determine exposure. For example, between 1982 and 1997, consumption of dioxins and PCBs in the United Kingdom decreased by 75%, and due to strict controls concerning production, use, and disposal of PCBs and dioxins, it is anticipated that intakes will decrease further.

Caffeine

Caffeine is a methylated xanthine that acts as a mild central nervous system stimulant. It is found in a number of foods and beverages (**Table 6**), the main sources being coffee, tea, cocoa, chocolate, and soft drinks, as well as in prescription and nonprescription medicines, such as diet pills, headache treatments, and cold and flu medicines. Tea and cocoa also contain significant quantities of theophylline and theobromine, which are caffeine derivatives that have not been as widely researched.

Once caffeine and its derivatives are consumed, they are absorbed into the blood and body tissues and can cross the placenta to the fetus. The body

Table 6 Caffeine content of beverages and foods

Beverage or food	*Content (mg)*
1 cup (190 ml) of instant coffee	~75
1 cup (190 ml) of brewed coffee (filter or percolated)	~100–115
1 cup (190 ml) of decaffeinated coffee (brewed or instant)	~4
1 cup (190 ml) of tea	~50
1 cup (200 ml, using manufacturers' instructions) of drinking chocolate	1.1–8.2
250 ml serving of energy drinks (containing either caffeine or guarana)	28–87
330 ml serving of cola (regular and diet)	11–70
50-g bar of chocolate	5.5–35.5

metabolizes caffeine more slowly during pregnancy, especially in the last few months; the half-life of caffeine increases from approximately 5 to 18 h during the second and third trimesters. Blood caffeine concentrations are therefore raised during pregnancy with no change in intake. In contrast, smoking is known to increase caffeine metabolism appreciably.

Although very high doses of caffeine are teratogenic in animals, no link between consumption during pregnancy and birth defects has been demonstrated in humans. However, high maternal caffeine intakes (>500 mg/day) have been associated with increased fetal heart rate and newborn cardiac arrhythmias. Although there is no reliable evidence linking caffeine intake during pregnancy with sudden infant death syndrome or preterm birth, a number of studies have reported significantly increased risks of spontaneous abortion and low birth weight with caffeine intakes greater than 300 mg/day and some have also demonstrated increased risks at lower intakes (150 mg and higher). However, whether these associations are causal remains to be established because the effects of confounding factors such as smoking and alcohol consumption on these outcomes could not be determined. Concern has also been expressed about the reliability of using self-reported caffeine intake in many of these studies.

The lack of consistency between studies, particularly in relation to the dose at which an effect is reported, makes it very difficult to identify a threshold level of caffeine intake that presents an increased risk during pregnancy. The available data suggest that a moderate level of caffeine consumption is safe, although there may be concerns at high levels of intake. The Food Standards Agency in the United Kingdom advises pregnant women to moderate their caffeine intake to no more than 300 mg/day. This is equivalent to approximately three or four cups of coffee (**Table 7**). This figure is endorsed by the European Union Scientific Committee on Foodstuffs, which states that "up to 300 mg/day appear to be safe." In practice, many pregnant women reduce their coffee intake as a result of a spontaneous aversion to the taste and smell, particularly in early pregnancy.

Table 7 Approximate equivalent of 300 mg of caffeine

4 average cups or 3 average-size mugs of instant coffee
3 average cups of brewed coffee
6 average cups of tea
8 cans of regular cola drinks
4 cans of 'energy' drinks
400 g (8 standard 50-g bars) of milk chocolate

Avoiding Foods to Prevent Allergy

Food allergy has been estimated to affect approximately 1 or 2% of infants and young children in Western Europe and is assumed to be increasing in line with other forms of atopic disease, although evidence to support this is limited. Some food allergies (e.g., peanut allergies) can persist into adulthood and in severe cases can be life threatening. Most confirmed food allergies are associated with a relatively limited range of foods, including cow milk, eggs, tree nuts, peanuts, soybeans, wheat, fish, and shellfish.

The development of food allergy depends on several factors, including genetic factors and early exposure to allergenic proteins in the diet, food protein uptake and handling, and the development of tolerance. However, it remains uncertain whether sensitization occurs in utero and, if so, whether this occurrence is restricted to specific stages of gestation. There is little evidence to support any benefit of avoiding specific foods during pregnancy to reduce the risk of allergic disease in a genetically susceptible child. Indeed, such a strategy may be counterproductive because it has been suggested that exposure to foreign proteins that cross the placenta is important to establish a normal immune response that enables the infant to develop normal tolerance to the many foreign proteins in the environment. Because restrictive diets may limit the supply of essential nutrients, these should only be practiced under medical supervision. Inappropriate and unnecessary exclusion of foods could prevent both mother and infant from obtaining the nutrients they need, resulting in significantly reduced weight gain and a tendency toward lower birth weights. Nevertheless, because of the severity of reactions experienced from peanut allergy, COT advises against the consumption of peanuts and foods containing peanuts during pregnancy where there is a strong family history of atopic disease.

Food Additives and Herbal Supplements

Pregnant women often express concern about food additives. However, all additives have to be approved as safe for almost all but a small proportion of the population who may experience rare reactions to them before they can be used in foods. The presence of an 'E' number demonstrates that it has passed safety tests and been approved for use by the European Community. In the United Kingdom, COT sets an Acceptable Daily Intake for each additive, which is the amount that can be eaten daily with no risk to health. This may limit the amount of an additive used or restrict its use to certain food products. Even when an additive has been approved, new research is constantly reviewed and approval for any additive will be withdrawn if doubt is raised about its safety.

A number of herbal supplements and preparations may be used during pregnancy, most commonly to relieve gastrointestinal symptoms. Although the use of many herbal remedies is safe during pregnancy, this cannot be assumed simply because a product is described as 'natural.' Many plants, trees, fungi, and algae can be poisonous to humans, and many pharmaceuticals have been developed or derived from these sources because of the powerful compounds they contain. Very few randomized, clinical trials have examined the safety and efficacy of alternative therapies during pregnancy, and women should be warned to use any medicine, including herbal remedies, with care during pregnancy and with the advice of a doctor or pharmacist.

Summary

In addition to the consumption of a healthy, balanced diet, there are food safety precautions that need to be followed to ensure a safe pregnancy. A summary of the evidence and current advice described in this article is given in **Table 8**.

Table 8 Advice regarding dietary habits and food safe during pregnancy

- Pregnant women should pay careful attention to food and personal hygiene so as not to expose themselves to any risk of food poisoning, which is not only very unpleasant but also potentially very dangerous to the unborn child in some cases (e.g., with listeriosis and toxoplasmosis).
- Foods that have been linked with the bacteria *Listeria monocytogenese* should be avoided. These include pâtés and mold-ripened, soft cheeses (e.g., brie and camembert). Pre-prepared foods should be heated until they are piping hot, and fruit and vegetables should be washed well, especially if they are to be eaten raw.
- To reduce the risk of toxoplasmosis, pregnant women should avoid eating raw or uncooked meat, unpasteurized goat's milk or goat's cheese, or unwashed fruit and vegetables. After handling raw meat, chopping boards, utensils, and hands should be washed thoroughly. When gardening or emptying cat litter trays, rubber gloves should always be worn.
- Undercooked foods (e.g., meat, poultry, and eggs), foods containing raw egg (e.g., mayonnaise and soft-whip ice cream), and raw fish (e.g., sushi and smoked salmon) should also be avoided.
- Drinking alcohol heavily throughout pregnancy (>80 g or 10 units per day) is linked with fetal alcohol syndrome. Modest drinking (<10 units per week) does not appear to have harmful effects, but most professional bodies err on the side of caution and recommend that pregnant women abstain from drinking alcohol or limit their consumption to no more than 1 or 2 units per day.
- Supplements containing high doses of preformed vitamin A and foods containing large amounts of this vitamin (liver and liver products) are best avoided in countries where intake from a well-balanced diet should be sufficient. In areas of endemic vitamin A deficiency, supplementation can reduce pregnancy-related mortality and reduce rates of childhood morbidity and mortality. However, most experts agree that preformed vitamin A supplements in doses of more than 3000 RE should not be taken by women who may become pregnant. β-Carotene is safe for pregnant women.
- Although it is not clear if intakes of mercury and other contaminants, such as PCBs and dioxins, at levels that can be obtained from eating fish can influence children's neurological development, government organizations in a number of countries recommend that pregnant women avoid species of fish that have been found to contain high levels of these substances, including shark, marlin, swordfish, tilefish, and king mackerel. Some countries have also recommended limiting tuna intake (e.g., in the United Kingdom pregnant women are encouraged to consume no more than two tuna steaks or four medium-size cans of tuna per week).
- Consumption of caffeinated beverages (e.g., coffee, tea, and colas) has been associated with miscarriage and low birth weight, although many studies are confounded by high alcohol intakes, smoking, and drug and other substance abuse. In the United Kingdom, the Food Standards Agency recommends that pregnant women limit their caffeine intake to 300 mg/day.
- Avoiding specific foods during pregnancy is unlikely to reduce the risk of allergic disease in a susceptible child. However, where there is a strong family history of atopic disease, the avoidance of foods that may cause severe reactions (e.g., peanuts) may be advised. In the United Kingdom, the Food Standards Agency recommends that where a mother, father, or sibling suffers from allergic disease, peanuts or foods containing peanuts should be avoided during pregnancy and breast feeding and that infants should not given these foods until the age of 3 years.
- Additives permitted for use in foods undergo stringent safety tests over a long period of time before being approved and are safe for consumption during pregnancy by all but a small proportion of women who experience rare reactions to specific additives.
- Many pregnant women who would not consider taking over-the-counter medications often view herbal products as a safe and natural alternative. However, very few randomized, clinical trials have examined the safety and efficacy of alternative therapies during pregnancy. Pregnant women should be advised to seek advice from a doctor or pharmacist before taking any medication, including herbal supplements.

Dietary Guidelines and Safe Supplement Use

L H Allen, J M Graham and J E Sabel,
University of California at Davis, Davis, CA, USA

During pregnancy there is an increased demand for nutrients for maternal metabolism and growth of fetal and maternal tissues. Nutritional goals during pregnancy include consumption of a high-quality, micronutrient-dense diet and the avoidance of, or a reduction in, intake of substances that are potentially harmful to the fetus or pregnant woman. The majority of additional nutrients required for pregnancy can be obtained by appropriate selection of foods. However, many women consume vitamin–mineral supplements, medications, and other forms of supplements during pregnancy. It is important to understand the risks, as well as the benefits, of these nondietary substances.

Dietary Guidelines for Pregnancy

In general, pregnant women should follow the dietary advice provided by reputable national or professional organizations for all members of the public. For example, the Dietary Guidelines of the US Department of Agriculture include advice to eat a variety of foods; maintain or improve your weight; and choose a diet low in fat, saturated fat, and cholesterol and moderate in sugars, salt, and sodium. However, advice to control or maintain body weight, or to consume alcohol in moderation if it is consumed, is inappropriate in pregnancy. Specific guidelines for pregnant women are available and provide more specific information on recommended nutrient intakes, weight gain, the need for vitamin mineral supplements, activity, and the use of alcohol and other substances. Examples include a position paper by the American Dietetic Association and guidelines from the March of Dimes.

Most of the increased requirements for nutrients during pregnancy can be met primarily by an adequate dietary pattern, with a few important changes that are listed in **Table 1**. Milk products should be increased to 4 C (cups) (1 l) of milk, which will increase energy, protein, calcium, and vitamin D intake. For women who are lactose intolerant, dairy products that contain digested lactose should be used. Cheese and yogurt have less lactose compared to milk and can be substituted. Whole grain breads and cereals, leafy green and yellow

Table 1 Daily food pattern for pregnancy

Food	*Servings/day*	*Serving size*
Milk, yogurt, and cheese	2 or 3	1 cup milk or yogurt 1.5 oz. natural cheese 2 oz. processed cheese
Meat, poultry, fish, eggs, dry beans, and nuts	2 (6 oz.)	2–3 oz. cooked lean meat, poultry, or fish 1 oz. = 1 egg 0.5 cup cooked dried beans 0.5 cup tofu 0.3 cup nuts 2 T. peanut butter
Vegetables (includes dark green and yellow vegetables)	4	1 cup raw leafy vegetables 0.5 cup other vegetables, raw/cooked 0.75 cup of vegetable juice
Fruits, fresh or canned	3	1 medium apple, banana 0.5 cup chopped fruit 0.75 cup fruit juice
Breads and cereals	9	1 slice bread 1 cup ready-to-eat cereal 0.5 cup cooked cereal, rice, or pasta

From Kaiser LL and Allen L (2002) Position of the American Dietetic Association: Nutrition and lifestyle for a healthy pregnancy outcome. *Journal of the American Dietetic Association* **102**: 1479–1490.

vegetables, and fresh fruits should be consumed daily to provide additional vitamins, minerals, and fiber. Approximately 10 glasses (2.3 l) of fluids per day (as total beverages, including milk and juices) should be consumed to prevent intestinal stasis, which can occur from reduced activity and the pressure of the enlarging uterus. There is no evidence that suggests the need for additional electrolytes (sodium, chloride, and potassium) during pregnancy. However, important considerations that may influence electrolyte balance include extreme loss through sweat and use of diuretics.

Energy

Energy requirements increase during pregnancy, depending on prepregnancy weight, amount and composition of weight gain, stage of pregnancy, and activity level of the mother. The recommended dietary allowance for energy is increased by 300 kcal (1.25 MJ) per day for adults and 500 kcal per day for young adolescents (<14 years) during the second and third trimesters. A total of 2500–2700 kcal/day should meet the energy needs of most pregnant women. This increase should be sufficient as long as body reserves are not depleted at the onset of pregnancy.

Observed energy intakes tend to be lower than recommended, but it should be recognized that as long as the amount and rate of weight gain are within the desirable range, there is a wide range of acceptable energy intakes. Energy expended during physical activity tends to be the largest variable in estimating energy expenditure. Because individuals vary considerably in their level and intensity of physical activity, the best advice is for pregnant women to eat enough to satisfy their physiologic appetite and support an appropriate rate of weight gain. Dieting during pregnancy is not recommended because low energy intakes can result in ketosis, which may pose a risk for the developing fetus, as well as inadequate consumption of other nutrients.

Protein

Additional protein is necessary to support the synthesis of maternal and fetal tissue, with greatest demands during the second and third trimesters when requirements are 20–28 g per day more than nonpregnant requirements. Women in industrialized countries generally consume more than the recommended intake of protein during pregnancy. Studies of protein deficiency during pregnancy are limited in number and often confounded by low energy intakes. However, the few studies that provided either extra energy or energy plus protein to undernourished women suggest that limited energy intakes are more unfavorable for pregnancy outcome than limited protein intakes. High-protein supplements are not recommended during pregnancy because they have been associated with lower birth weight and increased mortality and prematurity. However, when supplements provide protein-to-energy ratios comparable to those found in usual diets, higher rates of prematurity are not observed. Vegetarian women can substitute meat, poultry, fish, and eggs by additional servings of beans, tofu, nuts, and soymilk (preferably fortified with calcium

and vitamin D). Vitamin B_{12} will also need to be consumed as supplements to achieve the recommended intake of 2.6 μg/day.

Obesity in Pregnancy

Obesity is one of the most common nutritional problems complicating pregnancy in the Western world. Complications resulting from obesity include macrosomia in the infant (even when pregnancy weight gain is inadequate) and increased incidence of diabetes mellitus, hypertension, preeclampsia, and multiple gestation. More recently, it has become apparent that obese women are more likely than average weight women to produce an infant with spina bifida and several types of birth defects, and simply being overweight increases the risk of birth anomalies (although to a lesser extent than obesity). Maternal obesity is an important risk factor for failure to diagnose fetal abnormalities, particularly neural tube and cardiac defects, because ultrasonographic visualization of fetal anatomy is impaired. Obese women are also more likely to have delayed labor and repeated cesarean sections.

Dietary recommendations for obese women should consider optimal maternal weight gain. Obese or overweight women do not need to gain as much weight during pregnancy as normal weight or thin women, and in fact their weight gain is usually lower without intentional dietary restriction. In part this is explained by their larger increase in basal metabolic rate during pregnancy compared to women with normal or low fatness. However, weight gains of 6.8–11.4 kg are recommended to at least account for the weight of the fetus and maternal support tissues. Because obese women may be resistant to the idea of gaining further weight, special attention may be required to explain that pregnancy is not a time for weight loss. Some practical guidelines for obese pregnant women are listed in **Table 2**.

Table 2 Practical guidelines for overweight or obese mothers

1. Weight loss is not advised during pregnancy.
2. For women with a BMI of 26.1–29.0, a weight gain of 7–11.5 kg and a normal dietary intake for pregnancy should be recommended.
3. For women with a BMI of >29.0, the mother should be advised to gain at least 7 kg during pregnancy.
4. Nutritional counseling should focus on lowering intake of energy-dense foods that are low in other nutrients.
5. Obese women should be made aware of the increased risk for glucose intolerance. Screening for gestational diabetes should occur at the first prenatal visit, with repeated testing at 28 weeks of gestation if negative.
6. Frequent blood pressure monitoring with a cuff of the appropriate size is essential. If the patient has chronic hypertension, appropriate medication and a reduced sodium diet are indicated.
7. Weight loss should be encouraged after delivery.

Modified from Wolfe HM and Gross TL (1994) Obesity in pregnancy. *Clinical Obstetrics and Gynecology* **37**: 596–604.

Alcohol and Caffeine

There is abundant evidence that associates heavy alcohol consumption with teratogenicity, although the mechanisms by which this occurs are not completely understood. Heavy drinking during pregnancy increases the risk of prenatal and postnatal growth retardation, mental retardation, major birth defects, and learning disabilities such as those seen in fetal alcohol syndrome. The impacts of either binge drinking or moderate alcohol consumption, defined as no more than one drink per day, have not been satisfactorily evaluated and therefore the recommendation is that women abstain from consuming any alcohol during pregnancy.

Caffeine readily crosses the placenta to the fetus, where it may affect fetal heart rate and breathing. A meta-analysis of 12 studies found an increase in spontaneous abortions, risk of miscarriages, and lower birth weight in heavy coffee drinkers, although possible effects of smoking and alcohol could not be separated. No studies in humans have shown a link between caffeine consumption and birth defects, although massive doses of caffeine given to mice are teratogenic. Reports of an association between prenatal caffeine consumption and motor development in humans have been conflicting. Because it has not been proven without a doubt that caffeine does not cause birth defects and other problems in humans, the recommendation is that all pregnant and lactating women should consume no more than 300 mg caffeine per day. The caffeine content is approximately 85 mg/150 ml cup of percolated coffee, 60 mg/15 ml of instant coffee, 40 mg/oz. of espresso, 30 mg/150 ml tea, and 36 mg/12 oz. (350 ml) cola beverages.

Artificial Sweeteners

High doses of saccharin are weakly carcinogenic in rats so it is recommended that saccharin be consumed in no more than moderate amounts during pregnancy. Safety concerns about the use of aspartame are limited to pregnant women with phenylketonuria; individuals with this condition should only consume this sweetener in amounts compatible with their need to strictly monitor their intake of phenylalanine. Safety of acesulfame-K during pregnancy has been confirmed in animal studies.

Nutrient Supplements

Many pregnant women have special circumstances that prevent them from consuming an adequate diet. These include lactose intolerance, substance abuse, being an adolescent or a strict vegetarian, and having multiple fetuses. For these women, a multivitamin–mineral supplement may have positive benefits, including a reduced risk of some developmental defects, improvements in immune function, and a reduction in the onset and/or progression of some cancers. Anemia is common during pregnancy and justifies treatment with iron supplements. However, some micronutrients commonly taken as supplements are potentially harmful to the developing fetus or, less often, to the pregnant woman, especially when consumed in relatively large amounts.

Vitamin A

Although poor maternal vitamin A status is associated with preterm birth, intrauterine growth retardation, low birth weight, and increased maternal infection in developing regions of the world, vitamin A deficiency is quite rare in industrialized countries due the higher intake of the preformed vitamin (retinol). An increase of 50 μg/day for the entire pregnancy period is added to the EAR for nonpregnant adolescent girls and women, based on accumulation of vitamin A in the liver of the fetus. Excessive preformed vitamin A (>3000 μg RAE) should be avoided shortly before or during pregnancy, especially in the early months, because of its potential teratogenicity, so the upper limit for vitamin A intake in pregnancy is set at 3000 μg RAE/day for all women of childbearing age. An alternative dose schedule is up to 8500 RAE weekly during pregnancy. Fetal vitamin A toxicity and birth defects have also occurred from ingestion of isotretinoin and etrentinate, drugs used for treatment of severe cystic acne. High intakes of βcarotene (a precursor of vitamin A) do not have the same teratogenic effects.

Vitamin D

Because of its importance in increasing calcium retention, recommended intakes of vitamin D are doubled during pregnancy. Vitamin D deficiency during pregnancy causes disorders of calcium metabolism, including neonatal hypocalcemia and tetany, hypoplasia of infants' tooth enamel, and maternal osteomalacia. Because the prevalence of vitamin D deficiency during pregnancy is high during the winter months at northern latitudes in regions such as Europe, the United States, and Canada, and Japan, vitamin D supplements may be necessary for women who live in these regions or who have little exposure to sunlight. A national survey in the United States conducted in the 1990s revealed that approximately 40% of African American women in the southeastern region had low blood levels of 25-hydroxyvitamin D, and that not drinking vitamin D-fortified milk was a risk factor for deficiency. In the absence of vitamin D fortification or supplementation, infants in Paris, for example, have higher plasma levels of parathyroid hormone and other indications of vitamin D deficiency if they are born soon after the winter months. Vitamin D supplements reversed the indications of vitamin D deficiency. High maternal intakes of vitamin D are toxic and were implicated as the cause of a syndrome that included mental and physical growth retardation and hypercalcemia in British infants between 1953 and 1957. Excessive amounts of vitamin D taken during gestation have also caused aortic stenosis and abnormal skull development in infants. The upper limit for vitamin D in pregnancy is 50 μg per day, the same as for nonpregnant women.

Folic Acid and Vitamin B_{12}

There is a substantial increase in folate requirements during pregnancy, from 400 μg Dietary Folate Equivalents in the nonpregnant state to 600 μg per day, because of increased erythropoiesis and fetal–placental growth. Increased folate intakes throughout childbearing age are recommended to prevent neural tube defects such as spina bifida and anencephaly, the most common birth defects, and to lower the risk of abruptio placenta. To be effective for preventing neural tube defects in women at risk for producing an infant with this condition, increased folate intakes are needed preconception and early in pregnancy. The neural tube closes by 28 days of gestation, which is before many women realize that they are pregnant. It is for this reason that increased folate intakes are recommended throughout the childbearing years. In the United States and Canada, fortification of flour with folic acid in recent years has greatly increased folate intakes and improved status in the population; prior to fortification, typical intakes of folate were only about half of the recommended amount. No adverse effects were reported in recent studies in which pregnant women consumed up to 4 mg of folic acid per day during pregnancy.

The RDA for vitamin B_{12} increases slightly during pregnancy to 2.6 μg/day. Vitamin B_{12} supplements are definitely required by pregnant women who are strict vegetarians; the vitamin is found only in animal products and the usefulness of the form of the vitamin found in algae and bacteria is not clear. An

adequate intake of the vitamin during pregnancy is at least as important as the woman's vitamin B_{12} status at conception because the recently absorbed vitamin is more readily transported to the fetus than is the vitamin in maternal liver stores. Homocysteinemia is emerging as a common risk factor for several abnormal pregnancy outcomes, especially for preeclampsia, birth defects, and low birth weight, although there has been little research on whether maternal vitamin B_{12} deficiency causes these problems. Infants born to women with low vitamin B_{12} intakes are at high risk of growth failure and neurobehavioral problems that emerge when the infant is a few months old and may be permanent. Although supplements containing the recommended dietary intake of the vitamin are probably adequate for pregnancy, no adverse effects of consuming higher amounts have been reported.

Vitamin C

Low plasma vitamin C concentrations have been associated with preeclampsia and premature rupture of the membranes. There has been some concern about fetal vitamin C dependency induced by excessive maternal vitamin C intakes, but this is based on only one anecdotal report. Requirements for the vitamin in pregnancy increase to 80 mg/day for adolescents and 85 mg/day for adult women, an amount estimated to provide sufficient quantities for the fetus. Those who are heavy smokers (>20 cigarettes/day) may need twice the RDA for this vitamin.

Vitamin K

Usual diets provide adequate amounts of vitamin K for pregnant women. Newborn infants are routinely given a supplement of vitamin K by intramuscular injection because exclusively breast-fed infants are at risk of developing fatal intracranial hemorrhage secondary to vitamin K deficiency. This practice is quite safe.

Iron

Demands for iron are increased by approximately 700–800 mg during pregnancy and most of this is needed during the last two trimesters. Because the risk of becoming anemic is greater during pregnancy and there is an increased risk of a compromised pregnancy outcome for anemic women (including lower birth weight and less neonatal iron stores), most recommendations in the United States advise all pregnant women with a well-balanced diet take a supplement of 30 mg of ferrous iron daily starting at their first prenatal visit. If iron deficiency anemia is detected by routine testing, the recommendation is that 60–120 mg of ferrous iron be given in divided doses throughout the day. The World Health Organization recommends 60 mg/day throughout pregnancy (plus 400 μg folic acid) because of the higher prevalence of iron deficiency anemia in most low-income countries throughout the world.

Gastrointestinal side effects, mainly heartburn, nausea, upper abdominal discomfort, diarrhea, and constipation, increase with high iron doses and contribute to poor compliance with taking daily iron supplements. Supplements of 15 mg of zinc and 2 mg of copper daily are also recommended for pregnant women taking >30 mg iron per day because iron can interfere with the absorption of other minerals if given as a supplement without food. It is therefore important not to exceed recommended intakes of iron during pregnancy. Research suggests that it may be as effective to consume the recommended intakes once per week as it is to take them daily because daily iron supplements gradually block the absorption of subsequent doses.

Zinc

Typically, zinc intakes are below recommended amounts for pregnancy even in industrialized countries. In populations in which zinc deficiency is common, the prevalence of malformations and low birth weight is higher, although the causal role of zinc deficiency has not been proven. Zinc supplementation is recommended for pregnant women who ordinarily consume an inadequate diet, smoke, are substance abusers, or are carrying multiple fetuses. However, copper absorption may begin to be impaired at zinc intakes of approximately 18.5 mg/day, and a daily intake of 50 mg zinc impairs both iron and copper absorption. These negative effects are believed to be stronger if the minerals are taken without food.

Sodium

Due to hormonal changes during pregnancy, sodium metabolism is altered. At one time, dietary restriction of sodium was a common treatment for maternal edema, although it is ineffective. The newborn infants of women who had restricted their sodium intake drastically during pregnancy were observed to have hyponatremia. In animals, sodium restriction during pregnancy leads to water intoxication along with renal and adrenal tissue degradation of the pregnant animal. Therefore, sodium restriction during pregnancy is not advisable.

Iodine

Typically, the iodine intakes of pregnant women in the industrialized world easily meet recommended intakes, often as the result of consuming iodized salt. Maternal iodine deficiency and suboptimal iodine intake have been associated with cretinism, mental development impairments in utero, and infant mortality. Iodine deficiency before or during early pregnancy has the most severe effects, and in regions of endemic iodine deficiency cretinism should be prevented by treating maternal iodine deficiency before or during the first 3 months of pregnancy. However, hypothyroidism in the mother and fetus can be corrected by iodine administration in the third trimester. It appears to be safe to administer massive amounts (500 mg iodine) to pregnant women, orally or intramuscularly. There have been no reports of adverse effects of excessive iodine administration during pregnancy, and thus the upper limits are the same as for nonpregnant women (1100 μg/day for adults).

Teratogens

The World Health Organization estimates that 15% of all clinically recognizable pregnancies end in abortion. Of these, 50–60% are due to chromosomal abnormalities. In addition, 3–6% of all offspring are malformed. The causes of these malformations can be divided into three categories: unknown, genetic, and environmental. Environmental causes only account for 10% of all congenital malformations and can be further divided into maternal conditions, infectious agents, mechanical problems (deformations), and chemicals (including prescription drugs and high-dose ionizing radiation). Chemical environmental causes include consumption during pregnancy of the teratogenic agents discussed later. These account for less than 1% of all congenital malformations but are important in that the exposures to these chemicals may be preventable.

Several anticancer drugs cause problems for fetal development. Aminopterin can induce abortion within its therapeutic range, and it causes microcephaly, hydrocephaly, cleft palate, meningomyelocele, intrauterine growth retardation, abnormal cranial ossification, and mental retardation. Cyclophosphamide interacts with DNA and can result in cell death. Its use during pregnancy can result in growth retardation, ectrodactyly, syndactyly, and cardiovascular anomalies.

Some antibiotics cause abnormal fetal development if taken by the pregnant woman. Streptomycin can cause hearing problems, although the risk of this is quite low. Tetracycline may produce staining of the teeth and bones if taken late in the first trimester or during the last two trimesters.

Anticonvulsants can also cause adverse pregnancy outcomes. Carbamazepine produces minor craniofacial defects, fingernail hypoplasia, and developmental delays. Trimethadione causes 'fetal trimethadione syndrome,' characterized by V-shaped eyebrows, low-set ears, a high-arched palate, irregular teeth, central nervous system anomalies, and severe developmental delays. Valproic acid causes spina bifida and facial dysmorphology in the fetus of 1% of pregnant users.

Other potentially teratogenic drugs include androgens, which result in masculinization of the embryo and stimulate growth and differentiation of sex steroid receptor-containing tissues. Angiotensin-converting enzyme inhibitors are antihypertensive agents that have detrimental effects during the second and third trimesters, including fetal death, oligohydramnios, pulmonary hypoplasia, neonatal anuria, intrauterine growth retardation, and skull hypoplasia. The pregnant woman who uses cocaine risks preterm delivery, fetal loss, intrauterine growth retardation, microcephaly, neurobehavioral abnormalities, vascular disruptive phenomena, cerebral infarctions, and certain types of visceral and urinary tract malformations. Coumadin, a vitamin K analog, is an anticoagulant and in the first trimester can produce malformations, including nasal hypoplasia, stippling of secondary epiphysis, intrauterine growth retardation, and anomalies of the eyes, hands, neck, and central nervous system. Lithium carbonate, an antidepressant, has teratogenic effects in animals but these have not been confirmed in humans.

Contaminants

Most heavy metals, such as lead and mercury, are embryotoxic. High maternal serum lead concentrations increase the risk of abortion and adversely affect the central nervous system of the developing fetus, leading to a low IQ and abnormal behavior of the infant. PCBs are environmental contaminants that remain in the body up to 4 years after exposure. The fetus of a pregnant woman exposed to PCBs is at increased risk of fetal growth retardation, abnormal skull calcifications, deformed nails, and pigmentation of gums, nails, and the groin. Organic mercury compounds tend to accumulate in fat tissue and cause cell death due to the inhibition of cellular enzymes. These compounds cause cerebral palsy, microencephaly, mental retardation, blindness, and cerebellar hypoplasia in the infant.

Special Conditions

Nausea and Vomiting

Morning sickness or nausea is common in the early months of pregnancy. It is rarely a condition to cause alarm, except when there is excessive vomiting. In this situation, an acute protein and energy deficit and loss of minerals, vitamins, and electrolytes may result. Treatment of this condition is by consuming small frequent meals and a low-fat, high-carbohydrate diet. Prolonged, persistent vomiting (hyperemesis gravidarum) occurs in approximately 2% of pregnant women. Hospitalization is usually required, with intravenous fluid and electrolyte replacement to prevent dehydration.

Heartburn

Heartburn is a common complaint during the latter part of pregnancy due to the pressure of the enlarged uterus on the stomach in combination with the relaxed esophageal sphincter. This can usually be relieved by limiting the amount of food consumed at one sitting and avoiding lying in a reclining position after eating.

Constipation and Hemorrhoids

Pregnant women often develop constipation, most frequently during the latter stages of pregnancy. It is caused by reduced gut motility, physical inactivity, and the pressure exerted on the bowel by the enlarged uterus. The weight of the fetus and the downward pressure on the veins can lead to hemorrhoid formation. These conditions can be treated with increased consumption of high-fiber foods and dried fruits and higher fluid intake. Bulk-forming laxatives can also be used; however, there is a risk of alterations in electrolyte absorption with chronic use of laxatives.

Edema

Mild edema (fluid accumulation) is often present in the hands, feet, and legs in the third trimester. It is caused by the pressure of the enlarging uterus on the veins returning fluid from the legs. This fluid is often mobilized in the evening when the woman is lying down. This is a normal condition and does not require any special dietary or other treatment.

Diabetes in Pregnancy

For women with diabetes, nutritional counseling should include adequate dietary intake, frequent glucose monitoring, insulin management to meet the growth needs of the fetus, maintaining optimal blood glucose levels, and preventing ketosis and depletion of the mother's nutrient stores. The demands of pregnancy may impose a need for insulin in pregnant women whose condition was controlled through diet alone in the nonpregnant state. Because of hormonal changes during the first and second half of pregnancy, changes to the diet and the insulin dosage may be necessary.

Gestational diabetes occurs only during pregnancy and usually resolves after pregnancy. It occurs in 5–10% of pregnancies and most commonly arises after 20 weeks of gestation. Gestational diabetes can be treated largely through nutritional care and moderate exercise to achieve weight control. Nutritional recommendations are to limit protein intake to 15% of total calories, consume 55% of total calories as carbohydrate, and limit fat intake to 30% or less of total calories. Cholesterol intake should be 300 mg/day or less, simple carbohydrate intake should be limited, and sodium intake should not exceed 1000 mg/1000 kcal. Insulin is rarely needed, although blood glucose levels should be monitored daily.

Hypertension in Pregnancy

Pregnancy-induced hypertension is a syndrome characterized by hypertension, proteinuria, and edema. This condition usually develops in the third trimester and occurs in approximately 7 or 8% of pregnant women. It occurs more often in women who are young, pregnant for the first time, or are of low socioeconomic status. The exact cause of this condition is unknown, but most researchers agree that it is associated with a decreased uterine blood flow leading to reduced fetal nourishment. Previous treatments for this condition included sodium restriction and diuretics; however, neither of these has been successful in altering blood pressure, weight gain, or proteinuria in this condition.

Multiple Births

Women pregnant with twins or multiple fetuses should gain more weight than those with singleton births, approximately 15–20 kg. Nutrient supplementation should include at least zinc and vitamin B_6 in addition to the iron supplements recommended for all pregnant women.

Prevention of Neural Tube Defects

P N Kirke, The Health Research Board, Dublin, Ireland

J M Scott, Trinity College, Dublin, Ireland

Neural tube defects (NTDs) are major congenital malformations of the central nervous system resulting in fetal and perinatal death and severe handicap in the majority of survivors. The finding that folic acid can prevent most NTDs ranks as one of the most important medical research discoveries in recent times. In this article, the epidemiology of NTDs is reviewed, focusing primarily on the role of folic acid and, to a lesser extent, vitamin B_{12} in the etiology and prevention of these malformations. The causes of the approximately 30% of NTDs that are estimated not to be related to folate are also briefly considered. The mechanisms underlying the link between folate, vitamin B_{12}, and NTD etiology are examined, and the rapidly expanding research literature on genetic risk factors is reviewed. The main issues in using folic acid to prevent NTDs are discussed: ways to increase folate/folic acid intakes, supplementation, fortification, and safety. The role of other nutrients in NTD prevention is considered. Recommendations on using folic acid to prevent NTDs have been issued by various national health authorities and the main points in these recommendations are presented.

Epidemiology

Failure of the embryonal neural tube to close normally between 24 and 28 days after conception gives rise to a group of severe congenital malformations known as NTDs that includes spina bifida, anencephalus (approximately 50 and 40% of cases, respectively), encephalocoele, and iniencephaly. These anomalies are believed to be caused by an interaction of genetic predisposition and environmental factors, and many different factors have been pursued. Evidence of the importance of nutrition has accumulated since the 1960s, and the key role of folate/folic acid in the pathogenesis of these malformations was demonstrated conclusively in 1991.

Genetic and Environmental Factors

Evidence of a genetic component in the etiology of NTDs includes familial recurrence patterns, ethnic variation, and sex variation (more common in

females). More direct evidence of the role of genetic factors is the discovery that the gene encoding for the thermolabile variant of the 5,10-methylenetetrahydrofolate reductase enzyme is more common in individuals with spina bifida than in controls. The most striking environmental, or nongenetic, factors are the protective effect of folic acid and the marked variations in prevalence over time and between areas. The prevalence rates of NTDs at birth have been falling in most countries, particularly in regions that traditionally had high rates. It is assumed, but not scientifically proven, that better nutrition is a main factor determining this trend. Variations with season, social class (more common in disadvantaged groups), and, to a lesser extent, maternal age and reproductive history provide further evidence of the role of environmental factors. Several of these factors may be explained in whole or in part on nutritional grounds.

Folate/Folic Acid

There is a vast literature on the role of folate/folic acid in the etiology and prevention of NTDs. Evidence that folic acid can prevent NTDs comes from two main types of studies: observational studies of dietary folate intake and of supplementation with folic acid preparations and intervention studies. The strongest evidence on the efficacy of folic acid comes from randomized controlled trials, notably the Medical Research Council (UK) trial on NTD recurrence and the Hungarian trial on NTD occurrence (i.e., first-time NTDs). These and other intervention studies are summarized in **Table 1**. Following earlier research, the Medical Research Council trial published in 1991 conclusively established the efficacy of folic acid in preventing NTD recurrence. This trial used a research design to investigate the effects of both folic acid and a combination of other vitamins. The recurrence rate in the groups that received folic acid (1.0%) was significantly lower than that in the groups that did not take folic acid (3.5%), giving a 71% protective effect. Thus, 29% of NTDs were not prevented by folic acid, at least not at the very high pharmacological dose of 4 mg daily used in the trial. The multivitamin combination without folic acid had no protective effect. The main observational studies that have examined the effect of periconceptional use of vitamin supplements containing folic acid on NTD pregnancies are illustrated in **Table 2**. All of these studies but one found a marked protective effect of supplementation against NTD occurrence. In most of the studies of NTD occurrence, the daily dose of folic acid was between 0.4 and 0.8 mg. Studies of dietary folate intake also show a protective effect of high intakes during the periconceptional period. The consistent finding of a protective

Werler *et al.* (1993)	0.60
Shaw *et al.* (1995)	0.65

[a]The difference between folate-supplemented and unsupplemented groups was statistically significant in all studies except Mills *et al.* (1989).

effect of dietary folate and folic acid supplementation in virtually all these different types of studies is very striking. Further evidence implicating folate comes from studies linking maternal folate status to pregnancies affected by NTDs. The main studies that have been published on serum/plasma folate and red cell folate (RCF) are summarized in **Tables 3** and **4**. The differences between affected and unaffected pregnancies are more pronounced in the first trimester of pregnancy. Maternal use of folic acid antagonists during early pregnancy increases the risk not only of NTDs but also of other congenital defects.

Vitamin B_{12}

The role of vitamin B_{12} in NTDs is of particular interest because of the close metabolic relationship between this nutrient and folate. The results of some studies of maternal levels of serum vitamin B_{12} in NTD pregnancies are shown in **Table 5**. As for folate, lower levels of vitamin B_{12} are generally seen in affected pregnancies, especially in the first trimester. Studies based on amniotic fluid have

consistently found lower vitamin B_{12} levels in affected pregnancies. It is possible that the low levels of vitamin B_{12} coincide with low levels of folate, although the findings of a case–control study in Dublin suggest that they are independent risk factors and the distribution of the two ingredients in food is dissimilar. In another smaller study, lower levels of vitamin B_{12} in affected pregnancies were not independent of folate levels. On biochemical grounds, there is so much interaction between the pathways involving both nutrients that it is possible that deficiency of either could affect a common event in the closure of the neural tube. The role of vitamin B_{12} in NTDs is discussed further later.

Other Nutritional Factors

Vitamin C, vitamin A, and zinc have also been linked to NTDs. Lower maternal levels of white cell vitamin C were reported in affected compared to unaffected pregnancies in one small study. Large doses of natural or synthetic vitamin A consumed by the mother during pregnancy have been associated with congenital anomalies in her offspring. In a large US study of maternal vitamin A intake before and during early pregnancy, a total daily intake greater than 15 000 IU was associated with an increased risk of birth defects, especially of structures arising from the cranial neural crest (craniofacial, central nervous system, thymic, and heart defects), but the risk of NTDs was not raised. However, these findings have been challenged. Children born to women who have vitamin A supplements at levels found in current multivitamin preparations have not been shown to be at increased risk of birth defects. Although several studies have linked zinc deficiency or abnormalities in zinc metabolism to NTDs, the results have not been consistent. The role of zinc in NTD aetiology requires further clarification. Research on the association between riboflavin and folate and homocysteine levels in people homozygous for the

5,10-methylenetetrahydrofolate reductase C677T genetic polymorphism suggests a possible role for riboflavin in the aetiology and prevention of NTDs.

Research in the United States has shown that women who are obese (defined as prepregnancy body weight of more than 80 kg or body mass index greater than $29\,kg\,m^{-2}$) are more likely to have infants with NTDs and some other congenital malformations than women of average prepregnancy weight. In one study it was found that this association was independent of folate intake. Although the underlying mechanism is unclear, these findings suggest that it may involve something other than folate. Studies in the United States found that dieting behaviors involving restricted food intake during the first trimester of pregnancy and diarrheal illnesses during the periconceptional period were associated with increased NTD risk.

Other Causes of NTDs

It is estimated from the results of the Medical Research Council trial that approximately 30% of NTDs are not folate-related. The causes of this group of NTDs are unknown but are likely to include genetic and environmental factors. In this context, recent reports on obesity and NTDs are most interesting. Further research on this subject should result in a better understanding of the complex aetiology of NTDs. Nutritional factors other than folate may be involved—for example, vitamins B and C and zinc, as noted previously, and other nutrients.

Mechanisms

The possible mechanisms underlying the involvement of folate/folic acid in the etiology and prevention of NTDs are examined in this section.

Functions of Folate and Vitamin B_{12} and NTD Etiology

Folate acts as the intermediary in the transfer of methyl groups for two important processes in metabolism, namely the methylation reactions and the synthesis of the nucleic acids DNA and RNA

(**Figure 1**). The folate cofactor, N^5-methyltetrahydrofolate, acts via the vitamin B_{12}-dependent enzyme, methionine synthase, to remethylate homocysteine to produce methionine, which is converted to *S*-adenosylmethionine (SAM) via *S*-adenosylmethionine synthase. SAM is the universal methylator necessary for the synthesis of essential proteins, lipids such as myelin, and DNA. The folate cofactor also acts via methionine synthase to synthesize tetrahydrofolate, which, unlike N^5-methyltetrahydrofolate, can be polyglutamated and thereafter used to produce the nucleic acids DNA and RNA. Simple deficiency or metabolic impairment in the biochemical functions of either folate or vitamin B_{12} could, by interrupting DNA biosynthesis or methylation reactions, interfere with cell growth and function and tissue development during a period of very rapid cell proliferation of the fetal neural crest, thereby preventing normal closure of the neural tube.

Folate/Folic Acid and NTDs: Mechanisms

Does folic acid prevent NTDs by correcting simple dietary deficiency, by overcoming a problem in gastrointestinal absorption, or by overcoming some type of metabolic block? Recent research has helped to clarify the role of folate/folic acid in the etiology and prevention of these malformations. Blood samples were collected from women at their first antenatal clinic in the Dublin maternity hospitals and 81 women in this cohort subsequently had infants affected by NTDs. Folate and B_{12} status were compared in these 81 cases and in a control sample of 247 unaffected pregnancies by measuring plasma and RCF and plasma vitamin B_{12}. Although folate levels were significantly lower in the cases than in the controls, more than 91 and 86% of the cases had normal plasma and RCF levels, respectively. Thus, the vast majority of women who had an

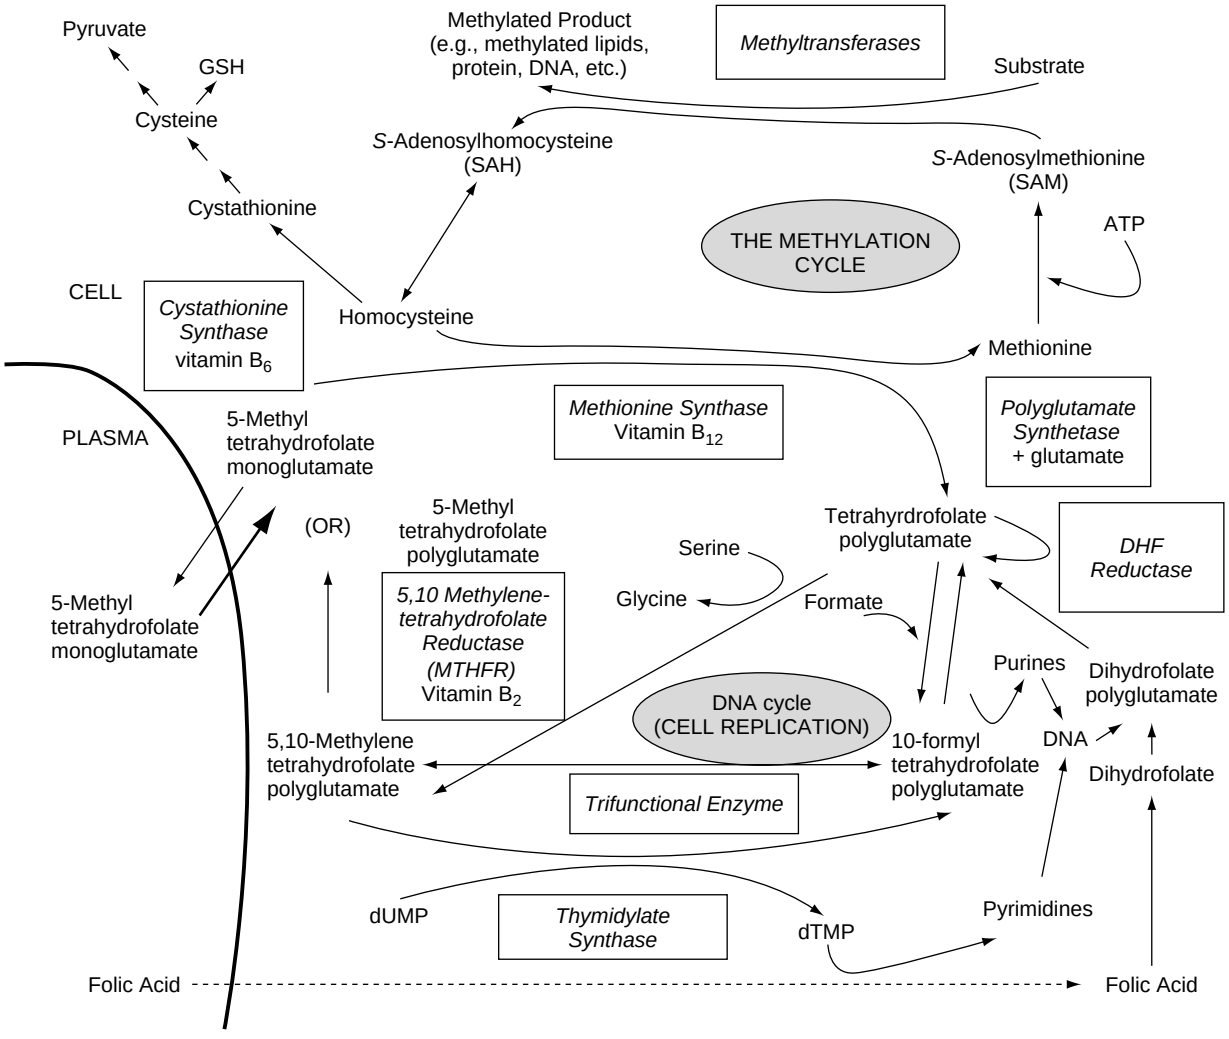

Figure 1 Intracellular pathways of folate and homocysteine metabolism and their relation to vitamin B_{12} function.

NTD birth were not folate deficient, as defined by conventional levels.

It has been suggested that women who have had children with NTDs may have a defect in gastrointestinal absorption of folate or folic acid, but there is no strong evidence to support this hypothesis. In a study designed to overcome the methodological problems of earlier investigations, folic acid absorption was similar in a group of nonpregnant women with a history of an NTD pregnancy and in control women with a normal pregnancy history. These findings suggest that the absorption of folic acid routinely consumed in supplements and fortified food products is not impaired in women with a history of an NTD pregnancy. However, autoantibodies against folate receptors have been reported in women who have had a pregnancy complicated by an NTD. These autoantibodies bind to the folate receptors and can block the cellular uptake of folate.

A woman's risk of having an NTD baby has been shown to be closely related to her early pregnancy levels of plasma folate and RCF, the relationship being stronger for RCF (**Table 6**). There is a strong dose–response effect. Those with RCF levels less than $150\,\mu g\,l^{-1}$ have more than eight times the risk of those with levels of more than $400\,\mu g\,l^{-1}$. Although the most marked absolute reductions in risk occur by elevating the lower RCF levels, risk continues to decrease as RCF levels increase well beyond what would be considered normal levels, with little further protection apparently being gained at levels higher than $400\,\mu g\,l^{-1}$. Most of the NTDs were born to women whose RCFs would have been considered to be in the normal range (i.e., $>150\,\mu g\,l^{-1}$). Thus, views on what constitutes desirable levels of RCF need to be reconsidered.

The lack of evidence of a simple dietary deficiency or of malabsorption and the marked dose–response relationship between maternal RCF level and risk of NTD point to a metabolic explanation for the aetiology of these conditions. Since it is estimated that folic acid can prevent up to 71% of NTDs, defects in folate-related enzymes or processes have been candidates for study. There are 16 folate-dependent enzymes in the internal metabolism of mammalian cells. The finding in the Dublin study of significantly higher plasma homocysteine levels in case mothers than in controls suggested that one or more enzymes involved in homocysteine metabolism may be abnormal. The main folate-related enzymes involved in homocysteine metabolism are illustrated in **Figure 1**. Homocysteine levels in the amniotic fluid of women carrying a fetus with an NTD have been reported as being higher compared with those of normal pregnancies. Evidence of deranged homocysteine metabolism also comes from metabolic studies conducted in Holland. In a study in which women who had given birth to an NTD baby were given a methionine-loading test, methionine intolerance and very high peak levels of homocysteine were found in a subgroup of the NTD women. Cystathionine synthase levels in skin fibroblasts taken from the methionine-intolerant women were normal. Plasma folate and vitamin B_{12} were found to be independent risk factors for NTDs in the Dublin study. Although the results of this study pointed to an abnormality in the methionine synthase enzyme, there is no strong evidence linking genetic variants of the enzyme to NTDs. However, it is possible that vitamin B_{12} status may influence NTD risk in ways other than directly affecting the activity of this enzyme.

Table 6 Distribution of cases and controls and risk of NTDs by red cell folate level

Red cell folate ($\mu g\,l^{-1}$)	*No. of cases (%)*	*No. of controls (%)*	*Risk of NTD per 1000 births*	*95% confidence interval*
0–149	11 (13.1)	10 (3.8)	6.6	3.3–11.7
150–199	13 (15.5)	24 (9.0)	3.2	1.7–5.5
200–299	29 (34.5)	75 (28.2)	2.3	1.6–3.3
300–399	29 (23.8)	77 (29.0)	1.6	1.0–2.4
≥400	11 (13.1)	80 (30.0)	0.8	0.4–1.5
Total	84 (100.0)	266 (100.0)	1.9	1.5–2.3

Genetic Risk Factors

The main focus of research on NTDs during the past decade has been the investigation of genetic risk factors with particular emphasis on the genes encoding the enzymes in the folate/homocysteine metabolic pathways. A common variant (C677T) in the gene for one of the folate-related enzymes, 5,10-methylenetetrahydrofolate reductase (MTHFR) (**Figure 1**), was identified in 1993 and has been shown to be associated with reduced enzyme function and lower blood folate and higher homocysteine levels. The most frequently studied association between a genetic polymorphism and a congenital malformation has been the relationship between NTD risk and this variant. In initial reports from Holland and Ireland published in 1995, homozygosity for the C677T allele was associated with an increased risk of having spina bifida or having an affected child. From the numerous studies on the link between this polymorphism and NTD that have been conducted in

many countries, it is clear that homozygosity for the variant in the child or mother is a risk in some populations but not others. A review showed that homozygosity for the variant in the child or mother doubles the risk of NTD. A large study of baby–mother pairs showed that the embryo's MTHFR genotype was more important than that of the mother in conferring risk. Studies have also shown evidence of a strong gene–nutrient interaction in that low maternal blood folate levels in early pregnancy and no periconceptional folate supplementation increase the risk associated with the variant allele. Although how the polymorphism causes NTDs is unclear, it may do so through its association with lower folate or higher homocysteine levels or by some other metabolic mechanism. It is estimated that homozygosity for the MTHFR C677T variant is likely to account for not more than approximately 13% of NTDs. Because it is considered that approximately 71% of NTDs can be prevented by folic acid, other mechanisms, possibly including variants in genes coding for other folate-dependent enzymes, problems with folate absorption, or even dietary deficiency of folate, may play a role.

In one study it was shown that the elevated homocysteine levels associated with homozygosity for the MTHFR C677T variant were seen only in those with low riboflavin status; the homocysteine levels did not differ by genotype in those with medium or high riboflavin status. The fact that the activity of the MTHFR C677T variant is influenced by the prevailing riboflavin status may help to explain why the variant is a risk factor for NTDs in some countries but not others. These findings, if confirmed, may be important in view of research reports that substantial proportions of populations have suboptimal riboflavin status.

Genes encoding other enzymes in the folate/homocysteine pathways have been studied. Polymorphisms in some of the genes that may be expected to be important because of their position in the pathways have been shown not to be important (e.g., methionine synthase and cystathionine beta synthase). Other polymorphisms in these pathways have been reported to increase the risk of NTD (i.e., NTD risk was estimated to be significantly higher in either cases or mothers compared to controls)—for example, the MTHFR 1298A → C variant, the reduced folate carrier 80A → G variant, the methionine synthase 919D → G variant, the methionine synthase reductase 66A → G variant, and the R653 Q variant in the trifunctional enzyme methylenetetrahydrofolate dehydrogenase/methenyltetrahydrofolate cyclohydrolase/formyltetrahydrofolate synthetase. For each of these five polymorphisms, however, the increased NTD risk is based on just one study, and other studies have reported negative results. Interactions between some genes in these pathways have been reported as increasing NTD risk—for example, the MTHFR 677C → T and MTHFR 1298A → C variants (two studies); the MTHFR 1298A → C and reduced folate carrier 80A → G variants (one study); the MTHFR 1298A → C, the MTHFR 677C → T, and the reduced folate carrier 80A → G variants (one study); and the methionine synthase 2756A → G and methionine synthase reductase 66A → G variants (one study). Again, other studies have not confirmed these findings. There have also been reports of increased NTD risk associated with polymorphisms in the genes encoding the thymidylate synthase and glutamate carboxypeptidase enzymes. These results need to be replicated in larger studies and in different populations to provide a clearer picture of whether these polymorphisms truly increase NTD risk.

The rationale for studying variants in genes involved directly or indirectly in folate metabolism is clear. However, the closure of the neural tube is a complex process involving the orchestration of many genes. It seems possible that polymorphisms in genes that are far removed from folate metabolism may also cause NTDs that are responsive to folic acid. The MTHFR gene variant is the first specific genetic risk factor to be linked to NTDs. This is the strongest evidence for the involvement of a metabolic derangement in the aetiology of these conditions. This breakthrough gives added impetus to the search for other genetically determined risk factors. Although there is no strong evidence implicating other genetic polymorphisms in the aetiology of NTDs, it is likely that such evidence will soon emerge.

Prevention

In the context of the prevention of NTDs, it is necessary to distinguish between primary and secondary prevention. Primary prevention concerns measures that prevent the development of NTD in the embryo. Secondary prevention refers to screening and termination of affected pregnancies. Primary prevention became a reality following the demonstration of the efficacy of folic acid in preventing NTDs and represented a major public health breakthrough.

A substantial body of research shows that taking extra folate/folic acid before conception and during the early months of pregnancy prevents approximately 50–75% of NTDs and is effective in preventing both occurrent and recurrent NTDs. For all women who may become pregnant, it is recommended that they take an extra 0.4 mg of folic acid per day for the primary prevention of NTDs. This is

in addition to the usual dietary folate intake, which is estimated to be, on average, approximately 0.2 mg per day in the United Kingdom. The most effective ways of using this knowledge to reduce the number of NTD births are discussed next.

Ways of Increasing Folate/Folic Acid Intake

As already noted, a woman can increase her folate intake in three ways: eating more folate-rich foods, eating foods fortified with folic acid, and taking folic acid as a medicinal or food supplement. Although all three methods are known to increase folate status, taking folic acid either as supplements or in fortified foods has been shown to be much more effective in achieving this goal than eating folate-rich foods. It is very difficult to achieve a total daily intake of 0.6 mg folate/folic acid from folate-rich (unfortified) foods alone. Furthermore, folate in unfortified food is not as bioavailable as folic acid in fortified food or in supplements. The only practical way of obtaining an extra 0.4 mg folic acid daily, as recommended, is by consuming fortified foods or folic acid supplements, and this should be made clear by health professionals. However, an improved general diet, especially consuming more vegetables and fruit, should be advocated preconceptionally and during pregnancy because it results in an increased intake of other vitamins and nutrients that are important for normal fetal development.

Supplementation

Since 1992, women of reproductive age have been advised to take an extra 0.4 mg of folic acid daily before pregnancy and during the first 12 weeks of pregnancy. Compliance with the recommendation has been examined in numerous studies conducted throughout the world. Knowledge of the appropriate use of folic acid for NTD prevention in women of childbearing age and in health workers increased markedly throughout the 1990s. Because folic acid can only work if it is taken before closure of the neural tube, the best indicator of periconceptional supplementation is the proportion of pregnant women who take a folic acid supplement before the pregnancy begins, and this proportion increased during the 1990s. In seven studies published from 1999 to 2003 and based on representative study samples in North America and Europe, the proportion of women reported as taking folic acid before pregnancy ranged from 33 to 49%, with a median of 36%. Supplementation is less common in unplanned pregnancies; in young, socially or educationally disadvantaged, and single mothers; and in those with no knowledge about the protective effect of folic acid. The most important predictor of nonsupplementation is unplanned pregnancy. Because unplanned pregnancy is very common (e.g., approximately half of all pregnancies are reported as being unplanned in the United States and Ireland), this factor constitutes the greatest logistical obstacle to planning optimal protection against NTD by periconceptional supplementation. The low supplementation rates reflect the relative lack of effectiveness of promotional campaigns as currently formulated. Public health programs promoting folic acid must be sustained and must pay particular attention to those at greatest risk of not supplementing.

Fortification

Supplementation is probably the most efficient method for ensuring individual protection against an NTD pregnancy but not for a general public health strategy. The disappointing results of supplementation programs led experts to consider fortification of foodstuffs as another public health strategy. There are two approaches to food fortification—voluntary and mandatory. In the former, it is left to individual manufacturers to add folic acid to specific products, whereas in mandatory fortification the relevant authority, with government approval and legislation, requires that a specified dietary staple or staples be fortified to a specified agreed level. The objective of a food fortification policy to prevent NTDs is to increase folate intakes for the target childbearing population as near as possible to the recommended intakes while maintaining safe levels of intake for the entire population. The United States first introduced mandatory food fortification. The Food and Drug Administration (FDA) authorized the addition of folic acid to enriched grain products in 1996 and made compliance mandatory by January 1998. The FDA decided on a level of fortification of 140 μg of folic acid per 100 g flour, and this was estimated to increase average daily intakes of folic acid by 100 μg in women of reproductive age. Studies of fortified foods in the United States have found considerably higher folate levels for many products than those required by the regulations, and the actual average daily increase is estimated to be 150–200 μg. The Canadian government introduced a similar fortification plan in 1998. Studies in both countries have shown that the markers of body folate status (serum and red cell folate and serum homocysteine) have increased dramatically in the population postfortification.

The effect on NTD rates has been striking, especially in Canada. Comparing NTD rates before and after fortification showed decreases of 55% in Nova Scotia and 49% in Ontario postfortification. A study in the United States reported a decrease of 19% in the NTD rate after fortification, and the smaller decrease was considered to be mainly due to the fact that pregnancy terminations for NTDs were not included in the US data and were included in the Canadian studies. These studies provide strong evidence of the effectiveness of mandatory food fortification of folic acid in preventing NTDs and point the way forward for other countries interested in solving this problem.

Fortification of flour was introduced in Chile in 2000 at a level of 220 μg folic acid per 100 g flour. Approximately 38 countries currently either fortify flour (including the United States, Canada, Chile, Argentina, and Israel) or have agreed to do so. In the United Kingdom, the government nutritional advisory committee (the Committee on Medical Aspects of Food and Nutrition Policy) recommended fortification at the level of 240 μg of folic acid per 100 grams of flour, but the Board of the Food Standards Agency decided to defer its implementation. No European Union country has decided to fortify flour to date.

Dose

The appropriate dose of folic acid in relation to mandatory food fortification and supplementation programs continues to be debated. The data from the Dublin study, which showed a marked relationship between early pregnancy maternal RCF levels and NTD risk, were used to examine the effectiveness of a food fortification intervention to increase maternal folate levels to prevent NTDs. The analysis showed that if, as a result of food fortification, all women in a population doubled their RCF level, the prevalence of folate-responsive NTDs would be reduced by 66%. If this increase were 150%, which could be achievable with sufficient fortification, the level of protection would be 73% of folate-responsive NTDs (equivalent to 53% of all NTDs). The finding that a woman's risk of having an NTD pregnancy is related to her early pregnancy levels of RCF in a continuous dose–response relationship suggested that folic acid intake is also related to risk in a continuous dose–response-type relationship, and this was demonstrated in a randomised trial that studied the effect of three different doses of folic acid on RCF levels and reduction in NTD risk. The results of this study in women of reproductive age showed that an extra 0.1, 0.2, or 0.4 mg daily during a 6-month period would be expected to reduce NTD rates by 22, 41, and 47%, respectively. According to another dose–response model that examined the effect of increases in a wide range of daily folic acid intakes on NTD prevention, a 5.0 mg daily dose of folic acid was estimated to decrease NTD risk by 85% in women with a presupplementation serum folate level of 5 ng per liter. These authors argue that the current recommended daily dose of 0.4 mg for folic acid supplements is too low and should be increased to 5.0 mg. They also argue, somewhat controversially, that no known or suspected adverse effects of the 5.0 mg dose have been recorded.

The 4.0 mg daily supplement recommended internationally by National Departments of Health for the prevention of NTD recurrence is based mainly on the unequivocal evidence of the efficacy of this dose in the UK Medical Research Council Trial. In another large nonrandomized intervention study, a daily dose of 0.36 mg folic acid seemed to offer similar protection because the recurrence rate in the treated groups was similar to that in the Medical Research Council trial. So while the recommendation of 4.0 mg to prevent recurrence is quite correctly based on the best scientific evidence, it is likely that a much smaller dose would be equally effective.

Duration of Supplementation

The minimum duration of supplementation necessary for prevention is not known. Although most national health authorities recommend that women take extra folic acid for at least 4 weeks before conception and until week 12 of pregnancy, supplementation for a shorter duration before closure of the neural tube may also be effective. Until more data are available, the official guidelines should be followed. Given the estimate that approximately half of all pregnancies are unplanned, however, it is important that a woman who has not been taking extra folic acid and who suspects that she may be pregnant immediately starts taking a folic acid supplement. This point requires greater emphasis.

Safety

The main concern about taking folic acid at levels greater than 0.4 mg per day is the possibility that the diagnosis of pernicious anemia, which is caused by vitamin B_{12} malabsorption and is more common in the elderly, would be missed since folic acid at high levels prevents the development of the anemia and thus its diagnosis. In this situation, nerve damage

progresses and becomes irreversible. To ensure that 95% of all women get 0.4 mg of folic acid per day through fortification of staple foods would mean that, depending on the diet and differences in eating habits, more than half of the population would get approximately 0.7 mg and 5% would get more than 1.0 mg per day. A compromise is to select a lower target figure for universal fortification that would aim to prevent most folate-responsive NTDs and not put the elderly at risk. This is what the FDA has done. At the 140 μg per 100 grams flour fortification level in the United States, it is estimated that 15–25% of children aged 1–8 years and 0.5% of men and women >70 years would have daily folic acid intakes higher than the tolerable upper intake level. When account is taken of the fact that actual fortification levels in the United States have been estimated to be as much as twice the planned level, the proportions of children and elderly with intakes higher than the upper level may be greater than projected. At the proposed fortification level of 240 μg per 100 grams flour in the United Kingdom, it is estimated that 10% of males would have folic acid intakes >1.0 mg per day. Folic acid in the dose range 0.5–1.0 mg may be absorbed in its original unmetabolized form and may be found in this form in the bloodstream. Circulating folic acid would then be taken up by body cells by a vitamin B_{12}-independent mechanism (**Figure 1**) and would have the potential to switch on the megaloblastic bone marrow in a vitamin B_{12}-deficient person, thereby preventing the development of the anemia and masking the B_{12} deficiency. Further research is needed, therefore, to determine the amount of folic acid in fortified food that is safe from this potential hazard. The incidence of B_{12} deficiency in the elderly has been reported to be as high as 15%, but estimates vary considerably. Some reassurance is provided by a U.S. study that suggests that fortification with folic acid has not been associated with an increase in masking of vitamin B_{12} deficiency.

Adding vitamin B_{12} as well as folic acid to fortified food has been suggested as a solution, but this is problematic. The vast majority of cases of vitamin B_{12} deficiency are due to the autoimmune disease pernicious anemia. In this condition, the absence of intrinsic factor prevents the absorption of physiological amounts of vitamin B_{12}. Thus, including vitamin B_{12} at levels of the dietary reference value (DRV) or less is unlikely to benefit such people because it is not absorbed in sufficient amounts. It has been suggested that if a large enough dose of vitamin B_{12} is added to the diet, then a sufficient amount will be absorbed by passive diffusion to prevent vitamin B_{12} deficiency. However, the amounts required to do this are between 200 and 400 times the DRV for vitamin B_{12} and most experts would be concerned about adding such a vast excess of an albeit apparently safe nutrient to the food chain.

Vitamin B_{12} deficiency is rare in children, but concern has been raised about possible unknown negative health effects of long-term exposure of children to levels of folic acid that are several times the DRV.

It is established that anticonvulsant drugs impair folate status and there is concern that folic acid supplements may reduce the efficacy of these drugs. However, folic acid supplementation of 4 mg daily is recommended for women taking anticonvulsant medication, and there is no evidence of negative effects of supplementation on the control of epilepsy.

A number of studies have suggested the possibility that periconceptional use of vitamin supplements containing folic acid may be associated with an increase in multiple births. A systematic review of the three randomized trials of periconceptional supplementation with folic acid or multivitamins or both (see **Table 1**), updated with new information from the Medical Research Council trial in women who took folic acid, found a consistent increase in the twinning rate. The pooled relative risk was 1.40 (95% confidence interval (CI), 0.93–2.11), but the increase did not reach statistical significance. Increased rates of multiple births were reported in mothers who took multivitamin supplements in two other studies. In a large prospective study of young women in China, there was no increase in the rate of multiple births in women who had taken periconceptional folic acid supplements (0.62%) compared to nonsupplementers (0.67%) (rate ratio, 0.92; 95% CI, 0.83–1.01). The other studies raised the question of whether folic acid or some other component of the multivitamin supplements was responsible for the increased multiple birth rate, and the Chinese study data suggest that folic acid is not associated with this effect. The association between periconceptional use of folic acid and multiple pregnancy has been shown to be confounded by use of in vitro fertilization (IVF). Pregnancies following IVF are strongly associated with both multiple pregnancies and periconceptional use of folic acid. A number of studies have reported no association between use of folic acid supplements and multiple pregnancy when adjustment is made for use of IVF. Research in the United States suggests that fortification has not resulted in an increase in multiple pregnancy rates.

There are reports of increased miscarriage rates in women who took vitamin supplements containing folic acid before and during early pregnancy. A review of the randomized trials of periconceptional supplementation of folic acid or multivitamins found a statistically nonsignificant 12% increase in the miscarriage rate among those who took folic acid alone or as part of a multivitamin supplement. It has been suggested that folic acid may extend the viability of fetuses that would otherwise miscarry at earlier stages of pregnancy and be unrecognized as such. In the largest study that has addressed this question, the rates of miscarriage were similar in Chinese women who had (1981 of 21 935 or 9.0%) and had not (174 of 1871 or 9.3%) taken supplements containing only 400 μg folic acid before and during early pregnancy. This study is the most scientifically rigorous examination of the hypothesis that periconceptional folic acid may increase the miscarriage rate, and the findings indicate that this is not so.

Other Nutrients

As noted previously, nutritional factors may be involved in the aetiology of some of the nonfolate-related NTDs. Although there is increasing evidence for the involvement of vitamin B_{12} and less evidence for vitamin C, riboflavin, and zinc, the available evidence is not strong enough to support dietary supplementation with these or other nutrients.

Because large doses of vitamin A are known to be teratogenic, women at risk of pregnancy and those in the early months of pregnancy should avoid liver products which can contain high quantities of vitamin A. In order to keep daily vitamin A intake below 10 000 IU, women in these groups should not take a multivitamin tablet that contains a dose of more than 5000 IU.

Recommendations

The Department of Health in the United Kingdom and the Department of Health and Human Services in the United States were the first to issue recommendations on the use of folic acid to prevent NTDs. The recommendations relate to the prevention of occurrent (first-time) and recurrent NTDs, and other national health authorities have adopted similar recommendations. The main points in these recommendations are given next.

Prevention of NTD Recurrence

To prevent NTD recurrence in the offspring of women or men who have spina bifida or encephalocoele, or a history of a previous child with NTD,

Such women and men should be counseled about the increased risk in subsequent pregnancies and about the protective effect of supplementation with folic acid.

Women with a previously affected pregnancy should, unless contraindicated, be advised to take 4.0 mg of folic acid daily from at least 4 weeks before conception until the end of the third month of pregnancy. In countries in which a 5.0 mg rather than a 4.0 mg preparation is available, the former can be used but the lower 4.0 mg dose should be used as soon as this preparation becomes available.

The 4.0 mg dose should be taken only under the supervision of a doctor because giving high doses of folic acid can complicate the diagnosis of vitamin B_{12} deficiency and epileptic women on anticonvulsant therapy require individual counseling before starting folic acid.

Prevention of NTD Occurrence

For the prevention of occurrence of NTDs, the US Public Health Service recommends that all women capable of becoming pregnant consume 0.4 mg of folic acid per day and that total folate consumption should not be more than 1.0 mg per day to avoid the possible risks of high intakes. The UK Expert Advisory Group recommends that women should take an extra 0.4 mg of folic acid daily from when they begin trying to conceive until week 12 of pregnancy. If a woman who has not been taking this additional amount of folic acid suspects that she may have just started a pregnancy, she should begin taking extra folic acid immediately and continue until week 12 of pregnancy. The US Public Health Service and the UK Expert Advisory Group have outlined three possible ways of achieving an extra intake of folate/folic acid: eating more folate-rich foods, eating foods fortified with folic acid, and taking folic acid as a medicinal or food supplement. It is recommended that women should use whatever source or combination of sources they prefer to ensure that they obtain the necessary extra folic acid. The effectiveness of these approaches in achieving the recommended increased population intake of folate/folic acid was considered under Prevention. As already noted, it is very difficult to achieve a total daily intake of 0.6 mg folate/folic acid from only foods naturally rich in folate. The only practical ways of obtaining the recommended extra 0.4 mg folic acid daily is by consuming folic acid supplements or fortified foods, and this should be emphasized when advising women. In countries in which there is mandatory food fortification, it is important that women

are advised to continue taking supplements because fortification is designed to deliver considerably less than the recommended extra 0.4 mg daily intake of folic acid. When taking supplements, the folic acid dose should be obtained from pills containing only folic acid rather than from multivitamin preparations because of the risk of taking harmful levels of vitamins A and D in early pregnancy.

