The need for attentiveness to the spiritual concerns of dying patients has been well recognized by many researchers (24,25). A survey conducted in 1997 by the George H. Gallup International Institute showed that people overwhelmingly want their spiritual needs addressed when they are close to death. In the preface to the survey report, George H. Gallup, Jr., wrote: “The overarching message that emerges from this study is that the American people want to reclaim and reassert the spiritual dimensions in dying” (26). In the study, survey respondents said they wanted warm relationships with their providers, to be listened to, to have someone to share their fears and concerns with, to have someone with them when they are dying, to be able to pray and have others pray for them, and to have a chance to say goodbye to loved ones. When asked what would worry them, they said not being forgiven by God or others, or having continued emotional and spiritual suffering. When asked about what would bring them comfort, they said they wanted to believe that death is a normal part of the life cycle and that they would live on, either through their relationships, their accomplishments, or their good works. They also wanted to believe that they had done their best in their life and that they will be in the presence of a loving God or higher power. It is as important for health care providers and other caretakers to talk with patients about these issues as it is to address the medical-technical side of care.

The 1990 Gallup survey found that 75% of Americans say religion is central to their lives; a majority feel that their spiritual faith can help them recover from illness (22). Additionally, it was found that 63% of patients surveyed believe it is good for doctors to talk to patients about spiritual beliefs (27). Lehman and colleagues found that 94% of patients with religious beliefs agreed that physicians should ask them about their spiritual beliefs if they become gravely ill; 45% of patients who denied having any religious beliefs still agreed that physicians should ask their patients about their spiritual beliefs (28). In this survey, 68% of patients said they would welcome a

spiritual question in a medical history; only 15% said they actually recalled being asked by their physicians whether spiritual or religious beliefs would influence their decisions. A study surveying more than 200 hospital inpatients found that 77% believed physicians should consider patients' spiritual needs. Furthermore, 37% wanted their physician to discuss spiritual beliefs with them more frequently and 48% wanted their physicians to pray with them (29). A Time/CNN poll found that 65% of people surveyed want their physicians to address their spiritual issues (30). In a *USA Today Weekend* health survey, the majority of people polled felt that doctors should talk with their patients about spiritual concerns, yet only 10% reported that their doctors had discussed such issues with them (27). This latter statistic is understandable because spirituality has frequently been overlooked in medical school curricula and in the standards of medical care.

DATA DOCUMENTING THE RELATIONSHIP BETWEEN SPIRITUAL BELIEFS AND ILLNESS

There is a growing body of evidence documenting the relationship between patients' religious and spiritual lives and their experiences of illness and disease (31). In addition to surveys demonstrating that spirituality is important to people and that a significant percentage of patients would like their physicians to discuss their spiritual beliefs with them, a number of studies show that having spiritual beliefs is beneficial to patients, particularly those with serious illnesses. Reviews of the literature indicate potential relationships between measures of religious commitment and health measures, including morbidity and mortality, in studies of many diseases (32,33,34 and 35). Research suggests that mortality is reduced after cardiac surgery among those who receive comfort and support from religion (36).

Spirituality has been found to be an important factor in bereavement. It has been reported that parents who have lost a child have found much support in spiritual beliefs after their child's death (37). Spirituality is important in coping with pain and with dying. Ninety-three percent of patients with gynecologic cancers noted that their spiritual beliefs helped them cope with their cancer (38). Patients with advanced cancer who found comfort from their spiritual beliefs were happier, more satisfied with their lives, and had diminished pain (39). In a questionnaire sent out by the American Pain Society, prayer was the second most common method of pain management after oral pain medications, and the most common nondrug method of pain management (Table 58-2) (40).

Personal prayer is the most commonly used nondrug method for pain management.
Pain pills, 82%.
Prayer, 76%.
Pain i.v. medication, 66%.
Pain injections, 62%.
Relaxation, 33%.
Touch, 19%.
Massage, 9%.

TABLE 58-2. PAIN QUESTIONNAIRE BY AMERICAN PAIN SOCIETY TO HOSPITALIZED PATIENTS

In a study of patients with human immunodeficiency virus (HIV), those who were spiritually active had less fear of death and less guilt about their illness. Fear of death was more likely among the 26% of religious patients who felt their illness was a punishment from God. Fear of death diminished among patients who had regular spiritual practices or who stated that God was central to their lives. Patients who believed in God's forgiveness were more likely to engage in discussions about advance directives (41).

Quality-of-life instruments used in end-of-life care try to measure an existential domain, which addresses purpose, meaning in life, and capacity for self-transcendence. In studies of one such instrument, three items have been found to correlate with good quality of life for patients with advanced disease: if the patient's personal existence is meaningful; if the patient finds fulfillment in achieving life goals; and if life to this point has been meaningful (42). This supports the importance of addressing meaning and purpose in a dying person's life.