Pre-eclampsia and Diet

E Abalos, Centro Rosarino de Estudios Perinatales, Rosario, Argentina
J Villar, World Health Organization, Geneva, Switzerland

Introduction

Hypertensive disorders during pregnancy are one of the main causes of maternal death worldwide, most of these deaths being attributed to eclampsia. Eclampsia is the occurrence of fits in a pre-eclamptic woman that cannot be attributed to other causes (such as epilepsy, etc.). Hypertensive disorders occur in 6–8% of all pregnancies contributing significantly to stillbirths and neonatal morbidity and mortality. Babies are also at increased risk of intrauterine growth restriction, low birth weight, and preterm delivery. Pregnant women with hypertension, either newly diagnosed or pre-existing, are prone to the development of potentially lethal complications, notably abruptio placentae, disseminated intravascular coagulation, cerebral hemorrhage, pulmonary edema, hepatic failure, and acute renal failure. The etiology of hypertensive disorders related to pregnancy, particularly pre-eclampsia, remains unknown.

The most important consideration in the classification of the disease is differentiating hypertensive disorders that antedate pregnancy from those that are pregnancy specific, of which the more ominous are pre-eclampsia and eclampsia. Pre-eclampsia is a pregnancy-specific syndrome of reduced organ perfusion secondary to vasospasm and activation of the coagulation cascade. Although our understanding of this syndrome has increased, the criteria used to identify the disorder remain a subject of confusion and controversy. In chronic hypertension, elevated blood pressure is the cardinal pathophysiologic feature, whereas in pre-eclampsia, increased blood pressure is important primarily as a sign of the underlying disorder. As might be expected, the impact of the two conditions on mother and fetus is different, as is their management.

Classification

There is controversy about the definition of hypertensive disorders during pregnancy, and several classifications have been suggested. Recently, the USA National High Blood Pressure Education Program Working Group on High Blood Pressure in Pregnancy updated the 1990 report, and classified the hypertensive disorders during pregnancy as: (a) chronic hypertension defined as hypertension observable before pregnancy, or diagnosed before the 20th week of gestation; (b) pre-eclampsia, which is a pregnancy-specific syndrome occurring usually after 20 weeks' gestation, determined by hypertension with proteinuria; (c) pre-eclampsia superimposed on chronic hypertension; and (d) pregnancy-induced hypertension or gestational hypertension, which is transient hypertension detected for the first time after mid-pregnancy if pre-eclampsia is not present at the time of delivery and blood pressure returns to normal by 12 weeks post-partum (a retrospective diagnosis). The system suggested by the International Society for the Study of Hypertension in Pregnancy (ISSHP) defines hypertension as a diastolic blood pressure of 90 mmHg or above on two consecutive occasions at least 4 hours apart, or a single diastolic blood pressure of 110 mmHg or more. The definition of pre-eclampsia has the same criteria for high blood pressure, but with the addition of significant proteinuria, usually at least 300 mg per 24 h or 1+ on dipsticks.

Pathophysiology of Pre-eclampsia

Pre-eclampsia is a syndrome with both fetal and maternal manifestations. The maternal disease is characterized by vasospasm, activation of the coagulation system, and perturbations in many humoral and autacoid systems related to volume and blood pressure control. The pathologic changes in this disorder are primarily ischemic in nature and affect placenta, kidney, liver, and brain. Of importance, and distinguishing pre-eclampsia from chronic or gestational hypertension, is that pre-eclampsia is more than hypertension; it is a systemic syndrome, and several of its 'nonhypertensive' complications can be life-threatening even when blood pressure elevations are quite mild.

The cause of pre-eclampsia is not known. Many consider the placenta as the pathogenic focus for all manifestations of pre-eclampsia because the delivery of both the baby and the placenta is the only definitive cure of this disease. There is no disease without the placenta. Thus, research has focused on the changes in the maternal blood vessels that supply blood to the placenta. Failure of the spiral arteries to remodel is postulated as the morphologic basis for decreased placental perfusion in pre-eclampsia, which may ultimately lead to early placental hypoxia. Oxidative stress and inflammatory-like responses may also be important in the pathophysiology of pre-eclampsia.

Research on how alterations in the immune response at the maternal interface might lead to pre-eclampsia addresses the link between placenta and maternal disease. A nonclassical human leucocyte antigen (HLA), HLA G, is expressed in normal placental tissue and may play a role in modulating the maternal immune response to the immunologically foreign placenta. Placental tissue from pre-eclamptic pregnancies may express less or different HLA G proteins, resulting in a breakdown of maternal tolerance to the placenta. Additional evidence for alterations in immunity in pathogenesis includes the higher frequency of nulliparous gestations with subsequent normal pregnancies, a decreased prevalence after heterologous blood transfusions, a long period of cohabitation before successful conception, and observed pathologic changes in the placental vasculature in pre-eclampsia that resemble allograft rejection. Finally, there are increased levels of inflammatory cytokines in the placenta and maternal circulation, as well as evidence of increased 'natural killer' cells and neutrophil activation in pre-eclampsia.

The mechanisms underlying vasoconstriction and altered vascular reactivity in pre-eclampsia remain obscure. Research has focused on changes in the ratio of vasodilative and vasoconstrictive prostanoids, since prostacyclin may be suppressed and thromboxane may be raised. More recently, investigators have postulated that the vasoconstrictive potential of pressor substances (e.g., angiotensin II and endothelin) is magnified in pre-eclampsia as a consequence of a decreased activity of nitric oxide (NO) synthesis and decreased production of NO-dependent or NO–independent endothelium relaxing factor (EDRF). Also under investigation is the role of endothelial cells (the site of prostanoid, endothelin, and EDRF production), which in pre-eclampsia may be dysfunctional, due perhaps to inflammatory cytokines (e.g., tumor necrosis factor alpha) and increased oxidative stress. Other systems postulated to play a role in pre-eclamptic hypertension are the sympathetic nervous system, calciotrophic hormones, insulin, and magnesium metabolism.

Finally, some nutritional deficiencies have been postulated as playing a role in the pathogenesis of pre-eclampsia. Their possible role in the hypertensive disorders of pregnancy are discussed below.

The Possible Role of Nutrition in the Pathophysiology of Pre-eclampsia

Epidemiological observations have long suggested a role for nutritional deficiencies (i.e., calcium, proteins, vitamins, etc.) in pre-eclampsia. However, intervention evaluations have failed to confirm such promising observations. We will describe here the evidence from randomized controlled trials that supports the relationship between different nutrients and pre-eclampsia.

Calcium

There is considerable evidence linking calcium intake and hypertension during pregnancy from observational and experimental studies. However, there is still no satisfactory explanation for the mechanisms involved in the calcium-mediated effect on blood pressure reduction. It has been postulated that parathyroid hormone could be involved in this relationship. Demonstrated alterations in extracellular calcium homeostasis in pre-eclampsia include hypocalciuria and decreased serum levels of calcitriol. Increased parathyroid hormone (PTH) and decreased plasma ionized calcium concentration have not been consistently observed. Also, consistent abnormalities of intracellular calcium metabolism have been described in pre-eclamptic women, such as increased intracellular free calcium concentration in platelets and lymphocytes. Increases in intracellular free calcium concentration in circulating cells are hypothesized to result from fluctuation in hormones or vasoactive substances that cause similar alteration in vascular smooth muscle. Pregnancy is a state of high calcium requirements as a result of fetal demands while maternal adaptive mechanisms are partially inhibited. These phenomena lead to the hyper-parathyroid state of pregnancy. An increase of parathyroid hormone serum levels would involve an increase of free intracellular calcium. Then, the concentration of intracellular free calcium in vascular smooth muscle cells determines the degree of tension, and is the trigger for muscular contraction. So the vasoconstrictive effect, with a rise in blood pressure, results from an increase in vascular smooth muscle tension.

Antioxidant Agents

An additional role for nutrition in the genesis of pre-eclampsia could be nutritional factors that strengthen oxidative stress, leading to pre-eclampsia. A nutritional factor could be the deficiency of antioxidant intake, specifically vitamin C and E. Vitamin C is central for the neutralization of both water-soluble and lipid-soluble free radicals; as a water-soluble molecule its ability to neutralize free radicals in the aqueous compartment is clear. Also, ascorbate is not made in humans and must come from diet. Vitamin E, a potent antioxidant, has been suggested to play a role in preventing pre-eclampsia.

Other Nutrients

Nutritional factors other than antioxidants can also contribute to oxidative stress. Hyper-homocysteinemia can occur as a result of dietary deficiencies. Hyper-homocysteinemia as a risk factor for pre-eclampsia is said to be altered, at least in part, by the genesis of oxidative stress. Vitamin B_6 and B_{12} and folic acid are involved at different steps in the metabolic pathway for removing or recycling homocysteine to methionine. Dietary deficiencies of any of these micronutrients can increase circulating homocysteine. Pre-eclampsia is characterized by increased triglycerides that favor the formation of small, dense low-density lipoproteins (LDLs). This lipoprotein variant has increased access to the subendothelial space where it is sequestered from blood-borne antioxidants. The relevant role of triglycerides in the genesis of pre-eclampsia is indicated by the fact that they are increased long before clinically evident disease. Similarly, free fatty acids are increased in pre-eclampsia and this increment can be observed months before the diagnosis. Recent studies indicate that this effect may be secondary to altered copper binding by albumin to which large amounts of free fatty acids are bound. Unbound copper is a potent stimulator of free radical formation. Ordinarily this effect of copper is prevented by protein binding (quantitatively, primarily to albumin). However, with fatty acid binding, albumin binds copper differently. In this configuration, copper bound to albumin maintains its ability to participate in redox reactions. Thus, it appears that increased free fatty acids can also contribute to oxidative stress.

All of these nutritional alterations may be amenable to dietary modification raising the possibility of nutritional prophylaxis.

Nutritional Interventions and Hypertensive Disorders of Pregnancy

Prevention

The ability to prevent hypertensive disorders of pregnancy is limited by lack of knowledge of its underlying etiology. Prevention is focused on identifying women at higher risk of developing pregnancy-induced hypertension or pre-eclampsia during

pregnancy, followed by close clinical and laboratory monitoring to recognize the clinical symptoms of the disease in its early stages. These women and their pregnancies can then be selected for more intensive monitoring or delivery. Although these measures do not prevent the disease, they may be helpful for preventing some adverse maternal and fetal sequelae.

As part of many other nonpharmacological interventions, some dietary interventions have been proposed to prevent the development of pregnancy-induced hypertension and pre-eclampsia.

Nutritional advice in pregnancy The relevant literature was reviewed in order to assess the effects of advising pregnant women to increase their energy and protein intakes on the outcome of pregnancy, and maternal and fetal/infant morbidity and mortality. Nutritional advice was assessed on a Cochrane systematic review and appears to be effective in increasing pregnant women's energy and protein intake, but the implications for fetal, infant, or maternal health cannot be judged from the available evidence. Pre-eclampsia prevention was assessed only in one small trial involving 136 women with no beneficial effects.

Protein/energy supplementation The effect of balanced protein/energy supplements for pregnant women on gestational weight gain and pregnancy outcomes was also evaluated. Pre-eclampsia prevention was assessed in three trials involving 516 women, with no significant beneficial effects. However, these trials had methodological flaws, so the results should be interpreted cautiously. In another pre-specified subgroup, only one trial involving 782 women evaluated pre-eclampsia prevention when isocaloric balanced protein/energy supplements were given to underweight pregnant women, showing no effect.

Energy/protein restriction for obese pregnant women Excessive weight gain during pregnancy has long been recognized as a risk factor for edema and impending pre-eclampsia. Epidemiological studies suggested that high maternal weight was positively associated with the risk of pre-eclampsia.

Energy/protein restriction for high weight-for-height or weight gain during pregnancy was another subgroup assessed in this systematic review. Pre-eclampsia was evaluated in two trials (284 women), which showed no reduction in the risk of occurrence. Similarly, there was no influence on pregnancy-induced hypertension (3 trials, 384 women). The limited evidence available suggests that protein/energy restriction of pregnant women who are overweight or exhibit high weight gain is unlikely to be beneficial and may be harmful to the developing fetus. Although weight reduction may be helpful in reducing or preventing high blood pressure in nonpregnant women, there is no effect on preventing pre-eclampsia, even in obese women. Clinicians frequently ask pregnant women to restrict their food intake in an attempt to prevent pre-eclampsia, despite the absence of evidence that such advice is beneficial.

Salt restriction Even in the early phase of pregnancy, marked hemodynamic changes occur including a fall in vascular resistance and blood pressure and a rise in cardiac output. To compensate for the increased intravascular capacity the kidney retains more sodium and water. Apparently, the set point of sodium homeostasis shifts to a higher level at the expense of an expansion of extracellular volume. In nonpregnant individuals, a strong positive association of sodium intake with blood pressure has been established, but the relationship between sodium intake and blood pressure in human pregnancy remains obscure to date. For decades a low-salt diet has often been recommended as treatment for edema, in the hope that restricting salt intake would treat, and also prevent, pre-eclampsia. Recently, this practice has been questioned, and even a high sodium intake has been proposed for pre-eclampsia treatment and prevention.

The concerns about the effect of a low-sodium diet during pregnancy on maternal nutritional status led researchers to investigate if such changes could alter other nutrient intake. It was shown that the reduction in sodium intake also caused a significant reduction in the intake of energy, protein, carbohydrates, fat, calcium, zinc, magnesium, iron, and cholesterol. Even though the majority of clinicians no longer advise women to alter their salt intake during pregnancy, this is still current practice in many countries worldwide.

A recently published Cochrane systematic review evaluates the effect of the advice about low dietary salt intake during pregnancy. The review includes two trials with data reported for 603 women. Both trials compared nutritional advice to restrict dietary salt with advice to continue a normal diet. Women with established pre-eclampsia were not enrolled, so this review provides no information about the effects of advice to restrict salt intake for treatment of pre-eclampsia. No effect was found in preventing pre-eclampsia or pregnancy-induced hypertension (1 trial, 242 women). Women's preferences were not reported, but the authors presumed that a

low-salt diet was not very palatable and was therefore difficult to follow.

Calcium supplementation A role for altered calcium metabolism in the pathogenesis of pre-eclampsia is suggested by epidemiological evidence linking low dietary levels of calcium with increased incidence of the disease. In agreement with these observations, several modifications in calcium metabolism have been observed in pre-eclamptic women and in calcium supplemented mothers.

A Cochrane systematic review of calcium supplementation during pregnancy has been published. Authors prespecified comparison groups taking into account the women's risk of hypertensive disorders of pregnancy (low versus increased), and the women's baseline dietary calcium intake (low: $<900\,mg\,day^{-1}$ versus adequate: $\geq 900\,mg\,day^{-1}$).

High blood pressure with or without proteinuria was evaluated in 9 trials involving 6604 women. Overall, there was less high blood pressure with calcium supplementation (relative risk (RR) 0.81; 95% confidence interval (CI) 0.74–0.89), but there was a variation in the magnitude of the effect across the subgroups. The effect was considerably greater in women at high risk of developing hypertension (3 trials, 297 women: RR 0.35; 95% CI 0.21–0.57) than in those at low risk (6 trials, 6307 women: RR 0.84; 95% CI 0.76–0.92). Taking into account the women's calcium intake, the effect was also greater in those with low baseline dietary calcium (5 trials, 1582 women: RR 0.49; 95% CI 0.38–0.62) than in those with adequate calcium intake (4 trials, 5022 women, RR 0.90; 95% CI 0.81–0.99).

There was a reduction in the risk of pre-eclampsia when evaluated from 10 trials involving 6864 women (RR 0.70; 95% CI 0.58–0.83). When predefined subgroups were considered, there was a significant reduction in women with low baseline dietary calcium intake (6 trials, 1842 women: RR 0.32; 95% CI 0.21–0.49), but not in those with adequate calcium intake (4 trials, 5022 women: RR 0.86; 95% CI 0.71–1.05). Pre-eclampsia was considerably reduced in women at high risk of hypertension (4 trials, 557 women: RR 0.22; 95% CI 0.11–0.43), and less consistently in those at low risk of hypertension (6 trials, 6307 women: RR 0.79; 95% CI 0.65–0.94).

The results from the largest trial conducted by the National Institutes of Health (NIH), which studied low-risk women with adequate baseline calcium diet, and in whom all women in both groups received low-dose calcium supplementation as part of their routine antenatal care, showed no significant effect on hypertension and that pre-eclampsia. Based on this, authorities from developed countries where adequate dietary calcium intake is common, discourage the use of routine calcium supplementation during pregnancy. Evidence from this review support the view that calcium supplementation might benefit women at high risk of gestational hypertension and women with low dietary calcium intake are at risk of developing pre-eclampsia, and current guidelines suggest supplementing calcium intake in these groups.

This recommendation is currently being evaluated in a large (8300 women), double-blind randomized controlled trial by the World Health Organization (WHO), conducted in seven locations around the world where calcium intake is low ($<600\,mg\,day^{-1}$) in which pregnant women received an extra $1.5\,g\,day^{-1}$ of calcium carbonate or a placebo from the 20th week of gestation. Results should be available in 2005.

Iron and folate supplementation Numerous trials involving various populations of pregnant women with normal hemoglobin levels have evaluated the effects of iron and/or folate supplementation on several outcomes, some of them including hypertensive disorders of pregnancy. A Cochrane systematic review of 2 trials involving 87 women with normal hemoglobin levels in which iron and folic acid were compared with no treatment showed no effect on the occurrence of gestational hypertension. Pre-eclampsia was not evaluated. In another Cochrane review of two trials involving 696 pregnant women already receiving iron, where some women were allocated to receive folic acid and others received no treatment/placebo, again there was no effect on the prevention of gestational hypertension.

Although evidence shows that iron and folate supplementation is not effective in preventing hypertensive disorders during pregnancy, they should be prescribed for other established beneficial effects on pregnancy such as prevention of anemia.

Magnesium supplementation Magnesium is one of the essential minerals needed by humans in relatively large amounts. Magnesium works with many enzymes regulating body temperature and synthesizing proteins as well as maintaining electrical potentials in nerves and muscle membranes. Magnesium occurs widely in many foods; dairy products, breads and cereals, vegetables, and meats are all good sources. It is therefore not surprising that frank clinical magnesium deficiency has never been reported to occur in healthy individuals who eat standard diets. However, dietary intake studies during

pregnancy consistently demonstrate that many women, especially those from disadvantaged backgrounds, have intakes of magnesium below recommended levels. Observational studies based on medical records reported that magnesium supplementation during pregnancy was associated with a reduced risk of fetal growth retardation and pre-eclampsia and that magnesium intake was associated with increased birth weight. Stimulated by these encouraging epidemiological studies, randomized clinical trials have been undertaken to evaluate the potential benefits of magnesium supplementation during pregnancy on pregnancy and neonatal outcomes.

A Cochrane systematic review of these randomized controlled trials was carried out in order to assess the effects of magnesium supplementation during normal or high-risk pregnancies on maternal, neonatal, and pediatric outcomes. Results from two trials (474 women) showed no apparent effect of magnesium treatment on prevention of pre-eclampsia. However, these results may have been confounded by the fact that in the largest trial all women (both magnesium supplemented and placebo groups) received a multivitamin and mineral preparation containing low doses of magnesium. Several of the trials also have poor methodological quality, especially related to concealment of allocation, which could give biased results. These authors conclude that dietary magnesium supplementation of pregnant women cannot be recommended for routine clinical practice because of the poor methodological quality of the current evidence.

Fish oil supplementation Studies of non-pregnant subjects suggest that fish oil, rich in long-chain n-3 fatty acids, has a moderate effect on blood pressure in normotensive as well as hypertensive individuals. A meta-analysis of controlled clinical trials of the effect of fish oil on blood pressure has demonstrated a significant reduction in systolic and diastolic blood pressure in untreated hypertensive non-pregnant individuals, but found no significant effect on normotensives. Fish oil has been shown to modify prostaglandin metabolism, and its effect on blood pressure has often been assumed to be due to such interference. Epidemiological studies suggested that marine diets could have a preventive effect on early delivery and hypertensive disorders of pregnancy.

Fish oil supplementation during pregnancy was evaluated in 1995 in a systematic review of 2 trials (5135 women), showing no effect on pregnancy-induced hypertension (2 trials, 5135 women) RR: 0.98, 95% CI 0.91 to 1.04. There was a statistically significant but modest reduction in the rate of pre-eclampsia (RR: 0.81, 95% CI 0.69 to 0.93). However, this reduction is strongly influenced by a single large trial conducted in 1942. Four other trials of fish oil supplementation involving more than 2000 women have been published recently none of which demonstrates any differences in the incidence of hypertension and pre-eclampsia between groups. Based on current evidence, fish oil supplementation is not recommended during pregnancy for the prevention of pre-eclampsia.

Zinc supplementation Zinc is proposed as playing an important role in many biological functions, including protein synthesis and nucleic acid metabolism. There is controversy in the literature in demonstrating the relationship between low serum zinc levels and abnormalities of pregnancy outcomes such as pregnancy-induced hypertension, prolonged labor, post-partum hemorrhage, preterm or post-term pregnancies, small-for-gestational age babies, or poor perinatal outcomes.

The role of routine zinc supplementation during pregnancy on outcomes for both mother and newborn was assessed in a Cochrane systematic review. Routine zinc supplementation in pregnancy had no detectable effect on gestational hypertension (four trials, 1962 women). However, there appears to be inconsistency among trials regarding the effects from other pregnancy outcomes. This may be related to variable population characteristics of women recruited in the various trials, as some included normal pregnant women with no systemic illness, other studies specifically selected women at high risk of low-zinc status, and in one study, participants were selected on the basis of proven low plasma zinc levels. There is at present no evidence of overall benefit from routine as opposed to selective zinc supplementation in pregnancy in pregnancy-induced hypertension or pre-eclampsia.

Vitamin (A, E, and C) supplementation An oxidant/antioxidant imbalance has been suggested among the possible pathogenic factors involved in pre-eclampsia. As vitamin E is one of the most important antioxidants, its levels and their relation with circulating levels of lipid peroxides in pre-eclamptic women has been intensively studied in recent years. As with other antioxidants, several studies found decreased vitamin E levels in serum from women with gestational hypertension and pre-eclampsia compared with controls. However, these findings could not be demonstrated in other studies. Increased ascorbate radical formation and ascorbate depletion were also found in plasma from women

with pre-eclampsia. Recently, a randomized controlled trial involving 283 women at very high risk of developing pre-eclampsia was conducted. Women were randomly assigned to receive vitamin C ($1000\,mg\,day^{-1}$) and E ($400\,IU\,day^{-1}$) or placebo at 16–22 weeks of gestation. The authors found a significant reduction in the risk of developing pre-eclampsia in the vitamin-supplemented group compared to controls (RR: 0.46; 95% CI 0.24–0.91). The authors concluded that supplementation with vitamins C and E may be beneficial for preventing pre-eclampsia in women at increased risk of the disease. However, these findings come from a single trial of 283 women and need to be further assessed in different settings and populations, as well as in low-risk women. The preventative potential of vitamins C and E is currently being evaluated in three large multicentre double-blind randomized trials in North America, in several institutions in the UK and in a new WHO multicentre trial in India, Peru, and Vietnam. Results are expected during 2006.

The role of vitamin A in pregnancy-induced hypertension and pre-eclampsia is another subject of controversy. It was proposed as a chain-breaking antioxidant in the free radical cascade. Some studies found significantly reduced serum vitamin A levels in pre-eclamptic and eclamptic women when compared to levels in healthy women in the third trimester. No trials have been published to date to assess the effect of vitamin A supplementation on pregnancy-induced hypertension or pre-eclampsia. A double-blind cluster randomized trial of low-dose supplementation with vitamin A or beta-carotene carried out in Nepal in 44 646 married women showed a 40% reduction in maternal mortality related to pregnancy in vitamin A supplemented women. However, differences in cause of deaths, including pre-eclampsia and eclampsia, could not be reliably distinguished between supplemented and placebo groups. Use of vitamin A supplements for the prophylaxis and management of pregnancy-induced hypertension and pre-eclampsia needs to be evaluated further before it can be recommended.

Treatment

The objectives of treatment for established pre-eclampsia or pregnancy-induced hypertension are to prevent eclampsia as well as other severe maternal complications. Close maternal evaluation is aimed at observing progression of the condition, both to prevent maternal complications and to determine whether fetal well-being can be assessed. As this disorder is often completely reversible and usually begins to abate with delivery, an imbalance between the mother's condition and the risk for fetus survival without significant neonatal complications *in utero* or in the nursery must be continuously evaluated. Even though the only definitive treatment of pre-eclampsia is delivery, some nonpharmacological approaches were proposed as part of an overall strategy of management of the disease to achieve these goals.

Unfortunately, there is no information from randomized controlled trials related to dietary approaches to the management of the disease in its mild to moderate stage, at which point conservative management is generally decided (**Table 1**).

Pre-existing (Chronic) Hypertension

Mild and uncomplicated chronic hypertension during pregnancy has a better prognosis than pre-eclampsia. However, there is an increased risk of superimposed pre-eclampsia and possible complications if pre-existing renal disease or systemic illness is present. The primary aim of therapy, if necessary, is to prevent cerebrovascular complications and to avoid progression to superimposed pre-eclampsia with its worse prognosis. Nonpharmacological management of this condition during pregnancy remains controversial.

In a published review of management of mild to chronic hypertension during pregnancy, no trials were found that compared nonpharmacological interventions with either pharmacological agents or no intervention in pregnant women. This comprehensive search identified 50 randomized controlled trials, but they involved either normotensive women or women with a history of pre-eclampsia. For the management of established chronic hypertension during pregnancy, no relevant evidence could be located to assess the effects of nonpharmacological interventions, such as limiting activity, diet modifications, or stress reduction.

Weight reduction during pregnancy, even in obese women, in general is not recommended to improve pregnancy outcomes. As weight reduction may be helpful in reducing blood pressure in nonpregnant individuals, for obese hypertensive women planning a pregnancy, weight reduction before conception is advisable. Even though obesity may be a risk factor for superimposed pre-eclampsia, there is no evidence that limiting weight gain during pregnancy reduces its occurrence.

Pregnant women with hypertension have a lower plasma volume than normotensive women, and some studies suggest that the severity of hypertension correlates with the degree of plasma volume

reduction. For this reason, sodium restriction is generally not recommended during pregnancy for the reduction of blood pressure. In addition, an increase in plasma volume reduction is a risk factor for intrauterine growth restriction. If, however, a pregnant woman with chronic hypertension is known to have salt-sensitive hypertension and has been treated successfully with low salt diet before pregnancy, it is reasonable to continue some sodium restriction for blood pressure control during pregnancy, but not for preventing superimposed pre-eclampsia.

High alcohol intake is related to hypertension in nonpregnant subjects, but is not associated with an increased risk for gestational hypertension, pre-eclampsia, or eclampsia. There is no conclusive evidence of adverse effects on pregnancy outcomes, including fetal growth, at levels of consumption below 120 g of alcohol per week. However, there are suggestions that excessive consumption of alcohol can cause or aggravate maternal hypertension.

There is no reliable information from well-designed randomized controlled trials assessing the best dietary approach for the management of pre-existing hypertension during pregnancy. Recommendations come from expert's consensus and authorities' statements. It seems that mild-to-moderate pre-existing (chronic, essential) hypertension without any risk factor should be managed in the same way as in the nonpregnant state. However, additional concerns are effects on fetal well being (mainly intrauterine growth restriction) and worsening of hypertension, particularly as a result of superimposed pre-eclampsia.

Conclusions

In short, based on the available data from systematic reviews (see **Table 1**) we can conclude that there is some evidence that calcium supplementation in populations with low calcium intake and/or at risk of developing pregnancy-induced hypertension could be beneficial. Data on antioxidants (particularly vitamins E and C) are promising, but there is a need for adequately designed randomized controlled trials of sufficient size to confirm these findings before widespread recommendation. Although pregnant women living in developing countries could be exposed to several other nutrient deficiencies, a lack of evidence precludes recommending other nutrient supplementation as part of their routine antenatal care in order

Table 1 Effectiveness of nutritional interventions in hypertension during pregnancy and pre-eclampsia

Intervention	*Hypertension during pregnancy*		*Pre-eclampsia*	
	Practice	*Research*	*Practice*	*Research*
Nutritional advice	No evidence	–	No effect; RR = 0.89 (0.42–1.88)	–
Balanced protein (<25%)/energy	No evidence	–	No effect; RR = 1.20 (0.77–1.89)	–
Isocaloric balanced protein (<25% of total energy)	No evidence	–	No effect; RR = 1.00 (0.57–1.75)	–
Energy/protein restriction for high PI or high weight gain	No effect; RR = 0.97 (0.75–1.26)	–	No effect; RR = 1.13 (0.59–2.18)	–
Salt restriction	No effect; RR = 0.97 (0.49–1.94)	–	No effect; RR = 1.11 (0.46–2.66)	–
Calcium	Possibly beneficial for women at high risk (RR = 0.35 (0.21–0.57)) and with low baseline intake (RR = 0.49 (0.38–0.62))	RCT in progress	Possibly beneficial for women at high risk (RR = 0.22 (0.11–0.43)) and with low baseline intake (RR = 0.32 (0.21–0.49))	RCT in progress
Iron and folate	No effect; RR = 1.15 (0.41–3.18)	–	No evidence	–
Folate	No effect; RR = 1.26 (0.90–1.76)	–	No evidence	–
Magnesium	No evidence	Needed	No effect; RR = 0.87 (0.57–1.32)	Needed
Fish oil	No effect; RR = 0.98 (0.91–1.04)	–	Possibly beneficial (data from low-quality studies); RR = 0.81 (0.69–0.93) Systematic review in process	–
Zinc	No effect; RR = 0.87 (0.65–1.15)	Needed	No evidence	Needed
Antioxidants	No evidence	RCT in progress	Possibly beneficial for vitamins C and E (data from one RCT); RR = 0.46 (0.24–0.91)	RCT in progress

PREMENSTRUAL SYNDROME

M C de Souza, Universidad de Mogi das Cruzes, São Paulo, Brazil

A F Walker, The University of Reading, Reading, UK

Premenstrual syndrome (PMS), the common disorder which affects woman of reproductive age, is characterized by changes in mood, behavior, or mental and physical functioning in the luteal phase of the menstrual cycle, and yet has no defined cause for its etiology. The different hypotheses proposed in the literature indicate several mechanisms and hence a range of possible therapeutic strategies. The involvement of nutritional factors in PMS has allowed a dietary approach for the management and treatment of women experiencing the condition. This article focuses on the definition, classification, and prevalence of PMS, emphasizing the hypotheses of etiology, including dietary factors, in the relief of PMS symptomatology.

Definition, Classification, and Prevalence

Premenstrual syndrome, or premenstrual dysphoric disorder (PMDD), is an association of distressing

physical, psychological, and/or behavioral symptoms which occur in the luteal phase (second half) of the menstrual cycle of sufficient severity to interfere with the normal activities and personal relationships of many women. Although the late luteal phase is the most common time for symptoms of PMS to be experienced, occasionally symptoms may occur as early as ovulation. To be classified as PMS, symptoms must be relieved by the onset of or during menstruation. Indeed, a symptom-free week after menstruation is necessary for differential diagnosis from other gynecological or psychiatric disorders.

Despite the plethora of research studies on the subject, there exists no commonly agreed definition of PMS among gynecologists and researchers. The lack of consensus is probably due to the large number of symptoms described. PMS was previously associated only with nervous tension and termed premenstrual tension (PMT). However, this term is no longer used as it only describes a limited range of the numerous symptoms experienced by many women. The most commonly mentioned symptoms of PMS are now grouped into psychological and somatic categories (**Table 1**).

Table 1 Summary of the most common premenstrual symptoms

Psychological	*Somatic*
Aggression	Abdominal bloating
Agitation	Acne/spots
Anorexia	Breast swelling
Anxiety	Breast tenderness
Craving for sweets	Change in bowel habit
Argumentative	Clumsiness
Confusion	Constipation
Crying/easy upset	Cramps
Decreased alertness	Diminished activity
Decreased libido	Diminished efficiency
Depression	Diminished performance
Emotional liability	Dizziness
Forgetfulness	Heart pounding
Hopelessness	Hot/cold flushes
Hunger	Headache
Impulsive behavior	General pain/aches
Increased appetite	Infections (e.g., cold)
Lethargy	Passing water frequently
Insomnia	Migraine
Irritability	Nausea/sickness
Lack of inspiration	Oedema
Loss of attention	Poor concentration
Loss of concentration	Swelling of extremities
Loss of confidence	Weight gain
Loss of self-esteem	
Pessimism	
Loss of self-control	
Nervous tension	
Mood swings	
Sadness	
Violent feelings	
Social isolation	
Suicidal tendency	
Tiredness	

Classification

The variable symptoms of PMS have been classified into four main categories by the American clinician and researcher Abraham in an attempt to facilitate research and elucidate the etiology of PMS and its links with lifestyle, including diet (**Table 2**). Abraham contended that each PMS category may exist alone or in combination with other categories. For example, PMS-D normally manifests itself in association with PMS-A, which is usually exhibited first.

Although other classification systems for PMS symptoms have been suggested, there is little evidence to suggest any greater merit of them over Abraham's system. In 1992 an attempt was made to systematize criteria and procedures for diagnosing PMS as LLPDD (late luteal phase dysphoric disorder) in the *Diagnostic and Statistical Manual of Mental Disorders*. Despite this, there remains much confusion surrounding the classification of PMS symptomatology, which has led to difficulties of data interpretation and diagnosis.

In the absence of quantifiable signs of PMS, most studies have relied upon the self-reporting of symptoms. The methods have largely fallen into two categories: the use of a retrospective Menstrual Health Questionnaire (MHQ) or use of a prospective Menstrual Diary (MD). While the MHQ may be helpful in screening prospective volunteers for studies of PMS, the requirements for a useful instrument for assessing PMS must include the use of prospective recording and the

Table 2 Abraham's classification of premenstrual symptoms

PMS category[a]	*Symptoms*
PMS-A (Anxiety)	Anxiety, irritability, mood swings, nervous tension
PMS-H (Hydration)	Weight gain, abdominal bloating and tenderness, breast tenderness, swelling of the extremities
PMS-C (Craving)	Premenstrual increased appetite, craving for sweets, fatigue, palpitations, headache
PMS-D (Depression)	Depression, withdrawal, lethargy, forgetfulness, confusion, insomnia, difficulty verbalizing

[a]PMS (premenstrual syndrome) is used in place of Abraham's PMT (premenstrual tension).

quantification of symptoms which identify and exclude psychiatric occurrences.

Prevalence

PMS can first appear at any stage in the reproductive life of a woman. However, the most prevalent age of onset is usually from 28 to 34 years and symptoms may be first noticed following pregnancy or oral contraceptive use. The reported prevalence of PMS differs greatly from 21 to 90% of specific female populations studied. Some of this variability relates to the difficulty of a precise definition of PMS, its classification, and the reporting method used. In addition, other factors, such as age, parity, race, culture, psychopathology, menstrual characteristics, occupation, social activities, family life, lifestyle, and stress, may play a part. Indeed, reaction to stress has been advocated by a number of gynecologists as an underlying cause of PMS.

The Etiology of PMS

Various hypotheses have been implicated in the etiology of PMS, including interaction between ovarian steroid hormones, endogenous opioid peptides, central neurotransmitters, eicosanoids, and peripheral autonomic and endocrine secretions. Despite all the investigations relating to these diverse fields, there is no firmly established biological pattern for PMS and its pathophysiology still remains obscure.

Gonadal Hormone Imbalance

As early as the 1930s, it was suggested that PMS was caused as a result of excessive levels of the female sex hormones in the blood. Later, deficient blood levels of progesterone were blamed, so that by the 1960s PMS treatment was dominated by progesterone administration. Despite this, the findings from several studies showed no clear link between low blood progesterone levels and the severity of the condition.

More recently, attention has been given to the significance of the oestrogen-to-progesterone ratio as a factor triggering PMS. In particular, it has been postulated that women with PMS-A (anxiety) have increased plasma concentrations of oestrogen relative to progesterone in the luteal phase compared with normal women. One possible mechanism is that low plasma blood levels of oestrogen and progesterone early in the luteal phase in PMS sufferers lead to an increased secretion of gonadotrophic hormones from the pituitary which, in turn, leads to a rise in oestrogen in the late luteal phase, owing to the stimulation of ovarian follicles. These follicles rapidly regress under the influence of the luteal secretion of progesterone. Excess oestrogen in the luteal phase may be the cause of fluid retention, breast tenderness, changes in carbohydrate metabolism, and mood swings associated with PMS. Although the ovarian hormone imbalance hypothesis remains unproven, administration of progesterone in the latter half of the cycle continues to be the first-line treatment for PMS by general practitioners in the UK.

The existence of subgroups of PMS of varying etiology may account for clinical observations that some women with severe premenstrual depression report, paradoxically, a worsening of symptoms during progesterone treatment. Indeed, such women have been reported to respond to oestrogen treatment. Their condition may be linked to progesterone excess, which has been suggested to occur in some women who experience PMS symptoms at midcycle. High luteal progesterone levels may lead to depletion of oestrogen receptors of the hypothalamus, which is consequently less sensitive to oestrogen, requiring a higher midcycle oestrogen surge for normal pituitary response. This is followed by an abrupt and pronounced oestrogen drop at midcycle which may even result in symptoms of hot flushes.

Angiotensin

It has been demonstrated that symptoms such as irritability, withdrawal, depression, hopelessness, tension, lack of initiative, and weight gain are linked to changes in urinary potassium/sodium ratio, which in PMS women is higher 3–4 days before the onset of menses and lower for the rest of the cycle compared with that in normal women. The reason for this may lie in the enhanced secretion of angiotensin promoted by higher progesterone levels during the luteal phase of the menstrual cycle.

Angiotensin is a hormone with vasoconstricting properties which acts on the kidneys by constricting efferent arterioles. This reduces blood flow from the kidneys and enhances excretion of the electrolytes sodium and potassium. An electrolyte imbalance occurring in PMS may alter neurotransmitter activity, in particular monoaminergic (noradrenalin and serotonin) and cholinergic neurotransmitters, affecting behavior and mood regulation. Angiotensin is also known to act directly on the adrenal cortex to promote aldosterone release (see below) and may be involved in stimulating antidiuretic hormone (ADH) secretion by the pituitary. Both of these hormones are directly involved in the maintenance of electrolyte balance.

Aldosterone

Aldosterone, the steroid hormone secreted by the adrenal cortex, promotes retention of sodium and excretion of potassium by the kidneys. An elevated secretion of aldosterone in the luteal phase would tend to lead to sodium retention and, as a result, promote fluid retention. Whether the high aldosterone levels found in PMS are a consequence of direct adrenal cortex stimulation or are promoted by increased adrenocorticotrophic hormone (ACTH) secretion from the pituitary is unknown, although circulating levels of gonadal hormones are known to influence electrolyte homeostasis via the angiotensin–aldosterone system, as stated above.

Prolactin

Fluctuation in prolactin levels has also been suggested as a cause for PMS. Prolactin is a pituitary hormone which regulates mammary gland development in women and is necessary for successful lactation. Latent hyperprolactinemia is thought to predispose nonlactating women to premenstrual breast pain. Prolactin levels rise acutely due to stress and higher levels promote sodium, potassium, and water retention. Noradrenalin has been implicated in promoting prolactin release, while the presence of dopamine reduces it. Both stress and high oestrogen levels promote noradrenalin secretion, while dopamine may be reduced in those consuming a diet low in certain nutrients (see below).

Thyroid Stimulating Hormone

In one study, a high percentage of women with PMS who were treated with thyrotrophin releasing hormone (TRH) were found to have low thyroid function. As thyroid hormone supplementation has been used in the past as antidepressant therapy, some recent studies have attempted to link thyroid dysfunction to PMS. Indeed, there are suggestions that PMS may be an early symptom of a progressive thyroid disorder and the severity of PMS increases as thyroid dysfunction progresses. Nevertheless, the use of thyroid hormone for the treatment of PMS remains controversial.

Opioids, Peptides, and Endorphins

Opioid and neuropeptides receptors are found in nerve synapses of the brain and the gastrointestinal tract, and their suppression by morphine is known to alter the perception of pain. Endorphins are substances also found in the brain and in the pituitary gland that have opiate-like activity. Indeed, the endogenous opioid of the pituitary, β-endorphin, has been described as the body's own analgesic, absence of which leads to symptoms sometimes described by PMS sufferers: cramping, craving for carbohydrates, insomnia, irritability, and nausea. This observation has led to the hypothesis that β-endorphin deficiency may be the cause of PMS. If this is the case, then it is only likely to hold true for a minority subgroup of PMS because although lacrimation, diarrhea, and pupillary dilation are common in β-endorphin deficiency, they are not common in PMS. On the other hand, PMS symptoms such as depression, breast swelling or tenderness, and weight gain are not common features of β-endorphin withdrawal.

Neurotransmitter Imbalance

Depression is a commonly reported symptom of PMS. Monoamines, such as noradrenalin and serotonin, are known chemical mediators of mood. Monoamine oxidases (MAOs) and catechol-*O*-methyl transferase are enzymes that metabolize monoamines and thus decrease the amounts available for neural transmission. Their activity can be affected by the greater fluctuation in progesterone and oestrogen levels found in women with PMS compared with normal women.

Oestrogen suppresses MAO type A activity and increases MAO type B activity. While MAO type A enzymes are involved in the breakdown of adrenalin, noradrenalin, serotonin, and dopamine, MAO type B enzymes deactivate only dopamine. Thus suppression of type A and increase in type B enzyme activity results in excess serotonin, adrenaline, and noradrenalin and a relative deficiency of dopamine, a situation which may trigger anxiety and depression.

PMS and Dietary Factors

Various reports, many of a preliminary nature, or based on clinical experience, suggest that women suffering from PMS consume more sugar, refined carbohydrate, and dairy products and less fiber, B complex vitamins, iron, zinc, and magnesium than normal women.

Carbohydrate

Carbohydrate-rich meals have been shown to improve mood in women with premenstrual depression. The reason for this has been indicated in animal studies: The availability of tryptophan to the brain increases following such meals. As tryptophan is a substrate for the synthetic pathway to serotonin, levels of this neurotransmitter rise, while levels of other neurotransmitters are maintained. Hence

premenstrual craving has been suggested as a compensatory response to deal with a relative lack of serotonin during this phase of the cycle. Indeed, PMS symptoms of craving, particularly for sweet foods, may be a useful indicator of the cyclical changes that occur in brain neurotransmitters in women.

Increased energy intake due to craving has been shown to range from 380 to 2000 kJ per day (90–500 kcal per day) during the luteal phase compared with the follicular phase in women with PMS. However, there is no obvious pattern of macronutrient intake. Some women consume more carbohydrate, some more fat, and some more protein. As might be expected, the increase in energy intake is accompanied by an increase in certain nutrients, such as magnesium, vitamin D, potassium, phosphorus, and riboflavin. Enhanced intake of several of these nutrients has been linked to alleviation of PMS symptoms (see below).

Magnesium

Magnesium deficiency has been proposed as a causative factor in PMS. Magnesium has a sedative effect on neuromuscular excitability and is involved as an enzyme cofactor in many reactions in the body. In the metabolism of essential fatty acids it also acts as a cofactor, working together with vitamin B_6, zinc, niacin, and vitamin C. At the cell membrane, magnesium acts as a regulator of both membrane rigidity and ion exchange, helping to maintain electrolyte balance. In addition, it moderates the action of calcium in stimulating cell functions such as hormone secretion.

Modern Western diets high in refined cereals lack magnesium. Many dietary surveys, including those sponsored by governments throughout the Western world, have shown that the mean intake of magnesium for women is below recommended dietary standards, with subgroups having exceptionally low intakes. Decreased intake or absorption or increased renal excretion may lead to a reduced intracellular magnesium. Indeed, perhaps the most consistent physiological abnormality yet found for PMS subjects has been the reduced magnesium level in red blood cells compared with controls.

While severe magnesium deficiency is characterized by a progressive muscle weakness, failure to thrive, neuromuscular dysfunction, and tachycardia, symptoms of marginal deficiency are more subtle. Nevertheless, there is accumulating evidence to suggest that magnesium supplementation of the diet can alleviate a variety of conditions in which there is an element of muscular overcontraction, such as hypertension and tension headaches. The stress of modern living plays a part by enhancing magnesium excretion in the urine even in otherwise normal subjects. This sets up a vicious circle, as magnesium deficiency itself increases susceptibility to stress by increasing the secretion of ACTH-mediated adrenal androgen, which is a central nervous system depressant.

Several mechanisms proposed for the development of PMS symptoms have been claimed to be promoted by magnesium deficiency. Low magnesium status may also be responsible not only for exacerbating gonadal hormone imbalance in women, but may promote an increase in the aldosterone-to-oestrogen ratio. Enhanced aldosterone levels promote potassium and magnesium excretion and sodium retention, thus inducing fluid retention as found in PMS-H. In addition, deficient levels of magnesium decrease blood glucose control in two ways: by decreasing the ability of the liver to metabolize glucose and by increasing insulin secretion in response to glucose. Hence, changes in appetite and craving, both common PMS symptoms, may be closely linked to magnesium deficiency through loosening of blood glucose control. A low blood glucose supply to the brain may cause craving as a signal for increased energy intake. Even the decreased brain dopamine levels postulated to be responsible for anxiety and irritability of PMS (see above) may be exacerbated by magnesium deficiency.

In support of some of these hypotheses, several scientific reports have demonstrated a role for magnesium supplementation in relieving symptoms of PMS. In particular, Italian workers have shown that in 32 women, who were given 360 mg magnesium or placebo per day from the 15th day of the menstrual cycle to the onset of menstrual flow, magnesium supplementation was an effective treatment for low mood in PMS.

Vitamin B_6

Vitamin B_6, in the form of pyridoxal phosphate (PLP), is a cofactor in a large number of important enzymic reactions throughout the body. Therefore it is a cofactor in serotonin and dopamine production in the hypothalamus. High oestrogen levels may lead to a relative deficiency in vitamin B_6 by altering tissue distribution and by inducing hepatic enzymes which increase the rate of vitamin B_6 breakdown. An oestrogen-induced deficiency in vitamin B_6 may reduce the synthesis of both serotonin and dopamine, an action that may alter the delicate balance between the two, normally maintained by adequate synthesis and breakdown. Adequate intakes of vitamin B_6 are also thought to be necessary for the

maintenance of normal intracellular magnesium levels, as this vitamin plays a fundamental role in the active transport of magnesium through the cell membrane. Thus, a synergetic role for magnesium and vitamin B_6 has been suggested, although this remains to be tested.

High doses of vitamin B_6 have been found to be effective in treating most of the most common symptoms of PMS in several double-blind, placebo-controlled trials. For this reason administration of dietary supplements is a popular therapy for PMS used by many medical practitioners. However, as large doses have been associated with dependency and sensory neuropathy, doses higher than 50 mg per day should be avoided.

Essential Fatty Acids

Gamma-linolenic acid (GLA) is thought to be the major active constituent of evening primrose oil (EPO), which is self-administered by many women for the relief of PMS symptoms. GLA is a fatty acid belonging to the n-6 essential fatty acid family. It is formed in the body from linoleic acid (from seed oils such as sunflower). In the body linoleic acid is elongated and further desaturated in a several-step process leading to arachidonic acid. GLA is one of the intermediates in this pathway, which, in response to a stimulus, can act as a substrate for a series of enzyme reactions giving rise to series 1 eicosanoids (biologically active substances, including prostaglandins), which have a broad range of activities in the body.

Under similar circumstances arachidonic acid present in the cell membrane gives rise to series 2 eicosanoids, which tend to be proinflammatory unless moderated by the presence of series 1 and 3 eicosanoids (series 3 are from n-3 fatty acids, which are high in fish oils). In people consuming a Western diet, it is common to find that when cell membranes are stimulated (e.g., stressed), production of series 2 eicosanoids is dominant. This is because arachidonic acid can be provided in the preformed state in the diet in meat, and body status of GLA and ω-3 fats can be low. Although low status of the latter may derive from poor diet choice, low GLA status may result because of the slow action of the enzyme δ-6-desaturase, which is involved in the first desaturation step in the metabolism of linoleic acid. Its action is further slowed by viral infection, age, alcohol, stress, and lack of magnesium or zinc in the diet.

The suggestion that PMS may be caused by eicosanoid imbalance is based on the assumption that failure of the normal conversion of linoleic acid to GLA results in low levels of prostaglandin E_1 (PGE_1) eicosanoids in relation to the other eicosanoids, and this sensitizes tissues so that they respond abnormally to normal levels of oestrogen and progesterone. In support of this hypothesis, studies from Japan, Finland, and the UK have shown that women suffering from PMS have lower blood levels of GLA and DGLA (dihomo-γ-linolenic acid, a compound related to GLA), although linoleic acid levels are higher. Additional support for a therapeutic role of GLA in PMS comes from six double-blind, placebo-controlled studies which have shown a significant improvement in symptoms from a daily supplement of GLA in the form of EPO, although one further study carried out in Australia showed no benefit.

Cyclical mastalgia, or breast pain, in the premenstrual phase may or may not be accompanied by other symptoms of PMS. In any case, similar abnormalities in n-6 fatty acid profile of cell membranes to that described above for PMS have been found in this condition and good response to GLA supplementation has been reported. Indeed, EPO is commonly prescribed by breast surgeons as the first-line treatment for the condition. In one study nearly half of hospital outpatients with this condition showed a benefit of EPO treatment without side effects, although doses of at least 4 g per day are required.

Other Nutrients

Apart from those already discussed, a role for deficiency of other nutrients in the etiology of PMS has been suggested, although few well-designed studies have been reported. Studies in vitamin E-deficient animals suggest that vitamin E supplementation may enhance the production of eicosanoids of series 1 and reduce the release of arachidonic acid from phospholipids. Hence, this combined action would reduce the inflammatory tendency implicated in some forms of PMS. Two double-blind, placebo-controlled studies in the 1980s indicated that supplementation with vitamin E may alleviate PMS symptoms, but at least one other study reported no effect. In one of the positive studies, daily supplements of 300 IU significantly alleviated PMS symptoms of anxiety after 2 months, while 600 IU per day was required for the same duration to reduce PMS symptoms of craving and depression. These levels of vitamin E are far greater than can be obtained through diet.

Zinc deficiency may be involved in the etiology of PMS. This suggestion stems from observations of low luteal-phase zinc levels in women suffering from PMS. Several mechanisms for involvement of zinc deficiency in PMS have been proposed. Zinc is involved in the regulation of pituitary hormone secretion, influencing,

in particular, prolactin and luteinizing hormone activity, which may affect predisposition to PMS. Zinc is a modulator of endogenous opiate-receptor binding in the central nervous system, a system also implicated in the condition. Zinc also takes part in the synthesis of PGE_1 by its involvement in the release of DGLA and hence may influence eicosanoid balance (see above). Nevertheless, no placebo-controlled study has been carried out to show the effects of supplementary zinc as therapy for PMS.

Women with PMS have been reported to have higher intakes of calcium than normal women owing to excessive intake of dairy products. Foods in this group are characterized by having very high calcium-to-magnesium ratios and PMS sufferers have been reported to have diets with higher ratios than normal women. As a high intake of calcium is known to reduce magnesium absorption, a high calcium intake has been proposed to result in a chronic magnesium deficiency and PMS. It has also been postulated that excessive calcium intake may cause the behavioral changes of PMS by calcium interference with glucose breakdown as a source of energy to the brain. However, a controversial placebo-controlled study on 33 women showed that daily supplementation of 1 g of calcium for 3 months significantly reduced PMS symptoms of depression and fluid retention.

Caffeine

Several surveys of unselected women have shown that those who consume large amounts of beverages containing caffeine are more likely to suffer from PMS. Although constant consumption of low doses of caffeine may exacerbate the stress reaction and tendency to PMS, paradoxically, acute, high-dose consumption has been used to treat migraine headaches, although it was not reported whether these headaches were present premenstrually.

Botanicals

There has been renewed interest in recent years in the therapeutic applications of herbal medicine for a wide range of conditions. The active phytochemicals of the majority of commonly used herbs and their physiological effects are well reported. It is only recently, and mostly in Germany, that clinical studies of efficacy in treatment have been undertaken. There is no doubt from the clinical experience of practitioners that phytotherapy has much to offer for treatment of hormone imbalance syndromes in women, including PMS, but more research-based evidence is required.

An important herb used by phytotherapists to treat PMS is the chaste tree (*Vitex agnus-castus* L.). Extracts of the berries have been shown to reduce the abnormally high prolactin secretion of PMS via the ability of certain of its phytochemicals to mimic the action of dopamine by binding to dopamine receptors in the pituitary. Other herbs traditionally used in phytotherapy for PMS contain phyto-oestrogens. These molecules may have oestrogen-like action, either due to the steroidal nature of their active constituents (false unicorn root, *Chamaelirium luteum* A. Gray) or to the spatial similarity of active groups in their constituents, which allow them to bind to oestrogen receptors. Among the latter group are isoflavonoids and lignans, which appear to have 'adaptogenic' properties: They are weakly oestrogenic at low circulating oestrogen concentrations and antioestrogenic at high oestrogen concentrations. Isoflavonoids are present in soya bean and its products and in medicinal herbs such as black cohosh (*Cimicifuga racemosa* Nutt.); these show a beneficial effect in reducing symptoms of PMS and the menopause. Lignans are present in high concentration in seed coats, including wheat, and are especially high in linseed (*Linum ussitatissimum* L.). The presence of lignans may explain why women who eat high quantities of whole grains, fruit, and vegetables are less likely to suffer from PMS.

PROSTAGLANDINS AND LEUKOTRIENES

G E Caughey, M J James and L G Cleland, Royal Adelaide Hospital, Adelaide, SA, Australia

Introduction

Prostaglandins (PGs) and leukotrienes (LTs) belong to a large, heterogeneous group of lipid mediators, collectively named eicosanoids, that exhibit a diverse array of physiological activities (**Figure 1**). Eicosanoids are synthesized by oxygenation and remodeling of their precursor 20-carbon polyunsaturated fatty acids (PUFAs), namely arachidonic acid (AA; 20:4 *n*-6). Whilst pivotally involved in many homeostatic processes, eicosanoids are also implicated in the pathophysiology of many chronic disorders (**Figure 1**). Since the discovery in the mid 1930s of prostaglandins as a component of human semen that potently induced uterine contractility, the field of eicosanoid biology has expanded to include the PGs, LTs, thromboxanes (TXs), hydroxyeicosatetraenoic acids (HETEs), lipoxins (LXs, including epi-lipoxins), isoprostanes, and the cyclopentaeone PGs (**Figure 2**). Except the latter two classes, which are generated by nonenzymatic oxidation, synthesis of these mediators is tightly regulated by a number of enzymes. Eicosanoids generally act as paracrine or autocrine agents, in that they exert their biological effects locally, either on the cell from which they were synthesized or on neighboring cells. This chapter will focus primarily on the synthesis and physiological roles of the PGs and LTs and the regulation of their synthesis by dietary fatty acids.

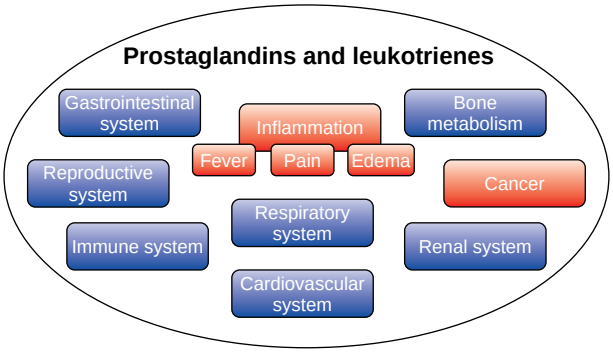

Figure 1 The diverse activities of prostaglandins and leukotrienes are reflected by their involvement in both normal homeostasis (blue) and pathophysiology (red).

Synthesis

Following an appropriate physiological or pathological stimulus, AA is released from cell membrane phospholipids by one of the many forms of phospholipase A_2 (PLA_2), which is generally regarded as the rate-limiting step in eicosanoid synthesis (**Figure 2**). There are two major biosynthetic pathways: the cyclooxygenase (COX/PGH synthase) pathway, which synthesizes the PGs and TXs; and the 5-lipoxygenase (5-LO) pathway, which synthesizes the LTs, HETEs, and lipoxins. The predominant cellular origins of PG and LT synthesis, their receptors, and their major physiological activities are summarized in **Table 1**.

Major Biosynthetic Pathways

Cyclooxygenase (COX)

COX catalyzes two enzymatic activities; namely, the conversion of AA to the hydroperoxy endoperoxide PGG_2, followed by its subsequent reduction to the labile product PGH_2. PGH_2 is the common substrate for a number of different cell-specific synthases, which convert PGH_2 to the individual PGs or TX, including PGE_2, PGI_2 (prostacyclin), PGD_2, $PGF_{2\alpha}$, and TXA_2 (**Figure 3**). Two isoforms of COX named

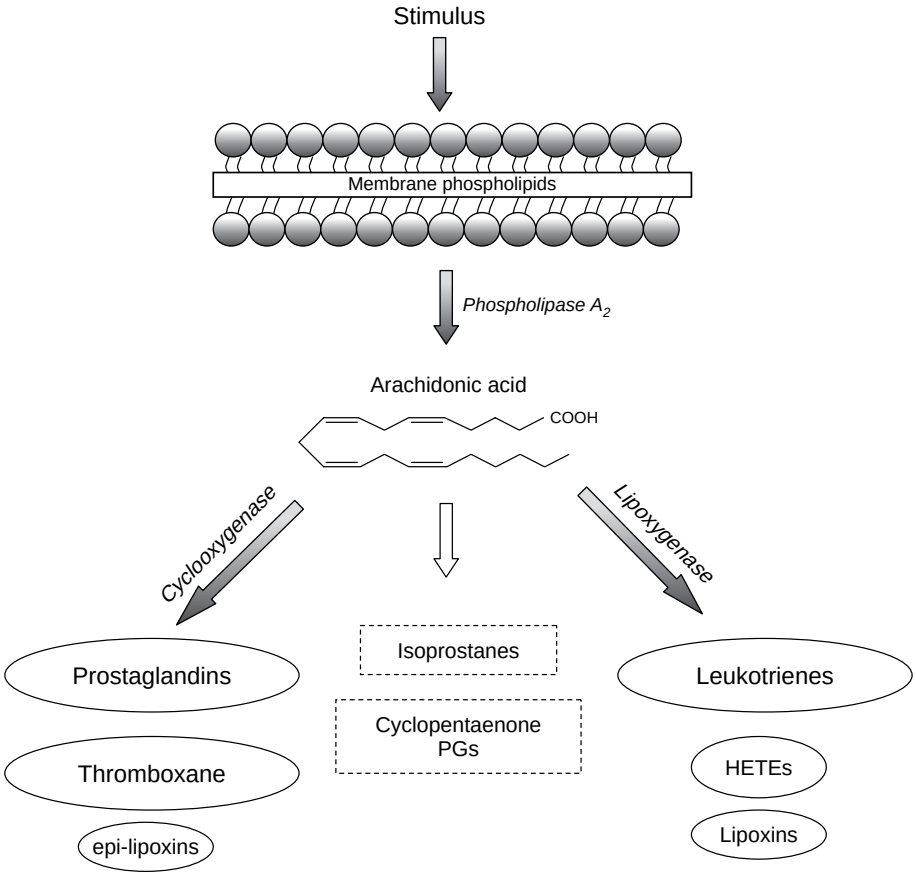

Figure 2 Metabolism of arachidonic acid to either the prostaglandins and thromboxane via the cyclooxygenase pathway or leukotrienes (and HETEs, lipoxins) via the lipoxygenase pathway. The isoprostanes and cyclopentaenone PGs are generated by nonenzymatic oxidation (dashed boxes). The epi-lipoxins are formed via interactions with cyclooxygenase and aspirin.

COX-1 and COX-2 were identified in the early 1990s and this led to renewed interest in the field of PG biology. Both isoforms catalyze the same reactions but are produced by different genes and although they share only about 61% sequence identity, the 3-dimensional crystal structures are virtually identical. After the discovery of the two isoforms, it quickly became apparent that their roles in many physiological processes were distinctive and that their expression and tissue profiles were differentially regulated. In general terms, COX-1 is constitutively expressed in most tissues and cell types and is responsible for the synthesis of the PGs required for the maintenance of normal physiology in the noninflamed state. Whereas COX-2 is generally undetectable in most tissues, its expression can be rapidly induced by a variety of inflammatory stimuli, such as bacterial LPS, cytokines, and growth factors. It is this isoform that synthesizes most PGs in inflammation and carcinogenesis. However, this division of the biological roles of COX-1 (physiological PGs) and COX-2 (inflammatory PGs) is an oversimplification of the biological reality. More recent studies have shown COX-1 can be induced or upregulated under certain conditions and that COX-2 is constitutively expressed in the brain and kidney. Thus, both COX-1 and COX-2 are involved in physiological as well as pathological responses.

The COX pathway is of major clinical importance because it is the major pharmacological target of nonsteroidal anti-inflammatory drugs (NSAIDs) and aspirin. Inhibition of PG synthesis is considered the primary mechanism responsible for both the therapeutic (anti-inflammatory, analgesic) and the toxic effects of NSAIDs. The clinically significant side effects of NSAIDs include renal impairment, dyspepsia, and upper gastrointestinal bleeding, the latter being particularly associated with inhibition of COX-1. By comparison, the anti-inflammatory and analgesic effects are associated with COX-2 inhibition. These observations provided the rationale for fast-track development of selective COX-2 inhibitors, which were promoted under the premise that they would have similar anti-inflammatory efficacy to conventional NSAIDs but would have significantly

Table 1 Predominant cellular origins and physiological activities of prostaglandins and leukotrienes

Eicosanoid/receptor		*Major cell origins*	*Physiological activities*
PGE_2	*EP_1–EP_4*	Most cell types	Potent vasodilator Stimulates bone and cartilage resorption Increases microvascular permeability Mediator of febrile responses Hyperalgesic
PGI_2	*IP*	Endothelial cells	Potent vasodilator Inhibits platelet aggregation
TXA_2	*TP_α, TP_β*	Platelets Monocytes	Potent vasoconstrictor and inducer of platelet aggregation
PGD_2	*DP_1, DP_2*	Mast cells	Vasodilator Inhibits platelet aggregation
$PGF_{2\alpha}$	*FP*	Monocytes Macrophages Uterine cells Epithelial cells	Potent vasoconstrictor and bronchoconstrictor Myometrial and smooth muscle cell contraction
LTB_4	*BLT_1, BLT_2*	Neutrophils Monocytes Macrophages Eosinophils Mast cells	Potent neutrophil chemotactic and chemokinetic agent Induces leucocyte adhesion Induces release of reactive oxygen species and hydrolytic enzymes by neutrophils
LTC_4 **LTD_4** **LTE_4**	*$CysLT_1$, $CysLT_2$*	Eosinophils Mast cells Macrophages Smooth muscle cells	Potent bronchoconstrictor Promotes vasoconstriction

fewer gastrointestinal (GI) side effects. Highly selective COX-2 inhibitors have been relatively successful with regard to their reduced GI toxicity. However, based on the role of COX-2 derived PGs in normal physiology, there exists the potential for other side effects such as increased cardiovascular events for at-risk patients and aggravated renal impairment in patients with reduced renal function.

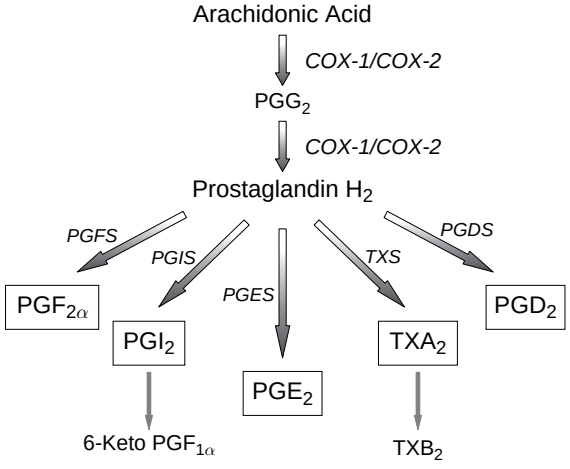

Figure 3 Metabolism of arachidonic acid (AA) to prostaglandin (PG) $PGF_{2\alpha}$, PGI_2 (prostacyclin), PGE_2, TXA_2, and PGD_2 by the COX pathway. PGI_2 and TXA_2 have very short half-lives (30 s) and are converted to the stable but inactive 6-keto $PGF_{1\alpha}$ and TXB_2, respectively.

Lipoxygenase

An alternative pathway available for the metabolism of AA is the 5-lipoxygenase (5-LO) pathway, which gives rise to the LTs which contain a conjugated triene structure. The 5-LO enzyme catalyzes the addition of oxygen at the 5th carbon of AA to produce 5-hydroperoxyeicosatetraenoic acid (5-HPETE) as well as the subsequent conversion of 5-HPETE to LTA_4. 5-LO is dependent on ATP and Ca^{2+} for activation, following which it translocates from the cytosol to the cell membrane in association with a transmembrane protein termed FLAP (5-LO activating protein). This translocation step facilitates substrate presentation, since the majority of AA is found in the cell membrane. LTA_4 may undergo one of two enzymatic reactions depending on the cell type. In the first, glutathione S-transferase (LTC synthase) catalyzes the addition of glutathione to the 6 position of LTA_4 to produce the first of three cysteinyl LTs (CysLTs), LTC_4. LTC_4 is then exported to the extracellular space through a specific transmembrane transporter. In the extracellular space subsequent peptide cleavage yields LTD_4 and then LTE_4. This represents metabolism from one active mediator to another and not a catabolic inactivation process. Collectively, these three CysLTs (historically known as the slow-reacting substance of anaphylaxis) contribute to the bronchoconstricting activity generated during anaphylaxis and they

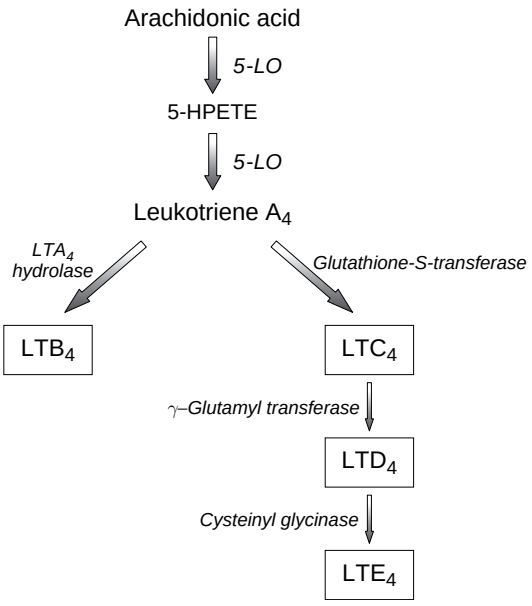

Figure 4 Metabolism of arachidonic acid (AA) to leukotriene B_4 (LTB_4) and the cysteinyl LTs, LTC_4, LTD_4, and LTE_4 by the 5-lipoxygenase (5-LO) pathway.

play a key role in asthma and allergic reactions. In the second reaction, LTA_4 hydrolase converts LTA_4 to the dihydroxy fatty acid LTB_4. Once formed, LTB_4 is actively exported from the cells where it acts as a potent chemoattractant and triggers adherence and aggregation of leucocytes. In addition, LTB_4 modulates immune responses and host defense against infections. Release of LTB_4 may contribute to the pathology of many inflammatory disorders, including asthma, arthritis, and inflammatory bowel disease.

PG and LT Receptors

The biological actions of both PGs and LTs are mediated through G-protein-coupled cell surface receptors, which are coupled to specific signal transduction pathways. Eight subtypes of PG receptors encoded by separate genes are characterized and include the PGE receptors (EP1, EP2, EP3, EP4), the TX receptor (TP), the PGI receptor (IP), the PGF receptor (FP), and the PGD receptor (DP). The tissue distributions of these receptors is linked to specific functional roles and can be grouped into three categories based on their signal transduction and activities:

1. Relaxant receptors (EP2, EP4, IP, DP): mediate an increase in cAMP and smooth muscle relaxation.
2. Contractile receptors (EP1, TP, FP): mediate an increase in intracellular calcium and smooth muscle cell contraction.
3. Inhibitory receptors (EP3): mediate inhibition of cAMP and inhibition of smooth muscle cell relaxation.

Two receptors for LTB_4, termed BLT1 and BLT2, have been identified at the molecular level and these differ in their affinity and specificity for LTB_4. BLT1 is a high-affinity receptor specific for LTB_4 and BLT2 is a low-affinity receptor, to which other eicosanoids can also bind. The major activities of LTB_4 appear to be mediated via BLT1. The precise role of BLT2 remains to be identified.

Two subtypes of the receptor for the CysLTs termed $CysLT_1$ and $CysLT_2$, were postulated based on pharmacological studies. This classification has recently been confirmed by molecular identification. To date, several high-affinity $CysLT_1$ receptor antagonists have been developed, which have been shown to be clinically efficacious in chronic asthma. By contrast, no high-affinity selective $CysLT_2$ antagonists have yet been described.

The development of specific agonists and antagonists for each of the PG and LT receptors, in addition to receptor knockout animal models, have aided in the characterization and understanding of the roles of these mediators in both normal physiology and disease states.

Physiological Activities of Prostaglandins and Leukotrienes

Bone Metabolism

Bone remodeling, the continuous process of bone resorption by osteoclasts and bone formation by osteoblasts, is mediated by a number of factors, one of which is PGE_2. However, the role of PGs in bone metabolism is somewhat contradictory, in that PGE_2 can have both anabolic and catabolic effects. For example, PGs can stimulate the differentiation *in vitro* of precursors of both osteoclasts (responsible for bone resorption) and osteoblasts (bone growth). Both bone resorption and formation by PGE_2 is mediated by the EP4 receptor. It has been suggested that the opposing actions of PGE_2 may serve to maintain a coordinated regulation of bone resorption and formation and may be dose related with stimulation of bone formation at low concentrations and inhibition at high concentrations.

Cancer

The involvement of PGs, in particular those arising from COX-2, in the causation and prevention of cancer has been identified recently. Much of the

evidence has come from epidemiological studies that indicate chronic use of aspirin or other NSAIDs can significantly decrease the risk of developing certain cancers (e.g., colorectal cancer). Additionally, aspirin and NSAIDs can lower the mortality rates and induce tumor regression from colorectal cancer and other forms of cancer. Angiogenesis, the development of new blood vessels, which is an essential step in tumor growth, is associated with the upregulation of COX-2 and presumably PG synthesis. COX-2 is upregulated in a variety of premalignant and malignant states and there is evidence that selective COX-2 inhibitors can inhibit the early development of malignant tumor growth, cause premalignant tumors to regress, and lead to death of established cancer cells.

Cardiovascular

The PGs and TX have a central role in the regulation of platelet aggregation and vascular tone and as such are particularly important regulators of the cardiovascular system. TXA_2 is a potent vasoconstrictor and inducer of platelet aggregation, whilst PGI_2 dilates blood vessels and prevents platelet aggregation. Under normal conditions, a dynamic balance based on the opposing actions between TXA_2 produced by platelets and PGI_2 produced by vascular endothelial cells maintains cardiovascular homeostasis and prevents thrombotic events (**Figure 5**). Altered metabolism of these mediators has been reported in association with atherosclerosis, in which there is a shift in the TXA_2/PGI_2 balance due to both increased TXA_2 and decreased PGI_2 synthesis. A proatherogenic state with increased platelet adhesion and aggregation at sites of endothelial injury is a result. This may lead to subsequent thrombus formation and vessel occlusion.

Platelets only express COX-1 and the cardioprotective effect of low-dose aspirin is attributed to its ability to inhibit irreversibly platelet COX-1 and hence TXA_2 synthesis. In the vasculature, it appears that endothelial cell COX-2, possibly upregulated by shear blood flow, is primarily responsible for the synthesis of PGI_2. Traditional NSAIDs inhibit both COX-1 and COX-2, thereby inhibiting platelet-derived TXA_2 and endothelium derived PGI_2. The balance may therefore be maintained but in a less stable state. In contrast, the selective COX-2 inhibitors reduce PGI_2 synthesis but importantly have no effect on platelet COX-1 activity, potentially altering the balance of TXA_2/PGI_2 to a prothrombotic state that may explain the potential thrombotic side effects associated with use of these drugs. Low-dose aspirin inhibits platelet COX-1 which cannot be regenerated by these anuclear cells thereby shifting the balance between TXA_2 (principally platelet COX-1 derived) and PGI_2 toward a less coagulable state.

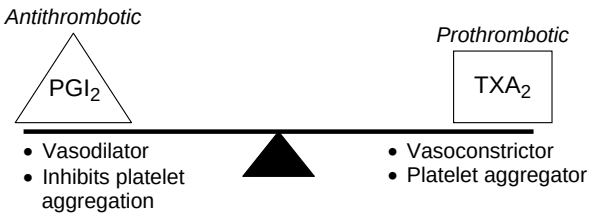

Figure 5 A dynamic balance between TXA_2 production by platelets and PGI_2 by vascular endothelial cells maintains cardiovascular homeostasis.

LTB_4 can also be implicated in cardiovascular events by virtue of its potent chemotactic effects and ability to induce leucocyte adhesion to vascular endothelial cells at sites of injury.

Gastrointestinal System

Of the COX isotypes, only COX-1 is constitutively expressed throughout the gastrointestinal (GI) system, where the main PGs produced are PGE_2 and PGI_2. Both have important cytoprotective effects on the GI mucosa, including reducing gastric acid secretion from stomach parietal cells, increasing mucosal blood flow, and stimulating the release of protective mucus. As stated previously, the upper GI toxicity commonly associated with classical NSAIDs is thought to arise from the nonselective inhibition of COX-1 activity in the stomach. Clinical trials with highly selective COX-2 inhibitors have demonstrated clinically meaningful reductions in the incidence of serious upper GI events by comparison to conventional NSAIDs.

COX-2 is expressed in peptic ulcers and the inhibition of COX-2 has been associated with delayed ulcer healing.

Immune System

Within the immune system, PGE_2 regulates a wide range of functions, particularly in the cell populations central to the cell-mediated immune response, namely T cells and macrophages. In these immune-modulating cells, the actions of PGE_2 are generally immunosuppressive. For example, PGE_2 inhibits antigen-induced T-cell proliferation and activation, cytokine production, cytokine receptor expression and macrophage proliferation, and class II major histocompatibility complex expression. Additionally, PGE_2 can

regulate the overall characteristic of an immune response by its ability to promote a Th2-type response, which is characterized by immunoglobulin (Ig) class switching to IgG1 and IgE and increased production of IL-4, IL-5, and IL-10. The ability of PGE_2 to inhibit many of the responses initiated by T-cell activation supports a central role for PGE_2 within the immune response. Moreover, PGE_2 has inhibitory and protective functions in autoimmune disease. Administration of PGE_2 or its analogs can ameliorate the manifestations of autoimmunity and reduce immune-mediated organ injury, and can also delay or prevent allograft rejection.

Inflammation

Inflammation is a complex of sequential and partly recursive cellular and biochemical changes in tissues in response to injury or infection. It is a normal homeostatic process that protects the host against the effects of everyday and incident trauma and invasive microorganisms. However, when this process becomes dysregulated unwanted inflammation and tissue destruction arises. Acute inflammation is characterized by hyperemia, pain, edema, and leucocyte infiltration. PGs are involved in these processes, as further illustrated by the analgesic effects and reduction in inflammatory swelling of NSAIDs. PGE_2 has been regarded as the principal PG mediator of pain and edema, but both PGI_2 and PGD_2 can exert similar effects. These PGs exert their hyperalgesic effects by increasing sensitivity of pain receptors to peripheral inflammation. PGE_2 dilates vessels and with LTB_4 leads to tissue swelling with both edema and leucocyte infiltration.

While levels of PGs and LTs are generally low in uninflamed tissues, their synthesis is increased substantially during an inflammatory response. As immune cells infiltrate the tissues, further increases in levels of PGs and LTs are observed. Induction of PLA_2 and COX-2 by inflammatory stimuli accounts for the high levels of PGs found at sites of inflammation. Cellular infiltration mediated by LTB_4 is contributed to by the chemotactic effects on leucocytes and altered adhesion molecule expression on endothelial cells.

Fever

Fever, a common symptom of many diseases, is elicited by exogenous pyrogens (such as bacterial LPS) or an inflammatory insult, which results in the production of cytokines such as IL-1β that act as endogenous pyrogens. These cytokines then stimulate the neural pathways that increase body temperature. PGE_2 is an important contributor to the febrile response and NSAIDs are used to treat pyresis. In COX-2-deficient mice, the febrile response to LPS is ameliorated, suggesting an important role for COX-2-derived PGs in fever production. Furthermore, mice deficient in the EP3 receptor fail to respond to either endogenous or exogenous pyrogens.

Respiratory System

The bronchoconstrictor activity of the CysLTs underlies their pathogenic role in asthma. Other relevant biological actions of CysLTs include: (1) increased microvascular permeability, which leads to airway edema; and (2) mucus hypersecretion. Both the 5-LO inhibitors and CysLT receptor antagonists have been used to treat asthma.

PGs, in particular PGD_2, are involved in many processes within the lung, including regulation of pulmonary vascular tone, maintenance of lung surfactant, regulation of capillary and alveolar permeability and control of bronchial mucous secretion.

Renal

Maintenance of normal kidney functions is dependent on PGE_2, which regulates vascular tone, blood flow, sodium, and water homeostasis, and renin secretion. PGE_2 can reduce sodium and water reabsorption and mediate the release of renin, which in turn can act to regulate blood pressure control. Under conditions of increased sodium reabsorption, PGE_2 can act as a counter-regulatory factor. PGI_2 is involved in potassium secretion by stimulating the renin–angiotensin system. Both isoforms are constitutively expressed in the kidney with quite selective and distinct localization. For example, COX-2 is highly expressed in the macula densa, which plays an important role in the coordinated regulation of glomerular filtration, proximal tubule function, and renin production, processes that are responsible for sodium and water homeostasis. In those with poor renal function, reversible renal failure has been associated with NSAIDs and highly selective CXO-2 inhibitors. This presumably reflects a crucial compensatory role for PGs in the compromised failing kidney.

Reproduction

PGs play important regulatory roles in the reproductive processes of ovulation, implantation, and parturition. Just prior to ovulation, there is an increase in PGE_2 synthesis by the preovulatory follicle in response to an increase in leutenizing hormone (LH). Induction of COX-2 (by LH) is necessary for this increase in PGE_2 synthesis and for the successful rupture of the follicle. After fertilization, PGs (PGE_2 and PGI_2) play a role in the successful implantation

of the embryo and, again, PGE_2 production appears to be COX-2 dependent. The importance of COX-2 in the reproductive process is further emphasized by studies in which COX-2 knockout mice (but not COX-1 knockout mice) have impaired fertility based on multiple reproductive failures, at the level of both ovulation and implantation, which can be restored by exogenous administration of PGE_2. Both PGE_2 and $PGF_{2\alpha}$ have potent uterotonic activities and are involved in uterine contraction during the initiation of labor and parturition. Administration of $PGF_{2\alpha}$ and PG analogs have been used extensively to induce labor since the 1960s. In addition, at the time of parturition, there is an increase in the uterine expression of EP1, EP3, and FP receptors, which act to potentiate smooth muscle cell contraction. In the neonate, COX-2-derived PGE_2 is required for closure of the ductus arteriosis, through an action by EP4 receptors on smooth muscle cells.

Regulation of Prostaglandin and Leukotriene Synthesis by Dietary Fatty Acids

The diverse physiologic and pathologic functions mediated by eicosanoids highlight the importance of their fatty acid precursors in the diet. Unlike cellular proteins that are genetically predetermined, the PUFA composition of cell membranes is dynamic and is pivotally dependent on dietary intake. The typical Western diet is high in the *n*-6 family of PUFA (up to 25-fold more *n*-6 fats than *n*-3 fats are consumed). This predominance of *n*-6 fat is due to the abundance in the diet of the 'parent' 18-carbon PUFA linoleic acid (LA; 18:2 *n*-6), which is present in high concentrations in corn, soy, safflower, and sunflower oils. Once ingested, LA can be converted to AA by a series of elongation and desaturation enzymes (**Figure 6**). Hence AA is the predominant PUFA of membrane phospholipids and substrate for eicosanoid biosynthesis in the Western context.

The enzymes involved in the metabolism of the 20-carbon PUFAs to PGs and LTs can use either *n*-9 (eicosatrienoic acid; EtrA 20:3), *n*-6 (arachidonic acid; AA 20:4), or *n*-3 (eicosapentaenoic acid; EPA 20:5) PUFAs as the substrate (**Figure 7**). When *n*-3 PUFAs are included in the diet, EPA, the *n*-3 homolog of AA competes with AA for incorporation into the cellular phospholipids. An increase in the concentration of EPA in cell membranes displaces AA, which will result in reduced substrate for the synthesis of the *n*-6 eicosanoids. EPA can also compete with AA as the substrate for either COX or 5-LO enzymes. This results in inhibition of the synthesis of *n*-6-derived PGs and LTs and the formation of the *n*-3 PGs and LTs. The *n*-3-derived PGs and LTs are similar in structure but can be considerably different in their biological activity. On balance, the *n*-3 PGs and LTs are less thrombotic and less inflammatory than the homologous *n*-6-derived mediators (**Figure 6**).

Although the *n*-9 fatty acid oleic acid (OA; 18:1 *n*-9) is consumed in substantial amounts in the diet, the elongase and desaturase enzymes that catalyze the conversion of OA to ETrA (20:3 *n*-9)

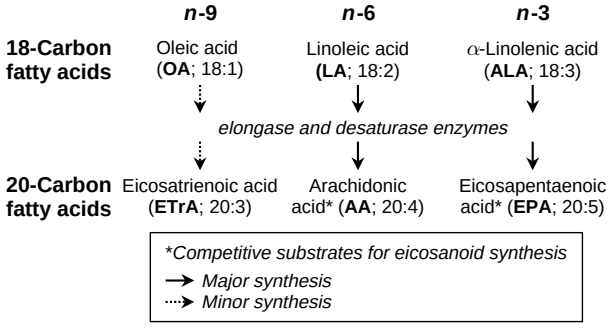

Figure 6 Dietary fatty acids and their metabolism after ingestion via the desaturase/elongase pathways.

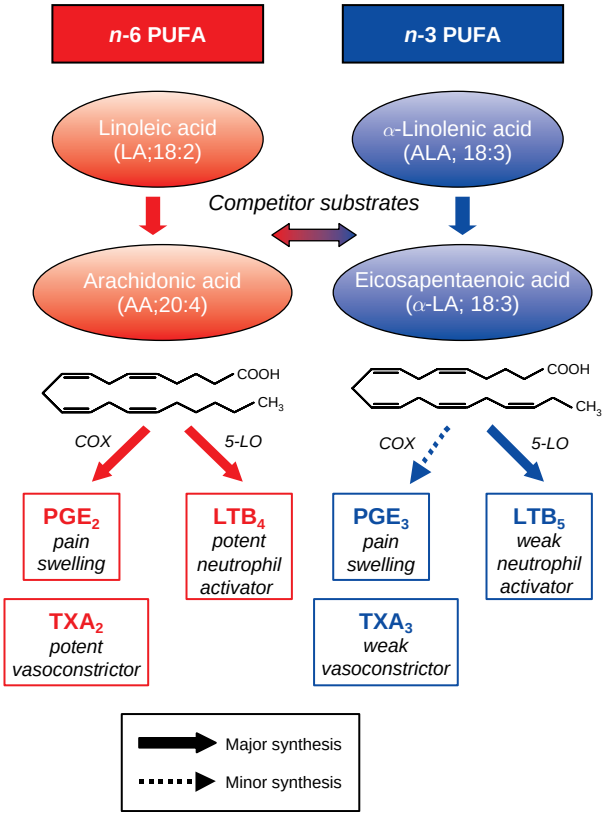

Figure 7 A comparison of the physiological activities between the *n*-6- and *n*-3-derived PGs and LTs.

preferentially metabolize the *n*-3 and *n*-6 20-carbon PUFAs, α-LA and LA, respectively. Metabolism of OA to ETrA is only quantitatively significant in essential fatty acid deficiency, which is very rare due to the abundance of essential fatty acids available in the diet and the small amounts required to avoid deficiency. Furthermore, ETrA can be metabolized by 5-LO but not COX because it lacks the *n*-6 bond necessary for PG and TX formation.

While Western diets are rich in *n*-6 and relatively poor in *n*-3 fats, there are populations in which *n*-6 fats are less dominant and more *n*-3 fats are consumed in total and relative terms (e.g., Greenland Eskimo, Japanese, and Mediterranean diets). In the extreme case of the Eskimos eating their aboriginal diet, which is based almost entirely on marine foods, there is a striking reduction in thrombotic vascular events and inflammatory diseases. The cardiovascular benefit has also been associated with traditional Japanese and Mediterranean diets. These benefits may be, in part, ascribed to a more favorable balance of *n*-6 and *n*-3 derived eicosanoids, although a myocardial membrane stabilizing effect of *n*-3 fats, independent of PG and LT synthesis, is also important.

Synthesis and Turnover

D J Millward, University of Surrey, Guildford, UK

Whole Body Protein Homeostasis

The regulation of the protein mass of the body requires mechanisms that control the protein content within cells, organs, and tissues and that coordinate this control during growth and body weight maintenance. Because all intracellular proteins exhibit turnover, regulation of the cellular protein content involves control of both protein synthesis and proteolysis. For some proteins, such control is understood in considerable detail. Less is known about the coordinated control of intracellular protein turnover to maintain an appropriate cellular composition, and even less is known about whole body coordination. There are two aspects of control: acute control during feeding and fasting and chronic control during growth and long-term maintenance.

The diurnal cycle of feeding and fasting characteristic of human nutrition results in gains and losses of body protein in overall nitrogen balance. Furthermore, such diurnal cycling occurs with an amplitude that increases with increasing dietary protein intakes. These oscillations in body protein content involve changes in whole body and tissue protein synthesis, proteolysis, and amino acid oxidation, and much effort has been invested in identifying the control mechanisms, particularly those that influence the efficiency of postprandial protein utilization.

Long-term homeostasis is a less well understood phenomenon. For the slow-growing long-lived human, most of the life span involves a constant body weight and the remarkable phenomenon of this long-term constancy of body protein at a characteristic mass is a particularly challenging problem. Regulatory mechanisms exist that allow restoration of body weight and especially protein content to its target size after an insult that induces wasting (i.e., catch-up growth) and that prevents the continuation of growth after the target size has been reached. However, such mechanisms are poorly understood.

One approach to the problem has involved the concept of a protein-stat mechanism, the central feature of which is an interaction between linear growth of bone, protein deposition in skeletal muscle, and dietary protein intake, with the growth of most other organs secondary to this interaction (**Figure 1**). Within this context, whole body protein content is controlled through an amino-static appetite mechanism, acting primarily to maintain skeletal muscle mass at a level set by the linear dimensions of the organism. Bone lengthening occurs at rates determined by genetic programming and an appropriate hormonal anabolic drive, exerted by dietary protein. Bone lengthening controls, by passive stretching, net protein deposition in skeletal muscle mainly through the regulation of new connective tissue synthesis, which controls muscle volume. Some level of muscle activity is also required for maximal muscle size. Provision of amino acids to allow muscle to accumulate myofibrillar protein and increase to its phenotypic size is regulated through appetite stimulation, which monitors net amino acid flow into muscle. This is most obvious in catch-up growth. After muscle wasting with loss of myofiber protein there is potential for expansion within the preexisting connective tissue framework. Muscle growth ceases in the absence of passive stretch when bone length growth ceases. The growth of most other organs is secondary to this main interaction, determined primarily by the level of protein intake and the consequent metabolic work and functional demand for the organ, and is not specifically limited in size.

Protein Turnover

Protein turnover occurs because of the presence within cells of proteolytic systems that degrade

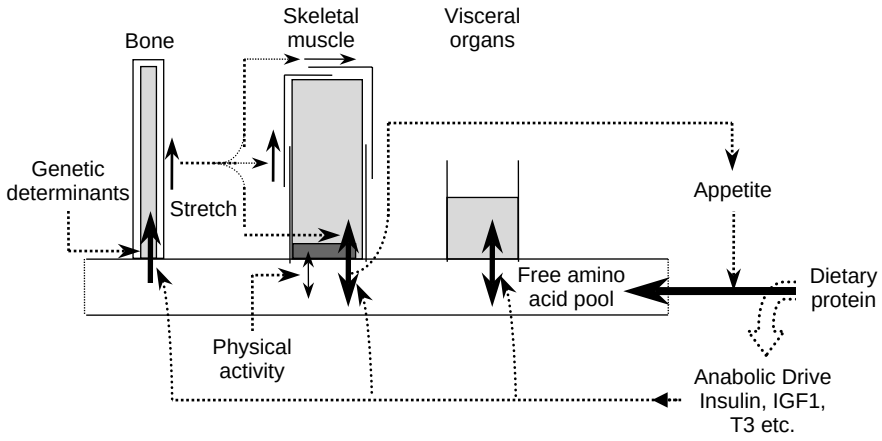

Figure 1 Protein-stat mechanism for coordinated control of body protein growth and maintenance. The protein content of skeletal muscle is controlled by long bone growth mediated through a passive stretch mechanism and anabolic signals in response to dietary protein intake, with the growth of most other organs secondary to this interaction—that is, growth rate for these organs is a function of metabolic and functional demand in response to food intake.

proteins for a variety of reasons ranging from the removal of proteins with an incorrect primary amino acid sequence ("error" proteins) to the provision of free amino acids during nutrient deprivation. However, the half-lives of individual proteins vary over at least three orders of magnitude within the same cells, identifying the process as specific. The nature and control of proteolysis are poorly understood. The physicochemical structure, especially hydrophobicity and ionic charge, influences susceptibility to proteolysis. Also, an amino acid sequence (PEST: proline, glutamate, serine, and threonine) influences susceptibility to proteolysis and occurs in several rapidly degraded proteins. The molecular basis for this remains largely unknown. For heterogeneous turnover of proteins within structures such as mitochondria, myofilaments, and multienzyme complexes to occur while functional integrity is maintained, complex coregulation is required, and there is evidence for at least three different systems involved in the case of skeletal muscle.

The lysosomal-autophagic system is present in all cells and involves acid proteinases (cathepsins) within a distinct vacuolar structure capable of engulfing and degrading complete organelles, ribosomes, as well as individual intracellular proteins and proteins entering cells via endocytosis. Lysosomal proteolysis is complete, and most is known about hepatic macroautophagy in which hepatic protein mass appears to be regulated by a receptor-mediated amino acid-dependent inhibitory process.

The ubiquitin–proteasome system is widely distributed among tissues, with a relatively broad protein specificity, catalyzing the hydrolysis of protein to peptides averaging approximately 8 amino acids long and exhibiting an ATP dependency. It involves two components. One is a recognition system involving ATP-dependent formation of a covalent link between the protein and a short polymer of ubiquitin, which is responsible for targeting the protein substrates toward proteolysis. This phase involves three separate reactions: ATP-dependent activation of ubiquitin, conjugation of ubiquitin to cellular proteins, and proofreading of the conjugates to either regenerate the target protein by removal of ubiquitin or commit the target protein to proteolysis by further ubiquitinylation. Proteolysis is mediated by the giant multifunctional protease, the proteasome. This comprises a core particle made of duplicate sets of at least 14 different proteins assembled in groups to form rings that are in turn stacked to form a donut-like structure within which the ubiquitin-conjugated proteins are unfolded by another ATP-dependent process and proteolytically cleaved to form peptides. A regulatory particle both delivers the ubiquitin-conjugated proteins to the core particle and removes ubiquitin from the peptides released after proteolysis. Proteolysis of the peptides is achieved by other systems, including the lysosomal system since degradation of ubiquitinylated proteins can also be achieved by the lysosome, or other poorly described proteinases and peptidases including the giant protease tripeptidyl peptidase II (TPP II) and various aminopeptidases. The relative importance of the two main systems capable of complete proteolysis, the lysosome and the proteosome, in various tissues remains uncertain. Most work on the regulation and activation of the ubiquitin–proteasome system has involved the accelerated

proteolysis in skeletal muscle atrophy, antigen processing, and removal of aberrant proteins rather than basal and nutritionally sensitive proteolysis. The third proteolystic system involves calpain and calpastatin, a calcium-activated proteolytic pathway that can initiate but not complete proteolysis. This comprises a highly conserved family of nonlysosomal calcium-dependent cysteine proteases composed of two ubiquitous isoforms (calpain I and II), several tissue-specific isoforms, and a 28-kDa regulatory subunit (calpain 4). *In vivo* calpain activity is tightly regulated by its endogenous and highly specific inhibitor, calpastatin. There is little evidence to suggest a role in nutritionally sensitive basal proteolysis.

Models and Tracer Methods for the Study of Protein Turnover

Studies of protein turnover have utilized isotope tracer techniques, radioactive tracers (^{14}C and ^{35}S) in animals, and stable isotopes (^{13}C, ^{15}N, and ^{2}H) in humans. Most studies utilize simplified models; the simplest and most widely used (**Figure 2**) is based on the measurement of the amino acid flux through the plasma amino acid pool. An example is the primed continuous intravenous infusion of ^{13}C-1-labeled leucine. During the infusion, the tracer isotopic enrichment is diluted by unlabeled amino acid from proteolysis (D) and the diet (I). At isotopic equilibrium constant labeling of the tracee is achieved, the magnitude of which (tracer/tracee ratio), in relation to the infusion rate (i), indicates the flux (Q), which is the total entry or exit rate of leucine through the pool. With the free leucine pool relatively small and turning over rapidly, isotopic equilibrium can be reached in 2–4 h if a priming dose is given as a bolus injection at the start of the infusion.

At isotopic and metabolic equilibrium, rates of entry and exit from the free leucine pool are equal for both labeled and unlabeled leucine so that Q is the rate of appearance or irreversible loss. Appearance is partitioned into dietary intake that is known (I) and entry from proteolysis of body protein (D) (i.e., no *de novo* synthesis of leucine occurs). Loss is partitioned into protein synthesis (S) and oxidative catabolism (O) to CO_2 and urinary N. The rate of leucine oxidation (O) is calculated from measurement of the production of labeled $^{13}CO_2$ in the breath and the labeling of the leucine or its keto acid in the plasma. This allows the components of protein turnover (D and S) to be calculated. Using the leucine content of tissue proteins, rates of leucine appearance and loss can be converted into rates of whole body protein synthesis and proteolysis.

^{13}C-1 leucine is especially useful since it is enables D to be calculated; it has a small pool enabling equilibrium to be achieved in a short period; decarboxylation is the first irreversible step in its catabolism, releasing $^{13}CO_2$ quantitatively; and its transamination product, α-ketoisocaproate, appears in the plasma and can serve as a measure of the labeling of the intracellular pool.

The latter advantage of leucine is especially important since determining isotopic enrichment of the precursor amino acid pool for protein synthesis is the most serious problem in these studies. Thus, amino acid pools are compartmentalized in the

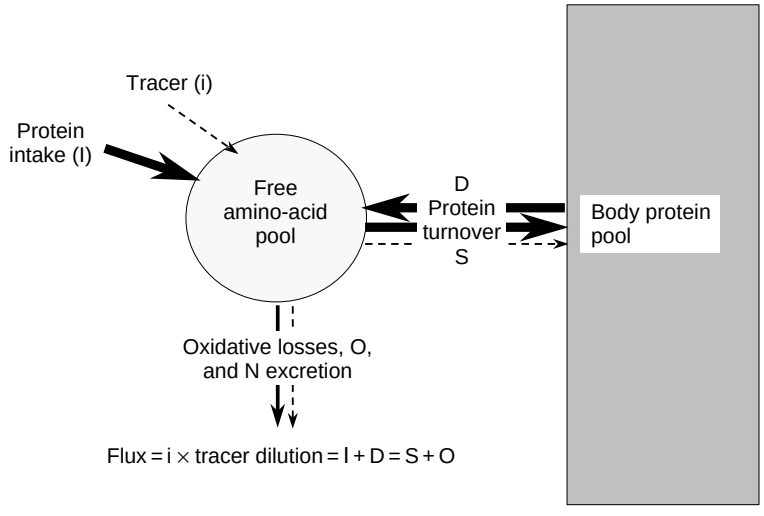

Figure 2 Single pool model for study of amino acid flux and protein turnover by tracer-labeled amino acid infusion. Movement of tracer is shown as dotted lines.

body, and the isotopic enrichment of tRNA-bound amino acids is lower than the measurable extracellular amino acid pool. Because it is difficult to measure labeling of amino acyl tRNA, a variety of indirect approaches have been used in an attempt to circumvent the problem. Equilibrium labeling of apolipoprotein B-100 has also been used to measure isotopic enrichment of hepatic amino acids. Thus, because apo B-100 turns over with a half-life of less than 1 h, during an infusion of several hours the protein labeling will reach a plateau representative of the hepatic precursor pool, and this has indicated a complex relationship between plasma and precursor enrichments for phenylalanine and leucine.

Flux rate measurements define whole body rates of protein synthesis and proteolysis, and each measurement is subject to error associated with the precursor assumption. Alternative methods have attempted to measure protein synthesis and proteolysis separately. In animal studies, a "flooding large dose" measurement of protein synthesis has been developed that enables all free pools to become equally labeled. Protein synthesis rates are calculated from measurement of isotope uptake into protein and free amino acid labeling during short periods after the dose. The method has been adapted for human use with a stable isotope, but there is evidence that the large quantities of the single amino acid stimulate protein synthesis.

Quantification of rates of proteolysis is especially problematic. In animal studies, proteolysis can be estimated from rates of synthesis and growth of tissue protein, and with careful design proteolysis rates can be measured over relatively short periods (e.g., 6 h following the administration of an endotoxin). Urinary excretion rates of 3-methyl histidine, a post-translationally modified amino acid not metabolized in the organism and excreted quantitatively in the urine, were proposed as a measure of myofibrillar protein degradation. Although the substantial contribution of small, rapidly turning over pools in microfilaments invalidates this approach for whole body studies, its release from incubated or perfused muscle can be used to determine myofibrillar protein degradation.

Simultaneous determination of protein synthesis and degradation can be made, in principle at least, from organ tracer balance studies (i.e., measurements of concentrations and isotopic enrichments of tracer amino acids across tissues such as the leg or forearm combined with measurements of 3-methyl histidine release). Such studies have identified a selective inhibitory effect of insulin on nonmyofibrillar protein degradation and stimulatory influences of amino acids on muscle protein synthesis.

All of these methods allow study of turnover of individual amino acids in protein and measurement of their nonprotein metabolic fate (e.g., oxidation). A different approach is to use ^{15}N glycine to study overall amino nitrogen turnover. Because of nitrogen exchange between amino acids by transamination, this label acts as a tracer for total free amino nitrogen rather than for any individual amino acid. The whole body nitrogen flux is estimated from the relative proportion of administered tracer excreted in the end product. This is then resolved into protein synthesis and proteolysis from measurements of N intake and excretion. The application of the method can be made simple by giving the ^{15}N label orally as a single dose. Although simple in concept, this approach is metabolically complicated with two urinary end products of nitrogen metabolism, urea and ammonia, each deriving from different pathways and each giving different flux values.

The choice of method must depend on the questions asked and circumstances of the subjects under study. ^{13}C carbon labeling is more suited to short-term (e.g., 3 or 4 h to 24 h) clinical measurements for which frequent blood and breath sampling is possible. Thus, the efficiency and mechanisms of postprandial protein utilization during meal feeding can be measured by means of ^{13}C leucine balance and turnover measurements. ^{15}N methods are more suitable for free-living subjects and patients, when urine sampling is possible but regular blood and breath sampling is inconvenient. The most famous example is the use of this method in an unassisted Antarctic crossing. Both methods involve many assumptions, but in practice the two approaches have been shown to give similar results.

Applications

Extent and Physiological Implications of Protein Turnover

In the human adult, approximately 300 g of protein turnover occurs each day (4 g/kg/day)—that is, three or four times the daily dietary intake. Rates vary between tissues with rapid turnover in visceral tissues and those with slow turnover in muscle. Liver and intestine account for approximately 8% of the lean body mass (LBM) and up to 50% of whole body protein turnover, with skeletal muscle, at 55% of the LBM, accounting for only approximately 25% of total protein turnover. Thus, whole body protein turnover varies with body composition and this largely explains developmental

changes. In the infant, turnover rates are much higher, ranging between 10 and 20 g protein turnover per kilogram per day, consistent with the higher proportion of metabolically active tissue and lower muscle mass. However, animal studies indicate a developmental decline in protein turnover in skeletal muscle that may be an additional component of the marked decline in protein turnover with age. In the elderly there is little evidence of any change other than that associated with the decline in LBM.

Protein turnover constitutes an appreciable fraction of the maintenance energy expenditure. On the basis of 5 mol ATP/GTP per mole of protein turnover (4 mol per peptide bond with 1 mol for amino acid transport, RNA turnover, and proteolysis), an energy cost of 22 kcal/mol ATP, and a molecular weight of 110 per mole of peptide bond, this is equivalent to approximately 1 kcal/g protein turnover. Thus, in the normal adult, protein turnover at 300 g/day accounts for approximately 20% of the basal metabolic rate. Therefore, changes in the protein turnover and metabolic rate would be expected to occur in parallel to some extent, and this is observed. Thus, the decline with age in both protein turnover and metabolic rate from birth to adulthood involves a factor of three or four in each case.

Regarding protein turnover and protein requirements, there is no a priori reason for any interrelationship, and there is little evidence of any. Thus, turnover does not consume amino acids, and amino acid catabolism and oxidation is not linked to turnover. Maintenance protein requirements decrease relatively little with age (<20%) compared with the 3- or 4-fold decrease in turnover.

Regulatory Mechanisms of Protein Turnover Control

The physiological importance of protein turnover is undoubtedly the regulatory flexibility it allows. With opportunities for control of both synthesis and proteolysis, the number of potential control sites is increased. In addition, because of the continuing turnover in the steady state, changes in the amount of protein can be achieved with low energy costs through inhibition of proteolysis to allow growth or through inhibition of synthesis to allow mobilization.

At the molecular level, regulation of protein synthesis is necessarily complex at both transcriptional and translational levels. Advances in molecular biology have revealed many examples of transcriptional control to the extent that changes in specific mRNA concentrations have become a surrogate measure of changes in rates of synthesis for specific proteins. Notable nutritional examples include control of hepatic export protein synthesis. Thus, the downregulation of albumin synthesis in response to either protein deficiency or the proinflammatory cytokine-mediated acute phase response is mediated largely at the level of transcriptional control of mRNA levels, with reductions in mRNA for albumin and other hepatic export proteins and increases in mRNA for acute phase proteins.

The concentration of ribosomes in tissues determines the capacity for protein synthesis and in this way controls overall tissue protein turnover rate and the changes associated with postnatal development. Cellular ribosome concentrations can change both acutely (e.g., during the diurnal cycle of feeding and fasting) and chronically in response to protein and energy intakes, increased functional demand, and hormones such as insulin, thyroid, growth hormone, and the glucocorticoids. Furthermore, these influences are tissue specific, with glucocorticoids, for example, increasing hepatic ribosome concentrations (as part of the hepatic acute phase response) and decreasing ribosome concentrations in muscle. In contrast, thyroid hormones increase ribosomes (and proteolytic enzymes) in both muscle and liver in association with a generalized increase in protein turnover.

Acute regulation of translation is exerted mainly through initiation, with reversible phosphorylations known to regulate at least four separate steps of the initiation cycle enabling very rapid changes in protein synthesis. Peptide hormones (insulin and insulin-like growth factor-1 (IGF-1)), glucocorticoids, and amino acids have all been implicated in such regulation, although the specific targets of control remain uncertain. Furthermore, there are major differences between the mechanisms observed in the young, rapidly growing animal and the adult animal. Thus, in skeletal muscle in the young rat, an insulin-mediated stimulation occurs. In adult human, muscle insulin is relatively ineffective, with amino acid levels the main stimulatory influence. Indeed, because insulin inhibits proteolysis and lowers amino acid levels, insulin alone appears to inhibit protein synthesis in human muscle.

Regarding the nutritional regulation of proteolysis, most is known about lysosomal proteolysis, especially hepatic autophagy, with both amino acids and insulin having inhibitory roles. Leucine, alanine, and insulin interact to regulate this pathway, with a leucine-sensitive receptor-mediated inhibitory pathway identified in liver. In the case of the ubiquitin–proteasome system, its activation in

skeletal muscle during fasting and following glucocorticoid treatment supports a role in the physiological regulation of protein turnover. On the other hand, both lysosomal and calcium-activated proteolysis are activated under the same conditions. Similarly, in response to protein deficiency when protein turnover rates generally decrease in tissues, in part through the decline in thyroid hormone levels, the activities of all three systems decrease. One control mechanism involves changes in cell volume. Thus, swelling acts like a proliferative anabolic signal, inhibiting proteolysis, whereas cell shrinkage is catabolic, stimulating proteolysis. These effects have been shown in liver, and there is evidence for such a mechanism in skeletal muscle.

Postprandial Protein Utilization

Overall nitrogen homeostasis within the LBM is maintained within a diurnal cycle of postprandial protein gain and postabsorptive loss. The amplitude of these diurnal changes increases as habitual protein intakes increase, with implications for the qualitative nature of the metabolic demands for amino acids and hence dietary protein. The key questions are how both acute and chronic protein intakes mediate such responses and, most important, what influences the efficiency of postprandial protein utilization and consequent protein requirements. Nutritional regulation of dietary protein utilization, protein turnover, and amino acid oxidation involve both hormonal responses to food intakes and direct substrate influences. Whereas interactions between insulin, thyroid hormones, and IGF-1 mediate the anabolic drive of dietary protein on muscle and bone growth in the growing animal, the control mechanisms involved in the transient gains and losses of protein during diurnal cycling differ since neither thyroid hormones nor IGF-1 levels vary from meal to meal or in relation to habitual protein intakes. On the basis of several studies on either insulin or amino acids alone or variations in meal protein levels, it appears that insulin and amino acids act as main acute regulators.

The mechanisms involved are best understood in the context of the interrelationships between the free and protein-bound amino acid pools. Many indispensable amino acids are potentially toxic and are maintained at very low concentrations in tissues, so rapid and regulated postprandial disposal is important. After a protein meal there are two pathways for amino acid disposal. The first comprises the various high-capacity, finely regulated oxidative pathways activated by a protein meal. In most cases, rates of amino acid oxidation are influenced by their tissue concentrations (generally similar to the K_m of the rate-limiting enzymes), together with substrate activation and covalent enzyme modification. Examples are phenylalanine hydroxylase and branched-chain α-keto acid dehydrogenase, which are both regulated by substrate binding and reversible phosphorylation and dephosphorylation. The second pathway is net protein deposition. This can be achieved by stimulation of protein synthesis or inhibition of proteolysis so that a regulatory link between postprandial hyper-amino acidemia and protein synthesis and proteolysis can be expected and does indeed exist.

For protein synthesis, amino acids cannot exert simple kinetic concentration-related influences since the low K_m of amino acyl tRNAs synthesis means that they are usually fully charged. Nevertheless, there is ample evidence for regulatory stimulation by amino acids. This remains poorly understood but in some cells is known to involve signaling events linked to the mammalian target of rapamycin, mTOR, which in turn regulates S6 (an initiation factor) as well as eEF2 (an elongation factor). However, stimulation of protein synthesis through increased amino acid levels may also stimulate amino acid oxidation pathways, as discussed previously. Although this allows effective removal of amino acids, in the context of an efficient protein utilization this would not be a preferred mechanism.

For proteolysis, amino acids exert an inhibitory influence as described previously, and this inhibition will reduce endogenous amino acid supply. This will prevent undue increases in amino acid levels and will therefore minimize amino acid oxidation and maximize dietary protein utilisation. Furthermore, since inhibition of proteolysis and lowering of intracellular amino acid levels can be achieved by receptor-mediated mechanisms involving insulin as well as specific amino acids (e.g., leucine), this allows the postprandial increases in plasma amino acids to mediate substantial amino acid transport into cells, resulting in protein deposition without any increase in intracellular amino acid levels and with minimal increases in amino acid oxidation. Thus, as a strategy for mediating postprandial protein utilisation, inhibition of proteolysis is predicted to be more efficient.

^{13}C leucine studies have provided clear experimental support for such a mechanism. The meal protein-dependent responses of protein synthesis, proteolysis, and leucine oxidation are shown in **Figure 3** based on measurements in adult subjects fed isoenergetic meals of increasing protein intake

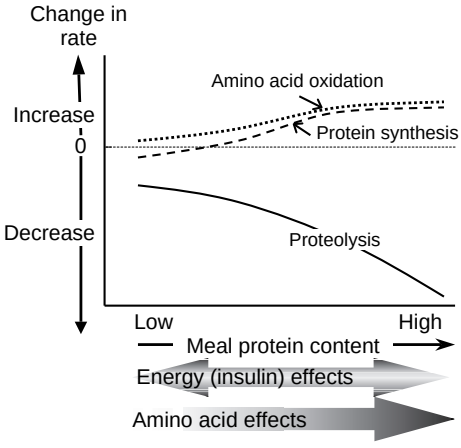

Figure 3 Feeding-induced responses of leucine kinetics shown as protein synthesis, proteolysis, and leucine oxidation. Patterns of responses reflect actual changes observed in ^{13}C-1 leucine infusion studies of feeding responses to frequent small meals of increasing protein intake, equivalent to daily intakes between 0.3 and 2.0 g kg^{-1} day^{-1}. (Adapted from Pacy PJ, Price GM, Halliday D *et al.* (1994) Nitrogen homeostasis in man: 2. The diurnal responses of protein synthesis, degradation and amino acid oxidation to diets with increasing protein intakes. *Clinical Science* **86**:103–118; and Gibson NR, Fereday A, Cox M *et al.* (1996) Influences of dietary energy and protein on leucine kinetics during feeding in healthy adults. *American Journal of Physiology* **33**: 282–291.)

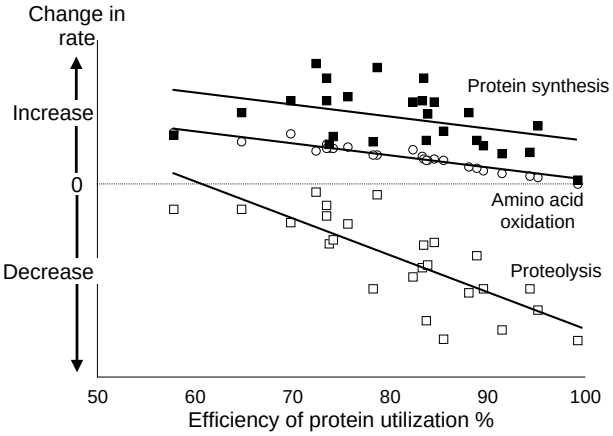

Figure 4 Relationships between the efficiency of protein utilization (Δbalance/Δintake) and responses of leucine turnover and oxidation to protein feeding observed in 24 normal adults fed frequent small meals containing protein intakes similar to the habitual intakes of the subjects. (Adapted from Fereday A, Gibson NR, Cox M *et al.* (1998) Variation in amino acid mediated, insulin activated inhibition of proteolysis determines the efficiency of protein utilization. *Clinical Science* **95**: 725–733.)

from 0.36 to 2.07 g protein/kg/day. Inhibition of proteolysis occurs at all levels of protein intake, but it increases with intake. However, the direction and magnitude of the response of protein synthesis reflect the level of dietary protein intake, with slight inhibition or no change at low intakes and stimulation at high intakes. Such studies clearly establish the importance of proteolysis as a regulator of tissue protein balance in the postabsorbtive and postprandial state. These and other ^{13}C leucine studies of postprandial protein utilization have allowed the separate influences of dietary energy and amino acids protein to be identified as shown in **Figure 3**. The response to energy alone involves insulin-mediated changes allowing leucine balance to becomes less negative through inhibition of proteolysis with minimal changes in protein synthesis or amino acid oxidation. In fact, because this tends to lower amino acid levels, there is a decrease in protein synthesis. With increasing amino acid supply as dietary protein intake increases, there is further inhibition of proteolysis by amino acids with increases in protein synthesis and, to some extent, amino acid oxidation, allowing net protein deposition as tissue protein.

The increase in amino acid oxidation with protein feeding is an unwanted response that reduces the efficiency of protein utilization. Although utilization of proteins such as milk is higher than that of wheat, as would be expected because of the lysine limitation of wheat gluten utilization, there is variability between individuals in the efficiency of postprandial protein utilization, ranging from 50 to 100% with milk protein. **Figure 4** shows the results of studies that have examined this variation. Efficient utilization involves maximal inhibition of proteolysis by protein feeding with minimal increases in free amino acid concentrations and consequent amino acid oxidation and stimulation of protein synthesis, indicating that the efficiency of protein utilization in individuals is determined by the sensitivity of the insulin-mediated inhibition of proteolysis to amino acid supply.

Current understanding suggests a mechanism indicated in **Figure 5**, in which the major target of insulin is inhibition of proteolysis, with amino acids acting to both enhance the inhibition of proteolysis and stimulate synthesis and oxidation. With tissue amino acid levels controlled by both diet and endogenous supply from proteolysis, inhibition of proteolysis will minimize any increase in amino acid levels, minimize oxidation, and maximize protein utilization. Since protein synthesis and amino acid oxidation appear to be stimulated in parallel, the optimum strategy for maximum efficiency of postprandial protein utilization appears to involve maximal inhibition of proteolysis and minimal postprandial increases in tissue amino acid levels.

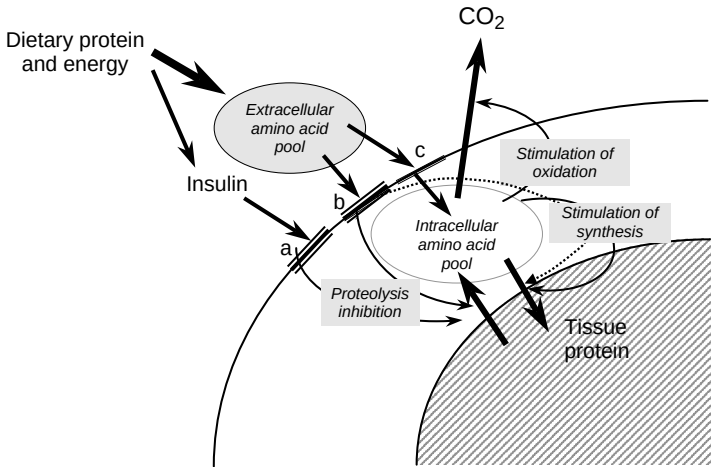

Figure 5 Scheme for the action of insulin and amino acid supply on postprandial protein utilization. Insulin and extracellular amino acids exert inhibitory influences on proteolysis and protein synthesis through receptor-mediated mechanisms (a and b), whereas amino acid uptake (c) and proteolysis regulate intracellular amino acid levels, amino acid oxidation, and protein synthesis in parallel. Maximal inhibition of proteolysis and maintenance of low intracellular amino acid levels is the optimal response. (Modified from Millward DJ, Fereday A, Gibson NR *et al.* (1996) Postprandial protein metabolism. *Baillier's Clinical Endocrinology and Metabolism* **10**: 533–549.)

In summary, postprandial protein utilization appears to be mediated by an insulin-mediated, protein-conserving influence of dietary energy that inhibits proteolysis, lowers amino acid levels, and reduces oxidation, with dietary amino acids augmenting the inhibition of proteolysis. The response of protein synthesis is primarily determined by the resultant intracellular amino acid levels that reflect the balance between the decreasing endogenous supply following insulin-mediated inhibition of proteolysis and the increasing exogenous supply as dietary protein intake increases, stimulating protein synthesis and increasing oxidation when amino acid dietary supply exceeds the capacity for its net deposition.

Requirements and Role in Diet

D J Millward, University of Surrey, Guildford, UK

Defining minimum amino acid and protein requirements is inherently difficult. Humans are exposed to a wide range of protein intakes, which enable full expression of their genotypical lean body mass throughout the range, and identifying the lower limits of this range has proved intractable. Without unequivocal symptoms of deficiency, the adequacy of an intake can only be assessed in terms of nitrogen or amino acid balance, which is unsatisfactory for several reasons. In particular, adaptation causes major difficulties in designing balance studies and interpreting results. Furthermore, balance methods are inherently imprecise and logistically extremely difficult. It is therefore not surprising that there is much debate about both the nature and the extent of protein requirements.

Terminology

Protein requirements are best discussed in terms of metabolic demand, dietary requirement, and dietary allowances. Metabolic demand concerns amino acids and is determined by the nature and extent of those metabolic pathways (e.g., net protein synthesis) that consume amino acids and that vary with the phenotype and the developmental and physiological state of the individual. The dietary requirement is the amount of protein and/or its constituent amino acids that must be supplied in the diet in order to satisfy the metabolic demand. The requirement will usually be greater than the metabolic demand. Thus, factors associated with digestion and absorption may limit digestibility (i.e., dietary nitrogen lost in the feces) and biological value (i.e., the availability of the absorbed amino acid pattern in relation to cellular needs, which influences urinary nitrogen excretion). Dietary allowances are a range of intakes derived from estimates of individual requirements taking into account variability between individuals. They are designed to meet the dietary requirements of the population. In the United Kingdom, these allowances are described in terms of Dietary Reference Values (DRVs) and in the United States as Dietary Reference Intakes (DRIs).

Metabolic Demands for Amino Acids

Current evidence supports the representation of the metabolic demands as in **Figure 1**. The metabolic demand for amino acids is to maintain tissue protein at appropriate levels and to provide for all amino acid-derived metabolites and any additional needs during growth, rehabilitation, pregnancy, and lactation. Tissue proteins are diverse, including structural or fibrous insoluble types and soluble globular

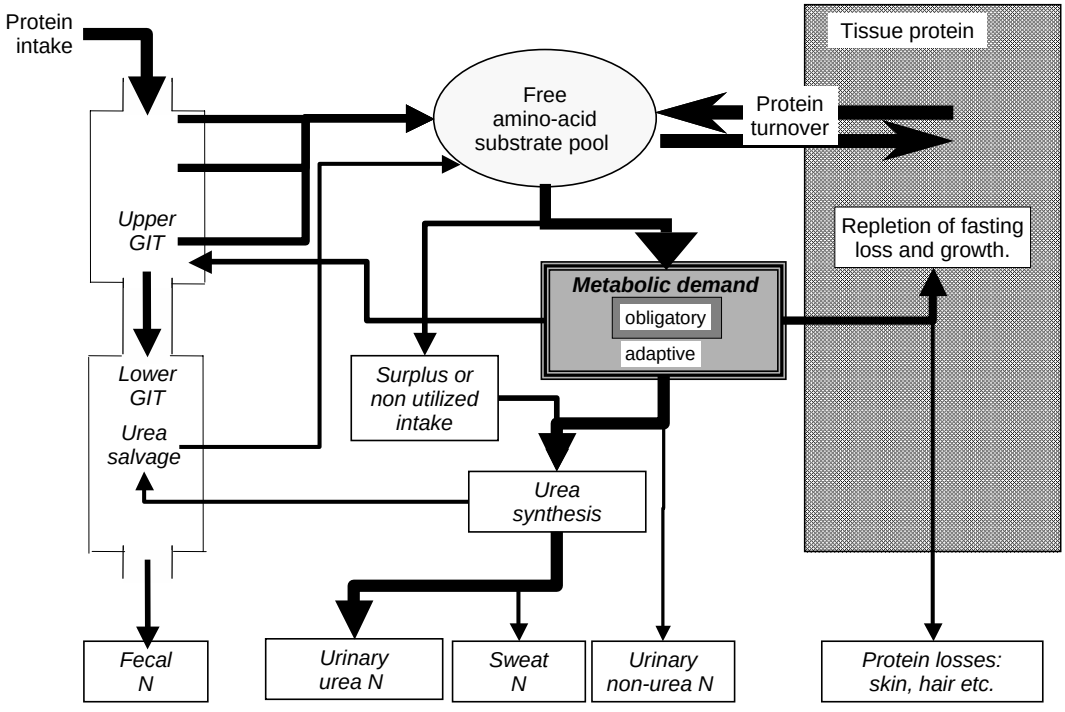

Figure 1 Schematic representation of the metabolic demands for amino acids.

species, with characteristic properties and functions that are determined by their amino acid sequence. All proteins are in a dynamic state of constant turnover (i.e., breakdown to constituent amino acids and resynthesis), although for the structural proteins this is slow or minimal. Nonprotein products include nucleic acids and a diverse range of smaller molecules, such as creatine, taurine, glutathione, hormones (e.g., catecholamines and thyroxine), neurotransmitters (serotonin and dopamine), and nitric oxide, a key regulator of blood flow and other physiological processes.

The metabolic demand is supplied from the free amino acid pool, the size of which, for most amino acids, is regulated within narrow limits. Regulation involves supply from three sources: dietary proteins after digestion and absorption from the upper gastrointestinal tract (GIT), tissue protein after proteolysis during protein turnover, and de novo formation, which may include amino acids and ammonia, deriving from urea salvage after hydrolysis and bacterial metabolism in the large bowel. Removal of free amino acids occurs by reactions in which they act as substrates, and these reactions are shown as three pathways, one of which is the metabolic demand. This pathway involves a number of irreversible pathways, including net protein synthesis and other irreversible metabolic transformations of individual amino acids. The second and quantitatively largest pathway is the removal for protein synthesis during protein turnover. At nitrogen equilibrium, because turnover involves the reversible removal of amino acids, with replacement through proteolysis, it does not exert a net metabolic demand (other than for those amino acids irreversibly modified during or subsequent to protein synthesis). The third pathway is the irreversible removal of amino acids by oxidation and nitrogen excretion provoked, for example, by the transient increases in some or all free amino acids after a protein meal. This would represent an inefficient utilization.

The metabolic demand for amino acids appears to involve obligatory and adaptive components. The obligatory component for subjects at equilibrium (i.e., maintenance) comprises conversion of some individual amino acids into important metabolites that are further transformed into nitrogenous end products, mainly urea and other compounds in urine, feces, or sweat, as well as net synthesis of proteins lost from the body as skin, hair, and any other secretions. These diverse biological demands for amino acids for maintenance represent an essential but probably quite small intrinsic metabolic demand for protein. The magnitude of this maintenance component is assumed empirically to be equal to the obligatory nitrogen loss (ONL)—that is, the sum of all nitrogen losses from the body observed in subjects fed a protein-free but otherwise nutritionally adequate diet after 7–14 days, by which time nitrogen losses have declined to a stable and reproducible low level with the subjects losing body protein at a constant daily rate. In normal adults, the obligatory urinary, fecal, and subcutaneous and other losses are approximately 29, 13, and 5 mg N/kg, respectively (i.e., 47 mg/kg/day), in total equivalent to 0.29 g protein/kg/day tissue protein mobilized to meet such demands. The ONL is a function of body weight and, as far as is known, varies little with age. After adaptation to a protein-free diet, net tissue proteolysis is assumed to provide for the nonprotein components of the obligatory demand at a rate determined by the metabolic consumption of the rate-limiting amino acid (the amino acid with the highest ratio of molar proportion in the metabolic demand to molar proportion in protein). Because the obligatory metabolic demand is for a mixture of amino acids with a profile that is unlikely to match that of tissue protein, the actual nitrogen content of the metabolic demand is likely to be less than that indicated by the ONL (i.e., less than an equivalent of 0.29 g protein/kg/day). This is because all amino acids mobilised to provide for the metabolic demand must be oxidized and will contribution to the nitrogen excretion, whereas only some of them will serve useful functions. The evidence for this is the lowering of the ONL in response to feeding selective amino acids, such as threonine, tryptophan, and methionine. In addition to these metabolic demands for maintenance, any net protein synthesis associated with growth, pregnancy, and lactation also constitutes an obligatory metabolic demand.

The adaptive component of the metabolic demand represents amino acid oxidation at a rate varying with the habitual protein intake that occurs as a result of the increasing activities of the pathways of oxidation of amino acids that regulate free amino acid pool sizes. Although this aspect of amino acid metabolism is least understood, it is likely that it is a consequence of the fact that humans grow slowly or maintain constant weight on diets that contain protein considerably in excess of minimum needs. Thus, in order to be able to rapidly dispose of excess protein and maintain the very low tissue concentrations of those amino acids, such as the branched-chain, aromatic, and sulfur amino acids, that may be toxic at higher concentrations, pathways of oxidative amino acid catabolism adapt (increase their V_{max}), enabling them to operate at the appropriate rate set by habitual protein intakes. Importantly, the

adapted rate of amino acid oxidation, characteristic of habitual intake, changes only slowly in response to either a change in dietary protein intake level or feeding and fasting. This has two main consequences. First, when intake falls below habitual intake mobilization of tissue protein occurs with a negative nitrogen balance for as long as it takes to adapt to the lower level of intake. This was previously identified as the labile protein reserves. It can be assumed that for intakes greater than the minimum requirement, full adaptation to the new level will include not only a change in the adaptive metabolic demand to match intake but also repletion of most tissue nitrogen lost during the adaptive transition. Second, because the adaptive rate of amino acid oxidation continues to some extent into the postabsorptive state, there are varying postabsorptive losses of tissue protein and nitrogen excretion with varying habitual intake—that is, a diurnal cycle of postabsorptive losses and postprandial gains with an amplitude that increases with the increasing habitual level of protein intake as shown in **Figure 2**. As such, the adaptive metabolic demand includes a component of net protein synthesis that repletes postabsorptive losses. The magnitude of this varies in a complex way with eating pattern and with the amount and quality (amino acid score) of the habitual protein intake.

Although amino acid oxidation and urea synthesis is assumed to be irreversible, this is not entirely true because of urea salvage. Thus, the rate of urea synthesis is usually in excess of the rate of urea excretion because some urea enters the large bowel and is hydrolysed by bacteria. Most of this nitrogen is utilized by bacteria, and since little is lost as fecal nitrogen, it is eventually returned to the systemic pool as ammonia and amino acids after bacterial death and proteolysis, including indispensable amino acids. Although the extent and nature of this salvaged urea nitrogen are poorly understood, it may provide nutritionally important amounts of amino acids.

The main practical implications of the previously discussed model are that true minimum metabolic demands and consequent protein requirements will occur when the adaptive metabolic demand has fallen to the lowest possible level, and it is not known with any certainty how long such adaptation would take. However, studies that have examined balance responses to changes in protein intakes suggest it is likely to be longer than the periods employed in short-term balance studies. This implies that short-term balances from which our estimates of the minimal protein requirement (MPR) derive may overestimate the value and also that some of the variability in protein requirements between studies may reflect variable completeness of adaptation to the test diets. Another implication of the adaptive metabolic demands model is that intakes and requirements are correlated, which has implications for the definition of risk of deficiency and safe intakes.

Protein Requirements

Plant versus Animal Sources

The nutritional requirement for protein will be the minimum intake that satisfies metabolic demands and that maintains appropriate body composition and growth rates, after taking into account any inefficiency of digestibility and metabolic

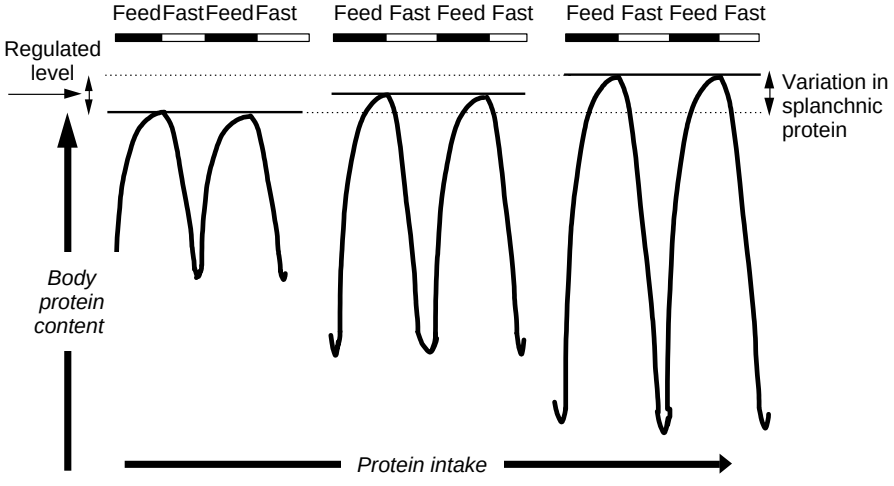

Figure 2 Balance regulation throughout the diurnal cycle with increasing habitual protein intakes.

consumption. With continuous and extensive amino acid interconversion, the pattern of dietary amino acids need not match that of the composition of tissue proteins or the maintenance metabolic demand exactly because some amino acids (aspartic acid, asparagine, glutamic acid, alanine, and serine) are dispensable and can be replaced by sufficient total amino acid nitrogen supplied from other amino acids or sources of nonessential nitrogen. However, there will be a minimum dietary requirement for those amino acid that are not interconverted, classified as indispensable amino acids (histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine), and for those that are formed only slowly from other amino acids and become indispensable under specific physiological or pathological conditions (conditionally indispensable; e.g., cysteine, tyrosine, taurine, glycine, arginine, glutamine, and proline). Traditionally, dietary proteins have been classified by their nutritional value (quality) measured in terms of their ability to provide for tissue growth in rapidly growing rats. In this case, marked differences are observed between most animal protein and plant protein sources, with relative nutritional value reflecting mainly relative amounts of specific indispensable amino acids. The similarity between overall tissue protein amino acid composition and that of most animal dietary protein sources and the contrast with plant protein sources resulted in clear distinctions between their quality, although when combined it is clear that plant proteins can provide the appropriate balance of essential amino acids.

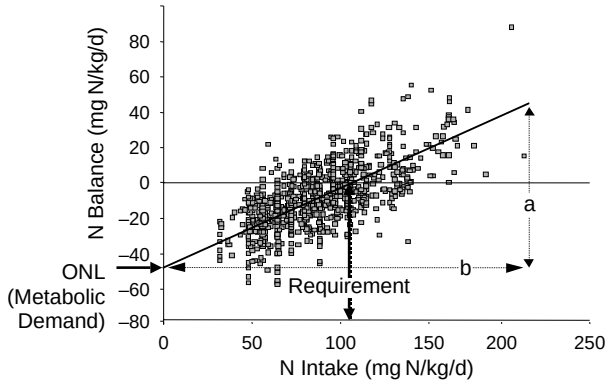
However, in human nutrition with growth occurring very slowly after the first few months of life, the nutritional demand for indispensable amino acids for tissue growth is much less and may be minimal. Little metabolic demand for amino acids is generated by protein turnover because of amino acid recycling. Some net protein synthesis is associated with skin and hair growth and with gastric secretions (e.g., threonine-rich mucus glycoproteins) that pass into the colon to be utilized for bacterial metabolism. The metabolic demand for maintenance of normal function and composition is a poorly understood pattern of amino acids utilized in the various metabolic pathways other than protein synthesis, but this pattern is almost certainly different from that required for growth (i.e., mainly the amino acid pattern of tissue protein) and may contain a much lower overall amount of indispensable amino acids. As such, a distinction between plant and animal dietary protein sources is much more difficult to demonstrate and is probably less relevant in human nutrition. Currently, there is considerable controversy regarding the magnitude of the requirements for indispensable amino acids in the human diet and there are different views about the relative importance of dietary protein quality in human nutrition. Some national bodies have stressed that in most mixed, nutritionally balanced diets, sufficient indispensable amino acids will be provided regardless of the relative amounts of plant or animal protein sources (e.g., UK Department of Health). However, others (e.g., US FNB/IOM) have argued that the requirements for indispensable amino acids in the human diet are higher than previously believed and that protein quality is important.

Nitrogen Balance

Nitrogen balance studies were initiated in the mid-nineteenth century by Carl Voit, and such studies have been central to the definition of protein requirements. The aim of nitrogen balance studies is simple—to define the relationship between intake and all losses (urinary, fecal, and surface—mainly sweat, skin, hair, breath ammonia, nail clippings, etc.) so that the intake that allows equilibrium and provides for all losses can be identified. Thus, when the intake equals the requirement,

$$\text{Balance} = \text{intake} - \text{losses} = 0$$

As indicated previously, the lowest level of losses observed, the ONL, is approximately 46 mg/kg/day, equivalent to a daily loss of 0.29 g protein/kg/day. When such subjects are re-fed with protein, losses of body protein decrease as the dietary protein provides for some of the metabolic demand. However, nitrogen losses increase with intake so that the required intake for balance is more than the ONL. The main objective of nitrogen balance studies has been to define how much extra protein above the ONL must be fed to achieve equilibrium. The literature on human nitrogen balance studies has been assessed in a meta-analysis, as shown in **Figure 3**. A linear regression of balance against intake will allow prediction of the ONL as the zero intake intercept. The slope of the balance curve ($a/b = e$) will indicate the efficiency of utilization, and the maintenance requirement (i.e., the amount that must be fed to balance all losses and produce equilibrium) is ONL/e. Thus, the currently accepted maintenance requirement (0.66 g/kg/day) derives from an analysis of the data shown in **Figure 2** (the median requirement calculated from individual regressions on each individual studied at more than three levels of protein intake).



Balance = e × intake-ONL
(e = efficiency of utilisation = Δbalance(a)/Δintake(b))

Balance = 0.47.intake – 48.1 mg N/kg/d
Requirement = intake for zero balance = ONL/e
= 105 mg N/kg/d = 0.66 g protein/kg/d

Figure 3 Meta-analysis of nitrogen balance studies.

Inherent Difficulties with Nitrogen Balance Studies

This apparently simple but laborious approach, which is currently the main method for investigating protein and amino acid requirements, is in fact beset with a large number of quite serious problems, as listed in **Table 1**.

The lack of precision results in balance being a small value compared with the much larger values of nitrogen intake and nitrogen excretion, resulting in considerable error. The various systematic errors mean that balance is usually overestimated, often with unrealistic positive balances (protein gains) at high intakes. The nonlinearity of the balance curve as losses increase to match intakes when body protein reaches the maximum level means that there is no simple term to define the overall shape of the balance curve allowing prediction of the requirement (as the zero balance intake). In practice, prediction of a zero balance–intake intercept is made from a few balance points by linear regression, and this will result in requirement values that will vary according to where the intake values lie on the balance curve; that is, studies conducted using low intakes will underestimate requirements, whereas studies conducted with supramaintenance intakes will overestimate requirements. The logic of this is that (i) reliable balance studies are those that are conducted with intakes very close to the actual requirement, and (ii) studies with intakes based on preconceived requirement values will tend to confirm such preconceptions.

Nonlinearity of the balance curve
Design
Dietary energy intake and physical activity influences balance
Accounting for adaptation

Energy–Protein Interactions

Body protein equilibrium can be influenced by intakes of energy, and ensuring that energy intakes are sufficient is difficult. Excess energy intake leads to weight and some lean tissue gain, whereas with too little intake, dietary and/or body protein is oxidised as an energy source. This means that the protein requirement is a function of the state of energy balance and the actual influence is quite marked. According to one analysis of nitrogen balance (NB) on intakes of energy (EI; kcal/kg) and N (NI; mg N/kg), $NB = 0.171NI + 1.006EI - 69.13$. This means that the intake for N equilibrium (the requirement) will vary from 1.4 to 0.32 g/kg/day according to whether energy intakes are equal to the resting metabolic rate (RMR) or equal to twice the RMR. In fact, two–thirds of the overall variability reported in the meta–analysis shown in **Figure 2** (SD = 31.9 mg N/kg) could be accounted for by an error of only approximately 0.2 of basal metabolic rate (BMR) in estimating the true energy needs of a subject.

Since nitrogen balance varies as a function of energy intake, it may be argued that protein requirements can only be defined in terms of a specified energy intake level, but what is the appropriate energy intake? Should populations with low protein staples consume more energy to achieve body protein equilibrium? Will this predispose to obesity? To what extent does variation in energy intakes at energy balance (i.e., with increasing levels of physical activity) influence nitrogen balance? These are difficult and currently unanswered questions.

Adaptation

With the metabolic demand for amino acids including both fixed and variable demands, the relationship between intakes and balance will be a function of time and the rate of adaptation. This is undoubtedly why the determination of human protein requirement by nitrogen balance has proved to be so difficult. Thus, when protein intake changes, the

metabolic adjustments involved with matching amino acid oxidation and urea excretion rates to the new intakes take considerable time to adapt to the new level of intake. The actual time taken for complete adaptation is poorly understood and controversial. In practice, most balance studies are 'short term,' with dietary periods of 2 weeks at each intake studied and with diet periods randomized to minimize metabolic carryover of prior diets. Two weeks is comparable to the time taken to stabilize excretion in subjects fed a protein-free diet while establishing the magnitude of the obligatory nitrogen losses. It may be that adjustment to a protein-free diet, an extreme metabolic change, occurs more rapidly than the adjustment from one intake to another, with evidence of changes over several months to an intake similar to the ONL, and more than 1 month is required to adjust to a lower but adequate intake (1 g/kg/day) after 2 months of a high-protein diet of 3 g/kg/day.

Dietary Protein Allowances and Implications of Adaptation

The Estimated Average Requirement (EAR) defines the notional mean requirement for the population group. The Recommended Nutrient Intake (RNI) is defined according to the range of interindividual variability and is two standard deviations above the EAR. The RNI (or Recommended Dietary Allowance) is thus an intake that will meet the requirement of most of the population assuming normal distribution of requirements and is therefore a 'safe allowance.' The Lower Nutrient Reference Intake, which is two standard deviations below the EAR, defines the lowest intake that will meet the requirement of some of the population. It follows from these definitions that in deriving dietary allowances from nitrogen balance studies, the variability in the reported values is very important since this is used to set the RNI. The currently agreed value is based on an EAR of 0.66 g/kg and a SD = 12% (i.e., 0.82 g/kg). Such calculations try to assess true between-subject variation rather than measurement errors. The range of individual values from the reported nitrogen balance meta-analysis is shown in **Figure 4**. Analysis of individual risk of deficiency (intake < requirement) assumes that the requirement is not correlated with the intake so that for an individual with an intake equal to the mean requirement value, the risk of deficiency is 50%, declining to less than 2.5% at the higher intake equal to the RNI.

The serious implication of lack of complete adaptation in short-term multilevel balance studies is that

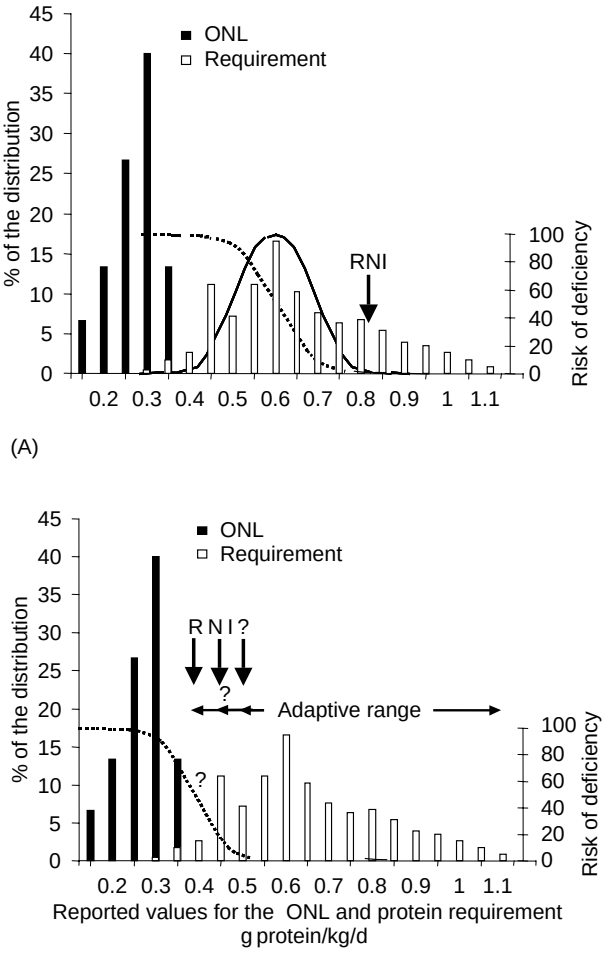

Figure 4 Distribution of reported values for the protein requirements and obligatory nitrogen loss (ONL) and calculation of risk of deficiency for an individual for current protein requirements model (A) and the adaptive metabolic demands model of protein requirements (B). The bars represent the distribution of reported mean values for the obligatory N loss (solid bars; $n = 15$ studies on 273 subjects) and individual values of intakes for N equilibrium expressed as protein equivalents (open bars; $n = 224$ subjects from 32 studies, after a 5% trim of outliers) from a meta-analysis of N balance data reported by Rand *et al.* (A) A normal distribution of requirements is shown (solid line), with the Recommended Nutrient Intake (RNI) and risk of deficiency for an individual (broken line) calculated assuming no correlation between protein intake and requirement. (B) RNI and suggested risk of deficiency (broken line), assuming most of the variation in reported requirement values reflects incomplete adaptation to the test diets with the true minimum requirement at the lower end of the observed range. Risk of deficiency in fully adapted individuals will not become significant until intakes fall below the upper range of the true minimum requirement (value currently unknown).

because of the very wide range of protein intakes in the human diet, mainly through variable meat intake, the apparent requirement indicated in a study may still reflect the prior habitual diet. That is, the apparent metabolic demands are higher than minimum

levels because of an adaptive component of amino acid oxidation set to balance previous intakes. This may explain the very wide range of reported apparent requirements analyzed in the nitrogen balance meta-analysis from approximately 0.4 to more than 1.1 g protein/kg/day. If adaptation does account for the variability, than a quite different analytical model would be implied (**Figure 4B**). Thus, the RNI would be much lower, with risk of deficiency for fully adapted individuals not increasing until intakes decrease to very low levels—close to values equivalent to the ONL. Such adaptive models pose difficult questions for public health nutrition.

Protein Requirements for Growth and Special Needs

For infants, children, and pregnant and lactating women, protein requirements are derived by a semi-factorial analysis of the components of the metabolic demands shown in **Figure 1**, with an assumed efficiency of utilization, all adjusted for individual variation to give the RNI. The main components as reported in the recent US Dietary Reference Intake (DRI) report are shown in **Figure 5**. The maintenance value is derived from nitrogen balance studies on children at 0.69 and 0.66 g protein/kg/day for ages 0.75–13 years and older than 13 years, respectively. The dietary requirements for growth derive from measured rates of protein accretion adjusted for an efficiency of utilization of 58%. To account for interindividual variability, the RNI includes the addition of 2 SDs for maintenance and dietary growth needs, calculated from a critical value (CV) that is the weighted mean of the CVs for maintenance (12%) and growth (43%).

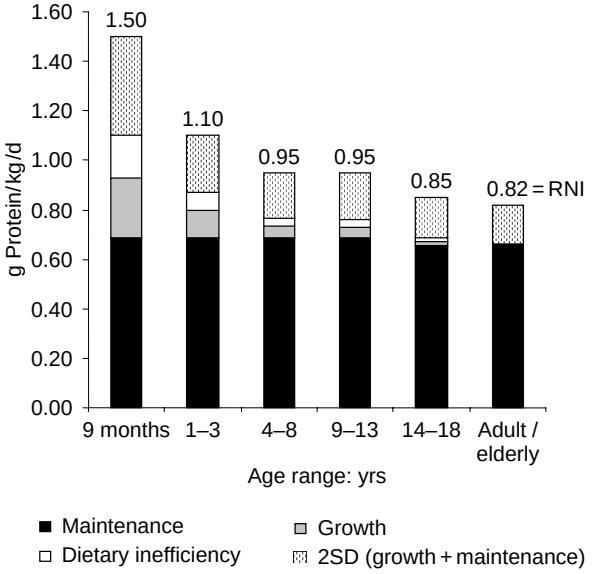

Figure 5 Factorial estimates of protein requirements throughout the life cycle. Overall values are averages of the separate values for boys and girls.

Pregnancy Requirements

These allow for protein retention in the products of conception and in the maternal tissues associated with the birth of an 'ideal' 3.3-kg infant. It is assumed that protein gain occurs in the maternal tissues in the early part of pregnancy and in the fetus mainly in the latter stages so that the metabolic demand is uniform throughout pregnancy. Thus, in the United Kingdom a single daily additional amount of 6 g protein throughout pregnancy is recommended. Lactation requirements of 11 and 8 g/day derive from estimates of the protein content of breast milk of healthy mothers (milk nitrogen $\times$ 6.25) assuming that daily breast milk protein content is constant for the first 6 months and declines thereafter. For the elderly, requirements are assumed to be the same as for younger adults since there is no evidence that they are higher than those of younger adults.