Writings on addiction also have supported the importance of finding meaning. The 12-step program Alcoholics Anonymous, one of the best known programs in the treatment of addiction, lists one of the 12 steps (which were described by some of the earliest members of the group) as “[we] came to believe that a power greater than ourselves could restore us to sanity” (43). In this view, addicts see their drug of choice as central in their lives; recovery hinges on the ability to find a meaning and purpose outside of oneself and one's illness.

The observations noted in patient stories (6,9) and in the writings of Foglio and Brody (8)—that illness can cause people to question their lives, their identities, and what gives their life meaning—is supported by research. For example, in a study of 108 women undergoing treatment for gynecological cancer, 49% noted becoming more spiritual after their diagnosis (38). In a study of parents with a child who had died of cancer, 40% of those parents reported a strengthening of their own spiritual commitment over the course of the year before their child's death (37). Illness, facing one's mortality, is an opportunity for new experience, self-awareness, and meaning in life.

Religion and religious beliefs can play an important role in how patients understand their illness. In a study asking older adults about God's role in health and illness, many respondents saw health and illness as being partly attributable to God and, to some extent, God's interventions (44). Prayer, in this study, appeared to complement medical care rather than compete with it.

Meditation has been found to be a useful adjunct to conventional medical therapy for chronic conditions such as headaches, anxiety, depression, premenstrual syndrome, acquired immunodeficiency syndrome, and cancer (45).

How spiritual modalities contribute to health and recovery is unclear. Koenig (46) and his colleagues propose an immune-related mechanism that might mediate the stress response. In a study of 1700 older adults, they found that those attending church were half as likely to have elevated levels of IL-6, which is an interleukin associated with stress and disease. The authors hypothesize that religious commitment, and perhaps spiritual practices in general, may improve stress control through better coping mechanisms, richer social support, and strength of personal values and world view. Benson and colleagues have studied the relaxation response and have shown it to be beneficial in a number of conditions, including hypertension (47), cardiac arrhythmia (48), chronic pain (49), insomnia (50,51), and depression and anxiety (52). Indeed, in more recent work, they propose a mechanism mediated through neural processes and their coupling to constitutive nitric oxide that could explain on a biochemical and neurological basis the beneficial effects seen with the relaxation response and possibly with spiritual beliefs (53).

Pargament and colleagues have studied both positive and negative coping, and have found that religious experiences and practices, such as seeking God's help or having a vision of God, extends the individual's coping resources and are associated with improvement in health care outcomes (54). Patients showed less psychological distress if they sought control through a partnership with God or a higher power in a problem-solving way, if they asked God's forgiveness or were able to forgive others, if they reported finding strength and comfort from their spiritual beliefs, and if they found support in a spiritual community. Patients had more depression, poorer quality of life, and callousness towards others if they saw the crisis as a punishment from God, if they had excessive guilt, or if they had an absolute belief in prayer and cure and an inability to resolve their anger if cure did not occur. Pargament et al. have also noted that sometimes patients refuse medical treatment based on religious beliefs (55).

SPIRITUAL COPING

How does spirituality work to help people cope with their dying (Table 58-3)? One mechanism might be through hope. Spirituality and religion offer people hope, and help people find hope in the midst of the despair that often occurs in the course of serious illness and dying. Hope can change during a course of an illness. Early on, the person may hope for a cure; later, when a cure becomes unlikely, the person may hope for time to finish important projects or goals, travel, make peace with loved ones or with God, and have a peaceful death. This can result in a healing, which can be manifested as a restoration of one's relationships or sense of self. Often our society thinks in terms of cures. Whereas cures may not always be possible, healing—the restoration of wholeness—may be possible to the very end of life.

Hope: for a cure, for healing, for finishing important goals, for a peaceful death
Sense of control
Acceptance of the situation
Strength to deal with the situation
Meaning and purpose: in life, in midst of suffering

TABLE 58-3. SPIRITUAL COPING

Religious beliefs offer a sense of hope. For example, in Catholicism, hope in Jesus' promise of victory over death through resurrection and salvation gives Catholics hope in a life beyond death. In the funeral rites, it is stated: “I believe in the resurrection of the dead and the life of the world to come” (56). In the Protestant view, the concept of salvation in death gives hope. Jesus' dying and rising from the dead means that those who participate in His death no longer participate in the sinful human nature (57). In Eastern traditions such as Buddhism and Hinduism, the hope of rebirth and a belief in karma offer people hope in the face of mortality (58). In Judaism, there are many diverse ways of viewing death. For some, hope is found in living on through one's children. In the orthodox and conservative views, there is a belief in a resurrection in which the body arises to be united with the soul (59). For patients both with and without specific religious beliefs, there is a need to transcend death, which also may be manifested through living on through one's relationships or one's accomplishments and deeds (60). Irion suggests that humans may create abstractions by portraying a life after death (61). For the religious, this may take the form of concepts found in their religious traditions. For others, life after death might be in terms of one's descendants. For some, it might be being immortalized in the memory of others or in the contributions one makes in life. Cultural beliefs and traditions can also contribute to how people find meaning and hope in the midst of despair (62).