Areas of Uncertainty

Requirements of Infants

Definitions of protein requirements have historically been problematic and controversial, and current values are no exception. It has been suggested that values for the protein requirement of infants and children proposed in the 1985 FAO/WHO/UNU report were overestimates, and this problem was not entirely resolved in the US DRI report. The argument derives from a comparison of the requirement values with the protein intake of the breast-fed infant. Thus, the average requirement defined by FAO/WHO/UNU for the 3-month-old infant is the same as the average protein intake of the breast-fed infant. Since infants of healthy, well-nourished mothers consuming habitual amounts of breast milk are assumed to be optimally nourished, average intakes of breast milk protein are assumed to represent the safe level of the requirement, which is higher than the average requirement. Resolution of the problem requires use of a lower value for maintenance and a higher value for the assumed efficiency of dietary protein utilization for growth, giving values for the EAR and RNI at 3 months of 1.06 and 1.37 g protein/kg compared with a mean protein intake of the breast-fed infant of 1.44 g/kg. Such values would be lower than those implied by the factorial model used in the US DRI report. However, at this age of most rapid growth, the nitrogen in breast milk is utilized with unusual efficiency—an indication of the special properties and

qualities of breast milk that are poorly understood. Therefore, it may be proposed that formula-fed infants require more protein because of less efficient protein utilization. Indeed, some have questioned whether the breast-fed infant is the ideal model for protein requirements, with breast milk protein levels being a compromise between feeding the infant and minimizing losses of maternal protein stores. However, given the lower rates of morbidity of breast fed compared to formula-fed infants, it is difficult to sustain arguments that breast-fed infants are less than optimally nourished.

Optimal Protein Intakes and Implications of Adaptation for Nutrition Policy

In general, protein requirements serve two purposes. One is as a basis for prescription (i.e., advice on safe diets through recommending appropriate dietary intakes). Adaptation implies a low but difficult to define RNI. Indeed, since natural diets, providing sufficient energy and other nutrients, usually provide more than the minimal amount of protein, the magnitude of the minimal requirement becomes to some extent an issue of scientific curiosity only. Formulation of policy in relation to prescriptive matters will inevitably and correctly be most concerned with satisfying the upper range of demands for protein and, where there is uncertainty, include positive margins of error. In this case, it is arguably unwise to adopt an adaptive model and reduce the RNI, even if agreement could be reached on the likely lower limit of adaptation. Indeed, an adaptive model does not imply that protein is an unimportant nutrient for the maintenance of human health and well-being but that indicators other than balance (nitrogen, protein, or amino acid) need to be identified. Thus, the most relevant measure is an optimal requirement allowing balance and supporting both optimal body function and minimum risk of chronic disease. There is increasing experimental evidence for the potential benefit of protein intakes considerably higher than the current RNI for bone health in the elderly and epidemiological evidence for benefit with respect to hypertension and ischemic heart disease. However, such influences are unproven, with no plausible mechanism identified in the latter cases. In any case, there are no quantifiable indicators. This results in a dilemma for those attempting to frame prescriptive dietary guidelines. From this perspective, it is probably wise to retain current values as an operational expedient until it becomes possible to quantify the benefits (and any risks) of protein intakes within the adaptive range.

The other purpose of requirement recommendations is as a diagnostic indicator of risk, often within an epidemiological context in which population groups rather than individuals are considered. In this case, indicators used to estimate prevalence of disease states or deficit risk are carefully chosen so as to strike an acceptable balance between false positives and false negatives. The main implication of adaptation for estimating risk of deficiency as intakes become less than requirements is a dramatic reduction in the prevalence of risk for most populations compared with that assessed according to the traditional model, which does not account for adaptation. As in the prescriptive context, this low risk of deficiency applies only to that of being unable to maintain nitrogen balance after full adaptation with otherwise nutritionally adequate diets satisfying the energy demands. Whether such populations enjoy optimal protein-related health in terms of immune function, bone health, or any other function is a separate issue and needs to be addressed as such. From this perspective, it follows that maintenance of nitrogen balance can no longer be used as a surrogate of adequate protein-related health, and that current lack of quantifiable alternative indicators is no excuse for ignoring the issue of adaptation.

Digestion and Bioavailability

Z A Bhutta, The Aga Khan University, Karachi, Pakistan

Proteins are the principal nitrogenous constituents of the protoplasm of all animal and plant tissue, and it is estimated that almost half of the dry weight of animal cells is composed of proteins. Proteins are crucial for the synthesis of body tissues and regulatory proteins, and it is also recognized that approximately 90% of all cellular proteins are present as enzymes.

The basic structural units of proteins are the amino acids, which are characterized by the presence of an amino NH_3 component and an acid or carboxyl group. Nitrogen thus comprises approximately 16% of all proteins by weight. Most naturally occurring amino acids are of the L configuration. These amino acids are in turn linked together by peptide bonds. Units of 2 or 3 amino acids are called dipeptides or tripeptides, respectively, whereas by convention any protein structure of less than 100 amino acid residues is called a polypeptide. The primary structure of a protein refers to the chains of amino acids constituting it, whereas the secondary structure is formed by the linkages between close amino acids by hydroxyl or sulfide bonds. More complex proteins have a tertiary structure due to the amino acids being held together by strong interatomic forces. The quarternary structure of a protein refers to the manner of association or binding between different units.

Dietary proteins are the major sources of protein intake and constitute on average approximately 10–20% of daily energy intake. In addition, they are the main sources for the essential amino acids, which cannot be synthesized by humans. Despite wide variations in dietary composition, the average daily protein intakes in different populations of the world range from 50 to 70 g, although it must be recognized that the intake may be much lower in deprived populations, in both qualitative and quantitative terms. Almost half of the total protein entering the gastrointestinal tract daily is derived from endogenous sources, mainly intestinal secretions and cellular desquamation. Salivary, gastric, biliary, pancreatic, and intestinal secretions contribute approximately 20–30 g per day, whereas desquamated villus epithelial cells contribute an additional 30 g, and a relatively smaller amount (2 g) is derived from plasma proteins leaking into the lumen.

An intricate and coordinated system of digestion ensures that under normal conditions, approximately 95% of ingested protein is digested and absorbed.

Digestion

The purpose of digestion is to hydrolyze proteins to small peptides and amino acids so that these can be absorbed. The daily protein load requiring digestion within the gastrointestinal tract includes both the exogenous protein derived from the food consumed and that from endogenous intestinal enzymes and cellular debris. The latter may constitute approximately 40% of the total gastrointestinal protein load, approximately 160–170 g. daily. The digestion of proteins in the gastrointestinal tract involves a coordinated series of events at different levels, with sequential digestion by proteolytic enzymes to a form that can be absorbed into the bloodstream. **Figure 1** is a sequential representation of the various sites of protein digestion and absorption in the gastrointestinal tract. The main gastric and pancreatic proteolytic enzymes and their physiological functions are summarized in **Table 1**.

Stomach Peptic Activity

The digestion of proteins begins in the stomach by the actions of pepsins, which are secreted as the

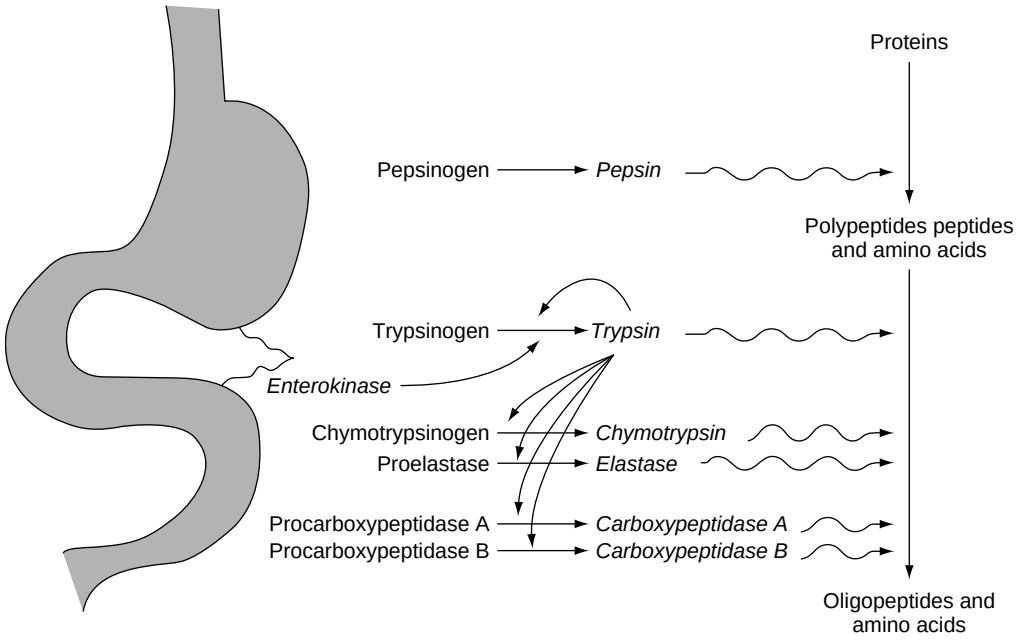

Figure 1 Cascade of protein hydrolysis in the gastrointestinal tract.

precursor form pepsinogen by the gastric mucosa main cells. The release of pepsinogen is stimulated by gastrin, histamine, and cholinergic stimulation and sinogens are converted to the active form pepsin by the loss of a small basic peptide. Pepsins remain active in the acid pH of the stomach and have a broad proteolytic specificity, splitting peptide bonds mostly involving phenylalanine, tyrosine, and

Table 1 Proteolytic enzyme activity in the gastrointestinal tract

Enzyme	*Precursor*	*Products*	*Catalyst*	*Substrate*	*Action*
Stomach					
Pepsins	Pepsinogens	Polypeptides of diverse sizes and some amino acids	Acid pH	Protein	Hydrolyse bonds between aromatic amino acids (e.g., phenylalanine or amino acid)
Pancreatic proteases					
Trypsin	Trypsinogen	Oligopeptides	Enterokinase Trypsin	Proteins Polypeptides	Cleaves internal bonds at lysine or arginine amino acids; cleaves other pancreatic proenzymes
Chymotrypsin	Chymotrypsinogen	Oligopeptides	Trypsin	Protein Polypeptides	Cleaves bonds of aromatic or neutral amino acids
Elastase	Proelastase	Oligopeptides	Trypsin	Elastin Other proteins	Cleaves bonds of aliphatic amono acids (e.g., alanine, glycine, and serine)
Carboxypeptidase A	Procarboxypeptidase A	Aromatic amino acids and peptides	Trypsin	Polypeptides at the free C-terminal end of the chain	Cleaves aromatic amino acids from C-terminal end of protein and peptides
Carboxypeptidase B	Procarboxypeptidase B	Arginine, lysine, and peptides	Trypsin	Polypeptides at the free C-terminal end of the chain	Cleaves arginine or lysine from C-terminal end of protein and peptides

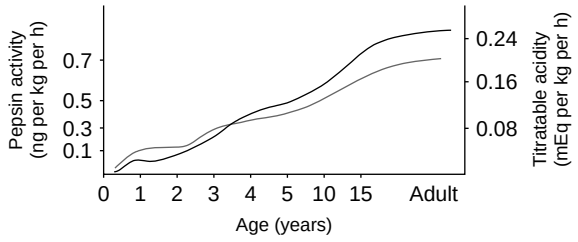

Figure 2 Postnatal development of gastric acid secretion and titratable acidity. Modified from Koldovsky (1987). Digestion and absorption of carbohydrates, proteins and fat in infants and children. In Walker WA and Watkins JB (eds), *Nutrition in Pediatrics*, Boston, Little Brown. Reproduced with permission from Little Brown & Company.

leucine. The level of peptic activity and acid production is lower in premature infants and increases in relation to gestational age; pepsin activity increases approximately twofold between infancy and adulthood (**Figure 2**). Immunohistochemistry indicates two distinct forms of pepsinogen: Pepsinogen I is only found in acid-secreting regions of the stomach, whereas pepsinogen II is also found in the mucous cells of the oxynctic and pyloric regions of the stomach as well as in the duodenal Brunner's glands. Although these two forms of pepsinogen have slightly different pH optima, their substrate specificity is very similar and both are rapidly inactivated by the alkaline pH beyond the pylorus.

A gelatinase liquefying gelatin is also found in the stomach. There is controversy regarding the presence of rennin (a peptidyl peptide hydrolase) in the stomach of young infants; however, the mild clotting activity in human infants is fairly rapid.

The completeness of gastric protein digestion is dependent on several factors, including the rate of gastric emptying, the pH of intragastric contents, and the type of protein ingested. Given the significant buffering capacity of food, it is unlikely that gastric proteolysis plays a major role in protein digestion. This is also verified by the fact that neither patients with achlorhydria nor those recovering from major gastric surgery appear to have a major problem with protein digestion.

Pancreatic Proteases

The pancreatic proteases are secreted as proenzymes and are activated in the lumen. The enteropeptidase (also called enterokinase) released from the brush border membrane removes a hexapeptide from the N-terminal end of trypsinogen, converting it to the active form trypsin. Trypsin, in turn, activates the other protease proenzymes and also autocatalytically promotes further activation of trypsinogen. The pancreatic proteases include the endopeptidases trypsin, chymotrypsin, and elastase, primarily splitting peptide bonds located within the protein molecules resulting in the production of short-chain polypeptides. These are further hydrolyzed by the exopeptidases carboxypeptidase A and B, acting on aromatic/aliphatic C terminals or basic C terminals, respectively, to remove single amino acids. The end product of this coordinated intraluminal digestion by these endopeptidases and exopeptidases is a mixture of neutral and basic amino acids (30%) with peptide chains varying in length from two to six amino acids (70%). The presence of excess amino acids in the lumen can further limit peptide hydrolysis (product inhibition).

The activity of enterokinase is noticeable after 26 weeks of gestation and its activity at term is approximately 10% of that of adults. Although pancreatic trypsin levels are substantial in both preterm and term infants, the secretory response to secretin and pancreozymin stimulation is somewhat blunted at birth compared with that at 2 years of age. However, such comparatively lower levels of protease activity in newborn infants do not appear to limit protein digestion significantly.

Brush Border Membrane and Cytoplasmic Peptidases

An important step in the final hydrolysis of peptides is their proteolysis to amino acids, either at the level of the intestinal brush border or within the cytoplasm of the intestinal mucosa. An important physiological observation is that protein absorption can occur both as amino acids and as peptides; indeed, absorption as peptides is considered a more efficient way of amino acid absorption compared with that of single amino acids (**Figure 3**). Even when a di- or tripeptide is subject to rapid hydrolysis by brush border peptidases, 30–50% of it is directly absorbed unconverted. The recognition that peptides are the main physiological routes of entry of amino acids into the enterocytes is a point of fundamental importance in the formulation of special protein hydrolysates and enteral feeds.

A range of peptidases are present at the level of the brush border membrane or cytoplasm with the capability of hydrolyzing oligopeptides of up to eight amino acid residues (**Table 2**). These oligopeptidases are synthesized in the rough endoplasmic reticulum of enterocytes and, after transfer through the Golgi apparatus, are transported to the brush border and extruded by exocytosis. There is little posttranslational processing of these peptidases, and they are attached to the brush border membrane by short anchoring pieces. The brush border peptidases differ in several ways from the cytoplasmic

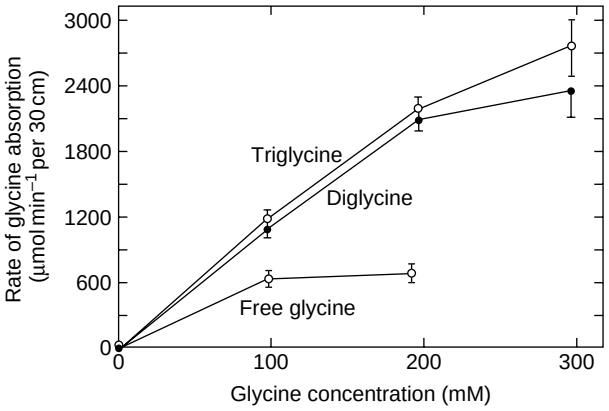

Figure 3 Rates of glycine absorption (mean ± SEM) from perfusion solutions containing equivalent amounts of glycine in free or peptide form. (From Adibi SA, Morse EL, Masilamani SS and Amiu P (1975) Evidence from two different modes of tripeptide appearance in human intestine: Uptake by peptide carrier systems and hydrolysis by peptide hydrolases. *Journal of Clinical Investigation* **56**: 1355–1363. Reproduced with permission from the American Society of Clinical Investigation.)

peptidases; the bulk of the hydrolysis of tetrapeptides and longer peptides occurs at the brush order, whereas the converse is true for dipeptidase activity, which is primarily within the cytoplasm. Most oligopeptidases are aminopeptidases, acting at the N-terminal amino acid. The brush border proteolysis rate is most rapid for tripeptides and least rapid for dipeptides, whereas the rates of hydrolysis of tetrapeptides and pentapeptides are somewhat intermediate. The brush border peptidases are capable of hydrolyzing all peptide bonds except those with praline at the C terminal.

In general, the cytoplasmic peptidases are more heat labile than brush border peptidases. Of the cytoplasmic peptidases, the most abundant is a dipeptidase that cleaves neutral dipeptides, whereas the aminotripeptidase has a high specificity toward tripeptides with N-terminal amino acids or those containing praline terminally.

Very little is known about the developmental aspects of brush border and cytoplasmic proteases. However, the activity of many of these proteases is discernible by 10–16 weeks of gestation and progressively increases during development. In contrast, γ-glutamyl transpeptidase activity decreases with increasing gestational age, but the significance of this transition is unknown.

Colonic Digestion

Although colonic digestion and fermentation is an important mechanism for energy production in plant-eating animals, its role in human nutrition is of minor importance. Colonic fermentation may lead to the production of short-chain fatty acids from undigested starch, nonstarch polysaccharides, or proteins reaching the colon, providing approximately 5–10% of daily energy requirements from this source. The contributory role of colonic protein digestion may become important for people with reduced small intestinal function such as short bowel syndrome.

Table 2 Peptidases present at the brush border membrane and cytoplasm of villous epithelial cells

Peptidase	*Action*	*Products*
Brush border membrane peptidase		
Aminooligopeptidases (at least two types)	Cleave amino acids from C terminal of 3–8 amino acid peptides	Amino acids dipeptides
Aminopeptidase A	Cleaves dipeptides with acidic amino acids at N terminal	Amino acids
Aminopeptidase I	Cleaves dipeptides containing methionine	Amino acids
Aminopeptidase III	Cleaves glycine-containing dipeptides	Amino acids
Dipeptidyl aminopeptidase IV	Cleaves praline-containing peptides with free C terminal	Peptides and amino acids
Carboxypeptidase P	Cleaves praline-containing peptides with free C terminal	Peptides and amino acids
Angiotensin I converting enzyme (ACE) γ-glutamyl transpeptidase	Cleaves γ-glutamyl bonds and transfers	γ-Glut amino and/or peptide
Endopeptidases (two, including PABA peptidase)		
Folate conjugase	Cleaves pteroyl polyglutamates	Monoglutamate
Cytoplasmic peptidases		
Endopeptidases (several, including Gly–Leu dipeptidase)	Cleaves most dipeptides	Amino acids
Aminotripeptidase	Cleaves tripeptides	Amino acids
Proline depeptidase	Cleaves X–Pro bonds in praline-containing depeptides	Proline and amino acids

PABA, *para*-aminobenzoic acid.

Absorption

As already indicated, although the final end product of protein digestion is amino acids, small peptides are the dominant form of entry of amino acids into enterocytes, where they are further hydrolyzed into amino acids and absorbed into the bloodstream (**Figure 4**). Thus, the vast majority of products of protein digestion that reach the bloodstream are single amino acids. Amino acid transport systems develop *in utero* by the end of the first trimester, whereas peptide transport systems can be demonstrated by the beginning of the second trimester.

It is recognized that the intestinal permeability of the preterm and newborn infant may be high, allowing the entry of small amounts of undigested proteins. The maternal antibodies from colostrum can enter the newborn's bloodstream relatively unaltered by a process of endocytosis and subsequent exocytosis. Although the intestinal permeability decreases with age, adults can still absorb larger proteins in abnormal circumstances. However, the predominant form of absorption and presentation of large foreign proteins is through the specialized microfold or M cells overlying the lymphoid Peyer's patches. This mode of absorption of intact proteins or polypeptides, however, is nutritionally insignificant.

Peptide Absorption

Di- and tripeptides can cross the brush border membrane by a main peptide transport system with broad specificity. This carrier protein can transport dibasic as well as diacid peptides and peptides consisting of up to three amino acid residues. However, there is some stereospecificity for this transporter because the longer the length of the amino acid side chain on the peptides, the easier the absorption. The transporter system also has greater affinity for dipeptides than tripeptides, and the acidic and basic amino acid residues in dipeptides lower the affinity for the transport system compared with neutral amino acids. In general, the absorption of L-isomers of amino acids in dipeptides is preferred over the D forms. The peptide transport system is coupled to the proton pump system rather than the sodium gradient. The oligopeptide transporter (Pept-1) in the brush border membrane is the major mechanism for protein absorption in the human intestine and is primarily responsible for the transport of di- and tri-peptides. Several factors may determine the levels of Pept-1, such as insulin, which may stimulate membrane insertion of the oligopeptide transporter from a preformed cytoplasmic pool, and cholera toxin, which decreases the activity of Pept-1 through an increase in the intracellular concentration of cyclic AMP.

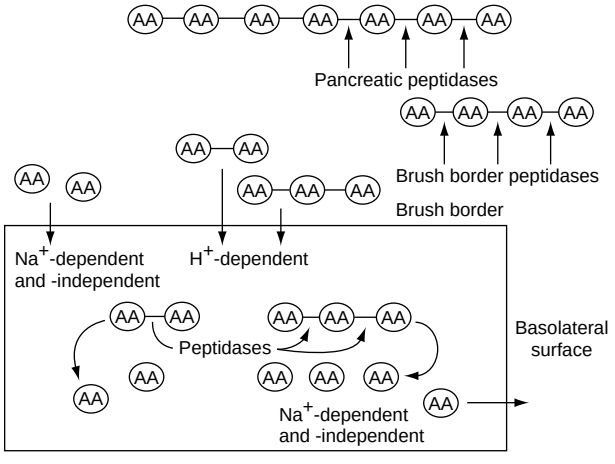

Figure 4 Small intestinal protein digestion and absorption. (Adapted from Shulman RJ (1996) Intraluminal digestion and absorption in the small intestine. In: Gluckman PD and Hayman MA (eds.) *Pediatrics and Perinatology: The Scientific Basis*, 2nd edn. London: Arnold. Reproduced with permission from Arnold (UK).)

Once in the absorbing cell, the di- and tripeptides are further hydrolyzed to the constituent amino acids by the cytoplasmic peptidases before absorption. The only small peptides that are known to enter the portal blood directly are those from gelatin that contain proline and hydroxyproline, and those from certain meats containing carnosine and anserine. However, their relative proportion in comparison to amino acids is inconsequential.

Amino Acid Absorption

Although some diffusion of amino acids does occur, they are mostly absorbed by active transport. Unlike peptides, which are absorbed equally well in both proximal and distal small intestine, amino acids are absorbed more rapidly in the duodenum and jejunum. Also in contrast to the parsimonious peptide transport system, there are multiple transport mechanisms for various amino acids at both the luminal end and the basolateral membrane of the enterocyte (**Table 3**). At the luminal end, the transporters are mostly located at the villous enterocytes. The villous enterocytes utilize approximately 10% of the absorbed amino acids for their own protein production, whereas the crypt cells derive their amino acid supply from the portal circulation. Of the various amino acids, glutamine appears to have a major role in the nutrition and regeneration of enterocytes, and it is now recognized that in the human intestine the predominant mechanism for assimilation of glutamine dipeptides is absorption as intact dipeptide rather than hydrolysis.

Table 3 Major amino acid transport systems in the intestinal epithelial cells

Transport system	*Substrates*	*Sodium gradient-dependent*
Brush border membrane		
B	Dipolar α amino acids	+
$B^{0,+}$	Dipolar α amino acids Basic amino acids Cystine	+
$B^{0,+}$	Dipolar α amino acids Basic amino acids Cystine	−
Y^+	Basic amino acids (e.g., lysine) Cysteine	−
IMINO	Imino acids (e.g., proline) β-Alanine	+
X^-_{GA}	Acidic amino acids (e.g., glutamate, aspartate)	+
β	β-Amino acids (e.g., alanine)	+
Basolateral membrane		
L	Broad selectivity	−
A	Broad selectivity	−
ASC	Neutral amino acids (e.g., alanine, serine) Cysteine	+
N	Clutamine, histidine, asparagines	+

Modified from Shulman RJ (1996) Intralumunal digestion and absorption in the small intestine. In: Gluckman PD and Heyman MA (eds.) *Pediatrics and Perinatology: The Scientific Basis*, 2nd edn. London: Arnold.

There are at least five different sodium-dependent transport systems for amino acid uptake. The sodium-dependent transport is facilitated by energy derived from Na^+/K^+-exchanging ATPase at the basolateral membrane. Most energy-dependent transporters are coupled either to cotransport of Na^+ or Cl^- or to the countertransport of K^+. An additional system of sodium-independent facilitated diffusion also exists and is predominantly geared toward basic and dipolar α amino acids. These passive transporters are either facilitated transporters or channels.

Digestibility

The digestibility of a protein is a measure of the amount of protein available from it for absorption after digestion; this is usually obtained from estimates of dietary nitrogen and fecal and urinary nitrogen. Digestibility is different from the other measures of protein quality, such as the amino acid or chemical scores and biological value, which respectively represent the essential and nonessential amino acid composition of the protein and the proportion of available nitrogen retained for growth or maintenance. Thus, a protein-based diet of high amino acid or chemical score may be poorly digested and of limited nutritional value. The digestibility of a protein is also dependent on the physical shape of the protein and the relative ease with which peptide bonds can be hydrolysed. Fibrous proteins with long polypeptide chains, such as collagen, keratin, and elastin, are relatively insoluble. In contrast, globular proteins, which are coiled and tightly packed, are comparatively soluble and thereby more digestible. Such proteins are insulin enzymes, hemoglobin, and albumin.

The apparent protein digestibility is a measure of the amount of protein intake (%) available for absorption and is usually calculated by estimation of fecal nitrogen and corresponding dietary intake:

$$\text{Apparent digestibility} = \frac{(\text{dietary nitrogen} - \text{fecal nitrogen})}{\text{dietary nitrogen}} \times 100$$

However, since not all fecal nitrogen is of dietary origin and some is derived from obligatory endogenous intestinal losses, a more appropriate measure is that of 'true protein digestibility.' This is derived as

$$\text{True protein digestibility} = \frac{[\text{dietary nitrogen} - (\text{fecal nitrogen} - \text{obligatory fecal nitrogen})]}{\text{dietary nitrogen}} \times 100$$

The obligatory fecal intestinal protein losses have been variably estimated to range from 20 mg/kg/day in young infant and preschool children to approximately 12 mg/kg/day in adults. These losses may result in some difficulty in interpreting digestibility findings. The estimated value of true digestibility of food and feed proteins is dependent on the excretion of metabolic fecal nitrogen (MFN). Results of many studies show that a high-fiber content of the diet increases MFN excretion and lowers the true digestibility of the diet protein. The exact estimation of MFN is only possible with isotopic methods. Experimental studies indicate that for human subjects the fecal digestibility values are significantly higher than the ileal values for Arg, Asp, Gly, Phe, Pro, Ser, Thr, and Trp, with the exception of faecal digestibility of Met, which is significantly lower than the ileal value.

Table 4 gives the true digestibility values for several common foods and diets. In general, milk and eggs have the highest true digestibility values of approximately 97%, followed by meats, fish, and

Table 4 Illustrative values of protein digestibility in humans

Protein sources	*True digestibility (%)*	*Digestibility relative to reference protein (%)*
Eggs	97	100
Milk and cheese	95	100
Meat and fish	94	100
Maize	85	89
Oatmeal	86	90
Whole wheat	86	91
Refined wheat	96	101
Polished rice	88	93
Soy flour	86	91
Soybean isolate	94	99
Millet	79	83
Peanut butter	95	100
Beans	78	82
Chinese mixed diet	94	99
Brazilian mixed diet	78	82
Guatemalan mixed diet	79	92
Indian rice and milk diet	87	92
Mixed American diet	96	101

Modified from Torun B (1985). Proteins: chemistry, metabolism and nutrition requirements. In Brunser O, Carraza F, Gracey M, Nichols B, Senterre J (eds). *Clinical Nutrition of the young Child.* New York, Raven Press, pp 99–119. Reproduced with permission from Raven Press.

poultry. Plants and legumes have comparatively lower protein digestibility values, ranging from 75 to 85%. Thus, in mixed diets, increasing the relative amounts of animal proteins compared with plant-based proteins results in increased protein digestibility of the diet. However, some fibrous animal proteins, such as keratin and collagen, are relatively indigestible. A useful approximation is to assume a protein digestibility of 75–80% for diets based on whole grain cereals and vegetables, 95% for diets based on refined cereals and animal proteins, and 85–90% for mixed diets. In general, the lower the true digestibility of a protein, the greater the amount required to achieve nitrogen equilibrium.

In addition to the differences in the nature of proteins highlighted previously, several other factors affect protein digestibility of a diet, including the presence of additional dietary factors such as trypsin inhibitors. The latter may be present in certain foods, such as navy beans and soybeans, and can be largely inactivated by heating, thus improving protein digestibility. Although moderate heating can promote digestibility by promoting breakdown of peptide cross-linkages and inactivation of protease inhibitors in natural food, strong heating, especially in the presence of a carbohydrate or oxidized lipids, may make the protein resistant to enzymatic hydrolysis. The Maillard or 'browning reaction' occurs after high, usually prolonged heating of a protein in the presence of a reducing sugar such as lactose or glucose, resulting in cross-linkages of the sugar with the free side chain of the lysine residues. This may make up to 30% of the lysine biologically unavailable. These changes are of particular importance in situations of marginally sufficient protein intake, in which cooking procedures may further aggravate protein malnutrition. The effect of heat treatment on the protein digestibility of a formulation was highlighted by a study using an elegant suckling rat model to investigate the digestibility different infant milk formulations. The data indicate that proteins from ultraheat-treated milk formulate were most rapidly digested (84%), resulting in an amino acid profile closest to that of breast-milk-fed pups, whereas the digestibility from powdered formulations (77–82%) and soy milk-based formulas was slower. The slowest digestion of protein was found in sterilized milk formula (72–74%), where the canned formulation was exposed to high temperatures for extended time period.

The Maillard reaction is highly influenced by the pH of foodstuffs or other agents. The reduction of pH that may be performed by increasing fermentation in the baking industry lessens the decomposition of lysine and tryptophan in proteins. Fermentation is widely used as a strategy to increase the digestibility of starch and improve the organoleptic properties of weaning foods and cereal-based preparations in developing countries. However, although the impact of fermentation on starch digestion is well established, the impact on protein digestibility is variable. Although some studies have suggested an impact on protein quality and digestibility of legumes and finger millet-based foods, other studies suggest that fermentation only modifies the gastric emptying rate and does not significantly affect the level of diet hydrolysis, the endogenous nitrogen stimulation, or the digestibility rate.

Despite several limitation, the digestion and absorption of ingested proteins is remarkably complete, with only a small fraction (3–5%) of ingested protein nitrogen escaping hydrolysis and excreted in the stools. In the context of infant nutrition, although breast milk is well digested, some proteins, such as secretory IgA, lactoferrin, and α_1-antitrypsin, escape digestion.

The protein digestibility-corrected amino acid score (PDCAAS) has been adopted by FAO/WHO as the preferred method for the measurement of the protein value in human nutrition. The PDCAAS is a combination of the chemical score of the limiting amino acid multiplied by true digestibility of the protein. The method is based on comparison of the

concentration of the first limiting essential amino acid in the test protein with the concentration of that amino acid in a reference (scoring) pattern. This scoring pattern is derived from the essential amino acid requirements of the preschool-aged child. The chemical score obtained in this way is corrected for true fecal digestibility of the test protein. PDCAAS values higher than 100% are not accepted as such but are truncated to 100%. Although the principle of the PDCAAS method has been widely accepted, critical questions have been raised in the scientific community about the validity of the preschool-aged child amino acid requirement values, the basis of correction for fecal instead of ileal digestibility, and the truncation of PDCAAS values to 100%. At the time of the adoption of the PDCAAS method, only a few studies had been performed on the amino acid requirements of the preschool-aged child, and there is still a need for validation of the scoring pattern. Also, the scoring pattern does not include conditionally indispensable amino acids.

These amino acids also contribute to the nutrition value of a protein. There is strong evidence that ileal, and not fecal, digestibility is the correct parameter for correction of the amino acid score. The use of fecal digestibility overestimates the nutritional value of a protein because amino acid nitrogen entering the colon is lost for protein synthesis in the body and is, at least in part, excreted in urine as ammonia. The truncation of PDCAAS values to 100% can be defended only for the limited number of situations in which the protein is to be used as the sole source of protein in the diet. For evaluation of the nutritional significance of proteins as part of mixed diets, the truncated value should not be used. In these cases, a more detailed evaluation of the contribution of the protein to the amino acid composition of the mixed diet is required. From such an evaluation, it appears that milk proteins are superior to plant proteins in cereal-based diets. Other studies have assessed the validity of the PDCAAS method in predicting the quality of protein products compared with the commonly used protein quality methods, protein efficiency ratio and net protein ratio. These data demonstrate that the PDCAAS method is inappropriate for predicting protein quality of protein sources that may contain naturally occurring growth-depressing factors or antinutritional factors formed during alkaline and/or heat processing.

Quality and Sources

B Torun, Center for Research and Teaching in Latin America (CIDAL), Guatemala City, Guatemala

The amino acid composition of food proteins and the efficiency with which they are digested to allow amino acid absorption determine their capacity to

provide nitrogen and essential amino acids for human growth and functions. This capacity, known as protein quality, influences dietary requirements: The lower the quality, the higher the required dietary protein intake. The nutritive value of food proteins is also influenced by protein concentration and the bioavailability of its amino acids. The latter can be affected by some forms of food storage and processing.

This article examines the ways of assessing the protein quality of foods and diets and the quality inherent to various protein sources. The following operational terms are used:

- Protein (or nitrogen) digestibility: The proportion of dietary nitrogen that is absorbed. 'True' protein digestibility is calculated correcting for endogenous or obligatory fecal nitrogen losses (i.e., nitrogen in epithelial cells, gastrointestinal secretions, and intestinal flora) (**Table 1**).
- Nitrogen balance (NB): The average amount of nitrogen that is retained or lost from the body. It is calculated from measurements of dietary, urinary, and fecal nitrogen and estimates of integumental (sweat, skin, nails, and hair) nitrogen losses (**Table 1**).
- Essential amino acids (EAA) (also called 'indispensable amino acids'): Amino acids that the diet must provide because humans cannot synthesize them from other components at a rate commensurate with normal bodily needs.
- Amino acid scoring pattern: Amino acid composition of a hypothetical reference protein that contains all EAAs in the amounts necessary to satisfy requirements.
- Amino acid scoring procedure: Calculation of the proportion of each EAA in a protein or diet relative to the scoring pattern (**Table 1**). It can be expressed as percentage or as a fractional value.
- Limiting amino acids: EAAs in food proteins that are present in lower proportions than in the reference protein (i.e., with fractional value <1.00, relative to the reference protein) (**Table 1**).
- Amino acid score (or 'chemical score'): Value of the limiting amino acid with the lowest score in a protein (i.e., the 'most limiting amino acid'). A protein is assigned a percentage score of 100 (or a fractional score of 1.00) when none of its EAAs are limiting.

Table 1 Calculation of operational definitions[a]

Definition	*Calculation*
Apparent digestibility	$\frac{I_N - F_N}{I_N}$
True digestibility	$\frac{I_N - (F_N - F_E)}{I_N}$
Nitrogen balance	$I_N - U_N - F_N - \text{Integ}_N$
Amino acid score	$\frac{\text{mg of EAA in 1 g of food protein}}{\text{mg of EAA in 1 g of reference protein (or EAA scoring pattern)}}$
Limiting amino acid	EAA with a score <1.00 (or $<100\%$)

[a]Digestibility and amino acid scores can be expressed as fractional values (≤ 1.00) or multiplied by 100 and expressed as percentages.
EAA, essential amino acid; F_E, endogenous fecal nitrogen; F_N, total fecal nitrogen; I_N, nitrogen intake; Integ_N, integumental nitrogen; U_N, total urinary nitrogen.

Assessment of Protein Quality

Metabolic Studies

The most accurate assessment of protein quality of foods for humans is through clinical or metabolic studies that measure nitrogen balance. A fixed amount of protein is fed to a group of individuals until a steady state is reached. At that point, excreta are collected and analyzed for their nitrogen content, and integumental nitrogen losses are generally estimated at approximately $5\,\text{mg N kg}^{-1}$ to calculate NB as follows: $\text{NB} = I_N - U_N - F_N - \text{Integ}_N$ (See abbreviations in **Table 1**). Measurements are repeated with different amounts of food protein and the relationship between nitrogen intake and nitrogen balance is evaluated (**Figure 1**). The slope of the line before NB reaches a plateau and the amount of dietary protein needed to attain "0" nitrogen balance are indicators of protein quality: The steeper the slope and the lower the amount of dietary protein to achieve balance, the higher the quality of the protein being tested.

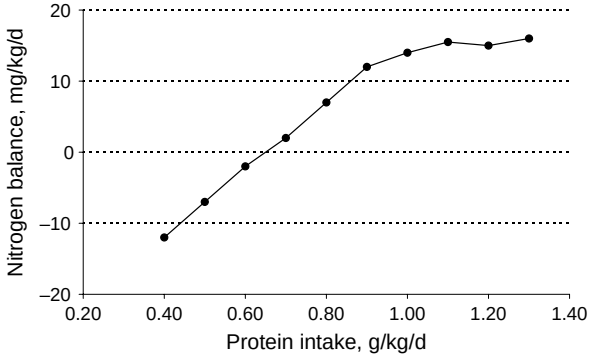

Figure 1 Plot of a nitrogen balance study. Nitrogen retention increases with protein intake until a plateau is reached.

Influence of Energy Intake on Nitrogen Balance

When food energy intake is insufficient to satisfy energy needs, amino acid oxidation increases in an effort by the human body to satisfy energy requirements. This raises urinary nitrogen excretion and reduces nitrogen balance. On the other hand, increased energy intake may reduce amino acid oxidation and urinary nitrogen excretion, thereby improving N balance until it reaches a plateau. This response, known as the protein-sparing effect of dietary energy, can be attenuated if the quantity or quality of food protein intake is inadequate. It has been postulated that the protein-sparing effect of dietary carbohydrates is mediated by increased insulin secretion, which inhibits proteolysis, hepatic gluconeogenesis, and renal ammoniagenesis. The protein-sparing effect of dietary fat may be due to a reduction of amino acid oxidation through an effect of free-fatty acid oxidation in the liver, whereby the increase in NADH/NAD inhibits branched-chained keto-acid dehydrogenase. For these reasons nitrogen balance must not be used to estimate protein quality when the amount of dietary energy is such that it produces weight loss or gain in an otherwise well-nourished individual.

Because of their high cost and experimental complexity, metabolic studies are done mainly to evaluate new, nonconventional protein sources and novel food processes that may affect protein quality. Other methods that can predict protein quality for humans rapidly and at low cost are used to evaluate diets and conventional foods routinely.

Assays in Laboratory Animals

Biological assays in laboratory animals have been used to assess food protein quality, based either on a protein's ability to support growth in young rats (protein efficiency ratio) or on nitrogen retention (net protein utilization). However, these assays underestimate the quality of some vegetable and animal proteins for humans. For example, the proteins of pulses and milk casein have a lower quality for rats than for humans because rats have a higher requirement of sulfur-containing amino acids. Thus, application of rat assay results to human nutrition can result in important quantitative errors. The discrepancy usually has economic rather than public health implications because rat assays generally err by underestimating protein quality for humans, but the value of certain animal proteins can be overestimated because of higher efficiency of utilization by the rat.

Amino Acid Score Adjusted for Digestibility

The concept of assessing protein quality on the basis of a protein's constituent amino acids was introduced in the late 1940s. It was later suggested that the calculations be corrected by the protein's digestibility. The validity of this approach and its correlation with results of metabolic and clinical studies were initially limited by lack of accurate procedures to measure tryptophan and sulfur amino acids, insufficient information on digestibility of proteins from various sources, and uncertainty about human amino acid requirements to prepare an adequate scoring pattern. Significant scientific and technological advancements now allow the use of an amino acid scoring procedure adjusted for digestibility as a good and practical predictor of protein quality for humans.

This method is recommended by expert committees of the World Health Organization (WHO), United Nations Food and Agriculture Organization (FAO), United Nations University (UNU), and the Codex Committee on Vegetable Proteins (CCVP), as well as by regulatory agencies of several countries, for routine evaluation of protein quality for humans. The elements required for its application are knowledge about the amino acid composition and digestibility of the food protein(s) under evaluation and a scoring pattern based on human amino acid requirements.

Amino Acid Analysis of Food Proteins

Modern methods that involve acid or alkaline hydrolysis of the protein followed by separation and quantification of the released amino acids by ion exchange, gas–liquid or high-performance liquid chromatography, and other chemical and microbiological methods for specific amino acids, such as lysine, methionine, cysteine, and tryptophan, provide data with a repeatability within laboratory of approximately 5% and a reproducibility between laboratories of approximately 10%. Although several national and international food composition tables include amino acid contents of foods, it is preferable to use analytical results from a reliable laboratory owing to technical shortcomings in the preparation of some tables and to the considerable variability between the reported values, especially for tryptophan, cysteine, and methionine.

Amino acid data are usually calculated as milligrams amino acid per gram of protein. If they are reported as milligrams amino acid per gram of nitrogen, they can be converted to the protein equivalents multiplying by specific protein factors that range from 5.7 (17.5% nitrogen) to 6.4 (15.6% nitrogen) for the major protein sources in the diet. The factor used for a mixture of protein sources is 6.25, corresponding to a nitrogen content of 16%.

Table 2 Calculating the lysine (lys) content of a rice, lentil, and chicken mixture

1. Protein sources in 100 g of the cooked mixture:

10 g dry polished rice
10 g dry lentil
20 g raw white chicken meat

2. Chemical composition:

	Rice	*Lentil*	*Chicken*
Protein (g per 100 g food)	7.0	23.7	19.2
Lysine (mg per 100 g food)	255	1739	1590

3. Lysine content of the mixture (mg per g protein):

Food	*mg lys per g protein*		*g component per 100 g mixture*
Rice	(255/7.0)	×	10
Lentil	(1739/23.7)	×	10
Chicken	(1590/19.2)	×	20

Weighted mean = (364 + 734 + 1656)/(10 + 10 + 20) = **60 mg lys per g protein**

Table 3 Amino acid scoring patterns for infants under 1 year and for older children and adults (mg amino acid per g protein)[a]

Amino acid	*Infant < 1 year*	*Older children and adults*	*Egg, cow's milk, and beef protein*
Histidine	26	(19)[b]	22–34
Isoleucine	46	28	47–54
Leucine	93	66	81–95
Lysine	66	58	70–89
Methionine + cysteine	42	25	33[c]–57
Phenylalanine + tyrosine	72	63	80–102
Threonine	43	34	44–47
Tryptophan	17	11	12[c]–17
Valine	55	35	50–66

[a]Composition of animal proteins shown for comparison.
[b]Essentiality of histidine not clearly determined after 1 year of age.
[c]Cow's milk proteins have less sulfur-containing amino acids and tryptophan than human milk.

To calculate the amino acid content of a combination of food proteins, as in a processed food based on several protein sources or in a mixed diet, a weighted mean of the published or analytical results of each component should be used, as illustrated in **Table 2**.

Amino Acid Scoring Pattern

For infants younger than 1 year, the scoring pattern should be based on the amino acid composition of breast milk, even if some EAAs in human milk exceed minimum requirements for infants of this age. For example, infants consuming cow's milk proteins, which have less sulfur-containing amino acids than human milk, show adequate growth and nitrogen balance. Thus, although the use of a scoring pattern based on human milk composition may somewhat underestimate the protein quality of some foods for infants, there is consensus to accept errors on the side of safety for this highly vulnerable age group.

International expert committees (WHO, FAO, UNU, and CCVP) have agreed that the scoring pattern proposed in the 1980s for preschool children—based on studies of amino acid requirements at the Institute of Nutrition of Central America and Panama and on recommendations of protein intake by FAO, WHO, and UNU—is robust and represents the best available estimate of EAA requirements for this age group. Published nitrogen balance studies on older children and adults have experimental flaws, and only a limited number of EAAs have been studied with amino acid oxidation techniques in adults. Since proteins with amounts of EAAs that satisfy the needs of young children will probably be adequate for older children and adults, the scoring pattern for preschool children is currently used for all after 1 year of age.

Table 3 shows the internationally accepted patterns for amino acid scoring applicable to infants and to persons after 1 year of age; the composition of high-quality animal foods is shown for comparison. The content of each EAA in a food protein is evaluated relative to the age-specific scoring pattern, to determine the protein's amino acid score and to identify the limiting amino acids as shown in **Table 1**. All EAAs present in proportions that exceed requirements are assigned a fractional score of 1.00 (or a percentage score of 100%), even if mathematical calculation gives a higher value. The EAA with the lowest value (i.e., the most limiting amino acid) determines the protein's amino acid score.

The only EAAs that are likely to limit the protein quality of mixed diets for humans are lysine, the sulfur-containing amino acids (methionine and cysteine), threonine, and tryptophan. Consequently, when information on all EAAs is not available, protein quality can be estimated on the basis of its score for these four amino acids.

Correction for Protein Digestibility

A protein may have a good amino acid composition relative to the scoring pattern, but if it is not fully digested and its constituent amino acids are not absorbed, its capacity to provide nitrogen and EAAs for human function will diminish. Not all food proteins are digested,

absorbed, and utilized to the same extent because of inherent differences in their source (e.g., inside vegetable cells with indigestible membranes), their physicochemical nature (e.g., protein configuration and amino acid binding), the presence of food constituents that modify digestion (e.g., dietary fiber, tannins, and other polyphenols), the presence of anti-physiological factors that interfere with protein breakdown (e.g., trypsin inhibitors and lectins), and processing conditions that alter the nature or release of amino acids (e.g., Maillard reaction and formation of polyamino acids and methylmercaptan). Consequently, amino acid scores as predictors of protein quality must be adjusted for protein digestibility and amino acid availability.

The standard for obtaining digestibility data is through metabolic studies in humans, in which the nitrogen excreted in the feces is subtracted from the amount ingested with the diet and expressed as a percentage of intake. This apparent digestibility value must be corrected for the amount of fecal nitrogen excreted when a person is consuming a protein-free diet to calculate "true" digestibility (**Table 1**). Ethical constraints and practical complexities do not permit the determination of obligatory fecal nitrogen losses on a protein-free diet in all age and physiological groups. It is recommended that existing published values for daily obligatory fecal losses in preschool children (approximately 20 mg $N\,kg^{-1}$) and adults (approximately 14 mg $N\,kg^{-1}$) be used to correct apparent protein digestibility values.

Protein digestibility values of specific foods and well-defined diets may be taken from reliable published data. **Table 4** shows some examples. When such data are not available for a mixed diet, a weighted average can be calculated from the true digestibilities of its constituent protein sources, as illustrated in **Table 5**. For new or novel products or processes, digestibility must be determined, preferably in humans. When cost and practicality do not permit performing metabolic studies in humans, standardized fecal balance methods in rats have been used. These methods have given true protein digestibility values of 93–100% for animal foods or food products (casein, beef salami, skim milk, tuna, and chicken sausage) and soya protein isolate; 86–92% for beef stew, chick peas, rolled oats, and whole-wheat cereal; and 70–85% for lentils and different types of beans. These value ranges are similar to those from human studies. Nevertheless, rat data must be used with caution for foods and diets that are known or suspected of being handled differently by the human and rat intestines. *In vitro* procedures have also been developed using combinations of trypsin, chymotrypsin, peptidase, and bacterial protease. Further research is needed to validate their use as predictors of protein digestibility in humans.

Table 4 True protein digestibility of selected foods and diets

	True protein digestibility (%)
Egg white	97
Whole egg, milk, beef, poultry, fish	95

Mexico, rural	80
Guatemala, rural	79
Brazil, rural	78
India, vegetarian	78

Table 5 Calculation of true digestibility of a mixed diet of rice, beans, wheat, and egg

Diet	*True protein digestibility (%)*	*Proportion of total protein (g per 100 g protein in whole diet)*
Polished rice	88	40
Black beans	69	35
Whole wheat	86	15
Whole egg	95	10
Estimated digestibility of whole diet	$(0.88 \times 40) + (0.69 \times 35) + (0.86 \times 15) + (0.95 \times 10) = \mathbf{82\%}$	

Calculations and Examples

The EAA composition and protein digestibility of the food or mixed diet being tested are determined. Then the percentage or fractional value of the most limiting EAA (noncorrected amino acid score) is multiplied by the percentage or fractional value of 'true' protein digestibility to obtain the corrected score, which is equivalent to protein quality. This value can be used as such or it can be expressed in relation to the corrected amino acid score of a reference protein or food, usually casein or an animal food (milk, egg, or beef).

Proteins that have no limiting amino acids are assigned an amino acid score of 100% (or 1.00) that must be only corrected for digestibility.

Table 6 Calculation of amino acid scores of single protein sources corrected for digestibility and in relation to the protein quality of cow's milk

Food	*Most limiting amino acid*	*Noncorrected amino acid score*	*True protein digestibility*	*Corrected amino acid score*	*Protein quality relative to milk*
Cow's milk	None	$>100 \rightarrow 100\%$	$\times 95\%$	$=$ **95%**	—
Polished rice	Lysine 36 mg per g protein	$(36/58) \times 100 = 62\%$	$\times 88\%$	$=$ **55%**	$(55/95) \times 100 =$ **58%**
Egg white	None	$>100 \rightarrow 100\%$	$\times 97\%$	$=$ **97%**	$(97/95) \times 100 =$ **102%**

Similarly, if the clinical or experimental assessment of 'true' protein digestibility gives a value greater that 100% (generally due to experimental variability), a digestibility correction factor of 100% (or 1.00) is applied to the amino acid score. **Table 6** shows examples of calculations for a single food as protein source. The same procedure can be used for food mixtures using a weighted average procedure based on the protein content, amino acid composition, and digestibility of the individual components. **Table 7** shows an example of those calculations. For simplicity, the example uses only the four EAAs that are most often limiting.

Protein Concentration

Protein concentration or density (i.e., the amount of protein per unit of food) is another factor of a food's protein quality. Protein-dense foods are especially important for young infants, whose small gastric capacity limits the amount they can eat, and for elderly people with poor appetite. Evaluation of a food's protein concentration must be done for ready-to-eat preparations because food processing and cooking can result in significant changes relative to raw foods. Meats, poultry, and fish usually have a higher concentration of protein after cooking or frying, whereas vegetable food preparations contain more water and less protein than the raw products (**Table 8**).

Protein/Energy Ratio

The percentage of protein energy in the diet (P/E ratio) has been used to describe whether a diet provides adequate amounts of protein. The reasoning is that energy requirements are the main driving force for food intake. Therefore, a diet is adequate if it satisfies the requirements for all nutrients when it is eaten in amounts that will satisfy energy needs.

P/E ratio is calculated by dividing the amount of metabolizable energy derived from dietary protein (grams of protein $\times$ 16.7 kJ or 4 kcal) by the total amount of metabolizable energy in the diet, multiplied by 100 to avoid using fractional values. However, the use of P/E ratio as an index of food's protein adequacy may be misleading because it only gives information about protein concentration and does not indicate the biological value or quality of the proteins. Its usefulness improves when amino acid score is taken into account to calculate what can be defined as a desirable P/E ratio, as in the examples discussed later.

The P/E ratio indicates the amount of protein that the diet provides relative to energy and does not imply a constant relationship between protein and energy requirements. For example, the lower limit of the desirable P/E ratio of a diet with an amino acid score of 85% is 6.2 for a young child whose daily requirements are 16 g protein and 5.1 MJ energy $((16\,g \times 16.7\,kJ/0.85)/5100\,kJ \times 100)$. For an adult male with daily requirements of 55 g protein and 12.8 MJ, the desirable P/E ratio is 8.4 $((55 \times 16.7/0.85)/12{,}800 \times 100)$.

Diets, especially those eaten by adults, often provide protein in amounts that surpass requirements, which elevates the P/E ratio. For example, almost all adult populations eat diets with P/E ratios between 10 and 15%. This is related to culture and food availability and does not reflect a biologically optimal ratio. Consistent with the calculations in the preceding paragraph, P/E ratios of 10 and 15 are adequate and it cannot be argued that one is nutritionally better than the other.

Improvement of Protein Quality

Amino Acid Profile

The amino acid profile of a food or diet can be improved by increasing the amount of constituent amino acids in its proteins, adding specific amino acids, or combining foods in proportions that result in a better amino acid pattern.

Genetic handling This has resulted in cereals with higher contents of the amino acids that limit their protein quality. For example, varieties of Opaque-2 corn have approximately 50% more lysine and 35%

Table 7 Calculation of protein quality of a mixed diet based on whole wheat, polished rice, and chicken breast

Raw ingredients	*Data from analysis or literature*							*Quantities calculated for the mixed diet*				
	Weight (g)	*Protein (g per 100 g)*	*Lys (mg per g protein)*	*SAA*	*Th*	*Trp*	*True digestibility (%)*	*Total protein (g)* $H = A \times B/100$	*Lys (mg)* $I = H \times C$	*SAA (mg)* $J = H \times D$	*Thr (mg)* $K = H \times E$	*Trp (mg)* $L = H \times F$

Lys, lysine; SAA, sulfur-containing amino acids: Thr, threonine; Trp, tryptophan.

Table 8 Protein concentration in selected raw and ready-to-eat foods (g protein per 100 g food)

Food	*Ready-to-eat*	*Raw*
Beef, lean	36.8 (cooked)	21.4
Fish	31.8 (fried)	20.0
Wheat flour	12.0 (white bread)	11.0
Egg, hen	11.3 (hard-boiled)	11.3
Lentils	7.1 (cooked)	23.7
Common beans	6.2 (cooked)	22.0
Maize	4.2 (tortilla)	9.4
Milk powder, cow	3.2 (12% in water)	26.1
Rice	2.5 (boiled)	7.2
Potato, no skin	1.1 (cooked)	1.8

more tryptophan than native corn, both of which are limiting amino acids in this cereal.

Fortification and enrichment The addition of synthetic amino acids eliminates or reduces the magnitude of limiting amino acids, for example, in lysine-enriched wheat flour.

Complementation The combination of a food that has one or more limiting EAAs with another food(s) that has a surplus of these amino acids results in an improved combined amino acid profile. A double complementation effect has been achieved in the formulation of vegetable mixtures based on protein sources in which one has a surplus of the EAA that is limiting in the other and vice versa (**Figure 2**).

Digestibility and Bioavailability

Various food processing procedures can improve protein digestibility by removing food constituents that reduce digestibility (such as dietary fiber), breaking down poorly digestible vegetable cell membranes, destroying or neutralizing anti-physiological factors, and increasing the food surface area that can come into contact with gastrointestinal enzymes. For example, soya protein isolate, polished rice, and refined wheat flour have higher protein digestibilities than soya flour, whole rice, and whole wheat, respectively (**Table 4**).

Food storage and processing in adverse circumstances can reduce protein quality by making some EAAs unavailable for use in the human body. These conditions should be avoided to preserve protein quality. Some examples are the storage of dried milk under mild to moderate heat and humidity, which renders lysine side chains unavailable after reacting with the reducing sugar, lactose (Maillard

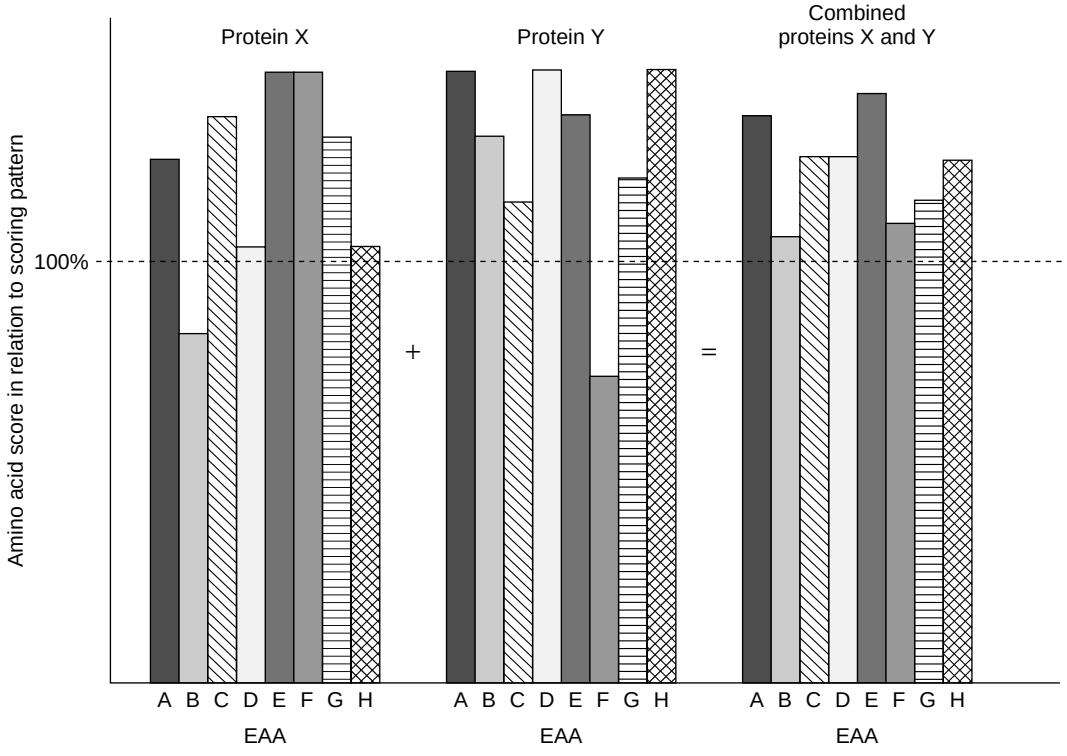

Figure 2 Amino acid complementation: When the two proteins are combined, protein X compensates the deficiency of amino acid F in protein Y, and protein Y compensates the deficiency of amino acid B in protein X. EAA, essential amino acids. From Torun B, Menchu MT and Elias LG (1994) Recommendaciones Dietéticas Diarias del INCAP. INCAP publication ME/057. Guatemala: Institute of Nutrition of Central America and Panama.

or 'browning' reaction); the severe treatment of protein with alkali, which causes lysine and cysteine residues to react and form lysinoalanine; and the treatment of proteins with oxidizing agents, which can result in a loss of methionine. Severe heating conditions in the presence of reducing sugars or oxidized lipids can make some food proteins resistant to digestion, thereby reducing the availability of all their amino acids.

Protein Concentration

Protein concentration can increase by genetic selection of protein sources, as in improved varieties of rice that have approximately 30% more protein than native rice, by the use of nitrogen-concentrating fertilizers that can raise the protein contents of several cereals or by industrial and home processing that reduce the water content of food preparations. Addition of concentrated protein sources, such as casein, soya protein isolates, soya flour, milk powder, or dehydrated egg, will also increase the protein concentration of foods and diets, as well as their amino acid score in some instances.

Protein Quality and Dietary Sources

Foods of animal origin, such as milk and milk products, eggs, meats, poultry, and fish, have excellent amino acid composition with a score of 100% and true protein digestibility of 95–98%. In addition, their protein concentrations often increase after cooking. Consequently, they are used as the reference for comparison of protein quality, provided that they are processed in ways that will not decrease amino acid bioavailabilty.

Almost all vegetable foods have one or more limiting amino acids. Soya beans and soya products are notable exceptions. In general, proteins in natural vegetable foods have digestibilities of 70–85%. Vegetable protein isolates, flours, and extruded products have higher digestibilities.

Among vegetables, pulses have the highest protein concentrations, ranging from 20–25% in most raw beans and peas to approximately 36% in soya beans. Pulses usually have limiting sulfur-containing amino acids.

Cereals and cereal products are the largest sources of protein in most areas of the world. Cereal grains and flours contain approximately 7–12% protein with a quality that is limited by their lysine content and, in many instances, also by threonine and/or tryptophan. Although deficient in lysine and threonine, rice has one of the best amino acid compositions among cereals, whereas sorghum and native maize (i.e., not genetically improved) are among the lowest.

Most nuts and edible seeds contain 8–18% protein. Many oil seeds have 12–20% protein, and the cake that remains after oil extrusion can have as much as 30–40% protein.

Deficiency

Z A Bhutta and H L Dewraj, The Aga Khan University, Karachi, Pakistan

Introduction

The term protein deficiency represents a state of deficit in body protein or one or more of the essential amino acids. Thus, the term protein deficiency can also be considered synonymous with negative nitrogen balance. The deficiency can result from a protein-deficient diet or other diseases and, in general, can also result from a global deficit of food. While protein-energy malnutrition is the more common form of protein deficiency, in general the features are comparable to those seen with kwashiorkor.

Dietary protein contributes all of the amino acids and fixed nitrogen necessary for the biosynthesis of tissue proteins and nonprotein nitrogenous compounds such as purines and pyrimidines. Dietary amino acids are required for the synthesis of new tissue constituents at all ages, particularly during growth. Amino acids consumed in excess of these needs are not stored but are degraded, the nitrogen being excreted and the carbon skeleton recycled. Each day more amino acids are degraded and resynthesized in the body than are ordinarily consumed in the diet.

All of the 20 fundamental amino acids must be present for protein synthesis to occur. The remarkable range of functions mediated by proteins is a function of the diversity and versatility of these 20 distinct building blocks of proteins. Nine of these amino acids (histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine) are not synthesized in the human body and are therefore 'essential' for well-being. In addition, arginine is essential in infancy, and in the preterm infant there is a transient need for dietary tyrosine and cysteine as well. The nutritional quality of dietary protein is influenced by its essential amino acid content. This implies that the protein intake contains sufficient 'nonessential' amino acids to minimize metabolic diversion of essential amino acids to cover nonspecific nitrogen requirements.

An adequate protein intake contains all of the essential amino acids in sufficient quantities to satisfy maintenance needs and to provide a surplus sufficient for the processes of normal growth and development. Serum concentrations of albumin and total protein serve as clinical indicators of the sufficiency of dietary protein intake in the absence of systemic disease. While the protein foods of animal origin (milk, meat, fish, and eggs) supply all of the essential amino acids; it must be recognized that some foods of vegetable origin supply most amino acids in adequate amounts.

Although the importance of hormonal regulation of protein metabolism is well recognized, there is increasing evidence that dietary protein may play a regulatory role by modulating the hormonal milieu leading to tissue accretion. Studies in recovering malnourished children and in normal children have shown a significant increase in circulating insulin-like growth factor I associated with higher protein intakes. Protein amino acid composition, however, appears to be of less relevance for these effects, which were observed with both animal and vegetable protein sources. Thus, it appears that dietary protein quantity is the major factor for this observed response. The amino acid composition of dietary proteins has a direct effect on growth by determining the supply of amino acids at the cellular level. Protein synthesis requires the presence of each component amino acid at the time of chain elongation. Thus, a dietary protein intake deficient in one or more essential amino acids will not be able to sustain protein synthesis. Many vegetable proteins have one or more limiting amino acids, e.g., with levels below those in high-quality reference proteins such as egg or milk.

It is important to maintain a balanced intake of amino acids in the diet, and to understand the relationships between different groups of amino acids and other nutrients such as vitamins. For example, when the most limiting amino acid in a diet generally poor in protein is increased, a deficiency of the next most limiting amino acid may be precipitated. Excessive intakes of certain amino acids, which may or may not be limiting, when added to a diet that is marginal in certain of the B vitamins, may result in an increased severity of the vitamin deficiency. In

other cases, an excess of an amino acid may reduce the utilization of another amino acid that is provided in normally adequate amounts to such an extent that a deficiency occurs.

Protein Turnover and Regulation

The term protein turnover reflects the balance of protein degradation and resynthesis. From a quantitative standpoint, by far the greatest influence on amino acid turnover and metabolism is this turnover cycle in which proteins are continuously degraded and resynthesized. Co-regulation of synthetic and degradative arms of the cycle is crucial to maintaining cellular viability, to regulation of growth and cellular protein mass, and to control of enzyme levels. At least 20% of basal energy expenditure is used in maintaining whole-body protein synthesis. Body protein mass and rates of protein gain or loss in a cell are entirely dependent on the balance of these mechanistically distinct processes, i.e., the relative rates, of protein synthesis and degradation. Although both processes are influenced by protein and energy nutritional status and by the same hormones (e.g., insulin, growth factors, growth hormone, and glucocorticoids), direction and magnitude of a response of either process are not easily predicted.

Nutritional status, especially amino acid intake, and the response of protein turnover to endocrinological changes interact in a complex way. As a result of these complexities it has proved difficult to identify a common response even when the same outcome variable (e.g., increased protein deposition) is achieved. For example, stimulation of proliferative growth involves a simultaneous increase in protein synthesis and decrease in protein degradation, while hypertrophic growth (e.g., of a muscle in response to increased workload) involves simultaneous increases in both protein synthesis and degradation. Similarly, increases in whole-body protein retention brought about by either increased intake of energy, limiting amino acid, or insulin infusion appear to involve primary changes in whole body protein degradation. On the other hand, separate evidence implies that changes associated with total protein intake or following growth hormone administration involve primarily protein synthesis. Furthermore, the magnitude of changes in whole-body protein turnover, even in response to a common nutritional manipulation, can depend on the prior nutritional status of the individual.

Developmental factors influence regulation of protein turnover as it relates to protein deposition. Protein synthesis appears to be of particular importance to nutritional regulation of growth of immature tissues during childhood, but the response of protein synthesis to protein intake becomes progressively smaller as subjects approach adulthood. In adults, protein degradation seems to be the critical factor regulating protein balance in the short term.

General Nutritional Factors Regulating Amino Acid Catabolism

Essential amino acid catabolism is primarily influenced by the following nutritional factors:

1. The degree to which total nitrogen intake approximates total nitrogen needs of the individual. This factor affects amino acid catabolism in general and is reflected in adaptations in urea synthesis.
2. The degree to which the pattern of amino acids in dietary protein matches amino acid needs. This is reflected directly in the efficiency with which a given dietary protein is utilized in productive processes (e.g., growth, lactation) and is the principal factor underlying differences in biological value of dietary proteins. This factor determines the regulation of the catabolism of individual indispensable amino acids independently of the total. This is the premise underlying recent nutrition interventions with specific high-quality protein intake in infected malnourished children, as a means of preventing amino acid diversion to acute phase protein synthesis.
3. The balance between essential and nonessential amino acids. Dietary indispensable amino acids represent 45% of total amino acid needs for protein deposition and 30% of total for maintenance and the rest consists of dispensable amino acids. Although nonessential amino acids do not have to be supplied in the diet, the organism still has a metabolic need for these nutrients, and if the diet fails to provide them, dispensable amino acids must be synthesized endogenously. An imbalance between dietary essential and nonessential amino acids intake will lead to catabolism of essential amino acids to supply nitrogen for nonessential amino acid synthesis.
4. The degree to which energy intake matches energy needs. Amino acid catabolism is also part of the body's energy supply in order to maintain ATP synthesis. Variations in nonprotein energy intake can have rapid and marked effects on overall amino acid catabolism.

Relationship between Protein Intake and Protein Need

Amino acid catabolism changes rapidly after protein intake. Even in the fed state, amino acid catabolism changes within hours in response to a change in overall level of dietary protein. An important factor in the immediate response to protein intake is the concentration of amino acids. The quantitative relationship between circulating amino acid concentrations and their rate of catabolism is not uniform, either between individuals or between diets. A persistently high or low intake of protein leads to an overall increase or decrease in rate of amino acid catabolism that is partially independent of circulating amino acid concentrations.

Both short- and long-term changes in protein intake alter the levels of insulin, glucagon, and glucocorticoids, all of which are capable of altering the function of amino acid catabolic enzymes. Glucagon, for example, both activates and induces a wide range of amino acid catabolic enzymes. The positive relationship between glucocorticoid level and hepatic amino acid catabolism has been known for many years. There is now additional evidence for direct regulation of catabolic enzyme synthesis by amino acids that is independent of hormonal effects. For example, the initial enzyme of the urea cycle, carbamoyl-phosphate synthase, is immediately responsive to changes in ammonia production via activity of glutaminase, which is in turn activated by ammonia.

Adaptation to Low Protein Intakes

Nitrogen Balance

Nitrogen equilibrium is a state in which, for given intake of nitrogen, an equivalent amount of nitrogen is lost from the body via urine, feces, skin, sweat, etc. In general, when protein intake is low, dietary protein is used more efficiently, urea nitrogen excretion is reduced, and amino acid synthesis pathways are stimulated. The liver plays an important role in the adaptive process since it is the only organ that can transform the nitrogen from amino acids into urea. The metabolic activity of the gastrointestinal tract is important in this adaptive process. Normally, one-third of the urea produced is passed into the bowel and can be hydrolyzed by the microflora. As a process of adaptation to reduced protein intake, the body retains a greater proportion of urea. Similarly, the intravascular circulating albumin mass is maintained by reduced breakdown and a shift of albumin from the extravascular to the intravascular compartment.

Factors Affecting Adaptation

Among the factors that can affect the adaptation to low protein intake are infections, diarrheal disease, and injuries. In infections, protein from muscle and skin is needed for the immune response and synthesis of acute phase proteins. This immunostimulation can lead to an overall negative nitrogen balance. **Table 1** indicates the relative contribution of various

Table 1 Estimated amino acid requirements for synthesis of some acute phase proteins (grams of amino acid per kilogram of protein)

Amino acid	*C-reactive protein*	*Fibrinogen*	*α-Acid glycoprotein*	*α-Antitrypsin*	*Serum amyloid A*	*Haptoglobulin*

Data from Reeds PJ, Fjeld CR, Jahoor F. Do the differences between the amino acid composition of acute-phase and muscle proteins have a bearing on nitrogen loss in traumatic states? *J Nutr* 1994; **124**: 1754S–1764S

amino acids to the production of acute phase proteins.

In other disorders such as injuries or burns, there may be more severe direct losses of nitrogen and altered adaptation. Energy balance is critical for nitrogen balance because of its nitrogen-sparing effect. Thus, if protein deficiency is accompanied by energy deficiency, the adaptation to a low protein intake cannot be achieved completely.

The process of adaptation is clearly dependent on prior nutritional status and overall protein deficits or reserves. It is estimated that the body of a human adult (65 kg) contains 12 kg of protein, about 50% of which is found in muscles. The well-fed human adult can lose about 3 kg of protein without disturbances to his or her health. The amount of body protein depends on, among other things, the dietary protein and carbohydrate intake; if carbohydrate is lacking, the amino acids are utilized for gluconeogenesis.

Protein reserves are not comparable to special fat depots, and not all body proteins can serve as protein reserve. Reserves are primarily organs that contain labile body protein such as liver, plasma (with protein such as albumin and enzymes), and the gastrointestinal tract. Although the protein turnover rate in muscle is very slow, this tissue is a very important protein reserve owing to its large mass. In general, however, during protein deficiency the labile body proteins are metabolized first, sparing the reserves. However, when deficiency is long term, all organs are affected to various extents. **Table 2** indicates the rates of loss of protein from various organs and tissues in rats on a protein-deficient diet. **Table 3** shows some different amino acid responses to a range of stresses.

Table 2 Relative losses of protein in different organs and tissues from rats over 7 days

Causes of Protein and Amino Acid Deficiency

Causes

Although the main cause of protein deficiency is a protein-deficient diet, the disorder can commonly occur in a variety of pathologic states. In particular, the disorder can be seen in the general context of starvation (although the deficits may be both protein and energy) or in disorders where there are specific protein losses from the body as in nephrotic syndrome or after burns.

Secondary protein deficiencies can be ascribed to six causes:

1. Irregular food habits and starvation states; this may be seen in both developed and developing countries in a variety of pathological states.
2. Inability to digest and absorb the protein that is consumed; this occurs in patients with chronic gastrointestinal disorders such as celiac disease, persistent diarrhea, or protein-losing enteropathy.
3. A disturbed protein metabolism, which may exist in patients with cirrhosis of the liver, but also in patients with hormonal disorders or in some cases of diabetes.
4. A continuous loss of protein; this predominates in patients with disease such as chronic renal disease, bleeding, or exudative gastroenteropathy. High losses of albumin into the urine are indicators of the nephrotic syndrome.
5. Increased protein turnover, which is characteristic in cases of systemic infection or fever. In many instances this may be subclinical and associated with protein diversion due to immunostimulation.
6. Enhanced catabolism of protein, with increased nitrogen losses, seen in patients with severe injuries, especially burns, or in postoperative stress.

Principles of Treatment of Protein Deficiency

The dietary treatment of protein deficiency depends on the cause of the deficiency and must depend upon a sound understanding of the underlying disorder. In most instances, isolated protein deficiency due to deficient intake is rare and most deficits include both macronutrients and micronutrients. In this situation, isolated repletion of protein or amino acids alone is inadequate and may even cause harm. This is well illustrated by the great 'protein fiasco' of the past when attempts to provide high protein supplements to malnourished children were found to be both inadequate and deleterious. Similarly, high protein supplements in pregnancy have been shown to actually increase rates of adverse pregnancy outcomes. Thus, the mainstay of treatment in such states of global deficiency includes balanced energy-protein and micronutrient supplementation.

In other instances, protein supplementation is critical. For example, in children with nephrotic syndrome, the daily intake of protein should be increased to 3–4 g kg^{-1} day^{-1} so that hepatic synthesis of albumin can compensate in part for the urinary losses. In other acute circumstances, infusion of albumin can be used to acutely correct deficits and circulatory abnormalities. However, in states of metabolic adaptation, care should be used in increasing protein intakes. For example, in cases of cirrhosis, the protein intake should be restricted to 20 g day^{-1} to reduce the risk of precipitating hepatic encephalopathy.

R

REFUGEES

R Bhatia and L N Richardson, United Nations World Food Programme, Rome, Italy

Since World War II, more than 100 million people have been forced to flee persecution or the violence of war to seek refuge in neighboring countries or in a different areas of their own countries. The optimism following the end of the Cold War was short-lived because an epidemic of civil conflicts erupted in several areas of the world. In 1993, 47 conflicts were active, of which 43 were internal. Armed conflicts have increasingly affected civilian populations, resulting in high mortality, widespread human rights abuses, forced migration, famine, and total collapse of governance in some countries.

The 1951 United Nations Convention defines refugees as "any person who owing to a well-founded fear of being persecuted for reasons of race, religion, nationality, membership of a particular social group, or political opinion is outside the country of his nationality and is unable, or owing to fear is unwilling to avail himself of the protection of the country." In 1969, the Organization of African Unity expanded this definition to include persons fleeing from war, civil disturbance, and violence of any kind.

'Refugees' cross international borders, but 'internally displaced persons' (IDPs) do not. However, both groups have been forced to leave their homes and undergo physical and mental trauma as they settle in harsh and unhealthy environments, where they are often unable to take responsibility for their own welfare. The terms refugee and internally displaced persons have major implications for the people concerned, particularly regarding their rights to protection and assistance, which are embedded in international law. The United Nation's High Commissioner for Refugees (UNHCR) is mandated by the international community to protect and provide assistance to refugees. Due to state sovereignty, the internally displaced are not included within UNCHR's mandate. Only on an ad hoc basis, at the request of the secretary general of the United Nations and the nation concerned, does UNHCR provide assistance to IDPs.

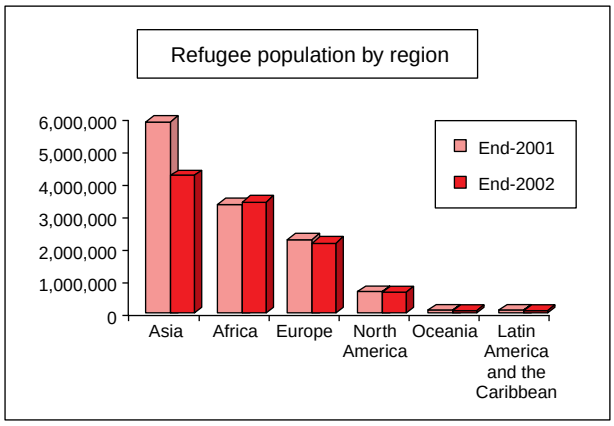
Trends

The escalation in crises and numbers affected since the early 1990s has had a dramatic impact on the nutrition and health of refugees. The number of people affected by natural disasters increased from 50 million in 1980 to 250 million in 2000. Similarly, approximately 30 million people were affected by conflict each year during the 1990s in more than 60 countries. The number of refugees has steadily increased from approximately 5 million in 1980 to a peak of more than 20 million in 1994, with a slow decline by 2003 to approximately 10.4 million. This is primarily due to the fact that more refugees are repatriating than are being forced to leave their countries, and new refugee flows have declined. The large numbers of repatriated refugees from Afghanistan, Angola, and Sierra Leone have contributed to the reduction in the number of refugees. In addition to the large numbers of refugees, in 2003 UNHCR assisted approximately 5.8 million of the estimated 20–25 million IDPs worldwide.

The largest numbers of refugees are in Asia, which is also the region from which more than half the world's refugees originate. Included in this region is Afghanistan, which in 2001 accounted for an estimated 3.8 million refugees, or one-third of the global refugee population. Africa is the second largest refugee region. Approximately 48% of the UNHCR persons of concern are female, 12% are children younger than the age of 5 years, and half of the population is between 18 and 59 years of age (**Figure 1**).

Nutritional Implications of Displacement

The public health and nutrition consequences of war and population displacement have been well documented during the past 25 years. The major determinants of high death rate among affected populations and the major priorities for intervention have also been identified. Clean water, sanitation,



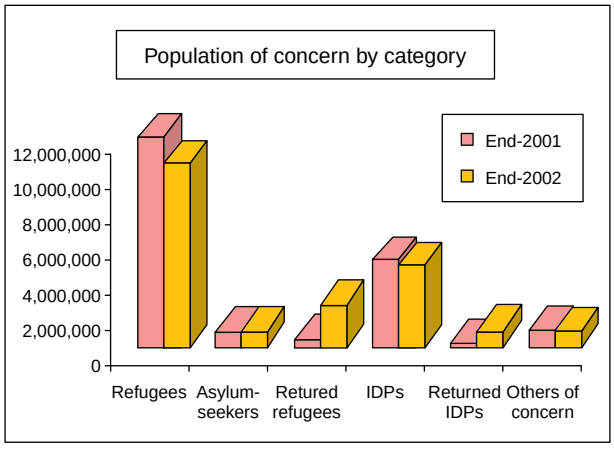


Figure 1 UNHCR Statistics, 2002.

shelter, and immunizations are essential components, but an adequate and diverse food supply remains the central factor in refugee nutrition. Today, it is acknowledged that acute malnutrition is a strong predictor of excess mortality among young children; even moderate malnutrition contributes to increased mortality in emergencies because a larger proportion of the affected population is usually moderately, rather than severely, malnourished; and; micronutrient deficiencies contribute significantly to diseases in emergencies.

Malnutrition results from a lack of food and/or prolonged inadequacies of food consumption, infection, or both. Malnutrition comprises a broad range of clinical conditions in children and adults that result from deficiencies in one or a number of nutrients. It has been defined as a state in which the physical function of an individual is impaired to the point at which he or she can no longer maintain adequate bodily performance processes, such as growth, pregnancy, lactation, physical work, and resisting and recovering from disease. The link between acute malnutrition and excess mortality has been documented for decades. The close correlation between these two factors was demonstrated during a Somali refugee operation in Ethiopia in 1988–89. During the period of peak incidence of mortality and prevalence of acute malnutrition, the food rations provided were less than 1400 kcal/person/day instead of the recommended 1900 kcal/person/day at the time (**Figure 2**).

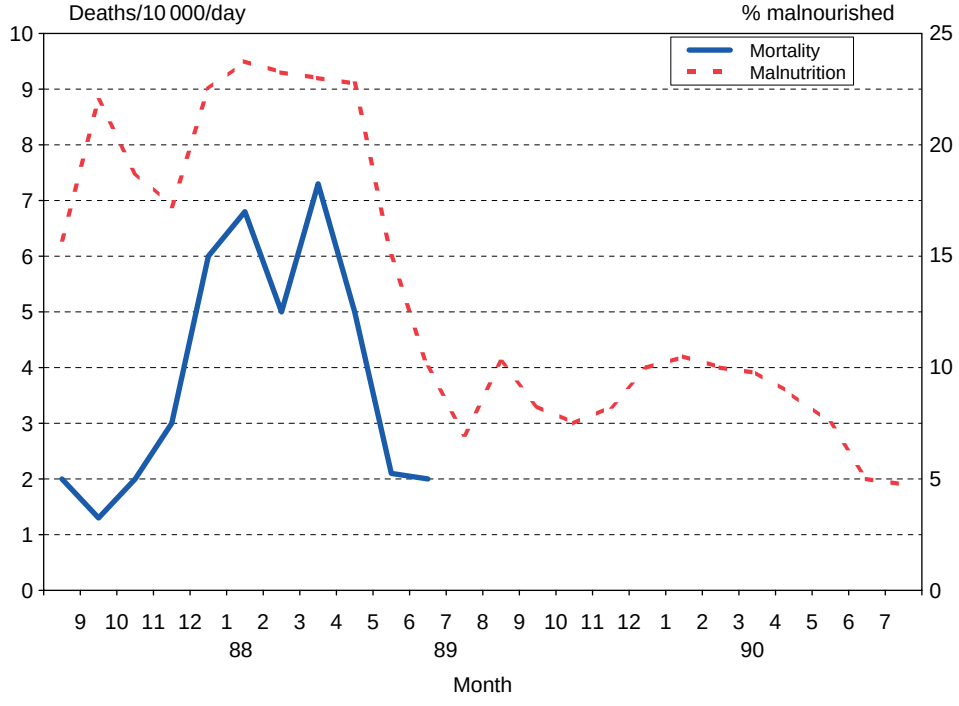

Figure 2 Relationship between malnutrition and mortality as seen in Ethiopia 1987–1990. Morbidity and Mortality Weekly Report (MMWR), July 24, 1992, vol. 41, page 10, Figure 8. Centers for Disease Control, Atlanta, Georgia.

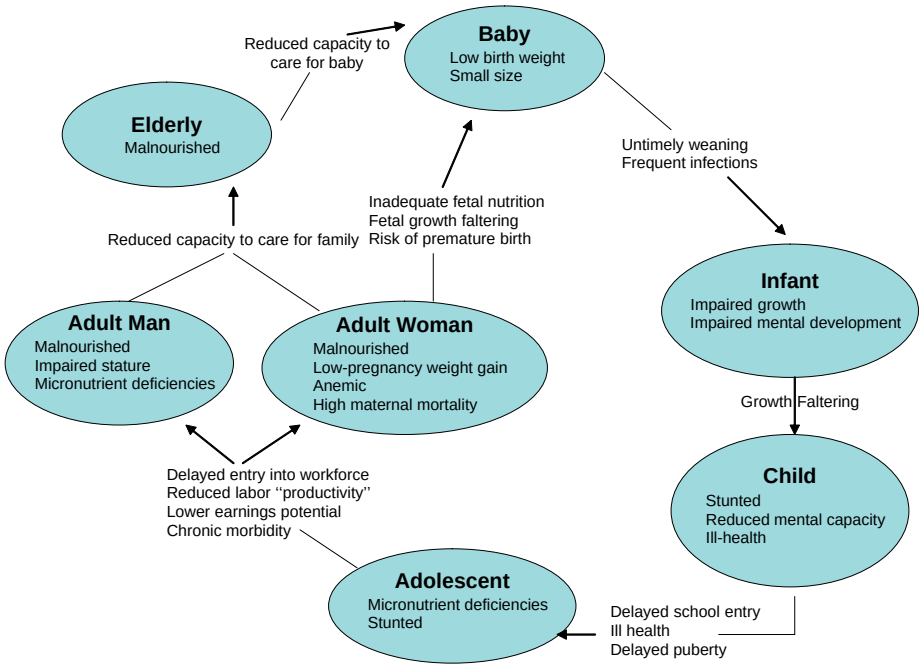

Figure 3 The life cycle and intergenerational transmission of malnutrition. (Adapted from James *et al.* (2000) The 4th Report on the World Nutrition Situation: Nutrition Throughout the Lifecycle. ACC/SCN January 2000. Geneva, Switzerland.)

Although the immediate aim of most food aid programs in refugee emergencies is to prevent excess mortality, there is also increasing evidence that malnutrition during critical periods of life has long-lasting effects. Malnutrition, or the risk of being malnourished, may be carried from one generation to another in an intergenerational cycle. Malnourished women give birth to malnourished infants who, in turn, are more likely to become malnourished adolescents and adults. Therefore, the nutritional status of refugees can have long-lasting effects on future health for individuals and generations (**Figure 3**).

Table 1 Types of malnutrition in refugees

Wasting (acute malnutrition)	Extreme thinness due to recent rapid weight loss; measured by weight-for-height *z* score
Stunting (chronic malnutrition)	Growth failure in a child that occurs over a slow, ongoing process; stunted children are short for their age; measured by height-for-age *z* score
Marasmus	A form of extreme PEM identifiable by severe weight loss or wasting; often there is good appetite and alertness
Kwashiorkor	A form of extreme PEM characterized by oedema, loss of appetite, and apathy; hair thins and may lighten in color to a light brown or red

Macronutrients

An inadequate supply of macronutrients and micronutrients (protein, fat, carbohydrates, and vitamins and minerals) results in protein–energy malnutrition (PEM), the most common form of malnutrition, especially among infants and young children. There are two types of growth failure associated with PEM: wasting (acute malnutrition) and stunting (chronic malnutrition). Wasted individuals (children, adolescents, or adults) are extremely thin, whereas stunted individuals are short for their age as a result of impaired growth during childhood. Severe PEM has a high case fatality rate and is often classified into two forms: marasmus and kwashiorkor. Both are identifiable by severe weight loss; however, the oedema associated with kwashiorkor can mask the otherwise dramatic skeletal appearance of marasmic individuals (**Table 1**).

Nutritional issues among refugees vary greatly from one region of the world to another. Rates of wasting, defined as weight for height less than −2 standard deviations of the reference population, have been as high as 50% in the Horn of Africa and as low as 5% in Southeast Asia, Malawi, and the Persian Gulf. Mortality rates in some of these populations during the acute phase of displacement have been extremely high—up to 60 times the expected rates.

Micronutrients

In addition to PEM. micronutrient deficiencies are key issues in nutrition-related morbidity and mortality. There is a misconception that people do not die of

Table 2 Micronutrient Deficiencies in refugees

Micronutrient	*Deficiency disease*	*Symptoms*
Iron	Anemia	Pallor, tiredness, headaches, breathlessness
Iodine	Goiter	Swelling of the thyroid gland in the neck
	Cretinism	Severe mental and physical disability that occurs in the offspring of women with severe iodine deficiency
Vitamin A	Night blindness	Inability to see well in the dark — an early sign of vitamin A deficiency
	Xeropthalmia	Including Bitot's spots and corneal ulceration and night blindness
Niacin	Pellagra	Affects the skin, gastrointestinal tract, and nervous system and is sometimes called the 3Ds: dermatitis, diarrhoea, and dementia
Thiamine	Beriberi	Loss of tendon reflexes; drooping of arms and feet; wet or cardiac beriberi resulting in heart failure
Vitamin C	Scurvy	Painful joints, swollen and bleeding gums, and slow healing or reopening of old wounds

micronutrient deficiencies because one does not often see the signs and symptoms as visibly as those for PEM. Nonetheless, these deficiencies can be fatal. In addition to deficiency diseases of vitamin A, iron, and iodine, conditions widely described as diseases of public health importance, epidemics of scurvy, beriberi, and pellagra, have been frequently reported among refugee populations, primarily because of limited access to a diverse diet and overreliance on one or two commodities (i.e., maize or polished rice). The importance of micronutrient deficiencies among the refugee population has only been documented since the late 1980s, and more attention is being paid to the usefulness of inclusion of micronutrient-rich foods and/or supplements in the management of refugee nutrition (**Table 2**).

Addressing Nutrition in Refugees

Due to the nature of displacement and the loss of livelihoods, refugee populations are extremely vulnerable. Often, refugees settle in camps with support from the international community and host government. In some cases, refugees may live in open situations in which they integrate into the local community. In almost all cases, refugees are dependent on outside assistance, although the level of need depends on the level of self-reliance the refugees are able to achieve. In some instances, refugees are able to bring some material goods with them when they flee and/or have some sort of income-generating activity, such as access to land and labour and employment. However, this very much depends on the policies of host governments. In these cases, refugees are not totally dependent on food aid, and nutrition management response takes these factors into account by adjusting humanitarian assistance and the food aid ration to meet the assessed needs.

There has been an evolution in the standards of food energy required for refugee populations. These were based on estimates of energy requirements from parameters such as body weight, demographic composition, environmental temperature, and activity levels. In the 1980s, the standard was approximately 1500 kcal/person/day, the minimum deemed adequate for survival. In the late 1980s, this was recalculated to 1900 kcal/person/day as a preliminary standard in order to include expenditure of energy for light activity as opposed to merely the basal metabolic rate. In the 1990s, the benchmark value was modified to a more realistic 2100 kcal/person/day. This was based on an increase in energy required for physical activity, some adjustments to the demographic composition, and an increase in the proportion of pregnant and lactating women in the population. It should be recognized that this recommended value is the average of the individual requirements based on developing nation population demographics and is not a specific provision for individual needs. In addition to the recommended kilocalorie content of the daily food ration, nutritional science has determined that the ration should have an optimal balance of fat and of protein (17 and 12%, respectively).

General Feeding Program

The sudden and massive reduction in food availability associated with displacement immediately affects the nutritional status of refugees. The first response is intervention through the implementation of general food distribution to ensure refugees have access to the required food ration. A general feeding program is the first line of intervention and the highest priority when a refugee population does not have access to sufficient food to meet its nutritional requirements. If the recommended adequate ration of 2100 kcal/person/day is not available, malnutrition levels may escalate.

Correcting Malnutrition

Even if the overall food needs of refugees are adequately met, inequities in the distribution system, disease, and various social factors may contribute to a high degree of malnutrition among certain groups. Children younger than 5 years of age, pregnant and lactating women, the chronically ill (e.g., tuberculosis and HIV/AIDS patients), and the elderly are considered vulnerable groups since they have specific nutritional requirements. A special nutrition intervention or selective feeding program targets these nutritionally vulnerable groups through supplementary feeding programs and those in need of nutritional rehabilitation through therapeutic feeding programs. Malnutrition prevalence rates, as well as an assessment of aggravating factors in the environment, are used as guidelines to determine if a nutrition intervention program needs to be initiated. Aggravating factors that influence the nutritional situation include an elevated crude mortality rate; epidemics of communicable diseases such as measles, diarrhoeal diseases, and respiratory infections; and an unstable social, political, or environmental situation.

Nutrition intervention programs are primarily managed by nongovernmental organizations (NGOs) that have specialization in the management of refugee nutrition. Other humanitarian partners have roles to play in the response to refugee situations, including host country authorities, United Nations agencies such as the World Food Programme, UNHCR, and UNICEF; and other multi-sectoral NGOs. There exist memorandums of understanding and partnership agreements among agencies to provide assistance to the affected populations. The need for partnership is essential for management of refugee nutrition and health programs. The Sphere Project was launched in 1997 to develop a set of universal minimum standards in vital sectors of humanitarian assistance. The aim of the project is to improve the quality of assistance provided to affected populations and to enhance the accountability of the humanitarian system in emergency response.

Supplementary Feeding Programs The most common nutrition intervention is supplementary feeding programs (SFPs) to address malnutrition in emergency situations. SFPs provide a high-quality food as a nutritional supplementation to the daily diet of malnourished populations. There are two main types of SFP—targeted and blanket. The goal of targeted supplementary feeding is to prevent people who are moderately malnourished from becoming severely malnourished. Blanket supplementary feeding, which provides all members of a vulnerable group with a food supplement, is intended to prevent the deterioration of nutritional status among a larger population group rather than narrowly defined individuals at specific nutritional risk. Implementation of SFPs can take two forms: prepared meals consumed on site (wet rations) or food rations issued weekly or monthly to take home for preparation (dry rations). Food supplements usually consist of a fortified blended food (FBF) mixed with oil, and sometimes sugar is included. Wet rations should provide 500–700 kcal, whereas the recommended dry ration is doubled to 1000–1200 kcal in order to account for sharing at home.

Therapeutic Feeding Programs Therapeutic feeding programs (TFPs) provide the severely malnourished with their full nutritional requirements in addition to medical care. They are initiated to reduce excess mortality among individuals facing severe malnutrition and have played an important role in reducing malnutrition-related mortality in emergencies. The first phase of a TFP focuses on treatment of infections, management of other medical complications, and metabolic stabilization. This phase has the highest mortality rate of all nutrition interventions due to the poor state of the patients and the intensive treatment required. The second phase of a TFP is a rapid weight gain period designed to rehabilitate the patient's nutritional status.

Recognition of severe acute malnutrition as a complex nutritional condition during the 1990s led to the development of certain foods defined explicitly for therapeutic treatment of malnutrition with the appropriate balance of energy and protein in order to avoid overloading the body's metabolism, which potentially may lead to cardiac shock. These products include F-75, F-100, and BP-100 biscuits and other ready-to-use therapeutic foods (RUTFs) such as 'plumpy nut.' In addition to balanced energy and protein, these products also contain several vitamins and minerals. For the first stage, TFP F-75 therapeutic milk is used, with the amount of milk given calculated according to the patient's age and weight. During the second stage, F-100 therapeutic milk, with a higher protein content required for rapid weight gain, is used. During the final stage of the treatment, a micronutrient-rich porridge is introduced and eventually, if possible, a family-type meal is introduced in order to reaccustom the patient to the kind of food eaten at home. Those who survive therapeutic treatment generally need further support under SFPs in order to reduce the likelihood of relapsing into a severely malnourished state (**Figure 4**).

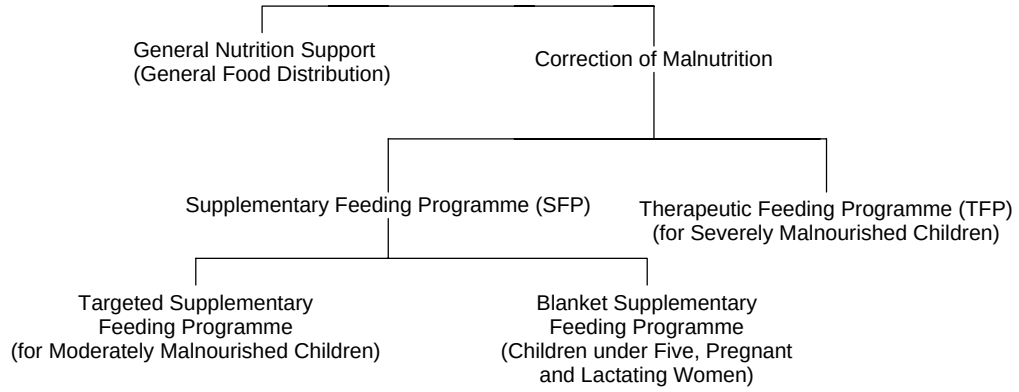

Figure 4 Nutrition interventions. (Adapted from Sphere Project (2004) *Humanitarian Charter and Minimum Standards in Disaster Response*. Sphere Project, Geneva, Switzerland.)

Community Therapeutic Care Community-based care is a recently developed public health approach to dealing with severe malnutrition and aims to treat the majority of people suffering from severe malnutrition in their homes. A community therapeutic care (CTC) programme initially is set up complimentary to traditional TFP components and represents a new approach to managing malnutrition in situations at the community level. A CTC programme has the same initial metabolic stabilization phase, and life-threatening infections are identified and treated just as in a TFP. However, once the patient is stabilized, he or she moves directly to an outpatient therapeutic programme that operates through existing health structures and, with the use of ready to use therapeutic foods (RUTFs), nutritional rehabilitation is initiated. When patients are no longer at risk of severe malnutrition, they are referred to SFPs for recuperation. This phase is followed by greater emphasis on community mobilization to increase the population's involvement and training of mothers who are selected based on their ability to raise well-nourished children even in the face of poverty. After a short training period on nutrition, these mothers team with members from their communities in order to educate them on the fundamentals of successful treatment and prevention of moderate malnutrition and the manufacturing of local RUTFs. At this point, a CTC truly becomes community owned and operated.

CTC is an innovative approach that is still under debate. Proposed benefits of this method are the improved coverage to increase the number of people treated and reduce overall mortality rates. In addition, local production of RUTFs would reduce the cost of treatment, and the shortened length of stay in centres away from the family would have economic and social benefits for the entire family. Finally, the decentralized nature of CTC would allow for earlier detection of

Table 3 Milestones in addressing nutrition in refugees

1960s:	Food response based on commodities available (donated)
	Limited recognition of relevance of nutritional content of rations
	Food provided based on resources rather than nutritional needs
1970s:	Focus on protein deficiency (in protein–energy malnutrition)
	Food ration comprised mainly cereal, pluses/beans, and oil
	Fortified blended foods (FBFs) used only in supplementary feeding
1980s:	Major relief agencies raise planning figure from 1500 to 1900 kcal/person/day
1990s:	Relief agencies raise planning figure for fully food aid-dependent populations from 1900 to 2100 kcal/person/day
	FBF included in most rations for completely dependent populations
	Basic six-commodity food basket becoming common: cereal, pulses, oil, salt, sugar, FBF
	UNHCR/WFP Memorandum of Understanding signed with clear roles and responsibilities
	Development of multi-UN agency and NGO policies and guidelines on common approaches to addressing malnutrition in emergencies
	Fortification of oil, salt, and flours, on international market
	Development of therapeutic foods for treatment of malnutrition (F100-F75)
	Local production of fortified blended foods
2000s:	Development of community therapeutic care approaches
	Development of capacity in nutrition in humanitarian staff
	Pilot testing of on-site milling and fortification in a refugee camp

Adapted from Toole M (1998) *An Overview of Nutrition in Emergencies*, paper presented to the ACC/SCN Working Group on Nutrition in Emergencies, April 11.

malnutrition, thereby reducing the incidence of severe malnutrition (**Table 3**).

Challenges

Nutrition interventions alone are not sufficient to address the multiple causes of malnutrition in refugees. The availability of public health inputs is essential in preventing increased malnutrition and in ensuring that nutrition intervention programmes have their desired effects.

Although the quality of nutritional assistance has improved considerably since the 1970s there is still room to move forward. Because so many factors – food, health, care, and environment — interact to determine nutritional well being, partnerships among agencies with different mandates is essential when trying to effectively address and correct nutritional issues. Refugee nutrition must be addressed in tandem with other services in order to ensure that underlying factors of malnutrition are being met and that nutrition interventions are effective.

RELIGIOUS CUSTOMS, INFLUENCE ON DIET

P Fieldhouse, The University of Manitoba, Winnipeg, MB, Canada

This article discusses the nature, function, and origins of food practices associated with religious beliefs. A review of historical and contemporary dietary practices in major world religions includes Christianity, Islam, Judaism, Hinduism, and Buddhism and is followed by a brief account of dietary tenets of Jainism, Sikhism, and the Baha'i faith.

The Function and Nature of Religious Food Practices

What people need to eat to survive as biological organisms and what they choose to eat as human beings are two different matters. While practically any food combination which supplies the requisite nutrients to meet physiological needs is adequate for biological purposes, this is clearly not the case for cultural purposes. People make choices from the foodstuffs available to them which reflect a constellation of social, economic, political, and cultural influences, as well as personal preferences. Religion is one such influence, and religious adherents around the world are more or less circumscribed in their food choices by the teachings of their chosen faith.

Religious dietary laws serve a number of different functions. They can provide a way for people to demonstrate their faith—to show that they accept religious authority. As a mark of group identity they strengthen feelings of belonging, and in this way act as a material reflection of the spiritual bonds which link co-religionists.

Conversely, dietary rules may serve to demonstrate separateness by clearly demarcating cultural boundaries between religions. Foregoing food during

religious fasts is a form of self-denial, showing that one is more interested in spiritual than in worldly values. Through sacrifices or sacrificial meals, food is used as a means of communicating with God or other supernatural forces. Offerings may be made to placate the God and so forestall disaster or to seek favors and good fortune. Finally, religious practices may serve, incidentally or purposefully, to encourage ecological sustainability through conservation and judicious use of scarce resources.

Cultural food practices are rich in examples of foods which are not allowed for consumption though they be freely available, and religious codes often exclude whole categories of foods from consumption. What must not be eaten may be determined by characteristics of individuals, such as age, gender, social or physiological status, or by external constraints such as time of day or time of year (**Table 1**).

Table 1 Comparative examples of religious dietary strictures

Religion	*Dietary stricture*
Food restrictions	
Judaism	Eat only animals with cloven hooves and which chew the cud, i.e., cattle, sheep, goats, deer
	Eat only forequarters of animal
	Eat only fish with scales and fins
	No blood
Islam	No blood
	No pork
	No intoxicating liquor
Sikhism	No beef
Hinduism	Must not kill or eat any animal
Days of the year	
Christianity	No meat on Fridays during Lent (Catholics)
	Fast on Wednesday and Friday (Greek Orthodox)
Judaism	No food preparation on Sabbath
Time of day	
Islam	Foods may not be eaten between sunrise and sunset during Ramadan
Buddhism	Monks do not eat after midday
Preparation of food	
Judaism	Ritual slaughtering of animals
	Separate utensils for meat and dairy products
Islam	Ritual animal slaughter
Hinduism	Ritual bathing and donning of clean clothes by Brahmins before eating
Fasts	
Christian	40-day Great Lent fast before Easter and a 40-day Advent fast (Greek Orthodox)
Islam	Month of Ramadan
	13th, 14th, and 15th of each month

Reproduced with permission from Fieldhouse P (1995) *Food and Nutrition: Customs and Culture*, 2nd edn, p. 124. London: Chapman & Hall.

Prescriptive rules of what must be eaten, when and how, are the counterpart of prohibitions. Religious food practices often require the use of specific foods in specific situations, especially during special celebrations such as feasts or fasts, where particular foods often have important symbolic values.

Religious food customs originate in three main ways. Some are required by God and are described in scriptures; others are decreed by religious or political leaders; still others arise through adaptation or co-option of preexisting food practices. Pagan festivals were frequently assimilated and given new meanings as modern religions assumed dominance over older forms of worship. Indeed, religious food practices are far from static; they are subject to continuous adaptation and reinterpretation. Changes may occur as a result of religious reform or revisionism, acculturation, or individual, family, or community adaptations.

Immigration provides a good example of how changing circumstances may result in changing attitudes to food. Through the process of acculturation dietary practices are modified in the light of availability of foodstuffs and as an adaptation to new cultural rules, customs, and expectations.

Continued compliance with traditional rules may depend on social contexts. Adherents who are strict when with members of their own religious group may be willing to be more lax when alone or with a different social group. Even without such external forces, adherence to religious dietary laws or guidelines varies on a national, regional, community, family, or individual level. In many cases religions have developed several branches, sects, or schools of thought which make different demands on members. Such variability in practice should be kept in mind when reading the following descriptions of normative customs. **Table 2** summarizes the size and distribution of contemporary religious followings.

Dietary Practices in Selected World Religions

Christianity

Early Christians observed Mosaic dietary laws. However, the concept of uncleanliness described in Leviticus was rejected by St. Paul and, as Christianity spread across cultural and geographical boundaries, dietary laws largely disappeared (except in the Eastern Orthodox Church). Food, rather than being a way of marking separateness, became a symbol of the communality of religious experience. The celebration of the Eucharist, or Communion, with ritual sharing of bread and wine, though it varies in form

from the austere to the elaborate, has retained an underlying significance as a meal shared by the followers of Jesus. The saying of a short prayer before and after eating, establishing a direct connection between God and good food, is also common amongst Christian groups.

Notwithstanding the general deemphasis of dietary laws, certain strictures persisted. Until 1966, Roman Catholics were required to abstain from eating meat on Fridays (since applied only to Fridays during Lent) in symbolic remembrance of the death of Christ. The historic consequence of meat avoidance on Fridays was the regular consumption of fish; fish on Fridays became identified with Roman Catholicism and sometimes fish was deliberately avoided by some other Christian sects who did not wish to be mistaken for Catholics.

In modern times, some Christian sects have established new dietary rules. Seventh Day Adventists are a Protestant sect who emphasize healthful living through eating the right foods and taking exercise and rest. Most Adventists are lacto-ovo-vegetarians. Tea, coffee, alcohol, and tobacco are also avoided. Eating between meals is discouraged on the grounds that the body needs sufficient time to assimilate what is eaten at mealtimes. The religiously inspired food practices, which emphasize cereals, fruits, vegetables, and pulses, has conferred nutritional benefits on the Seventh Day Adventists, who, as a group, have a lower prevelence of chronic diet-related diseases such as heart disease than the general population.

Like the Seventh Day Adventists, members of the Church of the Latter Day Saints (Mormons) assert the importance of eating a well-balanced diet in order to nourish the body as the temple in which the soul resides. Vegetables and herbs are emphasized while meat should be used sparingly. Tobacco, alcohol, and caffeine are avoided. A 24-h fast for those in sound health occurs once a month, and money or food saved is contributed to the welfare of the poor. The fast is a religious discipline and is not a dietary requirement.

In contrast to Western Christianity, Eastern Orthodoxy imposes substantial dietary strictures on its adherents. Dietary laws revolve around fasting. There are two 40-day fasts at Lent and Advent, two shorter summer fasts, and regular fasts on every Wednesday and Friday in the year, excepting the two preceding Ascension Day. Fasts do not require total abstinence but rather prohibit the consumption of all animal products and fish except shellfish. The avoidance of olive oil (historically stored in casks lined with calf stomach) during fast periods is a symbol of true sacrifice and devoutness.

The Great Lent fast commemorates Christ's 40-day fast in the desert and is replete with symbolism. In preparation for the resurrection feast following the fast, hard-boiled eggs are dyed red to symbolize Christ's blood. These eggs are considered to be tokens of good luck and are broken open on Easter morning, representing the opening of Christ's tomb. On Good Friday, lentil soup is eaten to symbolize the tears of the Virgin Mary; often it is flavoured with vinegar as a reminder of Christ's ordeal on the cross. The Great Lent fast is broken after a midnight service on Easter Saturday with a lamb-based soup, olives, bread, and fruit.

Islam

It is probable that the prophet Mohammed, the founder of Islam, adopted existing Jewish practices, for example the prohibition of pork, as a way of encouraging Jewish converts to Islam and to distinguish Muslims from their Christian rivals. The Qur'an, a Holy Book given to Mohammed by Allah, contains dietary regulations which echo those of Judaism. Flesh of animals that are cloven hooved and those that chew the cud is lawful. Pigs, blood, carrion, and foods offered to other idols are forbidden, though one who eats these foods under constraint does not sin. Carnivorous animals and birds which seize their prey with talons are forbidden, as is the flesh of the domestic ass.

Alcohol is prohibited. Fish must be alive when taken from the sea or river, and only fish which have fins and scales are allowed, thus excluding shellfish and eels. To be acceptable to a Muslim an animal must be bled to death while the words 'Bismi 'llahi. Allah Akbar' (I begin with God's name. God is great) are spoken. Such meat is 'Halal,' or lawful, and is stamped with a Halal seal.

Fasting is one of the Five Pillars of Islam and is an important duty of Muslims. It is a way of expressing piety, self-restraint, and freedom from worldly desire and is a means of reaping spiritual rewards. Except for a few holy festival days Muslims may voluntarily fast whenever they wish. Strict adherents fast on Monday and Thursday of every week and on the 13th, 14th, and 15th of each month.

Ramadan, falling in the ninth lunar month, is the major fast of the Muslim year and is one of the most strictly observed of Islamic practices. The word is derived from 'ramz,' meaning 'to burn,' and may derive either from the fact that the fast was first observed in the hot season or because it was believed that fasting would burn away sins. The Ramadan fast involves abstinence from food and water between sunrise and sunset for the whole month and is prescribed for all who have reached the 'Age of Responsibility' (12 years for girls; 15 years for boys). The day's fast should be broken as soon

after sunset as possible and this often takes place at a mosque or at house parties, for it is highly commendable to provide food to others, especially the poor. A morning meal should be eaten as late as is possible prior to sunrise. The end of Ramadan is signaled by the sighting of the new moon and is celebrated with prayers and with feasting.

Certain groups are exempted partially or totally from the Ramadan fast. Anyone who is sick, on a journey, or engaged in hard labour may break the fast, but must make up the days later. Women who are menstruating or are in childbirth are similarly exempted, while pregnant or nursing women and elderly persons in poor health may defer fasting until later in the year or may 'substitute fast' by feeding the poor. Younger children are expected to undertake short fasts in preparation for when they reach the Age of Responsibility.

Judaism

The first five books of the Old Testament, known collectively as the Torah, contain what are probably the most detailed dietary directions of any major religion. These biblical injunctions have been interpreted, elaborated, and added to by rabbis over the past 2000 years. The term 'kashruth,' meaning 'acceptable,' is used to describe anything permitted by Jewish dietary laws. While pig avoidance has become the hallmark symbol of Judaism, it is but one of many restrictions. Only animals having cloven hooves and that chew the cud are permitted. Thus cows, sheep, oxen, and goats may be eaten, whereas pigs, hares, and camels may not. Permitted fish must have fins and scales, which excludes shellfish. Other forbidden foods include teeming winged insects except locusts, certain birds of prey, and bats.

To avoid confusion and to obviate the need to make difficult discriminations between animals, the prohibition was later extended by the rabbis to include all insects and birds of prey. Neither blood nor internal organ fat of otherwise permitted animals may be eaten. The sciatic nerve may not be eaten and, as its removal is difficult, often only the forequarters of an animal is used. The rest of the meat may be sold to non-Jews. Rabbinic additions to the Biblical laws decreed that milk from non-kosher animals is forbidden as it has the same qualities as the animal from which it comes.

Animals dying of natural causes or of disease are not permitted for consumption. Meat must be obtained from animals which have been ritually slaughtered under the supervision of a rabbi. A trained butcher, or shochet, slashes the animals throat with a single cut so as to allow the blood to drain completely from the body. The animal is examined for internal irregularities which might render it unfit for consumption and, if acceptable, is given a seal of approval. Following slaughter, soaking, draining, and salting of the meat ensure that all traces of blood are removed. Historically, Jewish migration was dependent on the availability of kosher meat and thus of access to the services of a shochet.

A prohibition against mixing meat and dairy products is based on the biblical injunction 'You shall not boil a kid in its mother's milk' (Exodus 23: 19). After eating milk, hand washing and mouth rinsing is all that is necessary before eating meat; however, depending on local custom, from 1 to 6 h must elapse after eating meat and before eating milk. Margarine and milk and cream substitutes have made this particular law easier to follow: Nevertheless, many observant Jews view the use of such substitutes as being spiritually wrong. In Israel, there has been a continuing historical struggle over the banning of pig rearing and pork eating. However, these practices continue today, pork being eaten by Christians and nonobservant Jews.

There are many fasts in the Jewish calendar, some of scriptural or rabbinical origin and others which mark private events such as family deaths. Fasting is a way of showing repentance, of teaching self-discipline, or of preparing to seek divine guidance. Generally fasts are observed by boys over the age of 13 years and 1 day and by girls over the age of 12 years and 1 day.

The Sabbath being a day of rest, all food preparation is carried out on Friday. Challah is a traditional Sabbath bread and, in a modern adaptation of an historical practice, two loaves are used to symbolize the double portion of manna provided by God to the Israelites on Fridays during their 40 years in the wilderness. Other festivals, including Rosh Hashannah, the Day of Judgement, and Yom Kippur, the Day of Atonement, are rich in food symbolism, but it is the major festival of Passover that perhaps sees the most elaborate food practices. All leavened products must be removed from the house, reflecting the fact that Jews did not have time to let bread dough rise when they were driven from their homes into exile. Pieces of bread may be deliberately hidden around the house, to be 'discovered' and removed. Unleavened bread called matzah is prepared or bought commercially.

On the eve of Passover it is customary for the firstborn to fast in symbolic remembrance of the historic sparing of the first-born. On the first and second night a special family meal, the seder, is eaten, which is itself a testimony to the symbolic power of food. Seder means order, and the meal indeed has a very definite structure which gives it

its ritual character. Partaking in this food event is an important way of transmitting culturally valued knowledge from generation to generation.

Hinduism

While vegetarianism and the specific prohibition on eating cows are two of the dietary hallmarks of modern Hinduism, early Hindu writings reveal that beef was eaten freely. Beef prohibition may have arisen as a response to the challenge of Buddhism, which was critical of Brahminism and its cattle-sacrificing practices, and so Brahmins championed the sacred cow concept in order to maintain their own position. It was perhaps subsequently strengthened by the need for Hindus to distinguish themselves from their new Muslim neighbours. Certainly by the time of the Rigveda, around 1000 CE, the prohibition was firmly ensconced.

For modern Hindus, the cow is a revered animal, a symbol of motherhood and fertility. The duty to protect cows is enshrined in the Constitution of India; slaughter of cows is prohibited by religious custom and in some provinces by legal bans. In villages and towns cows wander freely, foraging where they may; there are even special government-run homes for old and infirm cows.

Observance of dietary prohibitions is strictest in the upper Brahmin caste while beef (and pork) eating is tolerated amongst lower castes, for whom it may be an important source of supplementary protein. For these castes, giving up meat eating is one way to attempt to improve their social status. The caste system is an excellent example of the way in which social structure influences food practices. Concepts of purity and pollution determine who may eat what with whom and who may accept what food from whom. Eating with, or accepting food from, members of a lower class is polluting. In the hot–cold classification system used in traditional healing raw foods are considered to be 'hot' and are therefore purer than cooked foods, which are 'cold.' Brahmins who accept food cooked by a lower caste person lose ritual purity and thus caste status; however, they may accept ghee (clarified butter) and milk—for these are products of the sacred cow and cannot be polluted by touch.

Devout Hindus are vegetarian; meat, fish, and often eggs are avoided, the latter especially by women. An exception is made for the Ksatriya warrior caste, who may consume meat without loss of status, a concession probably related to notions of meat, strength and military prowess. Most castes will eat fish, though its actual consumption varies dramatically from region to region. Where fish is eaten, white fish is preferred for it is least like meat. Abstention from eating food is a much praised virtue. Some Hindus may fast 2 or 3 days a week, during which time they may eat only pure foods such as milk, fruit, nuts, starchy roots, and vegetables. Fasts are associated with calendric, caste, family, and personal events as well as with religious celebrations.

There are literally thousands of festival days celebrated by Hindus in different parts of India. Some are national, some regional, and some purely local. On festival days there may be great processions, when people visit shrines to pray and make offerings. Only food which is pacca (contains ghee) may be offered; it thereby becomes blessed and is then distributed to the waiting crowd. Ghee, as a product of the cow, is sacred and is an important component of many rituals. For example, during marriage ceremonies a ritual flame is kept burning with ghee.

The modern Indian festivals of Dussatra and Divali illustrate the agricultural origins of many contemporary celebrations. Dussatra marks the end of the rainy season when agricultural labour must begin again, as well as commemorating the legendary hero, Rama. It includes a ritual quest for alms by people carrying small fresh stalks of barley plants. Divali, known as the festival of lights, is a new year festival celebrating the sowing of winter crops. Lamps are lit and gifts are exchanged.

Buddhism

Founded in the sixth century BCE by Siddartha Gautama, Buddhism became the state religion of India in 250 BCE, though it is now a minority religion there, Buddhism has been the most influential of religious forces in spreading the practice of vegetarianism and has developed in different ways in many parts of the world, especially Southeast Asia, Tibet, China, Japan, and Korea.

Buddhism championed the concept of Ahimsa—noninjury to all living creatures—and had a profound influence on the subsequent development of Hinduism through its stand against cruelty toward animals and animal sacrifice. Buddhists refrain from eating meat or from harming any living creatures, though the prohibition is observed strictly only by monks and the devout laity. Lay Buddhists may eat meat or may raise meat for sale to non-Buddhists. Animals found dead may be eaten, as may fish (which are not 'killed' but merely removed from the water).

In contrast to other religions, Buddhism places emphasis on wrongful killing rather than wrongful eating. Thus flesh may be eaten if it was not procured for eating purposes or supposed to have been so. Monks personify the ideal. Food is obtained through begging, and it is meritorious for the laity to voluntarily provide food to the monks, thereby assisting in their own spiritual progress.

Other Religions

Jainism is an ascetic Asian religion whose adherents advocate ahimsa, or noninjury, both as an ethical and philosophical goal, and whose example has had a strong admonitory influence on non-Jains. The Jaina monastic community has a number of characteristic practices which evince an extreme regard for life. Monks carry a small brush with which they carefully sweep the floor before sitting or lying so as to avoid crushing any insects. They may wear masks to prevent inadvertent inhalation of small creatures, and strain their drinking water. Wild honey is avoided, as bees may be killed during its collection.

Ascetics have few or no possessions and must beg for food. Some choose in old age to die through ritual fasting. Most Jainas are not ascetics, although some strive to imitate monastic ideals by pursuing a progressive path of renunciation, leading to rebirth as an ascetic. The nonmonastic Jaina community practices vegetarianism and opposes the killing of animals. Because of this, agricultural and military occupations are not suitable to Jainas, who historically have chosen instead to enter the professions or to take up business interests.

Sikh means disciple, a follower of the 10 gurus. Sikhism was founded in the fifteenth century CE by the guru Nanak who proclaimed, "There is no Hindu; there is no Muslim." Nanak rejected the social distinctions of the Hindu caste system and required his followers to eat together as a symbol of unity. Sikhs retain the Hindu reverence for cows and thus do not eat beef. Other meat may be eaten, although some Sikhs are vegetarians. Permitted animals must be killed with a single blow, 'jhatka,' literally a sudden shake or jerk. Generally, Sikhs are not rigid about adherence to dietary laws and readily adapt to the food customs of other cultures.

Food plays a part in the *Baha'i* religion through fasts and feasts and through dietary injunctions which favour vegetarianism and abstention from alcohol. Vegetarianism is held to be a compassionate practice and one which is in line with God's will, though meat is not actually prohibited. Fasting is viewed as a spiritual undertaking and is symbolic of abstinence from selfish and carnal desires. It is deemed to have both physical and spiritual benefits. A 19-day fasting period occurs in March, during which there must be complete abstention from food and drink between sunrise and sunset. Exemptions are granted for travellers, the sick, pregnant and nursing women, while those engaged in heavy work may also be excused. Children under the age of 15 years and elderly persons over 70 years of age are not required to fast but may choose to do so. Obeying the fast is a matter for individual conscience and is not enforced; if food is eaten 'unconsciously' during the fast it is deemed to be an accident rather than a breaking of the fast. Unlike in Islam, there is no making up of fast days missed as the fast can only be kept during the designated time.

Nineteen Day Feasts (so called because they are held on the first day of each of the 19-day-long Baha'i months) bring Baha'is together to consult and discuss and to offer suggestions to their Local Spiritual Assembly. At a feast, which is entered into with right thinking, the 'heavenly food' of knowledge, understanding, love, and kindness is present, providing members with a sense of spiritual restoration. The significance of providing food at these gatherings appears to be related to the Baha'i injunction to serve one's fellows—rather than to the social solidarity of sharing food. The absence of guidelines or restrictions on what may be served indicates that it is the act of serving which is symbolic, not the food itself.

RIBOFLAVIN

C J Bates, MRC Human Nutrition Research, Cambridge, UK

Absorption, Transport, and Storage

Riboflavin (vitamin B_2) is not synthesized by higher animals. Therefore, it is an absolute dietary requirement for the synthesis of certain essential coenzymes that are needed for intermediary metabolism in nearly all living cells. Riboflavin must be transported from the food sources within the gastrointestinal tract, across the gut wall into the circulatory system, and thence into the cells of each organ. This transport process occurs against a concentration gradient, in order to ensure the efficient retrieval of the very small amounts that occur in many foods, and from the low concentrations in plasma to higher concentrations inside living cells.

Gut riboflavin transport systems have been studied by partly isolated segments of the small intestine within an anesthetized animal; by an isolated everted gut segment, or by 'vesicles', prepared from the 'brush border.'

Studies with these model systems have shown that the transport of riboflavin at low (e.g., micromolar) concentrations is temperature- and energy-dependent (it is inhibited by inhibitors of ATP production from energy substrates), it becomes saturated as the concentration of riboflavin increases, and it is sodium ion dependent. These characteristics are shared with many other types of small molecules that are actively transported across the gut wall. More specifically for riboflavin, the active transport mechanism involves phosphorylation (to riboflavin phosphate, also known as flavin mononucleotide, or FMN) followed by dephosphorylation, both occurring within the intestinal cells (**Figure 1**). This latter process is not shared by several other B vitamins, but it is one of a number of common strategies which the gut may use to entrap essential nutrients, and then relocate them, in a controlled manner and direction. A similar strategy is employed at other sites in the body, to ensure entrapment of circulating riboflavin by cells whose nascent flavin-dependent enzymes need a supply of the vitamin from beyond their borders.

Although the active transport of riboflavin across the gut wall and across other cell membrane barriers within the animal is a saturable process, if large pharmacological amounts are present then the slower and less efficient but nonsaturable process of passive absorption predominates and contributes significantly to the total mass transfer. The active transport process is increased in riboflavin deficiency and decreased if the riboflavin content of the tissues is high. The transport pathway involves calcium and calmodulin but not sodium. Specific riboflavin receptors have recently been identified, as has a role for microtubules in transport.

Although some of the available riboflavin in natural foods may be present as the free vitamin, ready for intestinal transport, a larger fraction is present in the form of phosphorylated coenzymes: FMN and flavin adenine dinucleotide (FAD), and there may also be very small amounts of a glucoside of the vitamin. These forms are all efficiently converted to free vitamin by enzymes secreted into the gut lumen, and they are therefore highly available for absorption. There are also small amounts of covalently bound forms of riboflavin, present in enzymes such as succinate dehydrogenase (succinate: ubiquinone oxidoreductase EC 1.3.5.1), which cannot be released by the hydrolytic enzymes in the gut and are therefore unavailable for absorption. Also unavailable (or very poorly available) in man is the riboflavin synthesized by the gut flora of the large bowel. Certain animal species such as rodents can utilize this riboflavin source by coprophagy.

A wide variety of artificial analogs of riboflavin have been prepared in order to explore the structural versus functional essentials of the molecule. Some of these analogs have riboflavin-like activity; others are inactive, while a number are antagonists, and can cause functional deficiency. These structural changes can affect absorption or the conversion of riboflavin to its coenzyme forms within the body. Certain drugs that are used for purposes unrelated to riboflavin function, such as the phenothiazines used as antipsychotic drugs, may have sufficient structural similarity to riboflavin to act as antagonists in some situations.

Absorption by Human Subjects

Studies of riboflavin absorption by human subjects require a combination of a test dose, usually taken by mouth, and a sampling procedure to estimate the amount absorbed, and possibly also its subsequent fate. The sampling compartment is generally the

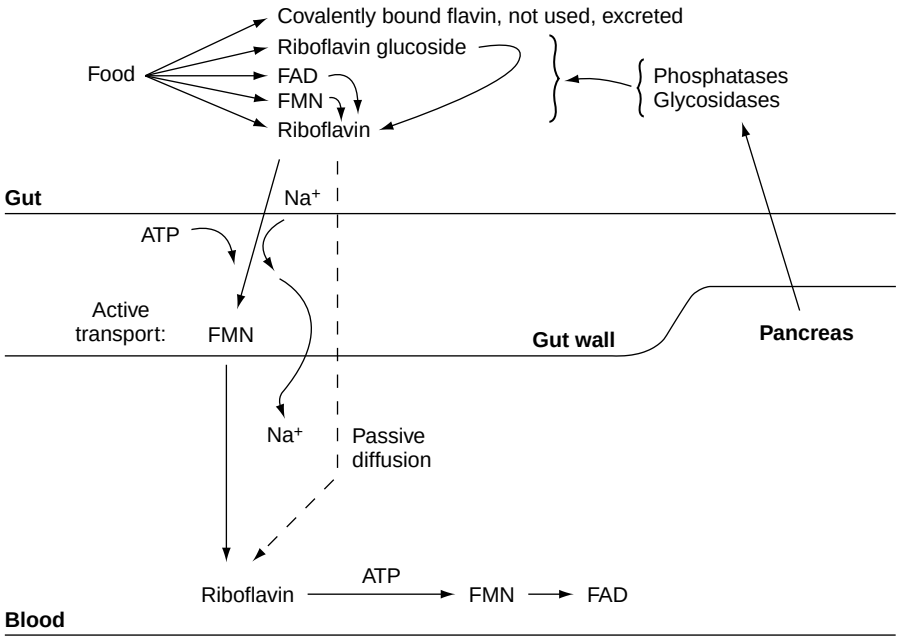

Figure 1 Characteristics of the absorption process for riboflavin and its coenzymes.

urine, since plasma has proved generally unsatisfactory. Fecal sampling is also useless because of the synthesis of riboflavin by bacteria in the large bowel. Although the use of riboflavin labeled with radioactive or stable isotopes is theoretically possible, this has not yet been applied to human studies. The majority of reported studies have relied on relatively large 'bolus' oral doses of riboflavin, comprising at least several milligrams, with urinary monitoring over the subsequent few hours. Riboflavin can be quantitated in urine by its very characteristic fluorescence, or by microbiological assay, or more accurately by high performance liquid chromatography.

For the maximum absorption of a test dose of riboflavin, the duration of exposure within the upper ileum is critical, since this is the region of greatest absorptive efficiency. There is little evidence to suggest that slow-release forms of the vitamin can enhance its absorption, but there does appear to be some absorptive advantage for certain synthetic lipophilic esters, such as the tetrabutyrate ester, which is hydrolyzed to the free vitamin during or after absorption. These have been shown to possess beneficial (e.g., antioxidant) properties in some model systems, but their usefulness in human medicine is still at a very early stage of assessment. The concomitant presence of food can enhance absorption, possibly by increasing the transit time. There is little evidence that the efficiency of absorption varies markedly with age or sex in humans.

Measurements of the plasma pool of riboflavin following test doses is not a viable method of measuring absorption, because redistribution to other tissue sites plus urinary excretion takes place too rapidly for this pool to be representative of the amount absorbed. Although the urinary response to a test dose has been the most commonly used approach to studies of intestinal absorption in humans, it suffers from the potential disadvantage that physiological intakes, and especially low intakes of riboflavin from 'poor' food sources, cannot be measured by this technique. Such studies of small doses are however needed, in order to determine the factors that modulate riboflavin absorption in developing countries, where dietary sources of riboflavin are minimal and clinical signs of riboflavin deficiency are common. A much more sensitive biochemical marker of riboflavin status at low intakes is the index known as 'erythrocyte glutathione reductase activation coefficient' (EGRAC), which will be discussed in greater detail below. It is possible to achieve a graded response to graded intakes of riboflavin, and studies of absorption efficiency using this alternative marker as the outcome measure may become feasible (and useful) in the future.

Riboflavin Transport at other Sites and Storage

As mentioned earlier, nearly all tissues require riboflavin. The free vitamin is trapped as one of its phosphorylated coenzyme forms, which then become specifically associated (and in a few cases covalently linked) to the protein chains of catalytic flavoenzymes. If not already covalently linked, the

flavin coenzyme can often be liberated by extremes of pH or by other nonphysiological maneuvers. In a few biological locations, such as the mature red cell, flavoenzymes such as glutathione reductase (NADPH: oxidized glutathione oxidoreductase EC 1.6.4.2) may exist partly in their apoenzyme form, i.e., without the flavin coenzyme and therefore without enzyme activity. An increased supply of riboflavin will permit the depleted coenzyme (in this case FAD) to be synthesized so that enzyme activity can be restored.

Different enzymes and different tissue sites differ in the tenacity with which they can retain flavin coenzymes in times of riboflavin deficiency, so there is a characteristic 'pecking order' for flavoenzyme protection, which appears to reflect the metabolic importance of the different metabolic pathways affected. Apart from this 'pecking order,' however, there is no repository of unused or nonfunctional riboflavin that can act as a 'store' in times of dietary deficiency. Although some organs (such as liver) have relatively high concentrations of flavin enzymes, all of the flavin seems to be present as coenzyme moieties of flavin holoenzymes. Each tissue has a characteristic 'ceiling' level of riboflavin at saturation, and a 'floor' level characteristic of severe depletion, and these are determined, respectively, by the total amount of apoflavoprotein, and the amount of 'resistant' holoenzyme, which cannot be depleted of its cofactor during riboflavin deficiency.

Riboflavin is secreted into milk, the concentration being species specific and to a moderate extent dependent on maternal status and intake. Riboflavin is also required by the developing fetus during pregnancy, which implies a need for active transport from the maternal to the fetal circulation; the flavin concentration being greater on the fetal side. Studies from India have identified a riboflavin carrier protein (RCP) present in bird (e.g., chicken) eggs, which is considered to be specific for riboflavin, and is essential for normal embryological development. If this protein is rendered ineffective (e.g., by immunoneutralization) by treatment of the bird with a specific antibody, then embryonic development ceases and the embryo dies. A genetic mutant lacking RCP is likewise infertile. A homologous protein, which can be rendered ineffective by the antibody to pure chicken riboflavin carrier protein, has been shown to occur in several mammalian species, including two species of monkeys, and also in humans. Very recent studies have suggested that circulating RCP levels and the immunohistochemical staining of RCP in biopsy specimens may provide new markers for breast cancer diagnosis and prognosis. Termination of pregnancy has been demonstrated by immunoneutralization of RCP in monkeys. There remains some controversy over the roles of RCP, however, and other, less specific riboflavin binders in blood, including gamma-globulins, also seem to play an important role. These studies have provided an intriguing example of the role of specific vitamin-transporting mechanisms, designed to ensure that the vitamin needs of the developing embryo will be efficiently met. Further evidence of the special needs of developing embryos has been provided by the demonstration that riboflavin analogs can cause teratogenic changes, even in the absence of any detectable damage to maternal tissues.

Metabolism and Excretion

The interconversions of riboflavin with its coenzyme derivatives are depicted in **Figure 2**. Clearly, the 'high-energy nucleotide' ATP is a cosubstrate and driving force (in energy terms) for both stages of the conversion to FAD. Some flavoenzymes specifically require

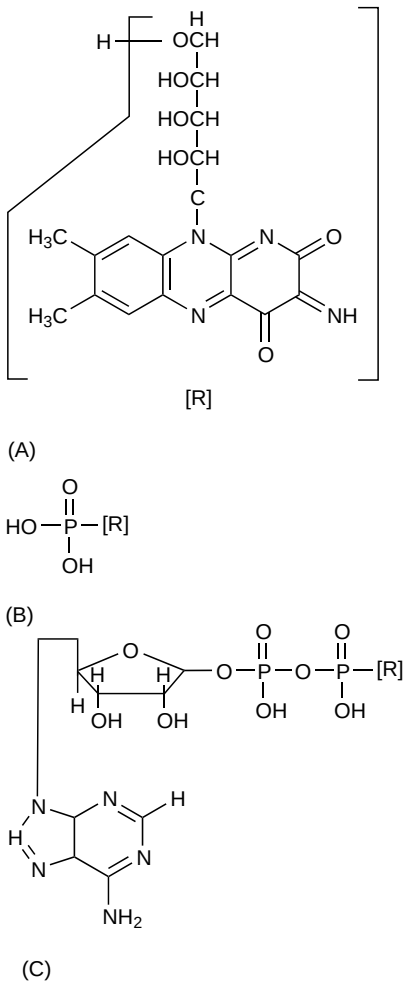

Figure 2 Structure of riboflavin and its coenzyme derivatives. (A) Riboflavin; (B) riboflavin phosphate (flavin mononucleotide, FMN); (C) flavin adenine dinucleotide (FAD).

Table 1 Categories of flavoenzymes

Category (subcategory)	*Example*
1-Electron transferases	Mitochondrial electron-transfer flavoprotein
Dehydrogenases	
Pyridine nucleotide dehydrogenases or reductases	Mitochondrial NADH dehydrogenase
Nonpyridine nucleotide dehydrogenases	Mitochondrial succinate dehydrogenase
Pyridine nucleotide-disulfide oxidoreductases	Glutathione reductase
Dehydrogenase-oxygen reductases	
Flavoprotein oxidases [$O_2 \rightarrow H_2O_2$]	Monoamine oxidase
Flavoprotein monooxygenases (1/2 $O_2 \rightarrow H_2O$)	
Internal (α-hydroxy fatty acid $\rightarrow$ fatty acid (n-1) + CO_2)	Bacterial lactate monooxygenase
External (RH $\rightarrow$ ROH)	Microsomal FAD-containing monooxygenase

Source: Merrill AH, Lambeth JD, Edmondson DE, and McCormick DB (1981) Formation and mode of action of flavoproteins. *Annual Review of Nutrition* **1**: 281–317.

FAD while others specifically require FMN; it is difficult to account for this dichotomy. **Table 1** lists the broad categories of flavoenzymes found in living tissues: the range of reaction types is considerable, but all of them clearly center around redox processes involving hydrogen transfer. This fact reflects the central biochemical reaction of the flavin coenzymes, which is the interconversion of the reduced, dihydro form of the flavin ring and the more stable oxidized form. One of the most important sites of action of flavoenzymes within higher animals is that of the electron transport chain in the mitochondria. The flavins, which form part of succinic dehydrogenase and NADH dehydrogenase, form an essential redox link between the oxidizable energy-rich substrates of aerobic metabolism, and the cytochrome chain leading to molecular oxygen, which can generate around 38 moles of energy-rich ATP per mole of glucose oxidized.

Hormone status can affect riboflavin economy in a number of important ways, and there is also some evidence that riboflavin status can affect hormone production. One important control valve for riboflavin economy is thyroid hormone status: hypothyroidism leads to reduced tissue levels of flavin coenzymes, and hence to inactivation of certain flavoenzymes, thus resembling the effects of dietary riboflavin deficiency. Both flavokinase (ATP: riboflavin 5′-phosphotransferase EC 2.7.1.26) and FAD pyrophosphorylase (ATP: FMN adenyltransferase EC 2.7.7.2) are sensitive to thyroid hormone status. In the kidney, synthesis of flavokinase and hence of flavin coenzymes is controlled by aldosterone in a similar manner.

The amount of absorbed riboflavin that can remain within the body and the circulation (in blood plasma) is strictly regulated by glomerular and tubular filtration and tubular reabsorption in the kidneys. The latter is an active, saturable, sodium-dependent transport process, with characteristics similar to those of active transport in the gastrointestinal tract. It is responsible for the very sharp and characteristic transition between minimal urinary excretion of riboflavin at low intakes, and a much higher level of excretion, proportional to intake, at higher intakes. This transition point has been extensively used to define and to measure riboflavin status and requirements (see below), and to permit studies of intestinal absorption *in vivo* (see above). Excretion of riboflavin is affected by some chemicals (such as boric acid, which complexes with it), and by certain diseases and hormone imbalances.

In addition to the excretion of unchanged riboflavin, there are also small amounts of hydroxylated breakdown products of the vitamin, which arise through normal turnover, either within the tissues of the body, or in the gastrointestinal tract from bacterial action, before absorption. The rate of destruction of riboflavin by this turnover pathway is very low in all species examined to date, and riboflavin within the mammalian body seems to be remarkably efficiently conserved, apparently throughout many cycles of cell turnover.

Metabolic Function and Essentiality

This section will deal in detail with the question: what goes wrong when deficiency of riboflavin is encountered, and how does riboflavin interact with other nutrients, or with biochemical and physiological processes, thus producing characteristic functional effects?

Fatty Acid Oxidation

The first example of serious metabolic disturbance seen in moderate riboflavin deficiency is a disturbance of fatty acid oxidation. The normal first stage in the spiral process of beta-oxidation of fatty acids within the mitochondria is the removal of two

hydrogen atoms from the two carbons located alpha- and beta- to the activated carboxyl end of the chain. The fatty acyl coenzyme A substrate is acted upon by one of several fatty acyl CoA dehydrogenase flavoprotein enzymes (e.g., long-chain acyl-CoA:(acceptor) 2,3-oxido-reductase EC 1.3.99.13), each of which is specific for a small range of acyl chains. The second stage in this process involves transfer of the electrons via another flavoenzyme, known as electron transferring flavoprotein dehydrogenase (electron transferring flavoprotein: ubiquinone oxidoreductase EC 1.5.5.1) and thence to the cytochrome chain and to oxygen. These flavoenzymes, unlike the flavoenzymes that are linked to carbohydrate oxidation, are highly sensitive to dietary riboflavin depletion. Characteristic disturbances of lipid metabolism can therefore be detected in riboflavin-deficient tissues and organisms.

Disturbances in fatty acid oxidation by isolated mitochondria, e.g., from livers of deficient animals, have been demonstrated, and one of the most characteristic metabolic changes, observed even in a mild deficiency state in experimental animals, is the appearance of abnormal dicarboxylic acids, and their derivatives, in the urine. These products seem to arise because fatty acyl intermediates become diverted away from the usual pathway of mitochondrial beta-oxidation, towards abnormal partial oxidation in the peroxisomes (which are less severely affected by the riboflavin deficiency state).

Genetically normal human subjects have not yet been shown to accumulate these abnormal urinary products but, in contrast, humans who bear an abnormal gene resulting in dicarboxylic aciduria do quite frequently respond to riboflavin supplements, showing a reduction in their excretion of abnormal fatty acid products. It seems that additional dietary riboflavin can help to overcome the inherent genetic abnormality, presumably by providing more of the coenzyme, and thereby making sure that all of the residual fatty acid oxidation machinery is working at its optimum capacity. Interestingly, the accumulation of dicarboxylic acids in urine is characteristic of riboflavin-deficient mammals but not of birds; chick embryos deprived of riboflavin via the genetic lesion of riboflavin carrier protein seem to die in hypoglycemic shock, but do not exhibit dicarboxylic aciduria.

Iron Economy

An important interaction of riboflavin with iron economy has been suspected for many years, partly because iron-deficient animals failed to respond readily to iron supplements if they were also riboflavin deficient, and also because the redox system involving riboflavin and its coenzymes has been shown to interact very readily with the redox system between ferric and ferrous iron.

Some recent studies in experimental animals have shown that not only is there evidence for some impairment of absorption of iron in riboflavin-deficient animals, and of its distribution between discrete compartments within the body, but also, more surprisingly and strikingly, a major increase in rates of iron loss from the intestinal mucosa, resulting in impaired retention of the body iron stores. This enhanced rate of iron loss is accompanied by hyperproliferation of crypt cells, and increased cellular transit along the villi, leading to an excessive proportion of immature villi, and probably also to a reduction in absorptive area. These studies begin to explain how a combination of iron deficiency and riboflavin deficiency, which is frequently encountered in human populations in many developing countries, may lead to a gradual deterioration of iron status, which is often accompanied by other intestinal lesions and by impaired gut function.

Riboflavin enhances the hematological response to iron, and deficiency may account for at least some of the anemia seen in human populations. Unlike iron-deficiency anemia, the anemia of riboflavin deficiency is reported to be normocytic and normochromic.

Malaria

Low dietary riboflavin intakes are frequently encountered in malarious areas of the world, and in a small number of studies there has arisen the apparently paradoxical observation that biochemical riboflavin deficiency is associated with a lower level of blood cell parasitemia than is encountered in riboflavin-replete subjects. Although neither animal nor human studies have indicated that riboflavin deficiency protects from the life-threatening sequelae of malaria, there does appear to be some interaction between the parasite and flavins within the blood cells, which is not yet fully understood. Interestingly, too, some of the prophylactic drugs used to prevent malaria infection have riboflavin-like structures.

Cataracts and Photoreceptors

Several micronutrients, especially those that can have antioxidant functions in living tissues, have recently been investigated in relation to possible protection against degenerative eye diseases, such as cataract. Studies in animal models have suggested, albeit indirectly, that riboflavin status may be important here, and several recent epidemiological studies, including an intervention study in one region of China, have supported the suggestion that

good riboflavin status, or riboflavin supplements, may be protective. Although the evidence must be considered as tentative and incomplete at the present time, this possibility clearly deserves further study.

Another intriguing role of flavoproteins in the eye involves a photoreceptor function that synchronizes circadian rhythms with the solar light–dark cycle, specifically via cryptocromes 1 and 2, which contain FAD and function as blue-light-sensitive photoreceptors.

Interaction with Vitamin B_6

There are several metabolic interrelationships between riboflavin and vitamin B_6. The conversion of pyridoxine or pyridoxamine phosphates to pyridoxal phosphate is catalyzed by a flavoenzyme (pyridoxaminephosphate oxidase EC 1.4.3.5), so that a deficiency of riboflavin may, at certain key sites, result in a secondary deficiency in B_6-dependent pathways. More evidence is needed to clarify the extent and importance of these interactions.

Effect on Folate Metabolism

Riboflavin in the form of FAD is an essential coenzyme for 5,10-methylene tetrahydrofolate reductase, a key enzyme of the folate pathway, which catalyzes the interconversion of 5,10-methylene-tetrahydrofolate and 5-methyltetrahydrofolate. Of the known single nucleotide polymorphisms affecting this enzyme, the best known are the C699T and A1298C variants. The former confer thermolability and potentially reduced enzyme activity in the TT homozygote. Marginal riboflavin status may, in some situations, be associated with increased plasma homocysteine levels (possibly predictive of increased vascular disease risk) that can arise as a result of reduced activity of this key enzyme of folate metabolism in TT subjects. Another example of a common gene polymorphism that affects related pathways is encountered with methionine synthase. These examples of gene–nutrient interactions, which may affect a sizeable proportion of some human populations, illustrate an area of increasing research effort, in which a synergism between a common genetic subtype and a marginal nutrient deficiency or imbalance may confer increased functional risk.

Physical Activity and Neuromuscular Function

Several recent studies have documented an apparent increase in riboflavin requirements accompanying an increase in physical exercise in human subjects. This may reflect the fact that anabolic influences and the accretion of new lean body mass creates a demand for the vitamin, for mitochondrial accretion. Intriguingly, there is also some evidence that indices of neuromuscular function, as illustrated by 'hand-steadiness, may be influenced by riboflavin status in communities where riboflavin deficiency is endemic. If confirmed, this might raise the possibility that peripheral neurological function could be affected by riboflavin status in mammals, including humans, as it is in birds.

Assessment of Riboflavin Status

Assessment of status for specific nutrients such as riboflavin is closely bound up with the estimation of requirements in human individuals and groups of subjects, and with the monitoring of human populations for evidence of the adequacy of their intakes. It is often cheaper, easier, and more accurate to collect a sample of blood or urine from an individual and carry out biochemical analyses that determine status than to carry out reliable measurements of intake over a period of time, since the latter requires considerable cooperation from the subject, and is also affected by uncertainties of food table nutrient values, in relation to specific foods and diets.

Biochemical status estimates are generally based upon urinary excretion or measurements of erythrocyte glutathione reductase (NADPH: oxidized glutathione oxidoreductase EC 1.6.4.2) and its reactivation with flavin adenine dinucleotide (FAD) in red cell lysates. Other biochemical indices, such as plasma or red cell flavin concentrations, have been less widely used, but their potential is increasing with the advent of new assay techniques such as capillary electrophoresis with highly sensitive laser-induced fluorescence detection. Functional indices directed towards the products of flavin-requiring pathways *in vivo* are not in common use except for the investigation of errors of metabolism or rare diseases. The two principal traditional status tests are considered below:

Urinary Excretion

As noted earlier, the amount of riboflavin excreted in the urine is negligible at low intakes of the vitamin. As the dietary level rises there is slow increase to a transition point, above which the slope of the excretion rate increases very sharply, and then remains proportional to intake until absorption is saturated. For population studies it has been found convenient to use the creatinine excretion rate as the denominator, and the suggested interpretation of urinary riboflavin excretion rates is: $<27\,\mu g$ riboflavin per g creatinine for deficient; $27–79\,\mu g\,g^{-1}$ for low; and $>80\,\mu g\,g^{-1}$ for acceptable. Detailed studies of the

relation between intake and excretion rate have recently shown that this index is sufficiently sensitive to distinguish riboflavin requirements between people on low-fat, high-carbohydrate diets and the slightly higher requirement associated with high-fat, low-carbohydrate diets. Metabolic states associated with general tissue catabolism can sometimes result in liberation of riboflavin during cell turnover; this increases its urinary excretion, even though dietary intake may be low.

The Glutathione Reductase Test

One rather serious drawback of the urinary excretion index for the assessment of riboflavin status is that it is relatively insensitive at low-to-moderate intakes, because the rate of excretion changes slowly and not very predictably with increasing intake in this region. Another important practical drawback is that 24-h urine samples are not easy to collect and excretion rates may fluctuate over short time periods. A more stable index was therefore sought and was identified in the degree of unsaturation of the red blood cell enzyme, glutathione reductase (NADPH: oxidized-glutathione oxidoreductase EC 1.6.4.2), with respect to its flavin cofactor, flavin adenine dinucleotide (FAD) (**Figure 3**).