Spirituality can offer people a sense of control. Illness can disrupt life completely. Some people find a sense of control by turning worries or a situation over to a higher power or to God (63). Similarly, people can use their beliefs to help them accept their illness and find strength to deal with their situation (43,64,65). Reconciliation may be an important aspect of a dying person's spiritual journey. Often people seek to forgive others or themselves as they review their lives and their relationships. Finally, finding meaning and purpose in the midst of suffering is integral to spirituality.

SPIRITUAL CARE

Spiritual care at its essence is relational (Table 58-4). Spirituality can be defined as a relationship not only with the transcendent, but also with others. The connection that physicians, other health care providers, and families make with the ill and dying patient is, at its root, spiritual. The care that the physician provides is rooted in spirituality through compassion, hopefulness, and the recognition that, although a person's life may be limited or no longer productive, it remains full of possibility (66). Even though a person can no longer have curative therapy, he or she can still find meaning and purpose in life. Patients who are seriously ill can still have relationships, and they can still heal. The physician and other care providers can offer the opportunity for healing by being present to the patient. The patient and the physician (or other health care provider) connect with each other in the context of this healing relationship. Patients want to have warm, caring relationships with their physicians, as the Gallup survey suggests (26). There are studies that document the importance of the doctor-patient relationship (67,68,69,70,71,72 and 73). Dr. Francis Peabody wrote in his 1927 medical classic, *The Care of the Patient*t, “One of the essential qualities of the clinician is interest in humanity, for the secret care of the patient is in caring for the patient” (74). This relationship can have potential positive impact on health care outcomes, compliance, and patient satisfaction (67,71,72,75,76 and 77).

Practice of compassionate presence
Listening to patient's fears, hopes, pain, and dreams
Obtaining a spiritual history
Attentiveness to all dimensions of the patient and patient's family: body, mind, and spirit
Incorporation of spiritual practice as appropriate
Chaplains as members of the interdisciplinary health care team

TABLE 58-4. SPIRITUAL CARE

Spiritual care emphasizes the importance of a relationship between two people. The physician may be the professional expert in most of the encounter, but the physician is still a human being. By relating from our humanness, we can help to form deeper and more meaningful connections with our patients. This requires an awareness of the physician's own values, beliefs, and attitudes, particularly toward the physician's own mortality. By confronting one's own mortality, one can better understand what the patient is facing. Also, the stress of working with seriously ill and dying patients can be better handled by an attentiveness to one's own spiritual and values framework. Many physicians speak of their own spiritual practices and how those practices help them in their ability to deliver good spiritual care and, in fact, good medical care (5,78).

One of the key components of this relationship is the ability of the physician to be totally present to the patient, i.e., the practice of compassionate presence. This means that the physician brings his or her whole being to the encounter and places full attention on the patient, not allowing distractions, such as time pressures, focus on the biomedical aspects of treatment, or other thoughts, to interfere with that attention. Integral to this is the ability to listen to the patient's fear, hopes, and dreams and to be attentive to all dimensions of a patient's and their family's lives: the physical, emotional, social, and spiritual. Some physicians suggest that current medical practices do not allow enough time for this. However, being wholly present to the patient is not time dependent. It simply requires the intention on the part of the physician to be fully present for their patients.

Obtaining a spiritual history is one way to listen to what is deeply important to the patient (21). When one gets involved in a discussion with a patient about his or her spirituality, one enters the domain of what gives the person meaning and purpose in life and how that person copes with stress, illness, and dying. The spiritual history affords the patient the space and opportunity to address his or her suffering and hopes. Having the physician inquire about the patient's spiritual beliefs gives the patient an opening and an invitation to discuss spiritual beliefs, if that is what the patient would like to do. It also enables the physician to connect with the patient on a deep, caring level. In fact, many physicians who obtain spiritual histories remark that the nature of the doctor-patient relationship changes. As soon as they bring up these questions, they feel that it establishes a level of intimacy, an understanding of who the person is at a much deeper level than is typical. The relationship feels less superficial (21). Patients note that they feel more trusting of a physician who addresses and respects their spiritual beliefs. In one survey, 65% of patients in a pulmonary outpatient clinic noted that a physician's inquiry about spiritual beliefs would strengthen their trust in the physician (28).