As noted earlier, an inadequate supply of dietary riboflavin results in low circulating levels, and hence a gradual progressive loss of cofactor from this red cell flavoenzyme over a period of several weeks. Since the enzyme protein (apoenzyme) remains intact and reactivatable by FAD, it is possible to remove a small sample of blood, collect, wash and hemolyse the red cells, and then measure glutathione reductase activity with and without the FAD cofactor. If the individual is riboflavin replete, then the added FAD has almost no effect and the 'activation coefficient,' or ratio of FAD stimulated to unstimulated activity ('EGRAC') is between 1.0 and 1.3–1.4. If the individual is deficient, then added FAD produces a larger stimulation, and the 'activation coefficient' is higher. For people living in communities with very low intakes of riboflavin and a significant prevalence of clinically recognizable deficiency, activation coefficients as high as 2.0–3.0 are quite common. In Western countries, few values as high as 2.0 are encountered. However, recent population surveys in the UK have indicated that the proportion of values between 1.3 and 1.8 is considerable across all age ranges. Whether this apparent evidence of marginal deficiency has a technical, assay-related explanation, or is a result of decreasing intakes of riboflavin-rich foods, such as cows' milk, is uncertain.

This test has the advantage that it is highly sensitive to, and predictive of, the extent of tissue depletion in the range of severe-to-moderate deficiency; it is robust and requires only a small sample of blood, and it can be automated by modern enzyme rate reaction analyzers. Riboflavin supplements given to deficient subjects result in rapid and reproducible restoration of the saturated condition of the enzyme,

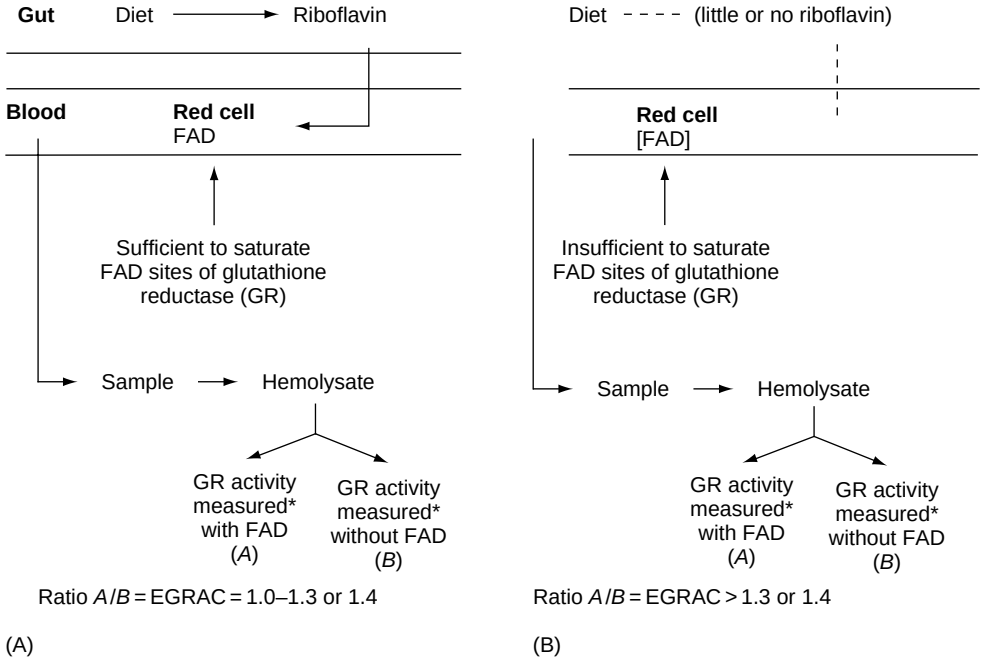

Figure 3 Basis of the glutathione reductase for riboflavin status: (A) riboflavin sufficient; (B) riboflavin deficient. *Reaction of oxidized glutathione with reduced nicotinamide adenine dinucleotide phosphate.

and graded supplements can be given to estimate human requirements.

There are minor operational differences among different published versions of the analytical procedure for 'EGRAC,' which result in small between-laboratory differences in the interpretation of the normal range and there are also some instances of specific factors that cause ambiguity of interpretation. The best known of these is the human genetic variant resulting in glucose-6-phosphate dehydrogenase (D-glucose-6-phosphate: NADP+ 1-oxidoreductase EC 1.1.1.49) deficiency. Both homo-and heterozygotes are affected, and in such subjects erythrocyte glutathione reductase becomes almost saturated with FAD, even when they are riboflavin deficient. Other tests of status, such as high-performance liquid chromatography (HPLC) measurement of riboflavin in blood fractions, are then required.

Some groups of people have increased requirements for riboflavin, which is related to special metabolic states. There is, for instance, a progressive increase in requirement during pregnancy, followed by a decrease during lactation. Babies exposed to phototherapy for neonatal jaundice also have increased requirements. In certain circumstances, the use of oral contraceptives may increase requirements, but the evidence is conflicting. The largest and most dramatic increases in requirements have been seen (as noted above) in a subgroup of people with inborn metabolic errors leading to dicarboxylicaciduria and associated clinical abnormalities. Although certain drugs are known to affect riboflavin status indices, there is no clear consensus on the question of the need for supplements by people who are prescribed such drugs – clearly this area needs further study.

Requirements

As with most micronutrients, the evidence on which requirement estimates are based can be subdivided into the following broad classes of criteria:

1. prevention of clinical (pathological) deficiency;
2. attainment of specified blood levels or tissue stores of riboflavin;
3. titration to the urinary excretion threshold;
4. tests based on cofactor saturation of one or more accessible, diet-sensitive, flavin- dependent enzymes, such as erythrocyte glutathione reductase; and
5. physiological function.

Of these five classes of criteria, the first has been useful in defining 'minimum' requirements, but as a practical test of status it has several drawbacks. First, clinical signs of deficiency in human communities tend to be nonspecific and multifactorial. Second, studies resulting in clinical deficiency in controlled trials would be ethically unacceptable. Third, the classical clinical deficiency signs such as angular stomatitis and cheilosis do not always correlate closely with, or respond rapidly to, changes in dietary riboflavin supply or biochemical evidence of deficiency. Additional factors such as local infection are likely to be critical.

Use of physiological functional indices in relation to riboflavin deficiency (analogous to dark adaptation for vitamin A; clotting factors for vitamin K, etc.) has not proved possible, because the analogous riboflavin-sensitive physiological processes are insufficiently specific or easily measurable for use in population studies. Of the biochemical indices, urinary excretion and the flavin-dependent enzyme, erythrocyte glutathione reductase, are generally considered to be the front-runners in the race for acceptance in human studies. These have already been described in the previous section.

For avoidance of clinical deficiency signs in normal healthy adults, the basic requirement for riboflavin is 0.55–0.8 mg day^{-1}. The UK reference nutrient intake for riboflavin is l.3 mg day^{-1} for men and l.l mg day^{-1} for women, rising to l.6 mg day^{-1} during pregnancy and lactation. For formula-fed infants, the reference intake is 0.4 mg day^{-1}. Requirements may increase to some extent as a result of heavy exercise or dieting, and abnormal status has been observed in the presence of anorexia nervosa.

In the US, the current recommended dietary amounts (RDAs) are 1.3 mg day^{-1} for men and 1.1 mg day^{-1} for women, rising to 1.4 mg day^{-1} in pregnancy and 1.6 mg day^{-1} in lactation, with proportional amounts, based on metabolic body weights and growth requirements, for children and adolescents. RDAs are 20% higher than estimated average requirements (EARs) for each group.

Dietary Sources and High Intakes

Table 2 lists the riboflavin contents of some commonly consumed foods in Western countries. As is the case with most other B vitamins, the richest food sources comprise items such as offal and yeast extract, with meat and dairy products also providing quite generous amounts; fruit and vegetables somewhat less, and the smallest amounts, in relation to their energy content, being present in ungerminated grains and seeds, such as nuts. There is an enormous difference in intakes and in status observed between most Western countries, where the dietary intake tends to be quite generous, and many developing countries, which depend on monotonous and riboflavin-poor staple foods such as polished rice. In developing countries, riboflavin deficiency tends to

Table 2 Riboflavin content of selected foods

Food	*mg per 100 g fresh wt*	*mg per MJ*
Meat, offal, and fish		
Stewed minced beef	0.19	0.22
Grilled pork chop	0.16	0.21
Calf liver, fried	2.89	3.94
Lamb's kidney, fried	3.10	3.95

Compiled and calculated from data in Food Standard Agency (2002) *McCance and Widdowson's The Composition of Foods*, 6th Summary edn. Cambridge: Royal Society of Chemistry.

be widespread. Although even a severe riboflavin deficiency is less obviously life-threatening than some other types of malnutrition that are commonly encountered in the Third World, it can nevertheless cause debility, through skin lesions and metabolic dysfunctions, and riboflavin-nutriture thus deserves an important place in future public health programs.

As with most other B vitamins, riboflavin and its cofactors are remarkably nontoxic even at high intakes. The reasons for this are probably associated with limitations on absorption, once the active transport process has become saturated in the gut; coupled with very effective urinary excretion of any absorbed vitamin that is in excess of cellular requirements.

SEASONALITY

F Branca and P D'Acapito, Istituto Nazionale di Ricerca per gli Alimenti e la Nutrizione, Rome, Italy

Introduction

The agroclimatic characteristics of some areas of the planet with lower technological development lead to seasonal fluctuations in food production and food availability, labor demand, and incidence of disease that affect the nutritional status of rural populations. Such cyclical stress has a negative impact on the well being, productivity, and potential for development in individuals with a pre-existing marginal nutrition. Approximately 400 million adults and 500 million children in the world may be affected.

Definition and Measures of Seasonality

Seasonality is defined as the cyclical change of food availability and agricultural labor induced by climatic changes in rural areas of least developed countries (LDC). In seasonal climates a bad, lean, or slack season, also known as the *saudure* (French, meaning junction between two agricultural cycles), is present for 2–3 months a year, often coinciding with rains, leading to cyclical stress on the health and nutrition of rural populations. Agroclimatic seasonality is relevant in populations practising subsistence agriculture and among hunter-gatherers, or in other agricultural systems in which background food security is poor; such as in areas where cash crops are mainly planted. Human interventions can alter this pattern, by changing the water and sun exposure conditions, with irrigation and greenhouses, but these techniques are not accessible to the majority of peasants in LDC.

Changes in rainfall, temperature, exposure to winds, and relative humidity, with respect to the water retention capacity of the soil, are responsible for a cyclical change of water balance that may restrict the period for plant growth to some parts of the year. The proportion of dry months in a year, named absolute seasonality, can vary between 0 (sufficient rains all year long) to 1 (lack of a period suitable for plant growth). If the vegetative cycle of corn (maize) is considered (120 days), then the areas of the world can be classified as follows: low seasonality when there are more than 200 days' vegetative season per year and two harvests are possible; moderate seasonality with 120–200 days' vegetative season and one to two corn

harvests possible; and severe seasonality with less than 120 days' vegetative season and barely one corn harvest possible. With even shorter vegetative periods, agricultural production is impossible in the absence of irrigation. The different areas of agroclimatic seasonality in the world are shown in **Figure 1**.

Factors aggravating the climatic seasonal effects may be the occurrence of pests, for example, the arrival of locusts arriving with the rainy season in Sahel. Furthermore, seasonal patterns of food production are often superimposed upon longer term cycles, which leads to the periodic appearance of drought and famines in sub-Saharan Africa and in Central Asia.

Effects of Agroclimatic Seasonality on Food Availability and Dietary Intakes

Subsistence farmers store their harvest and use it progressively until the next season, so that a fluctuation of food stocks can be observed during the year. Stores decrease as a result of human consumption, animal consumption, losses due to pests, rodents and microbiological contamination, and sales, barter or donations. The market price of food staples is also subject to great seasonal fluctuations, which are usually inversely related to the size of the domestic stocks.

As a result, both energy supply and dietary quality may be affected. The dietary changes observed in slack seasons may involve eating foods that are less preferred, but are more affordable, an option that is not biologically dramatic, but perceived by people as stressful. Households that are close to exhaustion of stocks of staple foods may use alternative food sources (root crops, gathered leaves and fruits, hunted small animals), may consume immature grains, or may reduce food intake by limiting portion size, reducing the number of meals, or skipping meals for an entire day. Dietary changes may also be due to reduced time available for food collection and preparation.

In areas of high climatic seasonality the magnitude of the reduction of energy intake can be in the order of 400–500 kcal and is associated with a reduction in protein and micronutrient intake. In

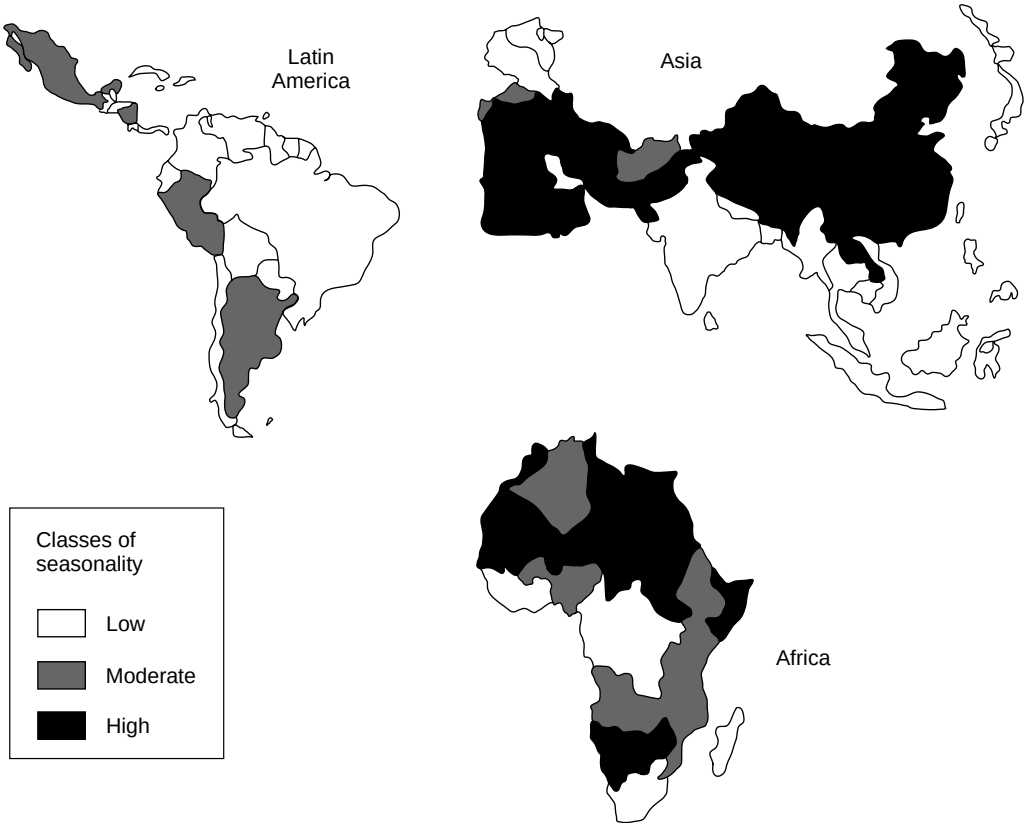

Figure 1 Agro-climatic seasonality in different world regions. Seasonality is calculated taking into account soil characteristics and water balance and is an expression of the vegetative period of a food crop allowed by such conditions. From Ferro-Luzzi A, Branca F, and Pastore G (1994) Body mass index defines the risk of seasonal energy stress in the Third World. *European Journal of Clinical Nutrition* **48**(supplement 3): S165–S178. Reprinted with permission of the Nature Publishing Group.

Cameroon, the rainy season is associated with a 20% reduction of energy intake, a 50% reduction of protein intake, and a 25% reduction of fat intake. However, the reduction in food intake is not a universal characteristic of areas prone to agroclimatic seasonality. In Mali energy intake in adults had minimal fluctuations between 11.7 MJ in the harvest season and 11.4 MJ in the rainy season.

Changes in dietary intake may affect household members unequally. For economic or social reasons some household members may be protected. In Northeastern Thailand energy intake in the rainy season is reduced in women but is constant in men. Children may be protected by maternal buffering, but may also be discriminated against in favor of male workers, who have to ensure the family's food supply. A study in Bangladesh showed that energy and proteins intakes were significantly different in male and female adults and in 1 to 4-year-old children, but were unchanged in older children. In another Bangladesh study (**Figure 2**) dietary energy intake was reduced in all age groups, including pregnant and lactating women, but the reduction in women (−28%) was far greater than that in men (−18%).

It seems that women consistently get the least food during seasonal shortages, regardless of their physiological status. In The Gambia a 12% reduction of intake has been observed in pregnant women and 29% in lactating women during the rainy season.

Seasonality does not spare weanlings, who in Bangladesh have a 33% difference in energy intake between highest and lowest intake seasons, or breast-fed babies, in whom a decrease in breast-milk intake has been observed. A decrease in breast-milk output in the early postpartum period (2–6 months) has also been observed in The Gambia during lean seasons: the daily output was $850\,g\,day^{-1}$ in a cohort of women who gave birth during the dry season and $540\,g\,day^{-1}$ in a second cohort who delivered during the wet season. Furthermore, breast-milk fat concentration was $3.95\,g\ 100\,ml^{-1}$ in the first cohort and $3.52\,g\ 100\,ml^{-1}$ in the second cohort, with a resulting decrease in energy content. The decrease in breast-milk output is not necessarily related to the deteriorating nutritional status of the lactating mothers, but rather to the limited time available for childcare,

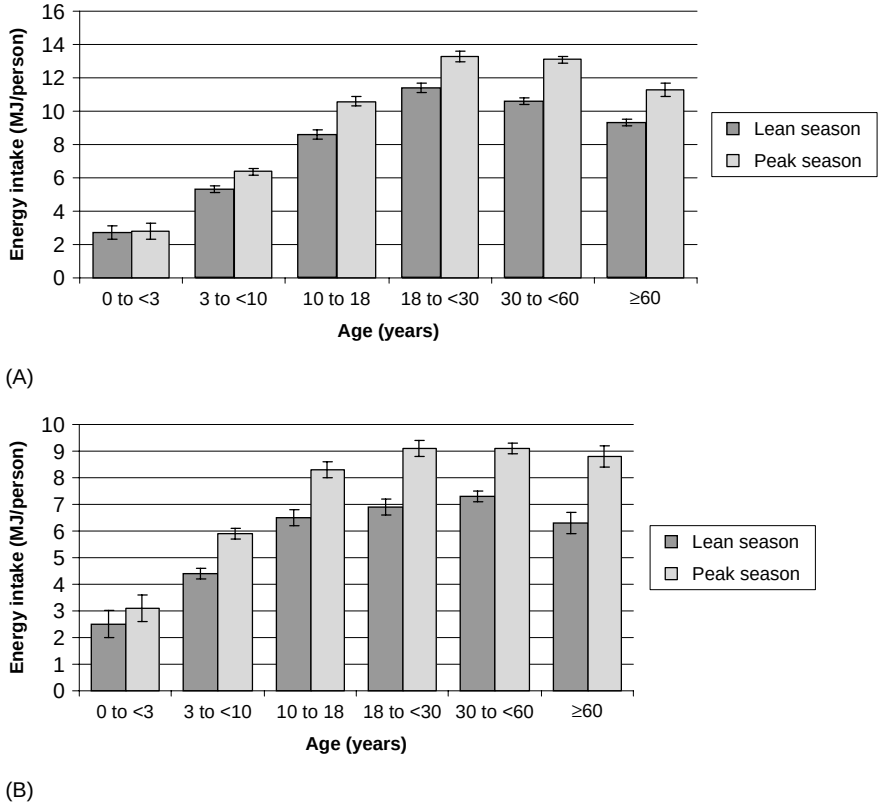

Figure 2 Seasonal changes in dietary energy intake in different age groups in Bangladesh: (A) males; (B) females. (Data from Tetens I, Hels O, Khan NI, Thilsted SH, and Hassan N (2003) Rice-based diets in rural Bangladesh: how do different age and sex groups adapt to seasonal changes in energy intake? *American Journal of Clinical Nutrition* **78**: 406–413.)

with a resulting reduction in suckling time. This latter circumstance has been specifically documented in Bangladesh.

The reduction in diet diversity may affect micronutrient intake, although not always in the same direction. In The Gambia fruit and vegetable intake was found to be seasonal and vitamin C intake varied from nil in the rainy season to about 100 mg day^{-1} in the dry season, affecting both plasma ascorbate and breast-milk ascorbate. In Cameroon, during the wet season calcium intake was reduced by 30%, iron intake by 20%, and thiamin by 15%. However, the consumption of leafy vegetables and fruit increased during the wet season, as did carotene (+100%) and ascorbic acid (+50%).

Effects of Agroclimatic Seasonality on Time Allocation and Energy Expenditure

The second important consequence of agroclimatic seasonality is the concentration of agricultural practices at certain times of the year. More time has to be devoted to often intense efforts, sometimes regardless of the actual physical capacity to perform them. Thus, although adult males are primarily involved, women and even pregnant women also have to spend more time in the field.

The increase in energy expenditure reported by different studies during the peak agricultural season amounts to 320–1050 kcal day^{-1}. In Mali, during the rainy season the energy expenditure from agricultural work is double that during harvest and triple that in the dry season, although the difference is smaller for women.

As a result of the increased demands on time for agricultural labor, time spent on activities is reallocated. Northeastern Thai men spend 2 h less resting and 1.5 h less in domestic work than in other seasons. Women not only spend less time sleeping and in leisure, but they also spend less time cooking, carrying out household tasks such as cleaning, collecting food and water, caring for the children, or carrying out income-generating activities such as handicrafts. The reallocation of women's time may have important consequences for their own health and well being and for the health of all the household members needing care. (**Figure 3**). Where possible, such household tasks may be reallocated to older children. In adolescent girls in Senegal the total energy expenditure measured by accelerometer was 5% higher in the rainy than in the dry season (100 kcal difference). In the rainy season the girls spent 1.5 h more on vigorous activities and more time in domestic activities.

Seasonal Patterns of Disease

A third factor subject to seasonal changes is morbidity. In most cases the slack season is also a wet season and the environmental changes may lead to seasonal outbreaks of diseases, such as acute respiratory infections, gastrointestinal tract infections, but also other infectious diseases such as measles, malaria, and guinea worm. Overall mortality also increases. A study in Mali showed that the duration of disease episodes in the rainy season was more than double that in other seasons and that the morbidity episodes in the rainy season accounted for more than half the yearly episodes, particularly fever, diarrhea, and respiratory illness.

Increased morbidity is a consequence of epidemic cycles and environmental factors, but is also related to increased susceptibility to infections, as a result of decreased food intake and increased stress. Impairment of immune function has been documented in a study in undernourished Gambian children aged 6½–9½ years, in whom seasonality influenced antibody responses to different vaccines. Some behaviors that are typical for the season also determine increased risk of disease. For example, food may be prepared only once a day and left over for the second meal, thus increasing the risk of contamination; there is less time for personal and household hygiene and this leads to easier spread of gastrointestinal and skin disorders.

Morbidity seriously affects the nutritional status of children and sometimes endangers their lives, but it also impairs labor capacity and imposes further time and financial burden on the households, who have to care for the sick and pay for their treatment.

Coping Strategies

People living in areas with agroclimatic seasonality have developed different strategies to cope with the environmental challenge. The earliest and most successful are aimed at maintaining an adequate level of food stocks, but when these fail, other more costly strategies are put in place and their presence indicates that a crisis is occurring.

The negative effects of seasonality can be prevented to a certain extent by selecting the appropriate crops, namely by using varieties with a shorter vegetative period and lower demand for water and by using reserve crops such as root crops, leguminous plants, and groundnuts. Manioc (*Manihot esculenta*) is used as a reserve crop in the Guinean zone, enset (*E. ventricosum*, false banana) is used in southern Ethiopia, and groundnuts (*Arachis Hypogaea*) in Sahel. Reliance on a single crop is highly risky, as failure of the crop due to a pest, a natural

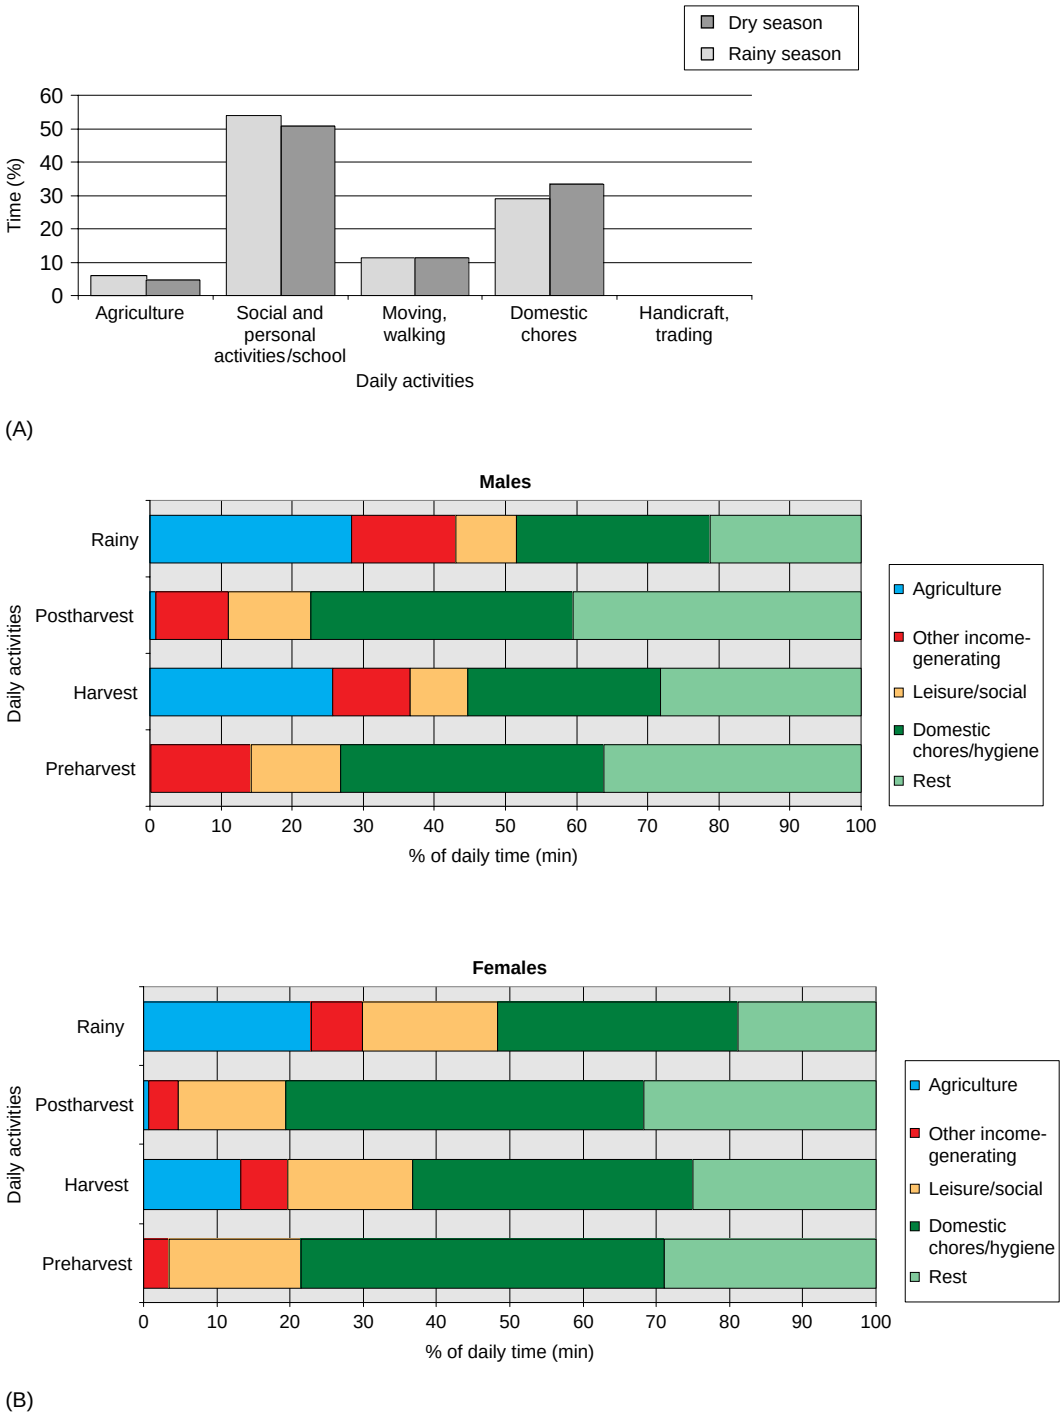

Figure 3 (A) Time allocation of Senegal rural adolescents in different seasons. (Data from Benefice E, Garnier D, and Ndiaye G (2004) *European Journal of Clinical Nutrition* **58**(2): 292–301.) (B) Time allocation of a Thai rural population in different seasons. Duration of daytime activities (night sleeping excluded) in four seasons. (Data from Murayama N and Ohtsuka R (1999) *European Journal of Clinical Nutrition* **53**(1): 39–49.)

disaster, or war may lead to permanent indebtedness and poverty. In areas where cash crops are common, the fluctuation of international market prices may also disappoint the expectations of farmers. The coffee crisis is a typical example. Furthermore, diversification allows people to shift some of the labor burden to different times of the year and to obtain a second harvest in the year.

In order to secure themselves a regular income, landless people who live on seasonal labor, will have

to seek off-farm labor opportunities. At times other than the peak agricultural season labor demand and wages fall and migration of the labor force to different climatic zones may take place. Migration may involve both adults and children, who in some cultures may be sent out to work as servants. At times of food shortage, children may also be sent out to stay with relatives with better resources.

Mutual support groups are created and donations in cash or food may be received by families who may be affected by crop failure or by the occurrence of an unexpected event, such as an illness or death of a family member. Food or money to buy food may be borrowed, although this strategy leads to permanent indebtedness. The final resort is the sale of household assets, particularly animals. This is a high-cost strategy, as the inability to maintain a permanent asset base traps people in poverty and permanent food insecurity.

Nutritional Impact of Seasonality

Body Weight, Body Composition, and Growth

People living in areas of high climatic seasonality are well aware of the nutritional impact of seasonality, as indicated by the language they use to define such seasonal stress periods. The Massa of Cameroon call the month of July in the middle of the wet season the month of 'Did you call me for food?' and they have a word to define 'hunger with threat,' when food shortage has been too long and life is in danger. However, it was not until the 1950s that the scientific community started to appreciate the presence of a nutritional impact of seasonality, and its functional significance is still a matter of discussion.

As described earlier, seasonal climates may affect nutritional status via a combination of reduced dietary intake, increased physical activity, and increased disease incidence, and may occur to a variable extent in different populations and socioeconomic groups. As a result, both energy balance and micronutrient status may be affected, and this is confirmed by the observation of changes in body weight and body composition in adults, growth performance in children, pregnancy weight gain, and birth weight as well as by changes in micronutrient status.

Body weight changes between 1 and 4 kg, corresponding to 2–5% of body weight have been observed in adults in areas of medium and high seasonality. Larger body weight changes occur in draught years or among pastoralists. Remarkable interindividual differences also feature in parallel with such mean values. Smaller changes are usually suffered by women and by people with a lower body mass index (BMI). Socioeconomic differences may go in both directions: wealthier people may either lose more weight, because they own land and have the opportunity and the need to perform more intense agricultural work, or lose less, because they rely on hired labor.

The composition of the tissue lost varies according to the size of the loss and to the initial energy stores. In a rural population in Mali the mean BMI was low ($19.8\,kg\,m^{-2}$ in men and $19.3\,kg\,m^{-2}$ in women), the weight loss in young active men (16–35 years) was 2.6 kg, corresponding to a 3.8% change in body weight, and changes in body fat were in the order of 1.5%. Arm muscle area was also reduced. In Northeast Thailand, where BMI in men was similar ($19.8\,kg\,m^{-2}$) but the weight change smaller (1 kg), a 1.5% reduction of the fat mass was also observed, but no reduction in the fat-free mass could be detected by anthropometry.

The vulnerable groups of the population are not spared by the seasonal stress. During the wet season, energy imbalance leads to the utilization of fat reserves in pregnant women and the women's own energy requirements compete with that of the fetus, leading to increased reproductive risk. In Sierra Leone, at the time of planting and harvesting, pregnant women are expected to continue working and are also more affected by malaria, anemia, and pregnancy-induced hypertension; as a result, in this season birth weights are the lowest in the year. In Taiwan predelivery skin-fold thickness of a cohort of women measured in the cold season was greater than that of a comparable cohort measured in the warm/wet season and a 150 g difference in mean birth weight was observed. In The Gambia a $0.4\,kg\,month^{-1}$ weight gain was observed among pregnant women during the rainy season, as opposed to $1.4\,kg\,month^{-1}$ during the dry season. Dry season mean birth weight was 160 g higher than in the wet season, and the prevalence of low birth weight was 13% in the dry season and 35% in the wet season. Perinatal and infant mortality were also higher in wet season cohorts.

Seasonal stress continues after birth for both mothers and children. In The Gambia lactating women lost on average $0.74\,kg\,month^{-1}$, at the same rate of nonlactating women. As shown earlier, during the wet season very young children get less attention and less breast milk from their mothers and their growth is affected. In Taiwan, children born in the hot wet summer season were smaller, but could catch-up in the following 3 months, while those born in the dry season had a larger birth weight but had a slower postnatal growth.

Seasonal impact is more evident at critical times when a more intense growth effort is required, in

order to catch-up from previous delays or at the mid-infancy growth spurt. In a rural area of The Gambia the lower weight and height gains observed in the wet season were not followed by corresponding increases at other times of the year. In Malawi the weight-for-age Z scores and height-for-age Z scores declined more rapidly during the rainy season among 1 to 6-month-old babies and among 13 to 36-month-old children, but not among the 7 to 12-month-old babies.

Weight and height increments are more sensitive indicators than achieved weight and height. In Bangladesh monthly height gain in children under 5 years ranged from a minimum of 12–20% of the reference value to 200–240% (respectively, in boys and girls), while height gain fluctuated between 52–60% and 165–180%. In Ethiopian children, height growth velocity showed a marked seasonal pattern, with values close to normal (−0.2 SD units) in July to December, a period characterized by better food availability, and lower values (−3.0 SD units) in January to June, a period characterized by intensive farm labor and heavy rains. Therefore, there was never an opportunity to recover from growth faltering and stunting was a continuous process in the first 5 years of life.

Unlike the younger children, the seasonal variables did not have a permanent effect in older children and adolescents. In the Ethiopian study, girls above the age of 10 years showed accelerated growth in the first semester of the year and delayed growth in the second semester, characterized by the wet season, so that the mean yearly growth rates were normal overall. This was also observed in Senegalese adolescents, in whom arm circumference and triceps skinfold were significantly lower during the rainy season, followed by a recovery in the postharvest season, but no change in the growth rate.

In young children, labor burden is not a critical variable, but the reduction of food availability, combined with the greater incidence of infectious diseases, especially diarrhea, leads to impaired growth. This is supported by the observation that seasonality may also affect urban children. In an urban area of The Gambia height-for-age showed little seasonal variation, but weight gain was poor during the rains and was not compensated by catch-up growth during the dry season. In older children and adolescents, the seasonal effects may instead be related to increased physical activity.

Figure 4 illustrates the magnitude of seasonal effects on mean weight changes observed in adult men and women in different regions of the world. In both sexes the observed values range between 1 and 5 kg, although the values greater than 4 kg have been documented during extreme environmental stress, as in drought.

Changes in Micronutrient Status

Few studies document the changes in micronutrient status that can be expected from the seasonal changes in dietary quality. In The Gambia both plasma ascorbate and breast-milk ascorbate had seasonal fluctuations connected with fruit and vegetable intake. Carotenoids also showed a three-fold fluctuation, while retinol was unchanged.

In another study in undernourished children in The Gambia significant seasonal changes were observed for hemoglobin levels and plasma concentrations of vitamin C and α- and β-carotene. Hemoglobin levels decreased with the wet season, while vitamin C and α- and β-carotene plasma levels were highest during the mango season (April–May) and during the rainy season (September–October) when green leafy vegetables are abundant. Zinc and retinol plasma levels were not significantly affected by seasonality.

Metabolic Adaptation

Adaptation to reduced energy intake is a possible biological mechanism to cope with seasonal energy stress. A small reduction in basal metabolic rate (BMR) has been observed. In a multicenter study carried out in India, Benin and Ethiopia the energy debt generated by seasonal changes in food intake and labour pattern was accounted for by the mobilization of fat stores in Benin, abundant in this population, and by a combination of a modest reduction of body weight in India and Ethiopia (0.3 kg and 1.6 kg respectively), together with a reduction in BMR that allowed a 30–50% saving of total energy expenditure. The adaptive response occurred at a relatively low level of energy deficit, i.e., 70 kcal day^{-1} in India and 90 kcal day^{-1} in Ethiopia.

Functional Consequences

The size of the nutritional impact is dependent on the magnitude of the seasonal stress and on the baseline nutritional status, as this sets the limit of the tolerable stress. Lean people will lose more fat-free mass than fatter people. At a BMI of 21, 50% of the weight lost is lean tissue. Therefore, in populations with a lower mean BMI there is a greater impact on their fat-free mass, with greater consequences for their productivity and fitness. A meta-analysis of the body weight change/body weight relationship indicates that farmers tend to maintain the loss at below 2% of their fat-free mass; people with lower BMI will lose less weight, but they will also have to limit their physical activity, which can have socioeconomic consequences. In some populations, body weight lost

can be as high as 4% of the fat-free mass, but this is probably the maximum stress cyclically tolerable.

Some authors maintain that the observed fluctuations may be regarded as an acceptable physiological response to energy imbalance or even a successful adaptive response. Indeed, having a maximum body weight at the beginning of the heavy work season may be more advantageous than keeping a constant body weight, because this minimizes the farm storage losses.

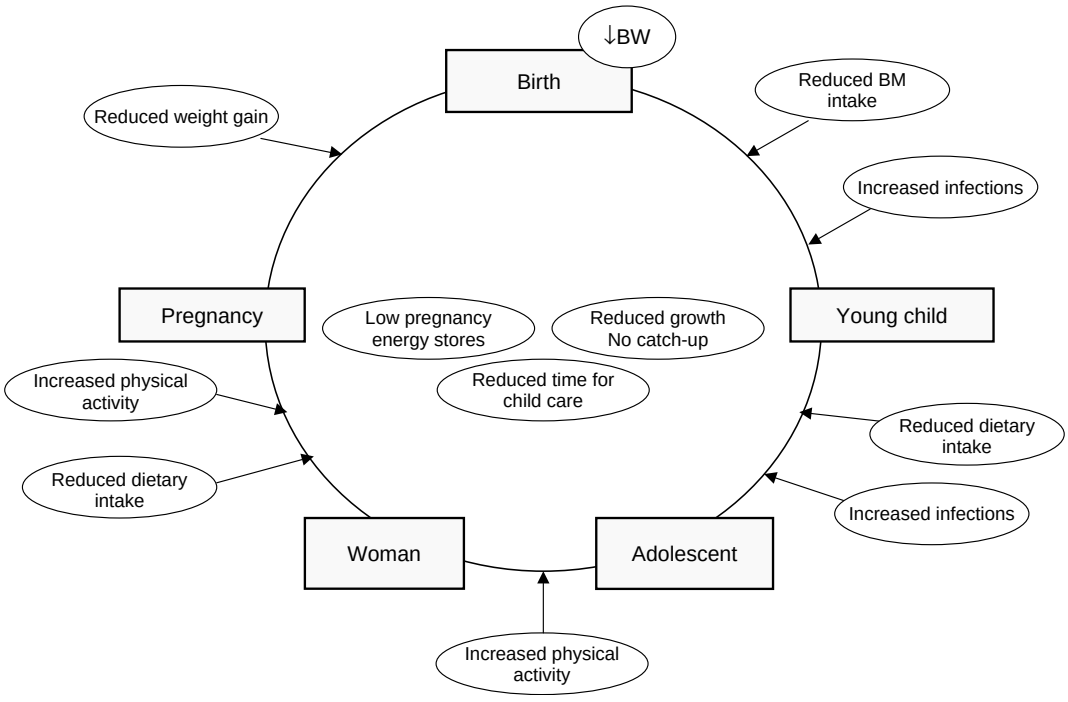

Figure 5 Model of the effects of seasonal stress on the intergenerational cycle of malnutrition. Seasonal factors are drawn outside the circle; biological and behavioral effects are drawn inside the circle. BW = Body weight, BM = Breast milk.

However, in some subgroups of the population living in seasonally prone areas such compensatory mechanisms may irreversibly affect other physiological functions such as reproductive performance and growth. While men have time to recover after the seasonal imbalance of energy, women are permanently undergoing stress and a greater impact on health, well being, and function should be expected. Furthermore, women's seasonal stress also has an impact on the early growth and development of young children, such that seasonal cycling may be considered as one of the factors responsible for the intergenerational cycle of malnutrition (**Figure 5**).

Young children suffer a double seasonal burden: the one imposed on themselves by disease and the one imposed on their mothers. Seasonal changes in children's weight and height velocity have also been observed in more developed societies. However, in high seasonal areas of LDC the periods of retarded growth in the youngest age groups are not followed by periods of adequate catch-up growth, such that height-for-age decreases progressively. Therefore, we suggest that stunting is listed among the functional consequences of seasonality, along with its correlates of impaired cognitive function, impaired metabolic function, and decreased productivity. The impact is going to be highest in younger children, and we may arbitrarily take the age of 5 years as a limit for increased seasonal vulnerability.

Extension of the Problem

Approximately one billion people live in areas of moderate and severe seasonality. Taking into consideration the BMI distribution of those populations, it is possible to calculate that 65% of the adults living in rural areas, i.e., 408 million people, are at risk of severe stress, most of whom are in Asia (90%) and the remaining 10% in sub-Saharan Africa.

Pregnant women and young children should, however, be added to this count. A rough calculation indicates that in those areas, the number of children under 5 years is about 500 million and the number of pregnant women approximately 20 million. They should also be included among the victims of seasonal climatic changes in LDC, thus bringing the estimate to about a billion people.

Nutrition interventions aimed at accelerating growth rates should then preferably be carried out at the time of the highest seasonal stress in these vulnerable population groups, particularly in younger children, in order to achieve the maximum long-term benefit.

SELENIUM

C J Bates, MRC Human Nutrition Research, Cambridge, UK

The realization that selenium (Se) may be an essential micronutrient for human diets has arisen only recently, in the second half of the twentieth century. Selenium deficiency, attributable to low soil selenium levels in farm animals, especially sheep that are afflicted by selenium-responsive 'white muscle disease,' has been recognized for at least half a century. However, the more recent identification of Keshan and Kashin–Beck diseases as endemic selenium-responsive conditions, occurring in a central 4000+-km-wide belt of central China and in areas of Russia, demonstrated conclusively that not only is selenium an essential element for man but also deficiencies occur naturally and require public health measures to alleviate them. Selenium incorporation into plants is affected by the acidity of the soil and by the concentrations of iron and aluminum present so that selenium content of human diets is modulated by these components of the environment. The very recent discovery that these diseases probably arise through the interaction of selenium deficiency with enhanced viral virulence has added a further layer of complexity, but it does not alter the fact that selenium is an essential dietary component that cannot be substituted by any other element. Another complicating factor is that moderately increased soil selenium concentrations result in the opposite condition of selenosis, or selenium overload, with equally debilitating consequences. Of all elements, selenium has a very narrow safe intake range, and unlike some other potentially toxic elements, it is absorbed efficiently by the intestine over a wide range of concentrations and across a variety of different molecular forms.

Unlike other elements, selenium can be incorporated in two distinct ways into proteins, either as a

functional active center (in specific selenoproteins) via a selective incorporation mechanism that ensures selenocysteine insertion or alternatively by a nonspecific incorporation pathway, in which selenomethionine (or selenocysteine) can replace methionine or cysteine at random, without apparently conferring any special functional characteristics on the recipient proteins. This dichotomy of incorporation complicates the task of measuring status and requirements because the different dietary forms of selenium contribute differently to these two contrasting types of incorporation. Selenomethionine and supplementary selenium in the form of selenium-enriched yeast, in which the incorporated selenium is largely present as selenomethionine, contribute to the random incorporation pathway. This is followed by a gradual turnover of selenium to enrich the specific incorporation pathway. Inorganic selenium, in contrast, feeds directly into the specific incorporation pathway via selenide. Although inorganic selenium may relieve functional selenium deficiency more rapidly than organic selenium, the inorganic forms are potentially more toxic; therefore, selenomethionine supplementation is often preferred because it is safer.

Selenoproteins seem to have a number of functions, comprising various catalytic roles (glutathione peroxidases, thioredoxin reductases, and iodothyronine deiodinases), structural roles, detoxifying functions (e.g., selenoprotein P), and storage and transport activities. Many of these functions are incompletely understood, and advances in this area should help to clarify uncertainties about human requirements and the role of selenoproteins in disease, especially in multifactorial conditions such as cancers. Several controlled intervention trials involving selenium are under way, and these should provide evidence to underpin public health programs in the near future.

Dietary Selenium, Absorption, and Mechanisms of Incorporation of Selenium into Selenoproteins

Rich food sources of selenium in human diets include Brazil nuts, offal, shellfish, and some other types of fish, although there is uncertainty about the extent of selenium bioavailability in some foods, which may in turn be linked to problems of mercury contamination. In the United Kingdom, cereal foods account for approximately 20% of total selenium intake, whereas meat, poultry, and fish account for 30–40%.

Selenium is readily absorbed, especially in the duodenum but also in the caecum and colon. Seleno-amino acids are almost completely absorbed: selenomethionine via the gut methionine transporter and selenocysteine probably via the cysteine transporter. Both selenite and selenate are >50% absorbed, selenite more readily so than selenate, and for these forms there is competition with sulphate transport. Selenite is more efficiently retained then selenate because part of the latter is rapidly excreted into the urine. Vitamins A, E, and C can modulate selenium absorption, and there is a complex relationship between selenium and vitamin E that has not been entirely elucidated for man. A combined deficiency of both nutrients can produce increases in oxidative damage markers (malondialdehyde, F_2 isoprostanes, and breath hydrocarbons) and in pathological changes that are not seen with either deficiency alone. Inorganic Se is reduced to selenide by glutathione plus glutathione reductase and is then carried in the blood plasma, bound mainly to protein in the very low-density lipoprotein fraction. Selenomethionine is partly carried in the albumin fraction.

Figure 1 summarizes the main pathways of interconversion of selenium in mammalian tissues. Selenium appears not to be an essential element for plants, but it is normally taken up readily into their tissues and is substituted in place of sulfur, forming the seleno-amino acids selenomethionine and selenocysteine, which are then incorporated at random in place of the corresponding sulfur amino acids into plant proteins. All branches of the animal kingdom handle selenium in essentially similar ways. When ingested, plant selenium-containing proteins liberate free selenomethionine and selenocysteine, either for incorporation at random into animal proteins or for metabolic turnover, to liberate inorganic selenide, which is the precursor of active selenium to be inserted at the active site(s) of the selenoproteins. Selenide is also supplied by the reduction of selenite and selenate that enters the diet from nonorganic sources (i.e., from the environment) or from dietary supplements of inorganic selenium. The inorganic forms of the element are absorbed with approximately 50–90% efficiency (i.e., only slightly less than the >90% efficiency of absorption of selenomethionine).

Selenide represents the 'crossroads' of selenium metabolism, from which it may either be committed to specific selenoprotein synthesis or be removed from the body by urinary excretion pathways that involve its detoxification by methylation to methyl selenides, of which the largest fraction is usually trimethyl selenonium. If used for selenoprotein synthesis, selenide combines with a chaperone protein, and the first metabolic step is its conversion to selenophosphate by the ATP-requiring enzyme

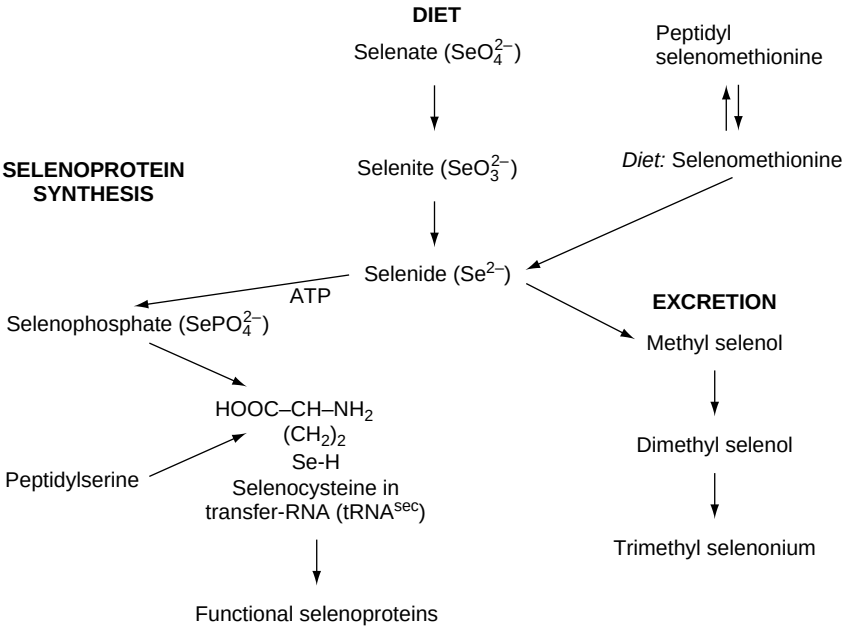

Figure 1 Interconversion of different selenium species in animal and human tissues.

selenophosphate synthetase, which is a selenoprotein. This then becomes the precursor for selenocysteinyl-soluble (or transfer) RNA, which is synthesized from a serine moiety attached to a specific soluble (transfer) RNA identified as $tRNA^{sec}$. This serine–tRNA complex is first dehydrated to aminoacrylyl–tRNA in a reaction that requires a vitamin B_6 cofactor, pyridoxal phosphate. This product then reacts with selenophosphate in a reaction that requires magnesium and the enzyme selenosynthase. The resulting selenocysteinyl–tRNA then recognizes a UGA codon in the messenger RNA sequence. This codon is also used as a stop sequence; therefore, the adjacent mRNA structure has to provide the correct 'context' (e.g., a stem-loop structure) to direct the incorporation of selenocysteine into the growing polypeptide chain of the selenoprotein. Other gene products are involved, and although the sequence of reactions and the participatory proteins have been studied in detail and largely elucidated for prokaryotes such as *Escherichia coli*, the analogous pathways are only partly understood for eukaryotes such as mammals. Specific selenoprotein synthesis is often tissue specific, with different versions of structurally similar selenoproteins being made at different tissue sites. In liver, for instance, provided that the selenium supply is generous, there is a considerable accumulation of cytosolic glutathione peroxidase type I, which can act as a storage repository of selenium for later liberation and redistribution.

Degradation of selenocysteine is catalyzed by selenocysteine lyase, which releases elemental Se, and this is then reduced to selenide by glutathione or other thiols. The urinary excretion pathway is very important for selenium homeostasis of the tissues. Urinary selenium tends to reflect recent intake rather than tissue status, but it can be a useful source of information about possible selenium overload.

Selenoproteins: Classification and Functions

Table 1 lists the selenoproteins that have been unequivocally identified in mammals, together with a summary of their main locations and known functions. Of the known glutathione peroxidases, three are tetramers and one (the phospholipid hydroperoxide-specific peroxidase) is monomeric in its quaternary structure. It appears to be this class of enzymatic activity that is critical for the action of selenoproteins in maintaining immune function, and indeed, glutathione peroxidase type I knockout mice are susceptible to viral mutation and increased viral virulence, as are selenium-deficient ones. Several other selenoproteins listed in **Table 1** also have antioxidant functions and activities. Reaction of glutathione peroxidase with peroxides yields selenic or seleninic acid at the active site of the enzyme, which is recycled by glutathione.

The three thioredoxin reductases act in conjunction with the sulfur protein thioredoxin and with NADPH to bind key transcription factors to DNA. The iodothyronine deiodinases modulate the thyroid hormones, helping to ensure an optimal supply of the

Table 1 Selenoprotein description and functions

Selenoprotein	*Molecular description*	*Function*
Glutathione peroxidases (GPx)		Removal of potentially harmful peroxides and modulation of eicosanoid synthesis
Type I	Tetramer	>50% of total Se in body; acts as Se buffer/store
Type II	Tetramer	May protect the intestine
Type III	Tetramer	Found in plasma and milk; synthesized in kidney
Type IV	Monomer	Phospholipid hydroperoxide GPx; abundant in testis; resistant to Se deficiency; involved in eicosanoid metabolism
Thioredoxin reductases (types I, II, III)		Transfers protons from NADPH via bound FAD to thioredoxin; regulates gene expression by redox control of binding of transcription factors to DNA; needed for cell viability and proliferation; can reduce dehydroascorbate and ascorbate radical to ascorbate
Iodothyronine deiodinases (types I, II, III)		Type I acts in liver and thyroid gland to convert T_4 to T_3; the other types occur in other tissues and also help to regulate thyroid hormone levels
Selenophosphate synthetase		Synthesizes selenophospate from selenide + ATP as first step in selenocysteine synthesis during Se incorporation into selenoproteins
Sperm mitochondrial capsule selenoprotein		Sperm structural protein required for integrity of sperm tail and its mobility; also an antioxidant, similar to GPx IV
Prostate epithelial selenoprotein	15 kDa	In epithelial cells; possibly redox function, similar to GPx IV
Selenoprotein P		Accounts for 60–80% of plasma selenoproteins; contains up to 10 selenocysteines per molecule; has a transport function; binds mercury; may protect the cardiovascular system and endothelial cells
Selenoprotein W	10 kDa	Small antioxidant protein found in muscle (+ heart); its loss may account for white muscle disease of sheep
18-kDa selenoprotein (SELT)		In kidney and many other tissues; not easily depleted in Se deficiency
SELR, SELN	12.6 and 47.5 kDa, respectively	
Spermatid selenoprotein	34 kDa	In sperm nuclei and in stomach; has GPx activity

There are 30–50 proteins that contain Se, as detected by ^{75}Se-labelling in mammals, only about half of which have been investigated.

most active member of the thyroid hormones, triiodothyronine. The different selenoprotein deiodinases are found at different sites in the body. If selenium and iodine are deficient in a human population, the thyroid deficiency is more severe (and goiters are larger) than if only iodine is lacking. This situation is endemic in some areas of central Africa, including Kivu province in the Central African Republic (formerly Zaire).

The sperm mitochondrial capsule selenoprotein has a structural as well as an enzymic role, and it is responsible for both the maintenance of motility and the structural integrity of the tail of the sperm. Both human and other mammals exhibit reduced sperm motility and increased sperm rupture under conditions of low selenium supply. A study in Glasgow, Scotland, recorded enhanced sperm motility and fertility in men who received a selenium supplement.

The precise functional roles of selenoproteins P and W are not well understood. Selenoprotein P contains more selenium (up to 10 atoms per molecule) than any other mammalian selenoprotein, and it can form equimolar selenium–mercury complexes, thereby probably helping to detoxify mercury. It is the major selenoprotein found in plasma and may also act as a selenium transport protein and selenium reserve. Selenoprotein W is found in muscle, and its decline may help explain the molecular basis of white muscle disease in selenium-deficient sheep.

Other selenoproteins have been characterized by their molecular size but not by their functions and health significance (**Table 1**).

Selenium Deficiency, Viral Disease and Mutation, and Immune Function

Initially, Keshan disease was thought to be a deficiency disease alone, involving inadequate intakes of

Se and also of Mo, Mg, and thiamin. However, seasonal variations in symptoms suggested that at least one other interacting factor was likely involved. Later, an enterovirus and a Coxsackie virus (strain B4) were isolated from affected individuals. The same Coxsackie virus was able to produce severe heart pathology in mice when they were fed Se-deficient grain from Keshan endemic areas.

Coxsackie virus strain B3, when introduced into Se-deficient mice, produces a myocarditis that is similar to that of human Keshan's disease, and this virus consistently undergoes mutation at six distinct amino acid (= nucleotide) sites in the Se-deficient but not the control animals. These mutated viruses are then able to produce myocarditis even in selenium-replete control mice. Thus, the virulence change has become permanent by mutation, and the increased virulence is no longer dependent on a simultaneous lack of selenium. Comparable selenium limitation-induced mutations in influenza virus have also been shown in Se-deficient mice. It is suggested that in the presence of a low selenium supply, a normally quiescent virus may become activated by increased oxidative stress and host cell apoptosis, the mutation to increased virulence being a survival strategy by the virus.

In HIV-infected individuals, the progression to AIDS and the decline in T helper (CD4) cell counts are accompanied by a parallel decrease in blood selenium levels. Selenium deficiency appears to increase the probability of mortality in HIV-infected subjects.

Human selenium supplementation (e.g., 200 μg/day), even in apparently selenium-replete individuals receiving a diet providing >120 μg Se/day, was able to stimulate the proliferation of activated T cells of the immune system. It elicited an enhanced response to antigen stimulation, an enhanced ability to generate cytotoxic lymphocytes, an enhanced ability to destroy tumor cells, and increased natural killer cell activity. Growth-regulatory interleukin-2 receptors on the surface of activated lymphocytes and natural killer cells became upregulated.

In a study in Liverpool, UK, healthy adult subjects with initial plasma selenium concentrations below 1.2 μmol/l were given placebo or 50 or 100 μg daily supplements of selenium as selenite for 15 weeks. After 6 weeks, they were given oral live attenuated polivirus vaccine, and after 9 weeks, ^{74}Se stable isotope was given intravenously to measure their body Se pool size. The Se supplements significantly increased the Se pool size, and the supplemented groups cleared the poliovirus more rapidly and their fecal viral RNA products exhibited fewer mutations. Cellular immune response (estimated by interferon-γ and other cytokines) was enhanced and there was an earlier peak of T cell proliferation and numbers in the supplemented groups. This study suggests that selenium supplements can improve a number of indices of immune function, even in individuals whose Se status is not severely deficient.

Selenium Distribution, Status Assays, and Dietary Reference Values

In an adequately supplied adult male human subject, the total body selenium content is on the order of 30–60 mg, of which one-third is found in the skeleton and two-thirds in the soft tissues. A substantial fraction of kidney selenium is retained even when selenium at other sites is severely depleted during deficiency, and renal selenium is more constant between human populations than selenium in other tissues or body fluids. Regulation of selenoprotein synthesis at the transcription level appears to ensure a hierarchy of preservation of individual selenoproteins at critical sites. The cytosolic glutathione peroxidase (GPx I) and selenoprotein P can donate selenium to other sites whenever overall depletion occurs. Selenium crosses the placenta readily, and breast milk selenium concentration is responsive to changes in maternal selenium intake. In the United States, breast milk Se concentrations are generally in the range of 0.19–0.25 μmol/l, but colostrum has levels that are two or three times higher than those of mature breast milk.

Selenium status can be measured in several ways. One recently developed and effective approach toward selenium concentration measurement is the use of inductively coupled plasma mass spectrometry. Older assays are based on the generation of selenium hydrides or fluorescent derivatives of selenium. Selenium status can be measured by its concentration in plasma or serum; in whole blood (a result that can be recalculated to provide red cell selenium concentrations); or in platelets, hair, or nails. The platelet concentration is considered to be a reliable medium-term index, whereas hair and nail concentrations can integrate selenium status, and hence intakes, over a longer term.

Glutathione peroxidase enzymatic assay in plasma or red cells is another frequently used approach to status measurement. In situations of severe to marginal deficiency, this has proven to be a sensitive and responsive index, varying consistently with variations in the selenium supply. However, once an adequate supply is achieved, there is no further capacity for increases in enzyme synthesis, and a plateau of activity is reached that does not respond

to further increases in selenium intake. Therefore, if a population exhibits a strong correlation between plasma (or red cell) selenium concentrations and glutathione peroxidase activity in blood fractions, or there is a major increase in GPx activity after selenium supplementation, this can be taken as evidence of suboptimum selenium status in the population. If there is little evidence of such a correlation or of a response to supplementation, then the population is likely to be adequately supplied. The absolute values of GPx activity are more difficult to interpret because there are many different versions of the assay in use in different laboratories, and interlaboratory harmonization has rarely been undertaken for this assay. Recent reappraisal has suggested that the plasma glutathione peroxidase (GPx III) assay may be more reliable than the blood cytosolic (GPx I) enzyme assay because haemoglobin tends to interfere with the reaction in erythrocyte extracts.

A summary of reference values and recommended intakes of selenium from three publications is presented in **Table 2**. Dietary reference values for selenium in the United Kingdom, set in 1991, were based on a number of criteria, including the facts that no evidence of deficiency was detectable in populations with intakes of 40 μg/day and that saturation of GPx in Chinese males occurred at an intake of approximately 41 μg/day (equivalent to 50 μg/day for a UK male based on a body weight comparison). On this basis, the UK Lower Reference Nutrient Intake (LRNI) was set at 40 μg/day for both male and female adults, and the corresponding RNI values were set at 75 μg/day for males and 60 μg/day for females, with lower values, proportional to body weight, for children. No extra increment was considered necessary for pregnancy, but for lactating women an additional 15 μg/day was added to both the LRNI and the RNI.

Table 2 Reference values for intakes of selenium (μg/day)[a]

Population group	*UK LRNI*	*UK RNI*	*US AI/ RDA*[b]	*WHO/ FAO RNI*
0–6 months	4–5	10–13	AI:15	6
7–12 months	5–6	10	AI:20	10
1–3 years	7	15	RDA:20	17
4–6 years	10	20	30	22
7–10 years	16	30	30–40	21–26
11–18 years, male	25–40	45–70	40–55	32
11–18 years, female	25–40	45–60	40–55	26
19–65 years, male	40	70	55	34
19–65 years, female	40	60	55	26
65 + years, male	40	70	55	33
65 + years, female	40	60	55	25
Pregnant	40	60	60	26–30
Lactating	55	75	70	35–42

USA: Food and Nutrition Board, Institute of Medicine (2000) *Dietary Reference Intakes for Vitamin C, Vitamin E, Selenium and Carotenoids*. Washington, DC: National Academy Press. WHO/FAO: WHO/FAO (2002) *Human Vitamin and Mineral Requirements. Report of a Joint FAO/WHO Expert Consultation, Bangkok, Thailand*. Rome: WHO/FAO.

More recently, selenium recommendations or reference values have been slightly lower. The US committee that set Dietary Reference Intakes in 2000 interpreted the Chinese estimate of 41 μg/day needed to saturate GPx in adult men, and data from New Zealand indicating selenium intake adequacy at 38 μg/day, as supporting an Estimated Average Requirement (EAR) of 45 μg/day for adults of both sexes, and hence an Recommended Dietary Allowance (RDA) (with 10% CV of requirements) of 55 μg/day for both sexes, increasing to 60 μg/day for pregnant and lactating women. However, RNI values set by an FAO/WHO committee, published in 2002, were much lower, at only 26 μg/day for women and 34 μg/day for men, based on the premise that full saturation of GPx is unnecessary and two-thirds saturation is probably adequate. Clearly, there has been considerable divergence of opinion between different committees, and this divergence underlies the current uncertainty about the overall adequacy of selenium intakes in many European countries, including the United Kingdom. In the United Kingdom, selenium intakes have declined considerably during the past 25 years because of the substitution of North American wheat imports by European wheat with a much lower selenium content. In contrast, selenium intakes in New Zealand have increased as a result of grain imports from Australia.

There are also recommendations for the upper limit of safe intake of selenium. For the United Kingdom, it was noted that evidence of toxicity was detectable at intakes of approximately 750–900 μg/day, and the UK panel recommended a maximum safe intake of 450 μg for adults (6 μg/kg body weight/day), which was confirmed as an official safe upper level (SUL) in 2003. In the US Dietary Reference Intakes, the upper level of 400 μg/day was based on a no adverse effect level of 800 μg/day divided by

an uncertainty (i.e., safety) factor of 2. The FAO/WHO committee also set an SUL of 400 μg/day for adults. In humans, at intakes of >3 mg/day, overt signs of selenosis include damage to nails and hair, skin and nerve lesions, mottling of teeth, nausea, weakness, and diarrhea. Urinary selenium excretion is high, and a garlic odour may be apparent in the breath.

Selenium Interventions

As noted previously, neither Keshan disease nor Kashin–Beck disease are now thought to be simple dietary deficiency diseases. They probably also involve viral components and may be exacerbated by environmental toxins, including mycotoxins. Thus, they are probably multifactorial, but importantly, public health selenium supplementation interventions have had a dramatically beneficial effect on the prevalence of these diseases. The main clinical features of Keshan disease are cardiac insufficiency and enlargement, electrocardiographic changes, and fibrosis. Those of Kashin–Beck disease are osteoarthropathy and necrosis of the joints and epiphysial plate cartilage. Both diseases occur in school-age children; Keshan disease also occurs in women of child-bearing age, but adult men are less affected.

In hilly and heavily eroded areas of China where these diseases were endemic, the use of selenium-enriched fertilizers was not feasible as an intervention because of the huge geographical areas involved and hence the high cost. Instead, direct human supplementation of at-risk and affected populations was introduced during the 1970s using a 0.5 or 1.0 mg sodium selenite supplement (according to age) per person per week. In Shaanxi province, following supplementation, the prevalence of Keshan disease declined from 12 per 1000 to undetectable levels between 1976 and 1985, and in Heilongjiang province the prevalence of Kashin–Beck disease declined from 44 to 1% of the population between 1970 and 1986.

An alternative approach to intervention, by selenium enrichment of crop and grassland fertilizers, was introduced in the 1970s in Finland. Here, there was no overt evidence of selenium deficiency in the human population, but Se deficiency disease had occurred, and had been successfully eliminated in farm animals, by supplementation of animal feeds during the 1960s. Fertilizer that was Se enriched at 16 mg/kg was then applied to cereal crops for human consumption. Grassland fertilizer was enriched at 6 mg/kg. As a result, adult human Se intake increased from 25–60 to approximately 100 μg/day. Serum Se increased from 65–70 μg/l in 1975 to 120 μg/l in 1989–1991. In 1990, the selenium level was reduced to 6 mg/kg fertilizer for cereal crops as a precaution against possible overload. Selenium intervention by fertilizer enrichment was judged to be a safe, economical, and easily controlled intervention.

New Zealand, which has a similar situation of marginal intakes and status, decided not to intervene on a population or nationwide basis but instead has taken steps to ensure that particular high-risk groups, notably people receiving total parenteral nutrition or children receiving special diets for phenylketonuria prevention, are adequately supplied.

Selenium and Chronic Disease

Several supplementation and epidemiological case–control studies have suggested a possible link between increased selenium intakes or status and protection against certain cancers. First, in intercountry comparisons and studies comparing different regions of the United States having different soil selenium levels, there was a consistent correlation between lower selenium levels and higher risk of cancer. A study of 34,000 male health professionals in the eastern United States found that toenail selenium levels were inversely proportional to prostate cancer incidence, with diagnoses recorded >2 years later, which helped to reduce confounding by reverse causality (i.e., the presence of cancer causing the low selenium levels). A study in China found that the incidence of hepatocellular carcinoma was lower in a community receiving selenite-fortified salt (15 mg/kg) than in adjacent control communities, and another intervention with selenium + vitamin E + β-carotene supplements seemed to reduce total age-adjusted mortality, especially from cancer. A controlled intervention in the eastern United States recorded an approximately 50% lower cancer mortality in a high-risk group of subjects who were randomized to receive 200 μg selenium/day as Se yeast for several years. Animal model studies have demonstrated reduced susceptibility to cancer induction with increased selenium intakes. Although these studies appear promising, caveats about their design and interpretation imply that none yet conclusively prove the hypothesis that additional dietary selenium is able to reduce human cancer morbidity and mortality. Trials in multiple locations (including Europe)—PRECISE (Prevention of Cancer by Intervention with Selenium) and SELECT (Selenium and Vitamin E Cancer Prevention Trial)—are ongoing and should help to resolve this important question.

Attempts to demonstrate disease-reduction benefit with respect to cardiovascular disease by selenium intervention have proven disappointing, despite the

theoretical benefit of lipid peroxide removal by GPx and apparently beneficial changes in intermediate markers such as platelet aggregation, vasoconstriction, and thromboxane:prostacyclin ratios following supplementation. Further studies of high-risk populations are needed, including a focus on the concerted action by combinations of selenium and vitamin E.

Other conditions for which supplementary selenium has been claimed to be beneficial include rheumatoid arthritis, pancreatitis and asthma, and mood alterations. Again, further studies are required.

Conclusion

The essential role of selenium in human nutrition and its discrete biochemical functions are rapidly being characterized. Severe deficiency and selenosis (toxicity) occur in different regions and are manifested by characteristic and life-threatening human diseases. The selenoproteins have a wide variety of roles, both catalytic and noncatalytic. Interactions with redox pathways appear to be common. Selenoprotein P, in particular, appears to play an important detoxification role. Selenium appears to play an important role in cell-mediated immunity. Selenium deficiency can cause viral mutation leading to increased virulence, and such mutation and its consequences appear permanent. Optimum human intakes of selenium are still a matter of debate because some studies have reported benefits (e.g., anticancer and immunological effects) when supplements are given, even to populations that appear to be generously supplied with the nutrient. The distinction between nutritional and pharmacological benefits is unclear, and further trials to determine risk–benefit balance at different intake levels are needed in a range of populations and age and gender groups.

Structure and Function
Disorders

Structure and Function

D Rumsey, University of Sheffield, Sheffield, UK

The small intestine is the barrier between the external environment and the interior of the human body that all nutrients must pass; it is the organ of nutrition. Absorption of nutrients across the barrier is only possible following the complex process of food digestion. Both processes occur largely within the small intestine. Complete digestion and absorption only take place if the optimal motility patterns of the small intestine occur. Each facet of small intestinal function, absorption, digestion, and motility is dependent on the other to produce human nutrition.

Furthermore, within the physiology of the small intestine, regulatory mechanisms exist to alter the rate of nutrient absorption, signal the passage of nutrients, and change the phases of metabolism. The complexity of function in the small intestine is also related to its structure, architecture, and cellular kinetics.

Structure of the Small Intestine

The small intestine is the main site of digestion and absorption within the gastrointestinal tract. It is a hollow tube greater than 6 m in length with a lumenal diameter of approximately 4 cm. The first 20 cm distal from the pylorus is the duodenum, the next 2.5 m is the jejunum, and the final half is the ileum. There are no anatomically distinguishing characteristics along the small intestine; any alterations in architecture are gradual.

All segments of the small intestine possess a mucosa with the same sophisticated structural pattern along its length. The mucosal lining is surrounded by two muscle layers. The first innermost layer consists of circular smooth muscle sheets orientated radially around the lumen. The second thinner layer of longitudinal sheets is surrounded by a thin serosal layer. The regulation of muscular movement (motility) is achieved by the enteric nervous system, which consists of two matrices of interconnecting neurones. The first (outermost) matrix is the myenteric plexus situated between the two muscle layers. Underneath the mucosa and above the circular muscle layer is the submucosal plexus, from which extend sensory neurones into the mucosa. Interneurons connect the two plexi, which in turn receive postganglionic parasympathetic nerve fibers.

The enteric nervous system is a highly complex network exhibiting a high degree of autonomy over gut function and employing as many as 20 neurotransmitters and neuromodulators as well as the classical neurotransmitter mechanisms of the autonomic nervous system. The enteric nervous system is only surpassed by the brain and spinal chord in its capacity for information processing.

Mucosal Structure

The lining of the small intestine is remarkably adapted for the function of absorption by increasing the surface area for transmucosal transport at three levels (**Figure 1**):

- The inner surface has circular folds, which increases the area by approximately 3-fold.
- The mucosa projects from the folds into the lumen with finger-like structures called villi approximately 1 mm in length. Villi increase the surface area by an additional 10-fold. The surface of each villus is covered with epithelial cells known as enterocytes. Absorption takes place across the enterocyte barrier.
- Small hair-like filaments known as microvilli project from the luminal surface of each enterocyte into the lumen. Microvilli increase the surface area for absorption by an additional 20-fold.

The three structures combine to increase the surface area by approximately 600-fold.

Each villus is supplied with its own connective tissue support known as the lamina propria, its own arteriolar and venous microcirculation with capillaries draining the basolateral regions of all the enterocytes, and its own lymphatic system.

Cell Kinetics of the Enterocyte

The life span and kinetics of small intestinal enterocytes are particularly important in understanding the process of absorption. Enterocytes have a

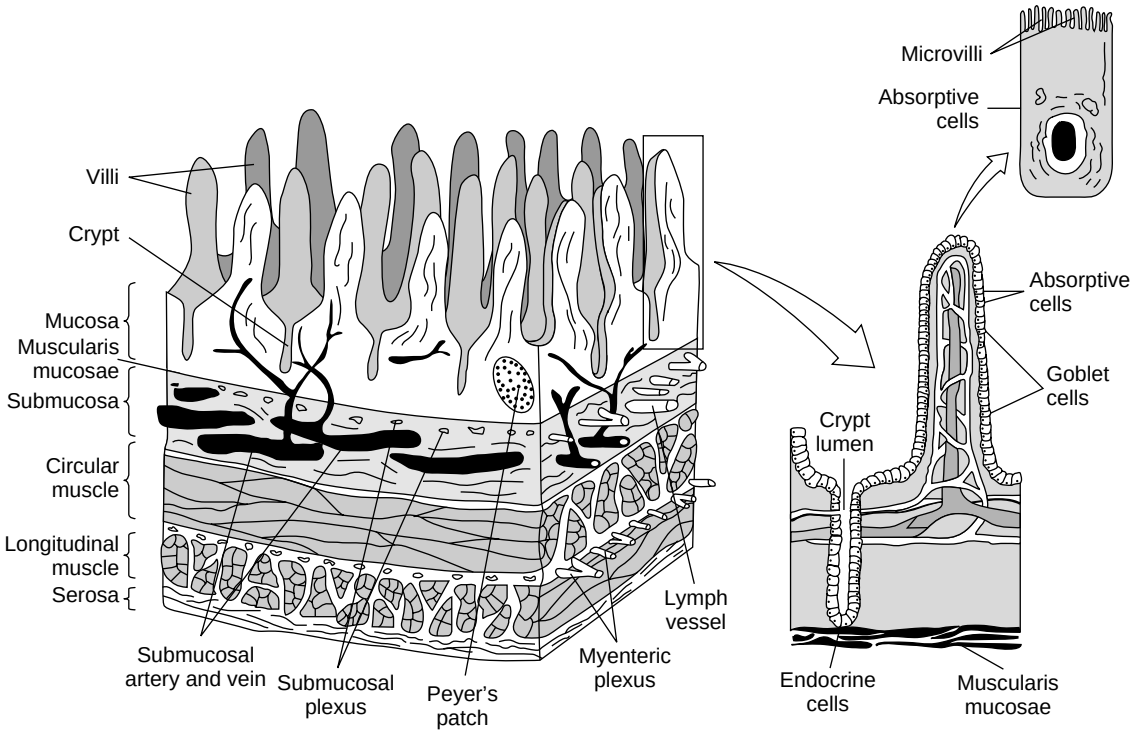

Figure 1 Wall of the small intestine. The intestinal surface area is enhanced by finger-like villi.

particularly short life and the epithelium of the small intestine is replaced every 3–6 days, making it one of the fastest growing tissues in the body. The high mitotic rates in small intestinal crypts make the tissue particularly vulnerable to irradiation and cancer chemotherapy. New cells are born in a proliferative zone within the crypts of Lieberkuhn below the villus.

After birth, new cells move in the direction of the lumen and mitosis continues for two or three more divisions while each cell remains within the crypt. As the enterocyte emerges out of the crypt, proliferation ceases and the process of differentiation proceeds so that the cell, now passing up the outer surface of the villus, reaches functional maturity with a full capacity of membrane-bound brush border enzymes toward the villus tip. On reaching the tip, enterocytes are sloughed off into the intestinal lumen and digested.

The short life span of the enterocyte bestows massive adaptive potential within the tissue since the rate of differentiation may be influenced by changes in any nutrient or other luminal factor to induce a rapid functional response.

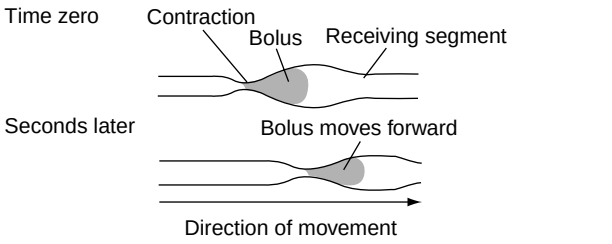
Motility

Vigorous controlled movement of the intestinal wall is essential for the two basic properties of segmentation or mixing and peristalsis or aboral propulsion (**Figure 2**). The two properties are interdependent since neither segmentation nor peristalsis alone would result in optimal digestion and absorption. The peristaltic export of chyme from the duodenal segment in an aboral direction is only effective following considerable segmentation mixing to optimise the homogeneous distribution of digestive juices digestion.

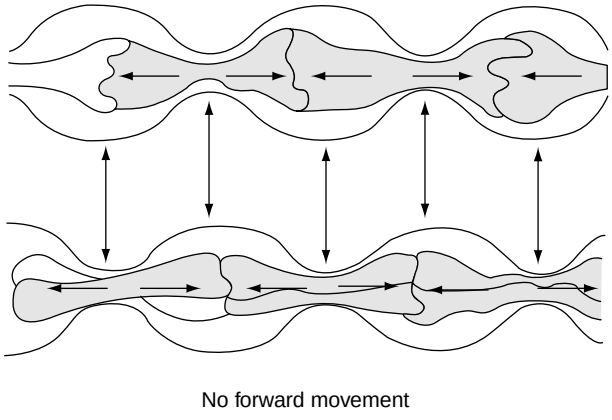
Although the neural basis of peristalsis has been acceptably modeled, answers to basic questions concerning the receptors involved and the occurrence of reverse or retroperistalsis in particular circumstances remain elusive. The precise sensory messages that are needed to switch motility from segmentation to peristalsis and vice versa are also unclear, except that the signals must be both chemical and physical since they are related to the passage and characteristics of the nutrients along the gastrointestinal tract.

Migrating Motor Complex

When the small intestine is emptied after the passage of a meal, segmentation contractions stop and is replaced by a pattern of motility called the migrating motor complex (MMC). The MMC is a series of weak peristaltic rushes in the aboral direction, but each rush only occurs along a short distance of the total length. The series begins at the level of the stomach and takes



(A)



(B)

Figure 2 Contractions in the gastrointestinal tract. (A) Peristaltic contractions are responsible for forward movement. (B) Segmental contractions are responsible for mixing.

approximately 2 h to reach the ileo-caecal valve at the distal ileum. It is considered that the MMC performs a 'housekeeping' function by sweeping debris, such as sloughed cells, residual chyme, and bacteria, aborally in the interval between meals. MMCs continue in the absence of eating. When food is introduced into the stomach, MMC patterns are replaced by segmentation contractions.

Passage of Chyme along the Small Intestine

Chyme is expelled from the stomach into the duodenum in 'packets' in response to the hormonal (cholecystokinin and secretin) influence on gastric emptying. The aqueous component of the meal is emptied first as larger solid particles are reduced by the activity of the gastric musculature. The lipid component of the meal is liable to separate within the stomach lumen and remain as one of the last fractions of the meal to be emptied.

Chyme appears to mix rapidly within the duodenum presumably by rapid segmentation action, and the early parts of the meal pass rapidly along the duodenum and jejunum possibly because the nutrient content of this initial packet is aqueous and therefore lower. Some observations suggest that certain meals produce retroperistaltic movements within the proximal small intestine.

The transit rate of chyme is reduced gradually through the second half of the small intestine, the ileum. The remnants of the meal are released across the ileo-caecal valve as the pressure of contents within the ileum rises.

Nutrient Regulation of Motility and Transit

Traditional experimental techniques in which simple nutrient substrates were introduced by tube into the 'starved' human duodenum found that, under these conditions, most nutrients were absorbed immediately within the proximal tenth of the small intestine. Real food offers a more complex problem for the small intestine since the processes of digestion have only been initiated within the lumen of the stomach. It is apparent that the major part of digestion takes place along a significant fraction of the whole small intestine, with the processes of absorption occurring, as a consequence, along the majority of segments. Certainly, enterocyte functional capacity on ideal villi is comparable to that on the jejunum.

These observations have been supported by findings that meals of a high nutrient density are more slowly emptied from the stomach and pass along the small intestine at a reduced rate. Evidence exists for a regulatory mechanism situated within the mucosa of the terminal ileum capable of sensing nutrient presence such as lipid and providing feedback restraint on motility patterns in the stomach, duodenum, and jejunum to slow the passage of meals in proportion to their nutrient density. This mechanism has been called the 'ileal brake' and, taken with the hormonal control of gastric emptying, explains the almost complete absorption of meals of the highest nutrient density.

Digestion

The chyme from the stomach is mixed in the duodenum with digestive juices from three sources: the pancreas, liver, and intestinal mucosa. The pancreas is an elongated gland situated beneath the stomach with two roles essential for human nutrition (**Figure 3**). Exocrine pancreatic function is the production of pancreatic juice for secretion into the duodenal lumen. Pancreatic juice is a potent mixture of enzymes and solutes that are essential for the process of digestion of protein, lipid, and carbohydrate and for producing the optimal pH environment within the duodenal lumen. Juice is secreted as an ultrafiltrate of plasma from acini, composed of clusters of secretory cells connected to ducts. The composition of these secretions is listed in **Table 1**.

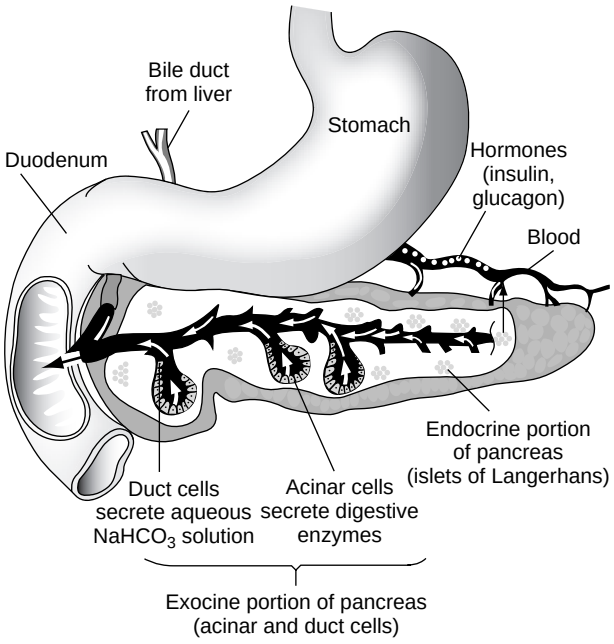


Figure 3 Exocrine and endocrine portions of the pancreas (glandular portions of the pancreas are grossly exaggerated). The exocrine pancreas secretes into the duodenal lumen a digestive juice composed of digestive enzymes secreted by the acinar cells and an aqueous $NaHCO_3$ solution secreted by the duct cells. The endocrine pancreas secretes the hormones insulin and glucagon into the blood.

The second function is the endocrine secretion of the hormones of intermediary metabolism, insulin and glucagon, into the hepatic portal vein supplying blood to the liver. The roles of insulin and glucagon in nutrition are discussed elsewhere.

Pancreatic Juice

The bulk of pancreatic secretion is a dilute solution of sodium bicarbonate ($NaHCO_3$) that neutralizes the acid effluent from the stomach and provides an alkaline environment for the enzymes present in the secretion (**Table 2**).

Table 1 Volumes absorbed by the small intestine per day

	Volume (ml)
Volume entering the small intestine	
Ingestion	
– Food	1300
– Drinks	1300
– Saliva	1500
– Gastric juice	2000
– Pancreatic juice	1500
Plasma secretions	
– Bile	500
– Intestinal secretion	1500
Total	9600
Volume absorbed by the small intestine	9000
Volume passing through the ileoaecal valve	600

Table 2 Constitutents of pancreatic juice

Secretion	*Function*
$NaHCO_3$	Establishes pH environment (pH 7–8)
Amylase	Digests complex carbohydrate
Carboxypeptidase	Digests proteins and polypeptides
Chymotrypsin	Digests proteins and polypeptides
Elastase	Digests elastin
Trypsin	Digests proteins and polypeptides
Lipase	Digests triacylglycerol
Nuclease	Digests nucleic acids

Enzymes Pancreatic proteolytic enzymes are secreted in an inactive form to avoid digestion of pancreatic tissue. Once within the duodenal lumen, the main enzymes, trypsin, chymotrypsin, and carboxypeptidase, are liberated and attack different peptide linkages in the protein molecule. Pancreatic amylase converts polysaccharides into smaller saccharide molecules, particularly disaccharide.

Pancreatic lipase is the only source for the enzymatic digestion of fat. Lipase hydrolyzes dietary triglycerides to monoacylglycerols and free fatty acids. Deficiency of pancreatic lipase results in serious fat malabsorption. Pancreatic amylase and peptidase deficiency is less serious since small intestinal enzymes would significantly minimize any loss of activity.

Regulation of Pancreatic Secretion

Pancreatic juice is stimulated to flow in response to increases in the blood concentrations of two gastrointestinal hormones, secretin and cholecystokinin. Both hormones are liberated from the duodenal mucosa in response to different components of the luminal environment. Secretin is secreted in response to acid and stimulates the pancreatic acini to secrete $NaHCO_3$ so that the acid contents emerging through the pylorus are neutralized.

Cholecystokinin (CCK) secretion is prompted by the presence of both lipid and protein in the duodenal lumen, and the effect of CCK on pancreatic acini is to promote the secretion of enzymes. All three types of pancreatic enzymes are stored in zymogen granules within the acinar cells and released into the ducts on stimulation. As the final components of the meal leave the stomach, acid and nutrient levels fall in the lumen and pancreatic secretion ceases.

Parasympathetic nerve stimulation is also recognized to produce a small stimulation of pancreatic juice flow probably as part of the cephalic and

gastric phases, preparing the duodenal environment for a meal.

The Role of Bile

The second main source of secretion is bile. Bile is formed in the liver canaliculi and passes down the bile duct into the duodenum. The opening of the bile duct into the duodenum, the sphincter of Oddi, is controlled by cholecystokinin levels. When the sphincter of Oddi is closed, bile is diverted and stored in the gall bladder.

Bile is a solution of $NaHCO_3$, similar to pancreatic juice, without enzymes and including a number of organic solutes, of which the bile salts are essential for the digestion of fat. Bile salts have a detergent action that emulsifies the large droplets of dietary fat into a water-soluble form, a micelle, rendering the fat molecules available for hydrolysis by pancreatic lipase.

Intestinal Mucosal Secretions

In contact with chyme, the intestinal mucosa secretes a mucous-containing watery fluid into the lumen that is devoid of enzymes. The mucous protects and lubricates, and water is necessary in excess for the multiple hydrolytic processes of digestion. Pancreatic juice is the sole source of digestive enzymes within the lumen of the small intestine. Enzymes are present within the intestinal mucosa but fixed in the enterocyte cell membrane.

Nutrient Absorption

Absorption is the transfer of the products of digestion together with minerals, micronutrients, and water from the gut lumen into the blood. The mucosa of the small intestine is adapted structurally to optimize nutrient absorption and enterocytes possess specific transport mechanisms to facilitate transport. The mechanisms responsible for the absorption of lipid molecules are significantly different from those governing the absorption of other nutrients.

Sodium absorption is central to the absorption of the majority of nutrients and is therefore considered first. Indeed, the interdependence of sodium, water, and nutrients, particularly sugars, is an important element in nourishment under pathological conditions, for instance, in considering the rationale for rehydration therapy. The enterocyte membrane possesses carrier proteins for the transport of specific substrates. A specific sodium transporter exists on the enterocyte basolateral membrane exporting sodium from the cell by an energy-dependent process. The effect of the sodium transporter is to maintain the low intracellular sodium concentration.

Different processes permit the passage of the sodium ion to pass from the lumen into the enterocyte across the mucosal membrane. Sodium may pass by passive diffusion down its concentration gradient or be transported by a (second) luminal transporter in association with nutrients such as glucose and amino acids. Also, some sodium may diffuse between the cells directly into the interstitial spaces. Water molecules follow sodium ions across the membranes.

Carbohydrate Absorption

The absorption of carbohydrate molecules is directly linked to the final stage of digestion (**Figure 4**). Luminal carbohydrate digestion produces largely the disaccharide molecules sucrose, lactose, and maltose. The enterocyte luminal membranes are richly endowed with disaccharidases, which hydrolyze the disaccharides to the monosaccharides glucose, fructose, and galactose. These membrane-bound enzymes are now considered to be associated with the protein transporter molecules described previously that facilitate the transport of sodium across the enterocyte luminal membrane. Sugars are cotransported with sodium ions against their own concentration gradients—a process of great nutritional value. Once concentrated within the enterocyte, the sugars pass by facilitated diffusion across the basolateral membrane into the interstitial spaces and from there diffuse into the capillaries of the intestinal villus.

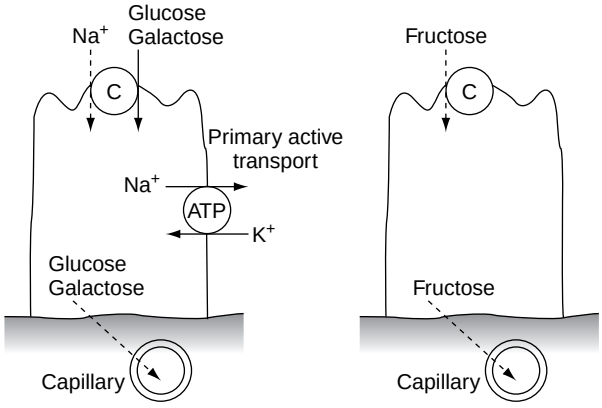

Figure 4 Carbohydrate absorption mechanisms. (Left) Secondary active transport: Glucose and galactose are absorbed using Na^+ cotransport systems. Sodium ions are removed using the (Na^+-K^+)-ATPase pump (primary active transport). (Right) Facilitated diffusion: Fructose absorption is passive but relies on a carrier molecule. Solid arrow, movement against concentration gradient; broken arrow, diffusion down concentration gradient; ATP, ATP-dependent pump; C, carrier molecule.

Protein Absorption

Similar to carbohydrate, protein digestion is incomplete within the lumen of the small intestine. However, considerably more amino acid has been produced through protein digestion, and amino acids are absorbed by secondary cotransport with sodium ion in the same manner as sugars. Some simpler dipeptides remain within the lumen, and these final peptide bonds are hydrolyzed by aminopeptidase enzymes within the enterocyte luminal membrane (**Figure 5**).

Lipid Absorption

The rate of gastric emptying is regulated to deliver packets of fat into the duodenum that may be easily digested and assimilated without overloading. The avoidance of duodenal overload is dependent on the efficacy of the neural and hormonal feedback mechanisms regulating gastric emptying and intestinal transit, the ileal brake.

The absorption of fat is a different process from that of carbohydrate and protein by virtue of the insolubility of the molecules of lipid in water (**Figure 6**). The products of lipase digestion, fatty acids and monoacylglycerols, are insoluble and so cannot diffuse through the chyme to reach the enterocyte membrane. The role of micelles produced by the action of bile salts is carriage of the lipid molecules to the enterocyte luminal membrane, where the fatty acids and monoacylglycerols diffuse from the micelle through the lipid component of the membrane to enter the enterocyte cytoplasm.

On this basis, the process of transport has always been assumed to be passive diffusion. Recently, it has been demonstrated that some carrier-dependent mechanisms are implicated. The observation that carrier dependency may be specific for certain lipids suggests that these pathways may be relevant at low lipid concentrations when the absorption of such lipids has priority. For the absorption of dietary levels of lipid, the main process of transport is probably passive diffusion, the rate being dictated by the concentration of luminal lipid.

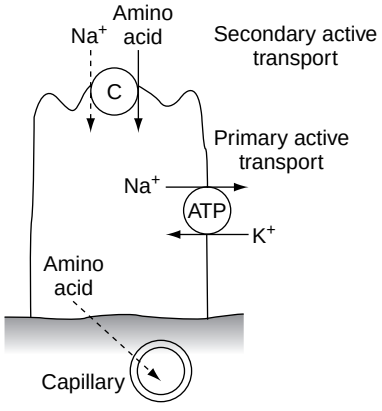

Figure 5 Amino acids (and some short peptides) are absorbed by secondary active transport using Na^+ cotransport. Solid arrow, movement against concentration gradient; broken arrow, diffusion down concentration gradient; ATP, ATP-dependent pump; C, carrier molecule.

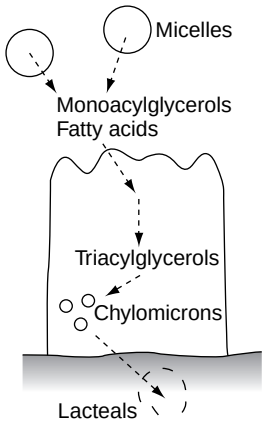

Figure 6 Lipids are absorbed by diffusion after digestion to monoacylglycerols and fatty acids. These are reconstituted into triacylglycerols and packaged as chylomicrons within the cell before entering intravillous lymphatic vessels (lacteals); these have an open endothelium (broken outline) and are therefore more permeable to larger particles than are the blood capillaries.

Lumenal micelles that have donated their fat burden across the mucosa are then free to take up more lipid from the droplet pool. Once within the enterocyte, long-chain fatty acids are bound to specific fatty acid binding proteins and transported from the cell membrane to the rough endoplasmic reticulum, where they are reesterified to reform triacylglycerols.

The intracellular triacylglycerol droplets are covered with a protein coat called apolipoprotein, which rerenders the lipid soluble once more. The coated droplets are called chylomicrons. Chylomicrons pass across the basolateral membrane of the enterocyte by exocytosis into the interstitial spaces, where they are inhibited from passing into villus capillaries by the basement membrane. Instead, chylomicrons pass into the lacteals of the villus and, from there, into the lymphatic system draining into the circulation at the great lymphatic duct behind the right atrium of the heart.

The luminal concentration of lipid, largely responsible for the rate of absorption, is more dependent on optimal intestinal mixing, peristalsis, and transit than other nutritional components.

Absorption of Minerals

Mineral absorption is normally proportional to dietary intake, with two important distinctions—the

absorption of iron and calcium, both of which can be regulated according to the needs of the body. Calcium absorption is related to the amount of specific binding protein within the enterocyte. The concentration of the calcium binding protein, which regulates calcium uptake from the gut, is secondary to vitamin D levels.

Iron absorption occurs in the duodenum and proximal jejunum. Following digestion, iron is in two forms. The first is haem iron bound to hemoglobin and myoglobin. The second form is free ionized iron in the ferrous and ferric state. Hem iron is absorbed by binding to a probable hem receptor, whereas free iron is likely to be absorbed by a specific carrier protein. Free iron is cytotoxic, so it is bound inside enterocytes to the large storage protein, apoferritin, or bound to transferrin for export to the bloodstream.

Absorption of Vitamins

Water-soluble vitamins are absorbed with water, many by sodium-dependent active transport, and fat-soluble vitamins are absorbed dissolved within the fat droplets in micelles. Vitamin B_{12} is unique in that it may only be absorbed combined with the gastric intrinsic factor by a specific mechanism in the distal ileum.

Gastrointestinal Hormones

The gastrointestinal hormones are a group of peptide molecules that increase in number every year. Most are extremely potent biological agents exerting their action at some distance from the site of secretion (endocrine) or close to the site of release (paracrine). The hormones are secreted in granules from entero-endocrine cells within the gastrointestinal mucosa in response to nutrient signals from the lumen. The precise physiologies of most of these molecules are still being clarified and the following review is restricted to those peptides on which there is broad agreement (**Table 3**).

Gastrin

Gastrin is secreted from the gastric antral mucosa in response to food in the stomach, particularly a meal high in protein. Gastrin passes into the blood and stimulates a large range of responses along the whole gastrointestinal tract involving both secretion and motility. The general physiology of gastrin is that of a promoter of gut function as food begins to pass along the gut and as a remover of the remnants of the previous meal. Gastrin secretion ceases as acidity rises within the stomach and duodenum.

Secretin

Secretin is produced by cells in the duodenal mucosa in response to the appearance of acidity and chyme. It performs at least four major functions associated with the passage of the meal through the duodenum. It stimulates the pancreatic duct and acinar cells to produce copious aqueous $NaHCO_3$ solution, it

Table 3 Functions of the major gastrointestinal hormones

Hormone	*Stimulus*	*Function*
Gastrin	Protein in the stomach	Stimulates gastric secretion Promotes gastric motility Promotes ileal motility Promotes colonic motility Relaxes ileocaecal valve Trophic action on gastric and intesintal mucosae
Secretin	Acid in the duodenum	Inhibits gastric secretion Inhibits gastric motility Stimulates pancreatic juice flow Stimulates bile flow (HCO_3) Trophic action on pancreatic exocrine tissue
Cholecystokinin	Fat/protein in duodenum	Inhibits gastric secretion Inhibits gastric motility and gastric emptying Stimulates pancreatic enzymes Gall bladder contraction Sphincter of Oddi relaxation Trophic action on pancreatic exocrine tissue Satiety signals
GIP	Duodenal chyme	Inhibits gastric emptying Inhibits gastric secretion Stimulates insulin secretion from pancreatic islets

GIP, glucose-dependent insulinotrophic peptide.

promotes a bicarbonate-rich bile flow, it inhibits gastric emptying, and it inhibits gastric secretion. The secretin secretion rate decreases as acidity production from the stomach decreases.

Cholecystokinin

Cholecystokinin is secreted from the same general duodenal mucosa as secretin but in response to the lipid and protein components of the meal. CCK has multiple roles that are not completely clear. The CCK molecule exists in a number of peptide chain lengths, each with differing properties but all with extreme potency. The effects of an elevation in CCK are as follows: Cholecystokinin is the main inhibitor of gastric emptying, slowing the release of nutrient-dense chyme from the stomach at a rate that is proportional to duodenal and pancreatic digestive function. CCK stimulates enzyme secretion from the pancreatic acinar cells and causes contraction of gallbladder wall muscle and relaxation of the sphincter of Oddi, allowing bile to flow into the duodenum.

Cholecystokinin levels directly influence levels of satiety and the perception of fullness in association with meals. Therefore, the signalling of fullness to the brain by means of CCK release is one possible pathway for the peripheral control of food intake and is of particular importance not least by virtue of the presence of CCK receptors known to be present within brain tissue. CCK secretion is inhibited by the absence of nutrients in the duodenal lumen.

GIP

Glucose-dependent insulinotrophic peptide is also known as gastric inhibitory peptide. GIP is the third duodenal peptide hormone now recognized to be the 'incretin' peptide important for the mobilization and attenuation of the insulin response to glucose as it is absorbed from the small intestine. GIP initiates the meal stimulus of the pancreatic islets, heralding the absorptive phase of metabolism. Lipid, carbohydrate, acid, and duodenal distension all serve to promote the secretion of GIP from the duodenal mucosa.

Trophic Action of Gastrointestinal Hormones

The gastrointestinal hormones gastrin, cholecystokinin, and secretin are recognized to possess trophic properties in that they are responsible for maintaining the cell populations of their target tissues. In the case of gastrin, the tissue in question is the gastric mucosa but also the intestinal mucosa; cholecystokinin and secretin are trophic for pancreatic acinar tissue.

Disorders

R D'Souza and J Powell-Tuck, Queen Mary's, University of London, London, UK

The small intestine is bathed in nutrients derived from food digested by salivary, gastric, and pancreatic enzymes and dispersed by the emulsifying effect of biliary secretions. Its mucosal cells are in intimate relationship with these nutrients, a wide variety of antigens, and the bacterial flora. This relationship is fundamental to small bowel function, which is both secretory and absorptive, providing a defense from bacteria while allowing absorption of both small and large molecules. The relationship is also crucial to the patterns of intestinal motility, which optimize mixing and surface contact during the postprandial phase and revert to a flushing, "housekeeper" role postabsorptively. Diseases of the small bowel represent a breakdown in these relationships, which characteristically result in a failure of normal absorption, inflammation, and abnormal secretory responses. The small intestine plays a fundamental role in completing digestion and absorption of carbohydrates, proteins, fats, minerals, and vitamins. Any disorder of the small intestine in its digestive or absorptive capacity or of its immune system may lead to nutritional abnormalities.

Food and Bacterial Interaction

Bacteria—anaerobes, lactobacilli, enterococci, and gram-positive aerobic organisms—colonize the gut after birth; in the upper small intestine there are 10^2–10^3 bacteria/ml and up to 10^9 bacteria/ml are present in the distal small intestine. The small intestine acts as an effective barrier, and together with the innate and acquired immune system, defends the body against foreign microorganisms. Bacteria,

derived from ingested food that is rarely sterile, colonize the gastrointestinal tract soon after birth. After eating, more than 100 species of bacteria are found in the upper small intestine but ingested bacteria are greatly reduced in number by gastric juices in the hour following the meal. The bacteria in the distal small intestine are not affected by the gastric secretions. The human gut has mechanisms to protect itself against environmental agents that are foreign to the body (immunity). Immunity can be either innate or acquired. Innate immunity comprises those defense mechanisms that a person is born with that can be mobilized on very short notice. There are a multitude of innate mechanisms that include barriers to infection (thick mucus, ciliary action, and gastric acid), phagocytic cells (neutrophils and macrophages), defense due to complement and humoral (antibody-mediated) mechanisms, and antibactericidal peptides such as α-defensins, trefoil factor peptides, and cathepsin G secreted by intestinal epithelial cells and Paneth cells at the base of the intestinal crypts. Adaptive immunity is more specialized and produces both a humoral and a cell-mediated immunity. It differs from innate immunity in that it remembers a previous infection and responds quickly to reexposure to a known foreign substance. Bacteria in the intestinal lumen are probed by dendritic cells, which reach out into the lumen to sample the bacteria and present them to lymphocytes in the lymphoid tissue present in the gut wall. Intestinal M cells achieve similar presentation by importing bacteria into the intestinal lymphoid tissue.

Infections/Food Poisoning

The vitally important area of food poisoning is dealt with in more detail elsewhere. This section outlines the principal infections affecting the small intestine. Bacteria such as *Campylobacter jejuni*, enteroinvasive *Escherichia coli* (EIEC), shigella, salmonella, and yersinia can cause food poisoning, which is dominantly colitic (dysentery) with a bloody, pus-containing diarrhea, by invading the mucosal surface. Enterohemorrhagic *E. coli* produce a bloody diarrhea secondary to adherence in the colon and toxin production. These then dominantly affect the colon. Yersinia and (non-typhoid) salmonella dominantly invade the lower small bowel (ileum), producing low abdominal pain and diarrhea. Yersinia infection can be acute or occasionally more chronic, mimicking Crohn's disease. Tuberculosis is another chronic infection that can affect especially the terminal ileum and mimic Crohn's disease. Other infective agents, such as enterotoxigenic *E. coli* (ETEC) and *Vibrio cholerae*, cause an acute watery diarrhea by producing toxins that activate intestinal cellular enzymes; they have their main effect on small bowel water and electrolyte transport systems. Viruses are common causes of gastroenteritis, with vomiting and diarrhea, particularly in young children (rotavirus, caliciviruses, enteric adenoviruses, etc.). Norwalk virus causes vomiting and diarrhea in all age groups and rotavirus is not uncommon in adults.

When a cause is found, travellers diarrhea is most commonly due to ETEC and other *E. coli*, campylobacter, shigella, and rotavirus. Persistent diarrhea sometimes arises from *Giardia lamblia* and other protozoal diseases. The source is usually contaminated food or water, and advice to avoid uncooked fruit, vegetables, and salad, uncooked meat and seafood, tap water, ice, etc. in high-risk areas is often not followed, perhaps because it is seen to detract from the very essence of most leisure travel. The problem of emerging drug resistance complicates the use of antibiotic prophylaxis.

Other infections that can affect the small bowel are fungi in immunocompromised patients and helminths and protozoans in tropical countries. These are beyond the scope of this article. *Giardia lamblia* is a protozoan that on colonizing the small bowel can cause diarrhea and malabsorption.

Patients with HIV and AIDS often have diarrhea caused by the effect of HIV on the gastrointestinal mucosa, but they are also prone to many viral, bacterial, fungal, and parasitic infections due to their immunosuppression.

Whipple's Disease

This is a rare multisystem disorder due to infection by an organism called *Tropheryma whippelii* that invariably affects the small bowel and may also be associated with skin pigmentation, arthralgias, endocarditis, and other heart problems and central nervous system abnormalities. In the small bowel, it causes malabsorption with diarrhea, steatorrhea, abdominal pain, distension, and weight loss. It is diagnosed by the presence of periodic acid-Schiff-positive granules in macrophages.

Electron microscopy shows accumulation of *T. whippelii* within these macrophages and the condition that was once fatal can now be cured by antibiotic treatment. Fluid and electrolyte replacement may be required. Most patients are malnourished until absorptive function returns to normal, and they should receive a diet high in protein and calories together with multivitamin preparations.

Anemic patients should receive iron or folate as required. Vitamin D, calcium, and magnesium should be administered until steatorrhea resolves.

Bacterial Overgrowth Syndrome

Bacterial overgrowth occurs due to stasis of luminal contents resulting from strictures, fistulas, jejunal diverticula, blind loops, pouches, or motility disorders. The intestine becomes excessively colonized with both anaerobic and aerobic organisms. The latter use vitamin B_{12} and other nutrients for their own metabolism; they deconjugate bile salts and in so doing prevent their use in fat absorption. Normal dietary fat should be substituted by medium-chain triglycerides. Hypoalbuminemia (low blood albumin concentration) may develop and cause oedema. Antibiotics should be given to eradicate the bacteria; surgery is sometimes required.

Food Allergy

Food allergy is an adverse reaction to food in which the reaction is immune mediated. The immunological response comprises food-specific antibodies (IgE mediated), immune complex production, and mucosal T cell-mediated reactions. Food allergy can be serious and lead to anaphylactic shock. This must be distinguished from food intolerance, which is a reproducible adverse reaction to a specific food or food ingredient, either as a result of abnormal absorption of a sugar due to an enzyme deficiency (e.g. lactose intolerance) or because of an exaggerated pharmacological response to chemicals in food, such as tyramine in cheese.

Food allergy is most common in infants and tends to become less of a problem as children age. Foodstuffs implicated are cows' milk (2.5% of infants reducing to approximately 0.5% after 3 years) and egg allergy, which usually disappear after the age of 5 years. Fish legumes, peanuts, soy, and cereals can all cause food allergies. True food allergy is relatively uncommon in adults, although food intolerance is not.

The history is vital in discovering food allergies and skin prick tests may also be useful. Dietary manipulation plays an important role and elimination diets with slow reintroduction of suspect foods may be necessary. Once the food allergen is discovered, treatment is mainly avoidance.

Celiac Disease

Celiac disease or gluten-sensitive enteropathy is the major small intestinal cause of malabsorption in the Western world. In the United Kingdom, it occurs in 1 in 120–300 of the population; it is more frequent in females. It may be associated with dermatitis herpetiformis, type 1 diabetes, rheumatoid arthritis, and autoimmune thyroiditis. It usually involves the upper part of the small bowel and is due to a T cell-mediated immune response to a constituent of wheat flour, gluten. This toxic component of gluten (identified as gliadin) causes damage to surface enterocytes with villous atrophy and crypt hyperplasia. There is marked reduction in absorptive capacity of the small bowel with resultant malabsorption of nutrients. Prompt clinical improvement occurs on withdrawal of the gliadin fraction of wheat gluten. Patients present with symptoms of diarrhea, steatorrhea, weight loss, and general malaise. Sensitivity to gluten occurs in other diseases such as dermatitis herpetiformis and results in a rash and similar intestinal changes to celiac disease.

The diagnosis is made by testing the blood for the presence of anti-endomysial antibodies or anti-transglutaminase antibodies and confirmed by duodenal biopsy, which shows villous atrophy and crypt hypertrophy, flattened surface epithelial cells, and a chronic inflammatory infiltrate into the lamina propria that resolve following a gluten-free diet. All cereal grains contain gluten (wheat, barley, and rye), and these should be removed from the diet. Maize flour, rice, potatoes, and gluten-free flour are available and acceptable. Response to oats is more difficult to predict, perhaps because they may be contaminated by wheat products. It often takes several weeks to respond to a gluten-free diet and response is seen by rapid gain in weight. Lifelong adherence to the diet is necessary for celiac patients.

Some patients present dehydrated, and fluid and electrolyte replacement may be required. Patients are often anemic secondary to iron, folate, or, much less often, vitamin B_{12} deficiency and should receive supplementation. Vitamin D and K deficiency is common and absorption of vitamins B_6 and C may also be impaired. Steatorrhea may also cause calcium, magnesium, or zinc deficiency. All nutritional deficiencies should be corrected until the intestinal lesion has resolved on the gluten-free diet.

In untreated celiac disease, as in other diseases that affect the absorptive capacity of small intestinal enterocytes, disaccharidase deficiency may result, with symptoms of diarrhea and abdominal distension in response to milk products that contain lactose. Once the mucosa returns to normal with the gluten-free diet, disaccharidase activity returns to normal and lactose (milk sugar) becomes tolerated again.

Tropical Sprue

Tropical sprue is a disease of unknown etiology that exclusively affects people living in or visiting specific tropical or semitropical areas, particularly Southeast Asia and the Caribbean, that resembles celiac disease in its intestinal changes. It presents with steatorrhea, abdominal cramps, bloating, and increased bowel sounds. Most patients improve or are cured with long-term broad-spectrum antibiotic treatment. Fluid and electrolyte replacement should be administered to the acutely dehydrated patient, and megaloblastic anemia is often secondary to folate or B_{12} deficiency, which should be corrected. Vitamin A deficiency may be an important feature. Sometimes, iron, calcium, or magnesium may be deficient, and these minerals should be replaced. Antibiotic treatment may be helpful.

Crohns' Disease

Crohns' disease is a chronic inflammation that can involve any part of the gastrointestinal system from the mouth to the anus. In the small intestine, Crohns' disease typically affects the ileum; however, other parts of the small intestine can be affected. It produces a segmental, full-thickness inflammation, with formation of fissures and abscesses, fistulas, and fibrotic stenoses, and it may follow a chronic relapsing course. The cause of Crohns' disease is unknown, although several hypotheses such as infections (mycobacteria, chlamydia, and viruses) have been put forward. The discovery of susceptibility gene variants in NOD2/CARD-15 suggests predisposition to the disease by abnormalities of the intracellular sensors of bacterial lipopolysaccharide and their effect on the caspase and nuclear factor-κB signalling pathways and macrophage function.

The inflammation of Crohns' disease can be treated by the use of defined formula artificial feeds or by the use of drugs, including aminosalicylates, antibiotics, steroids, and immunosuppressives such as azathioprine/mercaptopurine, methotrexate, and infliximab. There is evidence that improving nutritional status alone will reduce Crohns' disease activity. If these measures fail to control the disease, then surgical resections of the diseased segment may be necessary.

Crohns' disease presents an important model for the role of nutritional management in small bowel disease. Nutritional treatment of Crohns' disease may use defined formula feeds to reduce inflammation or may seek to correct nutritional deficiency consequent on reduced food intake (loss of appetite, nausea, abdominal pain, or diarrhea), malabsorption, or the changes in protein and energy metabolism that occur secondary to inflammation. It therefore seeks to:

- maintain adequate nutrition and correct any nutritional deficiencies;
- reduce disease activity;
- maintain nutrition against the background of intestinal failure or short bowel syndrome on a long-term basis; and
- treat or prevent growth failure (consequent on nutritional deficiency and inflammation combined) in children.

A wide range of nutritional deficiencies can arise in patients with Crohns' disease of the small bowel that result in defects in wound healing, increased susceptibility to infection, and specific nutrient deficiency syndromes. Patients become anemic from intestinal bleeding; inadequate iron, folate, and B_{12} intake; failure to absorb iron in the duodenum or B_{12} in the ileum; or because of impaired folate absorption. Vitamin B_{12} can be given by injections to avoid the problem of absorption, folic acid by mouth, and iron orally or, if necessary, by injection. Trace elements and vitamins that are deficient during relapses include zinc, ascorbic acid, calcium, and the fat-soluble vitamins. Osteomalacia, rickets, and osteoporosis may occur due to steroid treatment or malabsorption of calcium and vitamin D. Zinc deficiency can cause mouth and skin problems and results from loss of zinc in watery diarrhea.

Chemically defined artificial liquid diets can achieve induction of remission, although the response rate is slightly less than that achieved with steroids. They are particularly beneficial in children with growth failure or in patients with steroid-resistant disease.

Enteral nutrition is preferred to parenteral nutrition, but parenteral (intravenous) nutrition may be life-saving in patients with short bowel syndrome following multiple resections for Crohns' disease or in patients with treatment-resistant Crohns' disease, and it may have a place in supporting malnourished patients at the time of surgery.

Patients with Crohns' disease tend to self-select low-fiber containing foods and often feel bloated after eating foods high in non-starch polysaccharides. Exclusion diets have been tried with some success in Crohns' disease, often following initial treatment with liquid feeds, but there seems to be little consistency between which foods' exclusion benefits different patients. Some patients develop malabsorption of milk sugar (lactose) and a small minority are said to be intolerant of milk protein. Other diets such as yeast exclusion have their

advocates but there is little evidence for consistent benefit. Dietary fat reduction should not usually be recommended in underweight patients because the body gains nine calories for each gram of fat eaten, whereas nonhydrated protein and starch provide four calories each. Milk and milk products provide important, easily assimilable sources of protein, energy, and calcium and their exclusion should not be undertaken lightly.

Intolerance to lactose, the sugar of milk, increases with age. Patients who are lactase deficient (the enzyme required to split lactose into two smaller sugars that can be absorbed) pass unabsorbed lactose into the large bowel with resultant cramps and abdominal distension. Any patient with extensive inflammation in the small bowel, where lactase is located, may develop lactose malabsorption, which improves once the inflammation resolves. Evidence of lactose intolerance should be documented before withdrawal from the diet and calcium supplementation considered. Occasionally, a lactose breath test is required to detect lactase deficiency. Some patients with lactose intolerance who still wish to take milk can have lactase enzyme added to the milk or use lactase tablets that can be eaten prior to or while eating foods rich in lactose. Patients can eat aged cheese (reduced lactose content) or yoghurt made with live bacterial culture.

Patients with narrowing of the bowel (strictures) should consider a low-fiber diet to reduce the risk of intestinal obstruction. A low-fiber diet may be deficient in folic acid, ascorbic acid, calcium, and some B vitamins, and these can be supplemented.

Patients with small bowel Crohns' disease with resections may have diarrhea resulting from fat malabsorption (steatorrhea) and may have to restrict their fat intake from 100 to 70 g of fat. If steatorrhea still occurs, medium-chain triglycerides (6–10 carbon atoms) should be substituted for the normal fat diet because these are absorbed directly into the portal system. Oil, powders, or emulsions containing medium-chain triglycerides can be added to food or used in cooking and baking.

Patients with ileal resections due to Crohns' disease are susceptible to calcium oxalate kidney stones. These patients should have a low oxalate diet, modest dietary fat restriction, and dietary supplementation of calcium.

Hypogammaglobulinemia

Common variant hypogammaglobulinemia is a defect of acquired immunity. Most of these patients have diarrhea and malabsorption. Patients are prone to *G. lamblia* infections and small bacterial overgrowth. The disease may result in intestinal inflammation and is associated with celiac disease, refractory sprue, and Crohns' disease.

Stool cultures for bacteria, ova, and parasites together with duodenal aspirates may be needed. Duodenal biopsies show loss of plasma cells in the lamina propria. Patients may be treated with metronidazole for giardiasis or bacterial overgrowth and with gluten-free diet for celiac disease.

Sugar Malabsorption

The disaccharidases are localized to the apical cell membrane of the villous absorptive gut epithelial cell. Lactase, the disaccharidase that digests lactose, is the most important. Deficiencies of these enzymes may be due to a primary inherited enzyme disorder (permanent) or secondary to disorders resulting from mucosal damage or bacterial overgrowth. Disaccharidase deficiency results in an osmotic diarrhea, because the undigested sugar has a large osmotic pull, and abdominal distension.

Intestinal Pseudo-obstruction

Intestinal pseudo-obstruction encompasses several intestinal motor disorders characterized by episodes that suggest intestinal obstruction because defecation stops and abdominal distension, pain, and vomiting occur, but in which no mechanical obstruction is found. It may be due to primary abnormalities of the visceral muscle or nerves or be secondary to chronic renal failure, hypothyroidism, diabetes mellitus, amyloidosis, scleroderma, or muscular dystrophy. There is no effective treatment that is specific for intestinal pseudo-obstruction. If the patient has bacterial overgrowth, this should be treated with antibiotics. If nutrition is impaired, administration of liquid, low-residue feeds enterally is required; rarely, parenteral (intravenous) feeding is necessary.

Collagen Vascular Diseases

Collagen vascular disorders, such as polyarteritis nodosa, Churg–Straus disease, scleroderma, and systemic lupus erythematosus, may affect the small intestine, resulting in malabsorption and diarrhea and infarction. Malabsorption due to bacterial overgrowth can be treated with a course of antibiotics. Steroids and immunosuppressives are the mainstay of treatment.

Vascular Disease of the Small Intestine

Ischemic injury to the small intestine occurs due to obstruction to the superior mesenteric arterial supply by embolization of clot or local thrombosis of the vessels. It can also occur as a result of diminished blood supply to the small intestine due to conditions such as systemic hypotension or hyperviscosity states. Occlusion of the superior mesenteric artery results in ischemia or infarction of nearly all the small intestine and the right half of the colon. It may present acutely with sudden severe abdominal pain and shock consequent on the infarction with or without perforation of the affected intestine. In these circumstances, emergency surgery to remove the large segment of affected intestine is life-saving but may leave the patient dependent on long-term intravenous feeding (parenteral nutrition). Ischemia may present more chronically with poorly localized abdominal pain, typically occurring 30–60 minutes after food intake. This leads to food avoidance and weight loss. The intestinal mucosa can become ulcerated. The diagnosis depends on mesenteric angiography.

Malignant Tumors of the Small Intestine

The small bowel, like the stomach, is a common site for primary lymphoma. Tumors may originate from B lymphocytes (particularly mucosa-associated lymphoid tissue (MALT) lymphoma, which in the small intestine is termed immunoproliferative small intestinal disease (IPSID), Burkitt's lymphoma and immunodeficiency-related lymphomas, or T lymphocytes (particularly enteropathy-associated T cell lymphoma (EATL)), or it may mimic any of the lymphomas which arise in lymph nodes distant from the intestine, such as diffuse large B cell lymphoma and mantle cell lymphomas.

Intestinal lymphomas are another interesting example of disease originating from the interplay between the intestinal mucosa and the intestinal flora. In the stomach, MALT lymphoma is closely related to *Helicobacter pylori* colonization and may be cured by *H. pylori*'s eradication. IPSID may be responsive to antibiotics, also suggesting a relationship with small intestinal flora. EATL results from chronic malabsorption, most commonly celiac disease, and occurs mainly in the jejunum. It usually involves multiple segments of the small bowel and may therefore be difficult to resect surgically.

Small intestinal tumors are rare. The majority are adenocarcinomas that develop most commonly in the proximal small bowel. Metastasis by hematogenous or lymphatic spread is common with peritoneal seedlings. Rarely, secondaries from primary tumors elsewhere can be found in the small bowel.

Benign Tumors

Benign tumors are usually asymptomatic but may present with obstruction, intussusception, or bleeding. They include adenomas, leiomyomas (smooth muscle tumors), neurofibromas (isolated lesions or part of neurofibromatosis), or hematomas (Peutz–Jeghers syndrome characterized by multiple hamartomatous polyps). They can bleed or cause intussusception, in which the polyp, attached to the intestinal lining, is moved down the intestine by intestinal peristalsis and causes the intestine to telescope over itself, thereby resulting in obstruction.

Neuroendocrine Tumors

The small bowel is the most common site for carcinoid tumors that arise from cells of the neuroendocrine tissue. Carcinoid syndrome can occur if the tumor spreads to the liver, with episodes of flushing and diarrhea. Surgical resection of carcinoid tumors should occur. Once metastases have developed, various antiserotonin agents or octreotide can been used.

Congenital

The duodenum derives from the distal part of the foregut, whereas the jejunum and ileum derive from the midgut. Congenital disorders such as atresia (failure to canalize) or stenosis (constriction) or malrotation may occur during early development. Rarely, duplication of the bowel can occur with the risk of obstruction and bacterial overgrowth. Children with cystic fibrosis may develop small bowel obstruction due to meconium ileus (viscous mucus).

Meckel's Diverticulum

Meckel's diverticulum is a congenital anomaly located in the ileum in approximately 2% of the population. It can present with melaena or abdominal pain. In some patients, it can lead to intussusception and small bowel obstruction. It can be diagnosed with a radionucleotide Meckel's scan and treatment is by surgical excision.

Radiation Enteritis

Radiotherapy treatment of pelvic and abdominal malignancies can lead to radiation damage of the

small bowel and colon. Radiation damage to the small bowel and previous resections may cause decreased absorptive surfaces, bile salt malabsorption, and increased intestinal transit and hence nutritional deficiencies. Late radiation damage may cause ileal dysfunction with increased gallstones secondary to hyperoxaluria. Radiation-induced strictures and fistulas may cause stasis of bowel contents resulting in bacterial overgrowth and malabsorption.

Steatorrhea should be treated by reducing fat intake or replacing fat with medium-chain triglycerides with vitamin or mineral deficiencies corrected parenterally.

Abetalipoproteinemia

This is an autosomal recessive condition with abnormal lipid metabolism, retinitis pigmentosa, neurological deterioration, and acanthocytosis (abnormal red blood cells). The intestines and liver are unable to synthesize triglyceride-rich lipoproteins, chylomicrons, and very low-density lipoprotein. As a result, there is steatorrhea due to malabsorption of fat together with malabsorption of fat-soluble vitamins. Symptoms can be corrected by substitution of the normal fat intake with medium-chain triglycerides and polyunsaturated fat as corn oil. As they grow older, patients may be able to increase their fat intake. High-dose oral supplementation of fat-soluble vitamins, especially vitamin E, is mandatory from a young age because lack of these vitamins can cause progressive neurological and retinal deterioration.

Intestinal Lymphangiectasia

Intestinal lymphangiectasia is a protein-losing enteropathy with gastrointestinal lymphatic obstruction and excessive leakage of plasma protein into the intestinal lumen, with resultant oedema and hypoproteinemia. Patients have symptoms of diarrhea, steatorrhea, nausea, vomiting, and signs of ascites or pleural effusions. Bacterial infections due to lymphopenia and hypogammaglobulinemia occur. Patients often have malabsorption of fat-soluble vitamins and can also have hypocalcemia and hypomagnesemia. These must be supplemented.

Dietary management is often adequate to maintain remission. Patients should restrict their fat diet to less than 5 g per day. A high-protein, fat-free diet with medium-chain (C8–C10 fatty acids) triglycerides should be encouraged. Medium–chain triglycerides are absorbed directly into the portal system and are palatable and do not increase lymph flow.

Low-sodium diets, diuretics, and intravenous albumin have been used to alleviate symptoms. When these do not work, periods of fasting and parenteral nutrition can be used to alleviate very troublesome symptoms, although essential fatty acids must be added to the diet. Surgical resection is sometimes required.

Eosinonophilc Gastroenteritis

Eosinophilic gastroenteritis affects any part of the bowel from the mouth to the anus, although the stomach and small bowel are the most affected areas. Different layers of the bowel can be affected. It is characterized by eosinophilic infiltration of the affected areas of the bowel and a peripheral blood eosinophilia. It is a rare disorder for which the etiology is unknown.

In patients with mucosal layer disease (i.e., no involvement of muscle or serosal layer), food intolerance should be looked for. A trial of sequential elimination of milk, pork, beef, eggs, or gluten may be tried. Enteral elemental diets have been tried in some patients with success. Patients with mucosal layer disease who do not respond to dietary measures or patients with deeper layer involvement should try a course of steroids. Any patient who has traveled to the tropics should be considered for antihelminth therapy.

SOCIO-ECONOMIC STATUS

E Dowler, University of Warwick, Coventry, UK

In most societies there is an inverse relationship between socio-economic status and nutritional status, whether the former is measured as income, assets, or social class and the latter as food consumption or body dimensions. Socio-economic status is difficult to define consistently. The problems include how to define and measure basic subsistence, whether to examine the status of individuals or households, how to define and interpret social class differences, and how to understand differences in status between societies and in one society over time. People's circumstances often change, and sometimes the process of change may affect nutritional outcomes as well as the conditions themselves.

Basic subsistence usually means a level of living that enables people to survive and reproduce. Reproduction here means both physiological (women of childbearing age are menstruating and can conceive and carry children to term) and economic (a household has the means to feed, clothe, and house its members and take part in minimum social and economic exchange). Quantifying this basic level can be difficult: People disagree over the cutoff levels to define minimum energy or nutrient intakes for survival or reproduction, over the rates of child growth that are healthy, and over how much money or its equivalent is needed for a household to survive. Resolving these controversies depends partly on technical decisions and partly on agreed social value judgments. It also partly depends on who is making the decisions: experts in nutrition, health, or economics; social policy decision makers; or people living in the conditions concerned.

Disentangling what happens within the household—who owns or has access to what assets and resources—is difficult. Even someone living alone may be entitled to resources or a share of production from another household. However, most surveys use household data on consumption or asset ownership and then divide these by the number of household members to estimate individual shares. This approach ignores differences within a household over the control and management of resources, and it assumes everything is shared equally. (What would 'equally' mean for nutrients? Everyone eating the same, or everyone eating what they need?)

Social class and status are affected by social and cultural conditions as well as economic conditions; most classifications try to incorporate all three factors. Some of the work described here uses proxy measures of socio-economic status as an alternative to income. These proxies can be single indicators, such as mother's educational level or head of household's occupation. Alternatively, they can be composite indices, often drawing on census data, that combine single indicators such as crowding, occupation, car access, housing tenure, or employment status into one index (e.g., the Carstairs Index in the United Kingdom). These composite indicators usually describe households' rather than individuals' socio-economic status.

Current social and economic changes that are associated with increasing socio-economic differentials in developed countries include the growth in unemployment or insecure employment, unstable family structures, homelessness, migrancy, and reductions in welfare provision. Similar factors are in force in developing countries, with the addition of economic structural adjustment, globalisation of production and trade, and the spread of HIV/AIDS, which affects production and earnings through the illness and death of economically active young adults.

There is debate about the relationship between socio-economic status, nutrition (food and growth), and work productivity. Some argue that undernutrition contributes to poverty at the household, and potentially national, level because an inadequate diet can reduce an individual's work capacity either through a direct effect of food or indirectly over time because the individual is small and/or thin. Reduced work capacity results in lower productivity and economic return, which in turn contribute to increasing poverty and malnutrition—a 'vicious circle.' These effects may be seen in an individual and his or her immediate household or as part of the reduction in human capital in malnourished populations across generations.

Socio-economic Status and Disease Risk and Mortality

In the 1970s, the World Fertility Survey documented very large socio-economic differentials in child mortality in most of the 41 developing countries that participated. **Table 1** shows socio-economic differentials in mortality rates during the first 5 years of

Table 1 Mortality rates during the first 5 years of life (per 1000 births) for nine countries participating in the World Fertility Survey

life in nine of the countries that participated. During the past two decades, overall child mortality rates have declined by approximately 50%, but 10 million children younger than 5 years of age still die annually; socio-economic differentials in child survival remain and in some cases have widened. Being underweight (2 SD or more below expected weight for age) and micronutrient deficiencies are recognised as underlying causes of death from infectious diseases; fetal malnutrition, manifested as low birth weight, and not being breast-fed contribute to neonatal mortality.

The reduction in infant and child mortality rates and concomitant decline in fertility in many developing countries have led to changes in population age structure, overall health status, and mortality patterns. A shift toward an older population means adults diseases become as important as those of children. However, poorer adults certainly die younger than richer adults, whatever the causes. Many developing country populations seem to be shifting from an environmental exposure predominantly to infectious diseases (from poor water, sanitation, and insecure food supply) to one in which noncommunicable disease risks are more important (motor vehicles, unsafe workplaces, air pollution, smoking, alcohol, increased fat and sugar intakes, and decreased physical activity and social support). Current hypotheses on the fetal origins of some chronic diseases highlight the role of the early nutritional environment for the risk of adult diabetes and cardiovascular disease. Those in low socio-economic groups in developing countries, where low birth weight and inadequate infant nutrition are common, may face the double risk of infectious disease or death in childhood and, where children survive, noncommunicable diseases in adulthood.

These shifts in demographic, disease, and risk profiles, often referred to as the epidemiological transition, are occurring at different rates in most developing countries. **Table 2** shows mortality rates by major cause of death and by region, differentiating areas of high and low mortality. Understand causal determinants of health and being able to predict the consequences of changing exposures to risk are important. Expert working groups have reviewed data on the prevalence of risk factor exposure and hazard level for 14 epidemiological regions of the world. The contribution of these risk factors to global and regional mortality and burdens of disease has been calculated. **Figure 1** shows deaths and **Figure 2** shows disease burden in disability adjusted life-years on a global basis, differentiating areas of high and low mortality. One key finding of this analysis is the importance of nutrition in health worldwide. Approximately 15% of the global disease burden is attributable to childhood or maternal underweight or micronutrient deficiency, and a similar percentage is attributable to dietary risk factors such as high blood pressure, blood cholesterol, body mass index (BMI), and low fruit and vegetable intake.

The situation in developing countries is changing with time, and quite rapidly. For example, in Porte Alegre, Brazil, the poorest men have higher death rates from cancer and cardiovascular disease than wealthier men. Conversely, large population-based surveys in India suggest that the prevalence of coronary heart disease is nearly four times greater in those from higher than in those from lower

socio-economic groups. However, obesity rates are increasing throughout the world; in India, there are households with both an underweight child and an overweight adult. It seems increasingly likely that poorer people face greater risks than wealthier people from both infectious and parasitic diseases and from noncommunicable diseases.

The inverse relationship between socio-economic status and differential morbidity or premature mortality in developed countries is well documented. These differentials are seen in the main causes of mortality, coronary heart disease, and cancers, and they have particularly widened, and continue to widen, in countries where income inequality has increased. The differences seem to be cumulative: Those born into low socio-economic groups and who remain in them throughout childhood and adulthood have higher mortality risk than those who move up a class during their lifetime.

Studies have used various socio-economic indicators, such as occupational class, employment status, housing tenure, and car access. The mortality differentials are large and can be located in terms of people and places. **Table 3** shows data from the United Kingdom; the association between mortality and spatial indicators of economic and social advantage or disadvantage is very strong. However, the increasing polarization of wealth and poverty between households (a growth in two-earner and no-earner households) and places means, in fact, lower death rates occur where richer people are concentrated and higher death rates occur where disadvantaged people are concentrated. It is not just a matter of 'unhealthy places.'

Finally, there is evidence of a gradient of health and mortality rather than a threshold below which everyone does badly and above which most are reasonably healthy. The UK Whitehall longitudinal studies of civil servants showed that those in the second highest grade (not a low socio-economic group) had worse health and mortality risk than those in the highest grade. However, those in the lowest grade had the worst health and mortality risks, and studies in several countries have shown long-term unemployed to have high mortality risks.

Current thinking about why these differentials occur is that artefactual distortions or social selection cannot account for them, but that social conditions or material factors, perhaps partially mediated by life circumstances, beliefs, and behavior, offer the best explanations. Money is clearly important—having enough to meet basic needs but also for a sense of security. Psychosocial factors and the control people have over their working or social environment also play an important part. Indeed, increasing income inequality and insecurity, as much as absolute poverty, may be important predictors of mortality differentials. Biology also plays a part: The fetal experience, and nutritional challenge during the early years, may set an individual on a biological trajectory that is not able to withstand the effects of material and social poverty.

Socio-economic Differences in Food Consumption

The socio-economic status of a household can affect the members' diet in a number of ways. In general, those with higher incomes tend to spend a smaller proportion of that income purchasing food, although they may spend a larger absolute amount than those with lower incomes. Second, the kinds of foods that wealthier people buy will be different in quality (less contamination and better processed or packaged) and in nutrient density (e.g., see **Table 4**). Wealthier people are generally 'less efficient'

London: TSO.

purchasers of calories than poor people: Richer people can afford to buy foods that provide sufficient calories in total but in foodstuffs that are more pleasant to eat or that are less calorie dense. Poor people have to maximize the calories and nutrients they can obtain for as little cost as possible. However, many studies have shown that even the poorest do not eat a theoretical 'least-cost diet': Everyone tries to satisfy cultural demands for taste or tradition in food type or preparation methods. When low-income groups obtain more money, they are often observed to spend it on more expensive foods, which are sometimes less calorie dense than commodities bought previously but that carry higher status (such as meat) or are more tasty (such as fruit). Third, those who are poor tend to obtain most of their calories from basic staple foods, particularly roots and tubers or coarse grains (millets and sorghums); these starchy foods cost less in land or labor to produce than other foodstuffs. Poorer people also eat monotonous diets based on a few food types with little diversity; their nutrient base is restricted to a few key foods. Thus, it is difficult to meet dietary requirements for healthy living; dietary diversity is an indicator of food access and food security. As people move up the income scale, they substitute higher value grains (maize, rice, or wheat) and more processed or desirable versions of those grains (bread made from highly milled flour). They also obtain more calories from nonstaple foods and eat a more varied diet, including foods of animal origin, which in wealthier groups provide between 33 and 40% of total calories. People can also afford to express more health consciousness in food choice, buying leaner meat, more fresh produce, and expensive less-refined foods.

Variations in individual nutrient intake by income are usually less than variations between income groups in quantities and patterns of food purchased might suggest. Those who are poorest, whether by income or assets (e.g., landless labourers), tend to be very sensitive to food prices and will purchase substitute commodities as prices vary. However, people may also exhibit relative price inelasticity for a highly prized staple (e.g., they will buy rice no matter how expensive).

In developing countries, particularly those undergoing national economic changes through structural adjustment programs, there is evidence of deteriorating household food security among those whose incomes are declining and for whom reductions in welfare and food price subsidies have most significance. Those whose social and economic entitlement base is the least secure are most vulnerable to reduced food intakes following economic change. In general, energy and protein intakes, as well as micronutrient intakes, tend to vary inversely with income group, land-holding, or asset measures of socio-economic status, although the degree depends on local social and economic circumstances.

In developed countries or regions, there are fewer differences between income groups or social classes in per capita consumption of calories, proteins, or fats, although some surveys show that poorer groups eat

more energy as saturated fats or as refined sugar. However, most national and small sample surveys show marked differences in intakes of vitamins and minerals, such as iron and calcium. Those who are poorest (by whatever measure) often have very low intakes of these nutrients, well below reference levels, which indicates a high risk of poor health outcomes. Smoking can complicate this picture: Those with low incomes who smoke have lower micronutrient intakes than those who do not smoke, which is partly an income effect (they cannot afford to buy enough appropriate food) but also a direct effect of smoking (smokers have different dietary patterns—particularly lower fruit intakes—whatever their income). Those with lower incomes are more likely to be smokers.

Socio-economic status not only affects how much money people have to spend on food but also increasingly affects their social and physical environment, which has implications for food. In many countries, geographical socio-economic polarization means that poorer people tend to live in low-quality housing, with limited domestic equipment, in residential areas with few, if any, shopping facilities and insufficient public transportation. Food shops selling a wider range of better quality goods, often at cheaper prices than small local shops, tend to be located where the wealthier live or to be only accessible by car. Car ownership and housing tenure are becoming good indicators of health in developed countries; part of that relationship is mediated by economic and physical access to sufficient, healthy food.

These general findings have been examined in individual countries. For example, analyses of national survey data sets in the United States and Australia show weak relationships between nutrients and income. Educational status or household size were more predictive of low intakes. At the subnational (state) level, however, the relationship between nutrients and income is more evident, as in several European countries. A different approach from national surveys examines usage of food banks (free food provision). In many developed countries, the numbers using food banks as a main food source increased rapidly at the end of the twentieth century. Participants tend to be welfare recipients or unemployed, often with dependent children and female headed, and proportionately more are likely to be ethnic minorities. These characteristics usually indicate lower socio-economic status in developed societies.

Ethnicity is no guarantee of predictability of dietary quality, and in the United Kingdom as least, it shows a more complicated relationship with socio-economic status. For instance, members of black African, black Caribbean, or black British households in the United Kingdom, or black American or black African households in the United States, are more likely to eat a varied, healthy diet (higher micronutrients and lower proportion of energy from fat) than their white counterparts, whatever the income level. South Asian households in the United Kingdom are less homogeneous with regard to income and diet; some eat more pulses, whole cereals, and vegetables than white counterparts, but many also have high fat and saturated fat intakes.

Many studies have shown nutrient intakes to be low, dietary patterns less healthy, and dental caries higher in children from low socio-economic status households. Nonetheless, there is also evidence that parents, especially mothers, go without food, or eat less healthily, to ensure their children have enough and the best to eat in poorer households. Indeed, this is true throughout the world: Parents try to buffer their children from the worst consequences of low socio-economic status. Evidence that boys are fed better than girls is equivocal, even in south Asia.

Socio-economic Differences in Growth and Nutritional Status

Variations, both within and between populations, in body size at a given age and in the rate of maturation are partly genetic and partly environmental in origin. The most important determinants of birth weight and child growth—adequacy of the diet, quality of the environment, and access to health services—are also core elements of the standard of living. As a result, indices of child growth and birth weight have long been recognised as sensitive indicators of social inequality.

In most countries, women from poorer families produce infants of lower birth weight (with lower chances of survival) than do women from better-off families (**Table 5**). Some of this socio-economic

differential reflects the size of the mothers; women are often smaller in poorer families. However, differences in birth weight also reflect what Hytten calls a "comprehensive pattern of deprivation": a poorer quality diet, low pregnancy weight gain, mothers being underweight at conception, the absence of or poor quality prenatal care, poor housing, and behaviors such as smoking and alcohol and drug use.

Height in children and adults is positively associated with socio-economic status throughout the world. **Figure 4** shows the range of boys' heights from richer and poorer families in a number of countries. Social class differences in boys' heights varied from very little in Scandinavia to approximately 12 cm in the Indian samples. A number of studies have shown that when indicators of social position are expressed on a continuous or graded scale, the relationship with height is monotonic; that is, height increases with an increase in social position. This observation appears to be true even between groups from quite narrowly defined social strata, as shown by data from a single slum in Bangladesh (**Table 6**). A number of in-depth studies in developing countries of the relationship between socio-economic status and height of children have consistently shown height to be responsive to individual socio-economic indicators, whether of asset wealth or income, or proxy indicators, such as land-holding, grain yields, parental education, or occupation (**Table 7**).

A similar relationship can be shown in developed countries. For example, in the US National Health and Examination Survey, child height increased monotonically in relation to increments in both household income and parental education (the data were controlled for race). In Britain, the National Child Health and Development Study showed that the difference in height at age 7 between children born in social classes I and II and those in V averaged 3.3 cm; at age 16, the difference was 4.4 cm, in both instances controlling for confounding variables.

In recent years, social class gradients in height, weight, and age of peak height velocity and menarche have begun to attenuate in a few wealthy countries (Sweden, Norway, Finland, and Hong Kong). This seems to be because secular trends in growth have been faster among the lower than higher social class children, and it probably indicates general high living standards rather than growth in a 'classless' society.

Social class gradients in attained adult height are also well documented. In British adults, and Swedes born up to the mid-1950s, average height of manual and nonmanual classes differs by approximately 3 cm for men and 2 cm for women. These averages may mask the effects of upward mobility: Those who move up a class tend to be taller than those who stay within the same social class. In both Swedish and British populations, attained adult height has been shown to be related to economic conditions during childhood, independent of parental height and birth weight. Environmental influences exhibit an inter- as well as intragenerational effect on attained adult height. They also manifest in health outcomes as described previously: Social conditions contribute to nutritional deficiency in early childhood that results in delayed linear growth (indexed by shorter leg length), and this is associated with increased mortality risk for coronary heart disease in later life.

There is also consistent evidence of an association between temporal changes in socio-economic status and height or physical maturation, at both population and individual levels. For example, positive associations have been found between increased gross national product and average stature in France and decline in menarcheal age in Norway, and between per capita income and height in Italian conscripts and survivorship to adulthood. At the individual level, a Polish study showed that statural gains of sons compared to those of their fathers were significantly greater among fathers who had progressed socio-economically compared to their parents. Reversals in the secular trend in height or menarcheal age have been shown to coincide with periods of economic decline, such as occurred in Norway, Germany, and France during World War II and in three periods in Moscow (during the civil war following the October Revolution, during mass collectivization, and during the late 1930s and World War II).

Regarding indicators of 'thinness'—weight-for-height in children and BMI (weight/height^2) in adults—there is no evidence of a consistent monotonic association between thinness and social class or livelihood worldwide. In developed countries, poorer women, and increasingly men, are more likely to be overweight or obese, and this relationship is strengthening. For instance, in Britain the incidence of obesity among poorer women is twice that of women in the richest fifth of the population. In many low-income countries there is evidence of positive associations between indicators of socio-economic status and both child weight-for-height and adult BMI (**Tables 6–8**). For countries undergoing the epidemiological transition, the situation appears more complex. For example, national surveys in Brazil conducted during 1974 and 1989 indicate that at the population level, the frequency of underweight had declined, whereas obesity had increased. In both 1974 and 1989, inverse, monotonic social gradients in underweight were evident both in adults (BMI) and in children (weight-for-age), and the reduction was relatively uniform across the social strata. Among adults, although increases in the prevalence of obesity (BMI) were observed for each social strata, the proportionate increase was greatest for the poorest families. The relationship between measures of income and obesity over time was also not straightforward. For men, the social gradient in obesity was attenuated. Among women, the highest prevalence of obesity was no longer among the richest but in the middle-income group, and the greatest increases in prevalence had occurred among the poorest women. In China, where the epidemiological transition has been very rapid, national surveys in the late 1980s and early 1990s indicated an increase in adult underweight among the lowest income groups at the same time as an increase in obesity among the middle-

and higher income groups. In Asia in general, there is increasing obesity in all age groups, and it seems to be fastest among middle- and lower income groups, except in the poorest countries. For instance, 30% of Indian adolescents from higher economic groups and 20% of Malaysian adults are overweight.

The association between socio-economic status and weight-for-height among children is not consistent. In Britain, a social class gradient in overweight or obesity in primary school children is emerging; a gradient in overweight and obesity was found among both boys and girls aged 11–16 years, but not among those aged 5–10 years, in Perth, Australia. Strong and persistent inverse social class gradients in weight-for-height and obesity by early adulthood have been reported for Britain, the United States, Sweden, Italy, and Australia. Childhood to adult cohort studies in the United Kingdom and Sweden indicate a strong inverse social class gradient between social conditions in childhood and obesity in young adulthood, and this is now seen in men as well as women.

The relationship between socio-economic status and indicators of thinness in developed countries probably depends on a number of factors, which not only include dietary patterns but also physical activity in work and leisure, consciousness of and attitudes about body size and shape, as well as diet-related health issues.

The Future

Socio-economic differentials seem to be increasing in a number of countries, whether developed, developing, or those with 'transitional' economies. Several agencies use child and adult anthropometric indices as indicators of socio-economic status and to monitor the effects of social change. Recent longitudinal data from Sri Lanka and Nepal suggest that adult anthropometric indices may be more reliable than those of children because children are often buffered against seasonal nutritional stress by physiological and social support mechanisms. The Nepal data also indicate that adult body size does influence fitness, productivity, and reproductive performance. However, these disadvantages do not necessarily translate into equivalent socio-economic disadvantage for the whole household. The circle is neither necessarily vicious nor resistant to social and biological mitigating effects.

Physiological, Clinical, and Nutritional Importance of Sodium

Despite the fact that the body contains more calcium and potassium, sodium is arguably the most important cation because it dictates the volume of extracellular fluid (ECF) and its concentration affects osmotic concentration of both ECF and intracellular fluid (ICF). Abnormalities of ECF sodium concentration cause movement of water into or out of cells, thus altering the osmotic concentration of ICF in parallel and causing swelling or shrinkage of cells. The main impact of this is on the brain because its cells are rigidly enclosed by the cranium.

Sodium depletion is mainly caused by enteric, renal, or adrenal disease, and sodium retention is caused by renal disease; healthy kidneys are well able to excrete excess dietary salt. However, chronic ingestion of excess salt, whether or not it increases ECF volume, is a predisposing or exacerbating factor in hypertension. Until the 1980s, knowledge of the regulation of body sodium mainly concerned defenses against depletion, while in the 1990s there was a rapid growth in knowledge of the mechanisms that excrete excess sodium. This seems appropriate since most species, especially humans, dogs, and laboratory rats, are exposed to dietary sodium intakes well above their nutritional requirement.