Once the physician finds out what the patient's spiritual beliefs are, he or she can then address any spiritual practices that are important to the patient. These might be prayer, meditation, listening to certain music, enjoying solitude, or writing poetry. One can then incorporate these practices as appropriate. Chaplains and other spiritual care providers (spiritual directors, ministers, priests, rabbis, imans, music thanantologists, and others) are experts trained in the area of spirituality and religion. Working with these spiritual care providers is essential to holistic care. Chaplains should be integrated into interdisciplinary health care teams. Hospice teams often have chaplains as part of the care team.

ETHICAL ISSUES: ROLE OF SPIRITUALITY IN THE CLINICAL SETTING

It is critical for physicians and other health care providers to address spiritual issues with their patients because spirituality affects patients' clinical care in a direct

manner. Spiritual issues can impact clinical care in various ways, which are illustrated by the following cases.

Case 1

Spiritual beliefs may be a dynamic in patients' understanding of their illness. Julie was a 28-year-old woman whose husband left her recently. She learned through the family grapevine that he has acquired immunodeficiency syndrome. She came into a clinic and saw a physician for the first time to get tested for HIV. When she returned to the clinic for her test results, she found out that she was HIV positive. The physician attempted to present an optimistic picture by relaying all the newest information on treatment for HIV. The patient, however, continued to cry out about “God doing this to me.” The physician persisted in discussion of the medical and technical aspects of the diagnosis while the patient continued to make references to God. After some time, the physician asked the patient why she thought her illness was coming from God. She told the physician that she was raped as a teenager, got pregnant, and had an abortion. She said, “I have been waiting for the punishment for 15 years, and this is it.” The patient refused all medications and treatment.

Patients come to understand their health, illness, and dying through their beliefs, cultural backgrounds, past experience, and values. In this case, Julie had been carrying guilt for an event that happened many years before. The temptation for the physician was to alleviate this guilt by talking about how understandable the abortion was in the context of the rape. However, this is not what the patient felt, and by trying to erase her guilt, it actually precluded the patient from talking about her feelings. The physician instead listened to the patient and did not force the issue of medications and preventive care. The physician continued to see the patient regularly, listening to her issues around the diagnosis. She also referred Julie to a chaplain who worked further with Julie on these issues. It took approximately a year before Julie was able to see God as forgiving and was able to forgive herself. It was then that she could focus on the treatment of her HIV disease. Issues like these can be complicated. What part of Julie's beliefs came from strongly held religious dogma and what part from low selfesteem or depression? Chaplains are trained to understand the difference in the roots of these beliefs, and they are trained to help patients resolve these types of conflicts. In addition, physicians can be helpful by listening to patients, giving patients the time to resolve conflicts, and respecting patients' rights to their own beliefs.

Case 2

Religious convictions/beliefs may affect health care decision making. Frank was an 88-year-old man dying of pancreatic cancer in the intensive care unit. He was on pressors and a ventilator. The team approached the family about withdrawing support. The family was very religious and believed that their father's life was in God's hands; they believed there would be a miracle and that their father would survive.

These types of cases are very common and often are handled poorly. Physicians and intensive care unit teams get frustrated that patients' families can't see that their loved one is dying, and the family feels hurt and angry that the medical teams do not understand their beliefs. The discussion often gets polarized and difficult to resolve. It is critical that the medical teams, even if they do not agree with the family, respect family beliefs. Often, simply listening to the family about what they mean by a “miracle” can open up the conversation to many feelings that the family is experiencing. For example, the physician could simply say, “I can understand that a miracle would be wonderful,” and then wait to see what the family says. Or the physician could ask, “What does a miracle mean to you?” If families feel respected, they are not as likely to feel threatened and that the medical team opposes them. The medical team, in turn, can get to know the values and beliefs of the family. Referral to a chaplain would be critical in this case. The chaplain, someone who is not perceived as being a part of the medical team per se, can explore the issues of miracles in a very nonthreatening way.

In Frank's case, the chaplain worked with the family. Over time, they began to see the possibility of a miracle independent of whether their father was on a ventilator. The family was then at peace with withdrawing ventilator support. The family was invited to bring their minister in during the whole process, and there were prayers and rituals at the bedside. Their father lived for several days and then died at peace.

Case 3

Spirituality may be a patient need. Rebecca was a 60-year-old woman who had a stroke and had had diabetes and hypertension for many years. She was very debilitated, being wheelchair bound with a speech impediment. Her major coping strategy was prayer. She was