The nutritional requirement is a reflection of obligatory losses (maintenance) and the needs of growth, pregnancy, and lactation. Abnormal losses owing to disease, or in animals such as humans and horses which sweat extensively, raise the requirement. The impact of equine sweating is different from that in humans. Human sweat always contains sodium at concentrations well below plasma levels (and when aldosterone secretion is raised, levels of sweat sodium fall very low); horse sweat is hypertonic but this helps to offset the osmotic effect of the increased respiratory water loss during exertion, i.e., it may be a defense against hypernatremia, rather than a potential cause of sodium depletion. Similarly hypernatremia in many species induces 'dehydration natriuresis' – an appropriate defense.

Consideration of the physiology of sodium thus includes its distribution in the body, regulation of total content and concentration, causes of and responses to depletion or excess, and their nutritional implications.

Distribution

Sodium is a cation, i.e., a positively charged ion; its distribution and physiological effects are fairly independent of the negative ions (anions) that originally accompanied its ingestion though they may affect its absorption and excretion. Most sodium is in ECF (**Table 1**), kept there by the sodium pump, an enzyme system, Na^+/K^+-exchanging ATPase, which uses substantial amounts of energy (adenosine triphosphate; ATP) in maintaining a low intracellular sodium concentration and a high intracellular potassium (K^+) concentration. Sodium transport is a central issue in the physiology of sodium for a number of reasons:

1. It helps to maintain the ionic environment of ICF and the volume of ECF.
2. It prevents cell swelling (the Na^+ efflux exceeds the K^+ influx).
3. It establishes gradients which, in various tissues, allow transport of other cations in exchange, other anions in parallel or organic solutes – these are often cotransported with sodium down concentration gradients which are secondary to the low sodium environment created by the pump.
4. It establishes the membrane voltages on which excitability and secretory activities frequently depend.
5. The energy expenditure of the pump is a substantial portion of total metabolic activity and contributes to thermogenesis.
6. Sodium transport is not only a key factor in the retention and loss of sodium in the kidney, gut, salivary, and sweat glands but also influences the

Table 1 Summary of sodium (Na) distribution and requirements

Typical plasma Na concentration (mmol l^{-1})	145 (130–160)
Typical body Na content (mmol kg^{-1})	50–55
Typical proportion (%) of total Na	
ICF	10
ECF	50
Bone	40
Maintenance requirement in mammals (mmol per kg per day)	
Sheep	0.1
Cattle and goats	0.3–0.7
Pigs	0.6
Rats	0.6
Dogs	0.2–0.5
Humans	?<0.6

1 mmol = 23 mg Na^+, 58.5 mg NaCl.

excretion or retention of many other solutes. Thus, for example, diuretics intended to promote sodium excretion may also cause unintentional losses of potassium and magnesium. Similarly, when renal sodium excretion increases appropriately in response to ingestion of excess salt, there may also be unwanted losses of calcium and in postmenopausal women these may contribute to loss of bone mineral.

Bone also contains substantial quantities of sodium but, as yet, its significance is unknown since it does not appear to be mobilized during sodium depletion. Gut fluids contain considerable amounts of sodium, mostly secretory rather than dietary, and mostly reabsorbed in more distal regions of the intestine.

Extracellular Sodium

Most of the extracellular fluid is interstitial fluid (ISF) in the tissue spaces, providing the transport medium between capillaries and cells. The sodium concentration in plasma is slightly above that in ISF because plasma contains more proteins, notably albumin, which do not readily escape into ISF across the capillary membranes, and the effect of their negative charges is to hold more positively charged ions, notably sodium, in circulation (Gibbs–Donnan equilibrium).

The main effects of excess ECF volume are seen as expanded ISF, visible clinically as edema (or ascites when fluid accumulates in the abdomen rather than the tissue spaces). Mild edema is merely a cosmetic problem in itself but pulmonary or cerebral edema, or severe ascites, are potentially serious forms. Edema can result from excess ingestion or retention of sodium (overall expansion of ECF) or 'leakage' from plasma to ISF, with plasma volume continuously replenished by renal sodium retention. Such maldistribution of ECF occurs if plasma albumin is very low (renal leakage, hepatic impairment, or severe malnutrition), or with excessive capillary blood pressure (venous blockage, inactivity, heart failure, or arteriolar dilation, e.g., from heat or allergy), capillary damage, or lymphatic blockage. The latter prevents the removal of proteins that have leaked into ISF. Accumulation of protein in ISF undermines the osmotic gradient, normally favors uptake of water at the venous end of the capillary, where the pressure is lower. Since edema involves the expansion of a larger compartment (ISF) from a smaller one (plasma) it is only possible as long as the latter is replenished; hence the kidney, while seldom the primary cause of edema, is always the enabling cause; the use of diuretics is therefore appropriate in the treatment of nonrenal as well as renal causes of edema.

The main effect of inadequate ECF volume is to reduce plasma volume and thus to compromise cardiovascular function, in extreme cases by causing circulatory shock.

Regulation of ECF Sodium

In a mature, nonpregnant, nonlactating, healthy animal, sodium excretion matches sodium intake and is often used to estimate it, although this is not reliable, especially when intake is low. Dietary sodium is readily available, i.e., readily absorbed; thus the traditional view of sodium regulation emphasizes renal regulation of urinary Na^+ loss. This oversimplifies the more subtle interplay seen, for example, in herbivorous animals, where salt appetite may contribute to regulation by intensifying during sodium depletion. Moreover, in many herbivores the feces, rather than urine, may be the major route of sodium excretion and the gut may therefore be an important regulator of sodium balance. Indeed, it is interesting that sodium transport mechanisms in the small intestine show considerable similarities to those of the proximal part of the renal tubules (e.g., linked transport of Na^+, glucose, and amino acids) whereas the colon, like the distal nephron, responds to the salt-retaining (and potassium-shedding) hormone of the adrenal cortex, aldosterone. Indeed, diarrhea is essentially enteric diuresis; a failure of intestinal sodium and water reabsorbtion, which exceeds the compensatory capacity of the color.

Provided that the adrenal gland is healthy, urinary and fecal sodium loss can be reduced virtually to zero. Sweat loss can also be very low, although with severe exertion in hot climates the volume of sweat may exceed the ability of aldosterone to reduce its

sodium concentration and net loss of sodium can occur. Aldosterone also reduces salivary sodium (and raises $[K^+]$).

There are two components to the regulation of ECF sodium: the total amount of sodium retained and its concentration. The former is regulated by mechanisms that directly affect sodium, whereas the latter is essentially regulated via water balance. Thus, whatever sodium is retained in ECF is 'clothed' with the appropriate amount of water to maintain the normal plasma sodium concentration within narrow limits; deviations of less than 1% (hard to measure in the laboratory) trigger corrective responses. Thus, a raised plasma sodium concentration (e.g., after water loss) stimulates both thirst and renal water conservation; antidiuretic hormone (ADH) from the posterior pituitary reduces urine output through its effect on the renal collecting ducts. Even one of these mechanisms can defend body water; thus diabetes insipidus (inadequate production or effect of ADH) does not cause severe dehydration but polydipsia (increased fluid intake; 'thirst' is a sensation).

Excess salt intake does not raise plasma sodium concentration (hypernatremia) if water is available and the patient can drink; the excess sodium is diluted. The resulting increase in ECF volume then stimulates increased sodium excretion. Sodium also enables ECF to hold water against the osmotic 'pull' of the solutes in ICF and sodium thus functions as the 'osmotic skeleton' of ECF; it is the main determinant of its volume.

Plasma sodium concentration is therefore only indirectly related to sodium balance. When ECF volume, notably circulating volume, is severely reduced, this stimulus, rather than Na^+ concentration, becomes the main drive for thirst and ADH secretion. Until ECF volume is restored, water is retained (to protect ECF volume) even though this undermines the protection of ECF Na^+ concentration and, as a result, plasma sodium falls. Thus, during sodium depletion, contraction of ECF volume precedes significant reductions of plasma Na^+, which is therefore a poor index of sodium status.

Sodium-Retaining Hormones

Sodium depletion, by reducing plasma volume and renal perfusion, stimulates the production of renin (from the kidneys), which generates angiotensin in circulation. This hormone is a vasoconstrictor (so protects blood pressure), stimulates thirst (so helps to restore ECF volume), and, above all, stimulates sodium retention both directly (renally) and indirectly (by stimulating adrenal secretion of aldosterone); it thus reduces the sodium concentration of urine, feces, saliva, and sweat, but not milk.

Indices of aldosterone secretion (reduced sodium or potassium concentration in urine, feces, etc.) are often taken as evidence of sodium depletion or inadequate sodium intake, but the following points apply:

1. Aldosterone secretion is also stimulated directly by hyperkalemia (elevated plasma K^+) and promotes potassium excretion.
2. Such interpretations involve a subjective judgement concerning adequate or excessive sodium intake. Because physiologists and clinicians were traditionally more concerned with sodium depletion as well as its consequences and the defenses against it, elevated aldosterone secretion was readily seen as a warning signal. However, if sodium intakes associated with increased aldosterone have no other harmful effects, and especially if excess sodium intakes cause concern, low levels of aldosterone secretion might equally indicate excessive salt intake.

While sodium reabsorption in the distal nephron, influenced by aldosterone, is particularly important because it can produce sodium-free urine and promote potassium loss, the great majority of renal sodium reabsorption occurs elsewhere; about 25% in the loop of Henle and most in the proximal tubule. The loop is also a main site of magnesium reabsorption, hence the tendency for loop diuretics to cause hypomagnesemia.

The factors controlling proximal reabsorption are incompletely understood but their effect is clear: proximal reabsorption of sodium increases or decreases according to the need to enhance or diminish plasma volume. Since the fluid in the proximal tubule is similar to plasma, having been formed from it by glomerular filtration, it has the ideal composition for this purpose.

Natriuretic Hormones

Excretion of excess sodium involves not only suppression of salt-retention mechanisms but also activation of sodium-shedding (natriuretic) mechanisms. Two types of hormones are involved: atrial natriuretic peptide (ANP), produced by the cardiac atria when they are overstretched (reduction of ECF volume being an appropriate response to cardiac overload), and active sodium transport inhibitors (ASTIs), probably produced within the brain. These were probably the original molecules associated with the receptors binding cardiac glycoside drugs and are therefore also called 'endogenous digitalis-like inhibitors' (EDLIs);

their exact identity remains uncertain. Atrial natriuretic peptide has various effects that essentially oppose those of the salt retention induced by aldosterone: it increases sodium excretion, lowers arterial pressure, and promotes movement of ECF towards the interstitial compartment.

Other hormones (e.g., sex steroids, parathyroid hormone, calcitonin, thyroid hormone, prolactin) affect renal sodium retention or loss but are not thought to regulate it.

Adequate, Inadequate, and Excess Sodium

It is unlikely that adult daily maintenance requirement exceeds 0.6 mmol per kg body weight and could well be below this in many mammals. Newborn, growing, pregnant, or lactating animals have increased requirements. The appropriate sodium intake for humans remains controversial with some cultures managing on less than 1 mmol per day, while Western intakes may be in the range 200–300 mmol per day, more where processed foods are heavily consumed. There has been insufficient awareness among physicians and human nutritionists of just how high such intakes are, compared with requirements in other animals. Granted that humans are bipeds with a stressful lifestyle quite different from those of animals, there is no real evidence that human obligatory losses or sodium requirements are significantly greater. Rather, there is an ingrained tradition of regarding sodium intake as a benign pleasure, involving a harmless and healthy dietary constituent. The main warnings against this view come from the fact that hypertension is virtually unknown in low-salt cultures and that they do not even have an age-related rise in 'normal' blood pressure. Moreover, there are numerous studies that, when rigorously analyzed, indicate that human arterial pressure and salt intake are positively correlated; sufficiently to anticipate reductions in the prevalence of hypertension in response to manageable reductions in dietary sodium. Unfortunately, such reductions are still handicapped by inadequate food labeling and the fact that most sodium is added by the processor rather than the consumer. Humans, other than vegetarians, also have a very low potassium intake compared with other mammals; potassium may ameliorate the hypertensive effects of sodium.

Because obligatory losses of sodium are so low, dietary sodium depletion is hard to induce and sodium deficiency usually results from losses caused by renal, adrenal, or enteric disease; renal disease may cause either retention or loss of sodium. Globally, both in humans and animals, the most common cause of sodium deficits is acute diarrhea. Fortunately, sufficient gut usually remains unaffected for uptake of sodium and water to be stimulated by suitably formulated oral rehydration solutions. These essentially restore ECF volume (and acid–base balance), allowing natural defenses to overcome the underlying cause of the diarrhea. Despite some species variations, such solutions usually work best if their glucose:sodium ratio (in $\mathrm{mmol\,l^{-1}}$) is close to unity and they are virtually isotonic (i.e., they have a similar osmotic concentration to ECF; hypertonic solutions draw water into the gut). The function of glucose in these solutions is to promote sodium uptake; its nutritional contribution is trivial. Anions such as citrate, acetate, propionate, bicarbonate, and amino acids (e.g., glycine and alanine) may further enhance the uptake of sodium and therefore water. These sodium cotransport mechanisms are very similar to those of the proximal renal tubule. More recently, nutritional oral rehydration solutions that provide calories and glutamine (to sustain the form and function of enteric villi) have been successfully used in calves.

Sodium is thus central to the management of two of the most widespread clinical problems; hypertension (in humans) and diarrhea. Indeed, the World Health Organization (WHO) regards the discovery of oral rehydration, which depends on restoration of enteric sodium uptake, as the main life-saving development in twentieth century medicine. This powerful clinical application rests on a simple physiological observation concerning an elementary but vital dietary constituent.

Unresolved Issues

The control of renal sodium excretion is understood in great detail but the regulation of body sodium is not; key questions remaining unresolved e.g., how ECF volume is monitored, granted that most is interstitial rather than intravascular, and how the mechanisms regulating ECF volume and arterial pressure are integrated, granted that both use renal sodium excretion as their effector. The fact is that none of the common forms of general edema, i.e., excess interstitial fluid, is amenable to rigorous explanation, except via abstractions such as 'effective blood volume.'

The key nutritional concern regarding sodium is the human dietary requirement, assuming that excess intake predisposes populations to an age-related rise in arterial pressure. This is regarded as

normal but it is not seen in any population whose intake is closer to the likely requirement, compared with other mammals. For many individuals, this rise will ultimately destine them to antihypertensive therapy and predispose them to serious secondary hypertensive damage. While it is encouraging that governments are making serious attempts to reduce salt intake, it remains unlikely that it will be brought below 100 mmol day^{-1}, whereas if humans are like other mammals, requirement is unlikely to exceed 0.6 mmol kg^{-1} day^{-1} i.e., 40 mmol day^{-1} for a 70-kg human. Those who insist that human requirement is higher must provide evidence that human renal and colonic sodium conservation are uniquely inefficient or that the endocrine responses to lower salt intake, i.e., increased activity of the renin–angiotensin–aldosterone axis, diminished secretion of atrial natriuretic peptide and endogenous active sodium transport inhibitors, have pathological effects that outweigh moderation of the age-related rise of blood pressure.

Salt Intake and Health

C P Sánchez-Castillo, National Institute of Medical Sciences and Nutrition, Salvador Zubirán, Tlalpan, Mexico

W P T James, International Association for the Study of Obesity/International Obesity Task Force Offices, London, UK

Introduction

This chapter describes the historical importance of salt use, its production and trade throughout the centuries, and its significance in food preservation, in flavor enhancement and in food processing. Over the years, man has developed complex salt mining and drying systems, which are still in use today as the demand for salt continues to grow. Humans and other animals, exposed throughout evolution to very limited salt sources, have developed an intrinsic biological drive for salt with salt-specific taste receptors and highly effective hormonal and cellular transport systems for minimizing any salt loss from the intestine, kidney, and skin. Unfortunately, the use of highly salted food then induces a series of physiopathological responses including changes in blood volume and hormonal and cellular changes, which lead, in conjunction with other dietary and environmental factors, to a range of disorders including high blood pressure with its increased risks of stroke, coronary heart disease, and heart failure. Excess salt intake also seem to promote the development of osteoporosis, gastric cancer, and bronchial reactivity. The relationship of salt intake to these conditions will be described and the options for limiting intakes will be outlined.

Occurrence in Nature

The terms salt, sea salt, or table salt relate primarily to the compound sodium chloride. Sodium is the sixth most abundant element in the Earth's crust, constituting 2.8%. Sodium is a reactive element and is always found in compound form. There is a huge variety of salts containing sodium and many of these are found in food but in most societies the dominant form of sodium is as sodium chloride. Sodium chloride is very soluble in water and in seawater comprises about 80% of the dissolved matter.

A History of Salt Intake

The fundamental drive to obtain salt can be traced back to the earliest times when humans evolved in a hot African environment with scarce sources of salt. Evidence has been found of salt use during the Neolithic Age, and the Egyptian, Babylonian and Chinese civilizations all had special culinary uses for salt that are well documented. In China, for centuries the production of salt was a major industry. Salt sources were highly valued and were often protected. A tax on salt in the form of a head tax provided the Chinese government with a reliable source of revenue from about 2200 BC onwards. For centuries the only method of extraction practiced by coastal salt-workers was to boil sea water and this technique was employed in every maritime province of China as late as 1830. Solar evaporation was also used; shallow salt fields were filled with seawater which was shifted from field to field daily until salt crystallization began. A third method used in areas either far from the sea or on higher ground involved digging wells to tap sea water or salt-enriched aquifers.

Evidence for the exploitation of saline slicks in the Austrian Tyrol dates from the Bronze Age and to this day the salt mines of Salzburg in Austria and Krakow, Poland are still in use. For the Indians in Central America salt was so precious that to please their gods they abstained from eating salt and Mexican civilizations offered sacrifices to the Goddess of Salt, Vixtocioatl. Arab cultures still offer salt to visitors as a sign that their guest is safe; even a Bedouin robber will not violate the laws of hospitality once he has tasted his host's salt.

In pre-Roman times, the principal Italian road started at the salt works near the mouth of the Tiber River and cut through the Italian peninsula towards the Adriatic. In North Africa, the caravan route linked the salt oases, while salt roads were a feature of several South American countries. From remote parts of South America, such as the Amazon and Argentina, trails of more than 1500 km were linked to form the famous 'Cerro de Sal.' In the sixteenth century, sea salt crystals were traded from the sea through the Andes, gradually becoming more expensive further from the sea so that at distances of over 300 km only tribal chiefs used it. The common people made do with salt processed from palms and human urine. Salt from springs near Bogota was traded over a distance of 200 km to the north and south. Columbus' voyages were financed by the wealthy proprietors of the Mata Salt region of Spain, and when the first Spaniards arrived in South America in 1537, they found Indians exploiting local salt reserves on a large scale.

The financial structure of Venice was also substantially affected by the salt trade, which contributed to the emergence of Venetian capitalism and the vast fortunes of some Venetian merchants. In France, salt became a political issue in the fourteenth century; the tax on salt was the most hated of all taxes and a major issue prior to the French Revolution. At that time England, Germany, and Italy also taxed salt and in Britain the control of the world salt markets was a substantial contributor to its wealth in the seventeenth and eighteenth centuries. Liverpool, a minor tobacco port in the early eighteenth century, also became a major trading city in part due to its role in the salt trade.

During the earliest period of British rule in India the supply of salt was often tightly controlled and taxed. Gandhi emphasized the essential nature of common salt for human and animal well being, especially in a tropical country like India. Gandhi's 'salt march' to the sea broke the monopoly on salt use and led to his arrest and jailing. The following revolt, with 100 000 arrests, brought a change in the law to allow people to produce salt for their own use.

The production of salt currently depends on the same range of methods that have been used for centuries with substantial amounts being obtained by dry mining and with solution mining still involving water being pumped into rock salt deposits and the resulting brine being pumped back up to the surface for purification and evaporation. Solar evaporations, the oldest of the methods, is still used in hotter climates where salt pools allow the evaporation of sea water in the sun to produce salt. Currently, world salt production is over 210 million tons a year with 60% of the production being used to manufacture chlorine, caustic soda, and synthetic soda ash. About 20% of the world's production is for food use.

Salt in Food Technology

Salt enhances and modifies flavor, controls microbial growth, and alters nutrient availability and the texture/consistency of food. It also aids extraction methods, food formulation, and helps in the malting and fermenting of foods. In the production of some foods, e.g., pickles, cheese and fermented sausages, salt induces the withdrawal of water and various nutrients from the pickled tissue and provides an appropriate environment for growing the specific salt-resistant bacteria required for the fermentation or pickling process.

Sodium is also important in forming the texture of cheese, limiting bacterial growth and dehydrating cheese, thereby helping to form the rind. Most processed meats, e.g., ham and bacon, have added salt to season and cure the meat. Salt also inhibits bacterial growth and helps to emulsify the fat in sausages.

Sodium nitrate is used as a curing agent to prevent botulism as well as to provide the cured taste and red color of such meat products. Sodium polyphosphate is often added to poultry and fish fingers to increase their water-holding capacity and to bind the product. Salt is also effective in binding meat together by altering protein structures and dissolving some proteins. Salting fish has a flavoring and preservative role and fish may be treated in brine before being smoked.

In baking, salt enhances other flavors in the product; it also controls the rate of fermentation of yeast-leavened products and prevents the development of undesirable 'wild' types of yeast, which would lead to uncontrolled fermentation rates and variable products. Salt also strengthens the gluten in bread doughs, thus helping to ensure good dough handling and reducing the rate of water absorption. Sodium acid pyrophosphates are used in many industrial baking powders for specialty products. Salting of canned vegetables is primarily for flavor, but it can be used to separate mature, starchy green beans or peas, which will sink, from the younger, fresher beans, which float.

Processed 'snacks' are often heavily salted as a marketing feature, as are processed cereals and sodium-containing ingredients are added to many processed foods (**Table 1**), with sodium chloride accounting for about 90% of the sodium used by the food industry.

Table 1 Sodium-containing additives used in food processing

Additive	*Use*
Sodium citrate	Flavoring, preservative
Sodium chloride	Flavoring, texture preservative
Sodium nitrate	Preservative, color fixative
Sodium nitrite	Preservative, color fixative
Sodium tripoliphosphate	Binder
Sodium benzoate	Preservative
Sodium eritrobate	Antioxidant
Sodium propionate	Preservative
Monosodiumglutamate	Flavor enhancer
Sodium aluminosilicate	Anticaking agent
Sodium aluminum phosphate acidic	Acidity regulatory emulsifier
Sodium cyclamate	Artificial sweetener
Sodium alginate	Thickener and vegetable gum
Sodium caseinate	Emulsifier
Sodium bicarbonate	Yeast substitute

Other Uses of Salt

The universal use of common salt has allowed it to be used as a vehicle for combating widespread iodine deficiency by fortifying the salt with iodine, and fluoride has also been added as a preventive measure against dental caries. Chloroquine or pyrimethamine salt mixtures have been used to suppress the sporozoites responsible for vivax malaria.

The Impact of Refrigeration on Salt Intakes

Salt intake varies widely across the world. Some agricultural communities, e.g., the Yanomano Indians from Brazil and the Chimbus of New Guinea, do not consume salt other than that found in natural food sources. The Kamtschadales and the Tungouses nomadic tribes from the north of Russia and Siberia are also averse to added salt, whereas the Japanese have traditionally consumed large quantities of salt in pickled salted fish and vegetables.

Without some form of food preservation it would be impossible to supply urban populations with food in any systematic way. Refrigerators were introduced on a mass scale from the 1960s onwards and this was accompanied by a fall in salt consumption in most countries (**Table 2**); refrigeration has taken over from salting as a method of preserving food. In Japan, intakes as high as the 60-g intake of a farmer recorded in 1955 and the average of 27–30 g day^{-1} had fallen dramatically to 8–15 g day^{-1} by 1988. In the US, salt intake probably started to decline in the 1920s as refrigerators became widely available.

Dietary Exposure to Salt in the Young

Table 3 shows the average daily sodium intakes from food consumed by young people in the UK.

Table 2 Salt intake as NaCl (g day^{-1})

Changes in Mineral Composition of Food Induced by Industrialization and Urbanization

The process of industrialization and urbanization has affected the nutritional value of many of the more traditional foods as illustrated for Mexico in **Table 4**. Although home cooked corn (maize) tortillas, together with beans, formed the staple traditional diet, tortillas are now being produced differently: both industrially and by individuals at small market stalls in the cities.

The concentrations of the major nutrients sodium, potassium, calcium, magnesium, and phosphorus in unprocessed foods vary within narrow limits, but in processed or cooked foods, where salt (NaCl) or additions of other sodium-containing ingredients are common, the concentration range of sodium is higher. A large proportion of processed food has salt added; as more processed foods are eaten, the saltier the diet becomes. **Table 4** shows that the corn in its original form contains a very small concentration of sodium but is rich in potassium. Once the grain is milled, fractionated, and processed to produce tortillas, then the nutrient composition alters. Potassium is also lost during the initial washing procedure. Limestone is added to release the niacin from its bound form; this also induces a threefold increase in calcium content. Salt is not commonly added during tortilla preparation in the country, but a remarkable 70- to 200-fold increase is found in breakfast cereals and processed corn snacks as well as substantial potassium losses. Almost no calcium is found in modern breakfast cereals whereas traditionally prepared tortillas have almost 60 times more calcium.

Table 4 Effects of industrialization on the composition of Mexican foods

Food	*Mineral content (mg per 100 g fresh weight)*		
	Na	*K*	*Ca*
Corn	4	284	55
Tortilla (traditional)	11	192	177
Processed wheat tortilla	620	73	11
Breakfast cereals	866	101	3
Processed snacks	838	197	102
Beans			
Home cooked	14	470	67
Processed	354	371	26

Salt and Disease

The Roman word from which the name 'salt' is derived is Salus, Goddess of Health. Gandhi argued that salt was "essential for human well being, specially in a poor country like India where its inhabitants eat vegetables and rice which contain low salt." However, although its name evokes health, over the years a long-term excess intake of salt has come to be recognized as a major cause of hypertension and thus a risk for stroke and coronary heart disease. An excess of dietary salt may also affect gastric cancer, osteoporosis, and bronchial hyperreactivity. Evidence also suggests that high-salt intake causes left ventricular hypertrophy independently of blood pressure effects.

Salt Intake and Blood Pressure

When salt is ingested it is readily absorbed in the small intestine in association with other molecules such as glucose. The intestinal secretions also contain sodium at concentrations similar to those found in the plasma but the colon has a highly effective active transport system for absorbing practically all the sodium in the colonic contents; only about 1 mmol of sodium is normally excreted in the feces except in cases of severe diarrhea Once the sodium is absorbed the body ensures that the tonicity of the body fluids is finely maintained; so water is retained by the kidney and the blood volume tends to expand until the hormonal responses, e.g., from the atrial naturetic hormone (released in response to changes in atrial pressure) and in the renin-angiotensin system, lead to a fall in the kidney and sweat glands' reabsorption of sodium and therefore a greater sodium urinary excretion and loss in sweat. There are also adjustments in vasomotor tone and the neuronal responses as well as changes in the exchange of sodium and potassium across cellular membranes. The blood pressure then rises, as the kidney reflex demands a higher blood pressure in order to limit the body's extracellular volume expansion.

The degree to which the blood pressure rises in response to dietary salt depends on a range of interacting genetic factors and other environmental influences including the intake of potassium, magnesium, and calcium. The suppressive effects of these minerals in part explain the blood pressure-lowering effects of a diet rich in fruit and vegetables. Fat intakes have been shown to amplify resting blood pressures whereas moderately intense exercise is followed by a lower blood pressure. As fat intakes rise and physical activity falls in many modern societies the body weight and body fat of children and adults

increase. The greater storage of fat leads to changes in a range of hormonal secretions from the fat cells including angiotensinogen, a precursor of the renin-angiotensin axis affecting the kidney's excretion of sodium. Adiponectin secretion from expanding adipocytes falls thereby making the blood vessels much more sensitive to plaque formation, medial hypertrophy, and fibrosis. Salt-induced increases in blood pressure also involve an array of other hormonal responses including the potent vasocontrictor endothelin-1 and the vasodilator bradykinin, these being potentially involved in the blood pressure-independent effects of higher salt intake on arterial thickening, cardiac ventricular hypertrophy, and the synthesis of elastin and collagen in the artery. This makes them progressively thicker and less pliable.

Given this complex of interacting factors it is not surprising that the selective effect of salt intake on blood pressure has been hard to define. The role of salt in inducing high blood pressure is based on extensive animal experiments at the cellular and physiological level, on clinical studies and dietary intervention trials, as well as on major population analyses of blood pressure in relation to salt intake. Meta-analyses of longer term intervention trials to investigate the effect of salt reduction on hypertension also demonstrate that a modest reduction in salt intake has a significant effect on blood pressure in normotensive individuals and an even greater effect in those with pre-existing hypertension.

The response of neurohumoral mechanisms to salt loading varies in different individuals and for many years investigators sought to define what they termed 'salt-sensitive' individuals. There are rare genetic mutations associated with extreme salt sensitivity but within the general population there appears to be a more or less continuous variation in responsiveness consistent with multiple gene–environmental interactions. So perhaps it is not surprising that no clear cut-off points have been agreed for defining 'salt-sensitivity.' Patients with advanced renal failure do have an increased response of their blood pressure to salt loading but this is due to a loss of functioning nephrons.

Rural-urban differences in salt intake and blood pressure Migrant studies are useful in assessing the impact of environmental changes on blood pressure in different ethnic groups. Shaper's original study on Samburu men recruited from Kenyan villages to military camps was associated with a 12-mmHg increase in systolic blood pressure within weeks and similar findings were obtained in Ugandan villagers who had migrated to an urban environment. **Table 5** shows some of the differences between individuals living in their original Ugandan environment and those who had migrated to a more complex urban environment. The Ugandan analyses evaluated the rate of rise in blood pressure with age in the two communities and showed marked differences.

Table 5 Migration studies that assessed rural–urban differences in Uganda, Africa

	Villager	*Migrant*
Systolic blood pressure/age slope[a]	0.15	0.64
Urinary sodium (mmol l^{-1})[a]	82.4	108.6
Urinary potassium (mmol l^{-1})[a]	67.4	38.4

[a]Poulter, NR *et al.* (1990) The Kenyan Luo migration study: Observations on the initiation of a rise in blood pressure. *Br. Med. J.* **300**: 967–972.

Beaglehole also found that the blood pressure of Polynesian children migrating to New Zealand rose simultaneously with dietary changes and this increase was not explained simply by an increase in body weight. More recent studies, e.g., in Mexico (**Table 6**), show the effect of migration on both sexes. Blood pressure rises in association with increases in urinary sodium but pottasium excretion also rises and the men show a decrease in BMI.

Conversely, Japanese people migrating to the US showed marked reductions in the prevalence of hypertension and stroke mortality consistent with the known markedly lower salt intake in association with other environmental changes in the US.

In all these analyses, several dietary changes as well as altered salt intake have occurred, e.g., in potassium and calcium intakes together with weight

Table 6 The urinary 24-h output of electrolytes and the associated blood pressure (BP) differences in rural and urban Mexico

	Men		*Women*	
	Rural (n = 24)	*Urban (n = 19)*	*Rural (n = 54)*	*Urban (n = 58)*
Sodium (mmol day^{-1})	103.3	133.1	93.3	114.7
Potassium (mmol day^{-1})	41.6	56.7	36.9	50.4
Sodium/potassium ratio	2.64	2.51	2.67	2.44
NaCl (g day^{-1})	5.99	7.72	5.41	6.65
Systolic BP (mmHg)	110.4	114.3	104.4	113.8
Diastolic BP (mmHg)	73.3	75.6	67.0	72.8
BMI	25.5	25.1	24.1	26.6

BP, blood pressure; BMI, body mass index.

gain, altered intensities of physical activity, and doubtless psychosocial stress from entering an unfamiliar environment. Experimental, epidemiological, and clinical evidence suggests that dietary deficiencies of potassium or calcium potentiate the sodium induction of high blood pressure. Potassium loading prevents or ameliorates the development of sodium chloride-induced hypertension in several animal models and epidemiologically the ratio of urinary sodium to potassium (Na:K) is a stronger correlate of blood pressure than either sodium or potassium alone. Results of clinical trials also suggest that an increased potassium intake decreases blood pressure in patients with hypertension and the antihypertensive effect of potassium is more pronounced in persons consuming a high sodium chloride intake. With acculturation, primitive societies tend to increase their sodium intake and reduce the potassium content of their diet; therefore, the combination of a high potassium with a high salt diet is somewhat unusual. High potassium intakes were found, however, in the Aomori prefecture of Japan where there was a lower blood pressure and a reduced mortality from strokes despite high-salt intake.

There is also an inverse association within and among populations between dietary calcium and blood pressure. A low calcium intake may amplify the effect of a high sodium chloride intake on blood pressure, and calcium supplementation blunts this effect. High dietary calcium also preferentially lowers blood pressure or attenuates the development of hypertension in sodium chloride-sensitive experimental models.

Given all these dietary effects discerning the impact of salt intake changes as such is not easy. The migrant studies are crude compared with analyses of controlled dietary changes in the sodium intakes of volunteers. More robust analyses can also be obtained from the relationship between sodium intakes and blood pressure across a whole spectrum of different societies where account is taken of the possible effects of sodium intakes at different ages, of other dietary and environmental effects, as well as of differences in body size. The ability to reduce blood pressure by selectively limiting dietary sodium intake has also been assessed in a series of meticulous meta-analyses.

Genetic influences Primary hypertension has a well-known familial aggregation and has been calculated to be about 40% genetically determined. Children with a family history of hypertension are 30% more likely to remain in the upper quartile of systolic blood pressure than their peers. Young adults from families with hypertension have a greater rate of sodium excretion after a salt load than adults from normotensive families. Studies of twins also provide convincing evidence for a hereditary component to salt responsiveness. However, the effect of family history decreases with age as other environmental factors, e.g., weight gain, modify the risk. Studies have suggested that polymorphisms in certain genes, such as the angiotensinogen gene, might be implicated in the blood pressure response to a high-salt intake and genes whose products function prominently in the renin-angiotensin-aldosterone system are potential candidate genes contributing to essential hypertension. However, two meta-analyses assessed the relation of both insertion/deletion (I/D) polymorphisms of the angiotensin-converting enzyme (ACE) gene and the M235T angiotensinogen gene with primary hypertension and cardiovascular diseases and found no association with hypertension in ACE I/D gene polymorphism. Individuals homozygous for the deletion allele seem to have a higher risk of macrovascular and microvascular complications and the T allele encoding angiotensinogen may be a marker for hypertension, at least in white subjects, but great caution is needed before inferring that a single set of genes has a substantial impact on the development of higher blood pressures in response to increases in salt intake as so many neurohormonal mechanisms are involved.

Age-related changes in blood pressure In most populations, blood pressure increases with age but there are a few small groups who have not been exposed to modern environmental conditions and they do not show a rise in blood pressure with age. The Kuna indigenous population living on islands in the Panamanian Caribbean was among the first communities described showing almost no age-related rise in blood pressure or hypertension. Other populations in Africa, the Americas, Asia, and the Pacific region have the same characteristics. In many of these communities, the primary evidence that the protective factor is environmental rather than genetic was the blood pressure rise following migration to an urban environment. Among the many lines of evidence suggesting a role for salt intake in the pathogenesis of hypertension, particularly compelling has been the identification of these isolated communities where salt intake is low, hypertension is rare, and blood pressure does not rise with age. Salt intake in such communities generally provided less than 40 mmol of sodium per day, and typically much less. The age-related rise is rare at mean sodium excretion rates of <100 mmol per day but clearly there are many other dietary and environmental differences.

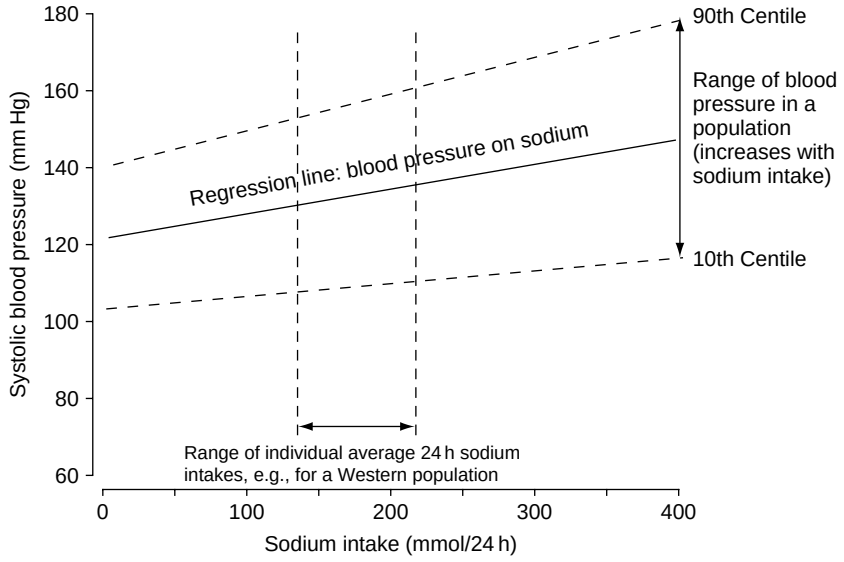

Figure 1 The relationships between sodium intake and blood pressure in the INTERSALT study. Adapted from: Frost CD, Law MR, Wald NJ (1991) Analysis of observational data within populations. *BMJ* **302**: 815–818.

Intersalt studies A major transnational study of over 10 000 men and women described the association between urinary excretion of sodium chloride (as a measure of salt intake) and blood pressure. After adjustments for body weight, alcohol intake, sex, and age, a higher sodium intake of 100 mmol day^{-1} was linked with a systolic blood pressure rise of 3–6 mmHg in adults aged 40 years but one of 10 mmHg when aged 70 years. Updated results suggest that the association between sodium excretion and blood pressure is stronger when not adjusted for body weight, but the relationship is present whether or not the adjustment is made.

Figure 1 summarizes the relationships between sodium intake and blood pressure in the INTERSALT study. Different populations may show different responses depending on the host of other environmental factors that may be involved. The figure also illustrates the fact that individuals within any population may show very different effects and that appreciable changes in salt intake may be needed before a clear change in blood pressure is evident. Part of the problem in displaying the relationship arises from the difficulty in establishing what the prevailing blood pressure of individuals is given the remarkable variation in blood pressure during the day and night; difficulty also arises because it takes many complete 24-h urinary collections to obtain a reasonable estimate of the customary sodium intakes. The age-related incline also implies longer term amplification of the pathophysiological changes in hormonal controls and in blood vessel reactivity and plasticity; thus, as the blood pressure increases the tendency to further increase is enhanced in an accelerating process. This emphasizes the potential importance of early interventions when the blood pressure is tending to rise. It also implies that interventions to alter the diet of the young may be particularly valuable. This is borne out by the observation in the Netherlands that newborn babies fed a reduced salt content in their formula milk for the first 6 months of life had very much lower blood pressures when reassessed at the age of 15 years.

Table 7 shows the estimated changes with age in blood pressures as the salt intake is increased by

Table 7 Predicted change in systolic and diastolic blood pressure (mmHg) for each 100 mmol per 24 h change in sodium intake for various centiles of blood pressure distribution

Age (years)	*Centile*

100 mmol sodium per day. Epidemiologists concerned with the subtle but substantial population effects are mostly of the opinion that salt is an important causal factor in determining the steady increase in average blood pressure and the prevalence of hypertension in Western societies.

Adults with episodic high blood pressure, e.g., as a response to mental stress, have a greater tendency to develop persisting hypertension. The higher the blood pressure level becomes, the greater the further increase in blood pressure. Thus, the age-dependent increase in blood pressure may be a particularly important factor to measure in both individuals and the community.

On a population basis it has been estimated that in affluent societies, where average population blood pressures are high, a reduction of 2 mmHg in diastolic blood pressure would result in a 15% reduction in the risks of stroke and transient ischemic attacks and a 6% reduction in risk of coronary heart disease. There may also be a reduction independent of the effects on blood pressure on other conditions such as left ventricular hypertrophy.

A higher frequency of salt responsiveness has been observed in adults with hypertension. Estimates of the prevalence of this sensitivity have ranged from 29 to 60% in hypertensive populations and 15–46% in normotensive populations, although the larger studies have indicated that over 50% of a hypertensive population and approximately 25% of a normotensive population are clearly salt responsive. Longer term, e.g., 27-year-long, studies have shown that those with initially normal blood pressure but a marked responsiveness to salt had an increased risk of cardiological events and death as had those with pre-existing hypertension. In the absence of a consensus on defining either the genetic polymorphisms relating to hypertension or the parameters of salt sensitivity the greatest benefits are likely to be achieved by taking a population approach to reducing salt intake.

The most recent meta-analysis, which related to studies with modest salt reductions and a duration of at least 4 weeks, showed that there were 17 trials in hypertensives and 11 trials in normotensives for analysis. The combined and pooled estimates found significant reductions in blood pressure of 4.96/2.73 mmHg in hypertensives and 2.03/0.97 mmHg in normotensives, which on a population-wide basis are significant effects.

Recently, new diagnostic thresholds to define hypertension were made available in the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. A new category designated 'prehypertension' is defined as systolic blood pressure values between 120 and 139 mmHg and diastolic blood pressure values of 80 to 89 mmHg. Individuals within this group require health-promoting life-style modifications to prevent cardiovascular disease since they are at increased risk for progression to hypertension. The thresholds for stage 1 hypertension are blood pressure values of 140–159 mmHg (systolic) and 90–99 mmHg (diastolic) with stage 2 hypertension being defined when blood pressure values are $\geq$160 mmHg (systolic) and $\geq$100 mmHg (diastolic) values, respectively. Both categories require life style modifications as well as drug therapy. Individuals with diabetes, who are recognized as being at greater cardiovascular risk, should keep their blood pressure below 130/80 mmHg.

Salt reduction in pre-existing hypertension Salt deprivation became the major means of treating hypertension in the early part of the twentieth century. The low-salt diets were notoriously unpalatable so patients reduced their food intake and the consequent weight loss helped to reduce the blood pressure further. A large number of trials of salt restriction have been conducted since then on both hypertensive and normotensive subjects and the overall analyses show that the greater the initial blood pressure, the more marked the fall in blood pressure, particularly if the sodium intake reduction persists. These data have been interpreted to suggest that the effect of a universal moderate reduction in dietary salt would substantially reduce a population's mortality from stroke and ischemic heart disease with an impact far greater than that achieved by drug treatment of those with high blood pressure. Thus, the World Health Organization (WHO) and most national dietary guidelines now call for a lowering of salt intake to 5–6 g day^{-1} on average or less.

More recently, two controlled intervention trials, the Dietary Approaches to Stop Hypertension (DASH) and the follow-up DASH sodium trial, compared three different types of eating patterns: (1) the 'control diet'; (2) extra fruit and vegetables; and (3) the 'DASH or combination diet,' which was lower in saturated fat, total fat, and cholesterol as well as having higher intakes of fruits, vegetables, and low-fat dairy products. All three eating plans used 3 g day^{-1} sodium. The results of the clinical trials found that the combination diet or 'DASH diet' decreased systolic blood pressure (SBP) by 11.4 mmHg below the control diet and decreased diastolic blood pressure (DBP) by 5.5 mmHg in

adults with hypertension. In adults without hypertension the decreases were 3.5 mmHg (SBP) and 2.1 mmHg (DBP).

When the selective effects of salt were examined without weight changes then reducing the salt intake from 9 to 3 g significantly reduced blood pressure by 6.7/3.5 mmHg on the controlled diet and on the higher potassium DASH diet by 3.0/1.6 mmHg. Thus, the combined effects of the DASH diet and low-salt intake on blood pressure were greater than either of the interventions alone. With this combination, mean SBP was 11.5 mmHg lower in participants with pre-existing hypertension, and 7.1 mmHg lower in participants without hypertension. The effects were observed in both sexes and across racial groups. The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure in the USA and the Scientific Advisory Committee on Nutrition from the Food Standards Agency, Department of Health in the UK have acknowledged that the clear and distinct effect of salt on blood pressure shown in the trial indicates that lowering salt intake as part of a healthy whole diet strategy would be most effective as a population-based approach to lowering blood pressures.

Gastric Cancer and Stroke

There is a strong geographical correlation between stomach cancer and stroke mortality, both of which correlate with salt intake. There are four recognized major etiological factors for gastric adenocarcinoma: infection with *Helicobacter* pylori, excessive salt consumption, and low intakes of ascorbic acid, carotenoids or more generically of vegetables and fruits. Sodium chloride induces atrophic gastritis and enhances the mutagenic effect of nitrosated foods. Salt may also play a role in the later steps involving the transformation of mucosal dysplasia to carcinoma. The salted pickles and salted fish of Japanese cultures appear to be strongly linked to the development of stomach cancers.

Osteoporosis

It has been known for many years that sodium intake is one of the major determinants of urinary calcium excretion. It has been estimated that urinary calcium losses increase by approximately 1 mmol per 100 mmol sodium intake. Experimentally sodium intake increases calcium excretion but also induces markers of bone resorption. It is hypothesized that trabecular demineralization may occur, leading to postmenopausal changes and an increased risk of vertebral fractures and cortical erosions. Further research is required in this area.

Bronchial hyper-reactivity

There have been no large-scale epidemiological studies, but a positive relationship between asthma mortality and regional purchases of table salt per person has been shown. In a randomized double-blind crossover trial in subjects with moderately severe asthma, the airway response to histamine was related to urinary excretion of sodium in a dose-response way, but only in men. A low-salt diet is regarded as having a potentially positive effect in patients with asthma and may help to reduce the need for anti-asthma drugs.

Sources of Salt Intake

Various approaches to measuring the daily salt intake in individuals have been tried. Salt comes from: (1) natural products; (2) salt added during industrial processing; (3) salt from catering; (4) other sodium-containing sources; (5) discretionary use of salt in cooking and table salt; and (6) sodium in drinking water. Traditional methods of estimating salt intake, e.g., with economic data, lead to marked errors and usually substantial overestimates. These have now been replaced by more modern methods.

Estimating Salt Intakes

The principal and most accurate method for estimating sodium intake is to measure sodium excretion rates in individuals who are asked to collect one or more complete 24-h urinary outputs. To measure absolute amounts a marker for completeness of collections is required. Measurement of intake from dietary assessment methods alone is considered unreliable. Until recently, however, there was no way of establishing how much of the 24-h sodium intake was derived from different sources, without the use of traditional weighing and analytical methods. A new technique involving the use of lithium has allowed a new approach; this method involves fusing Li_2Co_4 (used as a tracer) with NaCl. One preliminary 24-h collection and three full 24-h urinary collections are required.

Gains and Losses of Salt during Cooking

Only a small proportion of the salt added to water for cooking foods is eaten. A value of 24% was obtained by the lithium method for the average intake per head of the 'purchased' cooking salt used in cooking in the

UK. The only other data using traditional methods come from Hungary where 41% of the salt purchased by households was actually ingested.

Assessment of Total Discretionary Salt Use

Figure 2 compares the traditional and lithium marker techniques for assessing both total salt intake and the distribution of its sources. When table and cooking salt are combined to form a single value, the percentage contribution of these discretionary sources to the total intake measured by the lithium marker technique is significantly lower in the UK compared with that assessed by traditional methods, which do not consider salt losses during cooking and at the table. This intake in the UK seemed unusually low, but when discretionary sources (table and cooking salt) were assessed in various regions of Italy using the lithium marker technique, discretionary salt intake varied between 31 and 41% of total intake. In rural Benin the use of discretionary sources in women was higher (52%) and in rural Guatemala was as much as 77% of total intake. Thus, the more industrialized the food system the greater the proportion of nondiscretionary salt intake, which then makes it more difficult for individuals to reduce their salt intake. In Japan, salt is ingested in large amounts as pickled and salted fish and vegetables but these distinctive items may be considered discretionary sources of salt. Similarly, there are specific discretionary salted meat and vegetable extracts that are used for flavoring in Western societies.

Traditional data on table salt use are given in **Table 8** and new estimates in **Table 9**.

Pore Size in Salt Cellars

The pore size and hole number is important in determining the amount of salt actually shaken onto food. Smaller shaker hole areas lead to a marked fall in salt consumption, for example, to about a quarter of the maximum value.

Table 8 Sources of dietary salt in different countries assessed by traditional methods (grams per head per day)

Country	*Total*	*Nondiscretionary sources*			*Discretionary table/or cooking*
		Natural	*Processing*	*Catering*	
England	9.5		7.9		1.6

Implications of the Salt-Disease Relationships in Relation to Population and Individual Strategies for Improving Health

A population-based approach to reducing disease by reducing salt intake is a public health strategy directed at the whole population rather than those individuals considered to be at high risk. Such a strategy is based on the observation that a small reduction in risk of a large number of people may result in a large reduction in risk for the entire population. This does not mean, however, that individualized strategies cannot be used to help individuals considered at high risk because of pre-existing hypertension. Indeed, the greater reductions in blood pressure in hypertensives on reducing salt intake imply that there should be a special focus on this vulnerable group. So, ideally, both strategies are needed: the whole population strategy because the risk from cardiovascular disease associated with higher blood pressures is not confined to those who are considered clinically hypertensive, but includes large numbers of people in the upper 'normal' blood pressure range. Furthermore, many surveys in different countries show that a large proportion of hypertensives are not in receipt of any treatment. This emphasizes the value of dealing with a population that overall may be at a relatively high risk of premature mortality. Such measures should cause a downward shift in the population distribution of blood pressure, which would also benefit high-risk groups.

Individualized Approaches

Hypertensives can take steps to reduce their salt intake by modifying their diets. If these individuals come from societies where a substantial amount is eaten as discretionary salt then those responsible for adding salt to the cooking either in the home or in catering establishments need to be persuaded to take progressive measures to limit salt use and substitute herbs and other flavors. Individuals can also be asked to eliminate the addition of salt at the table but this can only make a minor contribution in most cases to reducing their salt intake. In theory it is possible for patients to select foods low in salt but this usually means selecting relatively unprocessed foods. Multimineral mixes may also be found to be more acceptable for use in households as these are a mix of different salts with, for example, the addition of potassium and calcium salts to the sodium chloride thereby both diluting the amount of sodium used and adding elements that counter the sodium's effects. Theoretically, food labels can be used to choose lower salted foods but this needs far too much sophisticated understanding for most consumers. The simplest test of an individual's ability to alter their diet and reduce salt intake by avoiding salted and pickled foods, heavily salted breads, prepared meats and snacks is to check their urinary excretion of sodium. The great difficulty in permanently changing diets is shown by longer term analyses of intervention studies, which reveal very modest long-term reductions in urinary sodium.

This emphasizes the need for population approaches such as that developed in Finland where children were taught at school how to select less salted foods and to alter the use of salt in cooking within the home. There was also a multipronged drive to persuade catering organizations and restaurants to limit the salt in cooking and the food manufacturing sector was persuaded to alter their product composition and limit salt addition as well as altering their fat and fatty acid content. As a result of these measures the average systolic blood pressure of the adults of North Karelia in Finland fell by 10 mmHg over a 15-year period and this was accompanied by a dramatic fall in stroke and coronary artery disease deaths of over 75%, helped substantially by the

simultaneous falls in the average total blood cholesterol levels of the population.

The importance of altering the salt content of foods, especially bread, which is often a major source of salt, was shown in Portugal where a village baker was persuaded to reduce the salt content of his bread. Two years later the average blood pressure of the villagers was significantly lower than that of a neighboring village where no changes had been made.

Thus, governments have a major role in persuading their health services to take a systematic approach to reducing salt in hospital foods and to engage in systematic patient and public health educational initiatives. The problem is that the salt industry and other sectors of the food industry often do their utmost to contest the evidence and find reasons why they should not progressively reduce the salt content of their products. We need to see major improvements in food labels and a traffic light-type warning system so that high-salt products can readily be identified. Several countries are embarking on the exercise of defining high-salt foods and taking steps to counteract the tendency for some soft drink companies to over-salt their snack food products so that they stimulate thirst and increase demand for their drinks! Only when countries follow the Finnish lead can we expect to see an appreciable fall in salt intake and a concomitant reduction in hypertension rates and cardiovascular disease.

Conclusions

Evidence suggests that sodium intake is an important determinant of blood pressure in the population as a whole, and influences the rise in blood pressure with age. The predominant source of salt varies from country to country. In the UK, for example, the greatest potential effect involves reducing the salt content of manufactured food. A different public health approach would apply to Italy, where discretionary intake of salt is two to three times greater than that of the UK and for Guatemala where intakes from these sources are high.

SPORTS NUTRITION

R J Maughan, Loughborough University, Loughborough, UK

Introduction

At an international Consensus Conference held at the offices of the International Olympic Committee in 1991, a small group of experts agreed a consensus statement that began with the opening statement: "Diet significantly influences exercise performance." This is a bold and unambiguous statement, leaving little room for doubt. However, the statement went on to add various qualifications to this opening statement. These qualifications reflect the uncertainties in our current knowledge, but are also a consequence of the many different issues that arise in considering the interactions between diet and performance and the diverse needs of athletes in different sports. In the years since that statement was formulated, the world of sport has advanced, with new world records and new champions. The world of science has also moved forward and there have been some important advances in our understanding of the interactions between nutrition and sports performance.

In considering the role of diet in the athlete's life, two main issues must be considered, each of which gives rise to many subordinate questions. The first question is how the demands of training affect the body's requirement for energy and nutrients: this then has implications for body composition (including the body content of fat, muscle, and bone), for the hormonal environment and the regulation of substrate metabolism, and for various disease states that are affected by body fatness, nutrient intake, and other related factors. The second question is how nutritional status influences the responses to and the performance in competition.

Athletes should be encouraged to follow eating plans that maximize the extent of recovery between training sessions, maximize the effectiveness of the adaptations that occur in response to each training session, and minimize the risk of illness and injury that might interrupt training or prevent participation in competition. This involves identification of each athlete's nutritional goals and the formulation of an eating strategy that will allow those goals to be met. There will be special issues in the period before and during competition that will influence nutrition needs, and separate dietary strategies will be necessary for training and for competition.

Nutrition for Training

The training load of athletes varies greatly between individuals, depending on the nature of the sport and the level of competition, and it also varies over time in relation to the competitive season. Training may consist of high-intensity resistance training, brief but intense sprints, prolonged moderate intensity efforts, or technical work. Each places different demands on the muscles, cardiovascular system, and other tissues, and each has different energy requirements. The aim of training is to induce changes in body tissues and organs that will improve exercise performance, but different adaptations are required in different sports. Increasing muscle mass, strength, and power is a key objective in many sports, but in other sports, these changes would hinder, rather than help, performance. The training stimulus, therefore, must be specific to the objectives of the event. Within limits, the greater the training stimulus – consisting of the intensity, duration and

frequency of individual training sessions – the greater the adaptation that takes place. As mentioned above, nutrition is important in promoting recovery between training sessions to allow an increase in the training load that can be sustained without succumbing to illness and injury, and also in allowing more effective adaptations to each bout of training. This may be important in complex sports such as soccer, where different training objectives must be achieved and where the training must also accommodate practice of a variety of skills.

Influence of Exercise Training on Energy Balance

Energy must be supplied by the diet to meet immediate energy needs (body functions, energy for activity, and growth) and for the maintenance of body energy stores. Energy stores, consisting primarily of fat, but including the key carbohydrate stores in liver and muscle, play a number of important roles related to exercise performance, since they contribute to size and function (e.g., muscle mass) as well as providing fuel for exercise. Athletes try to manipulate these factors towards the characteristics that offer advantages to their sport: this may mean a change in body mass, a change (usually a reduction) in body fat, a change (usually an increase) in muscle mass, and optimization of muscle and liver carbohydrate stores.

Not all athletes are able to correctly identify goals that are suitable for their sport and for their individual make-up. This can lead to various problems, including excessive restriction of energy intake in an attempt to achieve an unrealistically low body mass. If energy intake is too low, and especially if carbohydrate intake is inadequate, it may not be possible to sustain the training load without the risk of chronic fatigue, injury and illness. If an energy deficit is incurred, it may lead to changes in metabolic and hormonal function, which affect performance, growth and health. One outcome of low energy availability in female athletes is a disturbance of reproductive function and menstrual regularity. Other problems are likely to occur in male athletes. There is a real danger that the focus on achieving a specific body mass and body composition, may become more important than achieving success in competition.

Monitoring of body mass can provide a useful index of energy balance in some situations, but other biomarkers are generally better. Measurement of body fat stores, usually by measurement of skinfold thickness, can be helpful in setting targets and in monitoring progress. Other markers, such as measurement of urinary ketone levels, can identify athletes who are failing to achieve an adequate carbohydrate intake. Problems are most likely to occur when the energy expenditure is either very high or very low. Athletes with very high energy demands are likely to be training at least twice per day, leaving limited opportunities for eating the large amounts of foods that are necessary. Athletes with low energy demands and who must restrict energy intake to achieve a low body mass have two main problems: they must cope with constant hunger and they must also be careful in their selection of foods to ensure that they achieve an adequate intake of essential nutrients.

An athlete's energy requirements are set primarily by the training load and by body mass, although there is also a large interindividual variability even when these factors are constant. Measurements of oxygen uptake, heart rate, and other variables made after exercise show that the metabolic rate may remain elevated for at least 12 h and possibly up to 24 h if the exercise is prolonged and close to the maximum intensity that can be sustained. After more moderate exercise, the metabolic rate quickly returns to baseline level. Therefore, it seems likely that the athlete training at near to the maximum sustainable level and who already has a very high energy demand will find this increased further by the elevation of postexercise metabolic rate: this will increase the difficulties that many of these athletes have in meeting their energy demand. The recreational exerciser, for whom the primary stimulus to exercise is often to control body mass or reduce body fat content, will not exercise hard enough or long enough to experience substantial elevations of metabolic rate after exercise.

Macronutrient Demands

Protein

The idea that protein requirements are increased by physical activity is intuitively attractive, and high-protein diets are a common feature of the diets of sportsmen and women. The available evidence shows an increased rate of oxidation of the carbon skeletons of amino acids during exercise, especially when carbohydrate availability is low. Protein contributes only about 5% of total energy demand in endurance exercise, but the absolute rate of protein breakdown is higher than at rest (where protein contributes about the same fraction as the protein content of the diet, i.e., typically about 12–16%) because of the higher energy turnover. It is often recommended that athletes engaged in endurance activities on a daily basis should aim to achieve a protein

intake of about 1.2–1.4 g kg^{-1} day^{-1}, whereas athletes engaged in strength and power training may need as much as 1.6–1.7 g kg^{-1} day^{-1}. Those who take no exercise have an estimated average requirement of about 0.6 g kg^{-1} day and the recommended intake for these individuals is about 0.8–1.0 g kg^{-1} day.

In strength and power sports such as weightlifting, sprinting and bodybuilding, the use of high-protein diets and protein supplements is especially prevalent, and daily intakes in excess of 2–4 g^{-1} kg^{-1} are not unusual. Scientific support for such high intakes is generally lacking, but those involved in these sports are adamant that such high levels of intake are necessary, not only to increase muscle mass but also to maintain muscle mass. This apparent inconsistency may be explained by Millward's adaptive metabolic demand model, which proposes that the body adapts to either high or low levels of intake, and that this adjustment to changes in intake occurs only very slowly. This means that individuals such as strength and power athletes who consume a high-protein diet over many years will find that any reduction in protein intake will result in a loss of muscle mass. This is because of an upregulation of the activity of the enzymes involved in protein oxidation to cope with the high intake: activity of these enzymes remains high when there is a sudden decrease in intake, leading to a net catabolic effect.

Protein synthesis and degradation are both enhanced for some hours after exercise, and the net effect on muscle mass will depend on the relative magnitude and duration of these effects. Several recent studies have shown that ingestion of small amounts of protein (typically about 35–40 g) or essential amino acids (about 6 g) either before or immediately after exercise will result in net protein synthesis in the hours after exercise, whereas net negative protein balance is observed if no source of amino acids is consumed. These observations have led to recommendations that protein should be consumed immediately after exercise, but the control condition in most of these studies has involved a relatively prolonged (6–12 h) period of fasting, and this does not reflect normal behavior. Individuals who consume foods containing carbohydrate and proteins in the hour or two before exercise may not further increase protein synthesis if additional amino acids or proteins are ingested immediately before, during, or after exercise.

Various high (30%) protein, high (30%) fat, low (40%) carbohydrate diets have been promoted for weight loss, and some diets even suggest almost complete elimination of carbohydrate from the diet. Some of these diets have been specifically targeted at athletes, accompanied by impressive claims and celebrity endorsements. Proposed mechanisms of action of these diets include reduced circulating insulin levels, increased fat catabolism, and altered prostaglandin metabolism, but it seems more likely that these diets achieve weight loss simply by restricting dietary choice. These diets can be effective in promoting short-term weight loss, primarily by restricting energy intake (typically to 1000–2000 kcal day^{-1}). There is no evidence to support improvements in exercise performance, and what evidence there is does not support the concept.

Carbohydrate

Carbohydrate is an essential fuel for the brain, red blood cells, and a few other tissues. Fat and carbohydrate are the main fuels used for energy supply in muscle during exercise. In low-intensity exercise, most of the energy demand can be met by fat oxidation, but the contribution of carbohydrate, and especially of the muscle glycogen, increases as the rate of energy demand increases. Carbohydrate oxidation rates of 3–4 g min^{-1} may be sustained for several hours by athletes in training or competition. When the glycogen content of the exercising muscles reaches very low levels, the work rate must be reduced to a level that can be accommodated by fat oxidation. In high-intensity exercise, essentially all of the energy demand is met by carbohydrate metabolism. Therefore, repeated short sprints place high demands on the muscle carbohydrate store, most of which can be converted to lactate within a few minutes.

Carbohydrate is stored in the body in the form of glycogen, primarily in the liver (about 70–100 g in the fed state) and in the skeletal muscles (about 300–500 g, depending on muscle mass and preceding diet). These stores are small relative to the body's requirements for carbohydrate. Carbohydrate supplies about 45% of the energy in the typical Western diet. This amounts to about 200–300 g day^{-1} for the average sedentary individual, and is adequate for normal daily activities. In an hour of hard exercise, however, up to 200 g of carbohydrate can be used, and sufficient carbohydrate must be supplied by the diet to replace the amount used. Replacement of the glycogen stores is an essential part of the recovery process after exercise: if the muscle glycogen content is not replaced, the quality of training must be reduced, and the risks of illness and injury are increased. Low muscle glycogen levels are associated with an increased secretion of cortisol during exercise, with consequent negative implications for immune function.

Table 1 Suggested carbohydrate intakes for athletes in training

Immediate postexercise recovery (0–4 h): 1 g per kg body mass per h, consisting of several small snacks
Daily recovery (moderate duration/low intensity training): 5–7 g kg^{-1} day^{-1}
Daily recovery (moderate–heavy endurance training): 7–12 g kg^{-1} day^{-1}
Daily recovery (extreme training: 4–6 h or more per day): 10–12 g kg^{-1} day^{-1}

When rapid recovery is a priority, replacement of carbohydrate should begin as soon as possible after exercise with carbohydrate foods that are convenient and appealing. Thereafter, the diet should supply sufficient carbohydrate to replace the amount used in training and to meet ongoing demands of other tissues. Some recommendations for carbohydrate intake after training or competition are shown in **Table 1**. For athletes preparing for competition, a reduction in the training load and the consumption of a high-carbohydrate diet in the last few days are recommended. This maximizes the body's carbohydrate stores and should ensure optimum performance, not only in endurance activities, but also in events involving short-duration high-intensity exercise and in field games involving multiple sprints.

The high-carbohydrate diet recommended for the physically active individual coincides with the recommendations of various expert committees that a healthy diet is one that is high in carbohydrate (at least 55% of energy) and low in fat (less than 30% of energy). However, where energy intake is either very high or very low, it may be inappropriate to express the carbohydrate requirement as a fraction of energy intake. With low total energy intakes, the fraction of carbohydrate in the diet must be high, but the endurance athlete with a very high-energy intake may be able to tolerate a higher fat intake. Recommendations, as in **Table 1**, should be framed in absolute amounts relative to body mass, i.e., grams of carbohydrate per kilogram body mass.

The type of carbohydrate eaten is less important than the amount. It is valuable to choose nutrient-rich carbohydrates and to add other foods to recovery meals and snacks to provide a good source of protein and other nutrients. The presence of small amounts of protein in recovery meals may promote additional glycogen recovery when carbohydrate intake is less than optimal or when frequent snacking is not possible. Protein taken at this time may also stimulate protein synthesis in muscles, as described above. Carbohydrate-rich foods with a moderate to high glycemic index (GI) provide a readily available source of carbohydrate for glycogen synthesis, and should be the major fuel choices in recovery meals.

Fat

Fat is an important metabolic fuel in prolonged exercise, especially when the availability of carbohydrate is low. One of the primary adaptations to endurance training is an enhanced capacity to oxidize fat, thus sparing the body's limited carbohydrate stores. Studies where subjects have trained on high-fat diets, however, have shown that a high-carbohydrate diet during a period of training brings about greater improvements in performance. Even when a high-carbohydrate diet is fed for a few days to allow normalization of the muscle glycogen stores before exercise performance is measured, the exercise capacity remains less after training on a high fat diet. It must be recognized, though, that these short-term training studies usually involve relatively untrained individuals and may not reflect the situation of the highly trained elite endurance athlete where the capacity of the muscle for oxidation of fatty acids will be much higher. For the athlete with very high levels of energy expenditure in training, the exercise intensity will inevitably be reduced to a level where fatty acid oxidation will make a significant contribution to energy supply and fat will provide an important energy source in the diet. Once the requirements for protein and carbohydrate are met, the balance of energy intake can be in the form of fat.

Fat also serves other important functions in the diet. As well as providing essential fatty acids, it acts as a vehicle for the transport of fat-soluble nutrients. Some athletes try to minimize their fat intake, but this is not wise.

Micronutrients and Physical Activity

Many micronutrients play key roles in energy metabolism, and high rates of energy turnover (up to 20–100 times the resting rate) may be required in the active muscles during hard exercise. Although an adequate vitamin and mineral status is essential for normal health, marginal deficiency states may only be apparent when the metabolic rate is high. Prolonged strenuous exercise performed on a regular basis may also result in increased losses from the body or in an increased rate of turnover, resulting in the need for an increased dietary intake. An increased food intake to meet energy requirements will increase dietary micronutrient intake, but not all athletes have high-energy intakes. Athletes who restrict food intake to control or reduce body fat

levels may have low-energy intakes over prolonged periods. Athletes may also eat monotonous diets, with a limited range of foods, thus increasing the risk of an inadequate micronutrient intake. Supplementation with micronutrients may be warranted in some instances, but normally only where specific deficiencies have been demonstrated by biochemical investigations and where dietary modification is not an option. Individuals who are very active may need to pay particular attention to their intake of iron and calcium.

Iron deficiency anemia affects some athletes engaged in intensive training and competition, but it seems that the prevalence is the same in athletic and sedentary populations, suggesting that exercise *per se* does not increase the risk. The implications of even mild anemia for exercise performance are, however, significant. A fall in the circulating hemoglobin concentration is associated with a reduction in oxygen-carrying capacity and a decreased exercise performance. Low serum ferritin levels are not associated with impaired performance, however, and iron supplementation in the absence of frank anemia does not influence indices of fitness. Routine iron supplementation is not wise, as too much may be harmful.

Osteoporosis is now widely recognized as a problem for both men and women, particularly so in women, and an increased bone mineral content is one of the benefits of participation in an exercise program. Regular exercise results in increased mineralization of those bones subjected to stress and an increased peak bone mass may delay the onset of osteoporotic fractures; exercise may also delay the rate of bone loss. Estrogen plays an important role in the maintenance of bone mass in women, and prolonged strenuous activity may result in low estrogen levels, causing bone loss. Many very active women also have a low body fat content and may also have low energy (and calcium) intakes in spite of their high activity levels. All of these factors are a threat to bone health. The loss of bone in these women may result in an increased predisposition to stress fractures and other skeletal injury and must also raise concerns about bone health in later life. It should be emphasized, however, that this condition appears to affect only relatively few athletes, and that activity is generally beneficial for the skeleton.

Water and Electrolyte Balance

Few situations represent such a challenge to the body's homeostatic mechanisms as that posed by prolonged strenuous exercise in a warm environment. Only about 20–25% of the energy available from substrate catabolism is used to perform external work, with the remainder appearing as heat. At rest, the metabolic rate is low: oxygen consumption is about $250\,\mathrm{ml\,min^{-1}}$, corresponding to a rate of heat production of about 60 W. Heat production increases in proportion to metabolic demand, and reaches about 1 kW in strenuous activities such as marathon running (for a 70-kg runner at a speed that takes about 2.5 h to complete the race). To prevent a catastrophic rise in core temperature, heat loss must be increased correspondingly and this is achieved primarily by an increased rate of evaporation of sweat from the skin surface. In hard exercise under hot conditions, sweat rates can reach $3\,\mathrm{l\,h^{-1}}$, and trained athletes can sustain sweat rates in excess of $2\,\mathrm{l\,h^{-1}}$ for many hours. This represents a much higher fractional turnover rate of water than that of most other body components. In the sedentary individual living in a temperate climate, about 5–10% of total body water may be lost and replaced on a daily basis. When prolonged exercise is performed in a hot environment, 20–40% of total body water can be turned over in a single day. In spite of this, the body water content is tightly regulated, and regulation by the kidneys is closely related to osmotic balance.

Along with water, a variety of minerals and organic components are lost in variable amounts in sweat. Sweat is often described as an ultrafiltrate of plasma, but it is invariably hypotonic. The main electrolytes lost are sodium and chloride, at concentrations of about $15–80\,\mathrm{mmol\,l^{-1}}$, but a range of other minerals, including potassium and magnesium, are also lost, as well as trace elements in small amounts. Some athletes may lose up to 10 g of salt (sodium chloride) in a single training session, and may train in these conditions twice per day. These substantial salt losses must be replaced from foods and drinks, though the use of salt supplements is seldom necessary.

Failure to maintain hydration status has serious consequences for the active individual. A body water deficit of as little as 1–2% of total body mass can result in a significant reduction in exercise capacity. Endurance exercise is affected to a greater extent than high-intensity exercise, and muscle strength is not adversely affected until water losses reach 5% or more of body mass. Hypohydration greatly increases the risk of heat illness, and also abolishes the protection conferred by prior heat acclimation.

Many studies have shown that the ingestion of fluid during exercise can significantly improve

performance. Adding carbohydrate to the fluid confers an additional benefit by providing an energy source for the working muscles. Addition of small amounts (perhaps about 2–8%) of carbohydrate in the form of glucose, sucrose, or maltodextrin will promote water absorption in the small intestine as well as providing exogenous substrate that can spare stored carbohydrate. The addition of too much carbohydrate will slow gastric emptying and, if the solution is strongly hypertonic, may promote secretion of water into the intestinal lumen, thus delaying fluid availability. Voluntary fluid intake is seldom sufficient to match sweat losses, and palatability of fluids is therefore an important consideration. It is not necessary to consume enough fluid during exercise to match sweat losses, as a body mass deficit of 1–2% is unlikely to have adverse consequences. If exercise is prolonged and sweat losses high, the addition of sodium to drinks may be necessary to prevent the development of hyponatremia. Ingestion of large volumes of plain water is also likely to limit intake because of a fall in plasma osmolality leading to suppression of thirst.

Replacement of water and electrolyte losses incurred during exercise is an important part of the recovery process in the postexercise period. This requires ingestion of fluid in excess of the volume of sweat lost to allow for ongoing water losses from the body. Re-establishment of water balance requires replacement of solute, especially sodium, losses as well as volume replacement. If food containing electrolytes is not consumed at this time, electrolytes, especially sodium, must be added to drinks to prevent diuresis and loss of the ingested fluid.

Dietary Supplements

The use of nutritional supplements in athletes and in the health-conscious recreationally active population is widespread, as it is in the general population. A very large number of surveys have been published. A meta-analysis of 51 published surveys involving 10 274 male and female athletes of varying levels of ability showed an overall prevalence of supplement use of 46%, but the prevalence varied widely in different sports, at different levels of age, performance etc., and in different cultural backgrounds.

Many different supplements are used by athletes with the aim of improving or maintaining general health and exercise performance. In particular, supplement use is often aimed at promoting tissue growth and repair, promoting fat loss, enhancing resistance to fatigue, and stimulating immune function. Most of the supplements that are sold to athletes have not been well researched, and both safety and efficacy remain open to question for many of these products. Anyone seeking to improve health or performance would be better advised to ensure that they consume a sound diet that meets energy needs and contains a variety of foods. A recent development of concern to athletes is the finding of various prohibited doping agents in what should be legitimate sports nutrition products. Supplements for which there is good evidence of beneficial effects on performance include caffeine, creatine, and bicarbonate, but the risk of an inadvertent positive doping result must always be considered.
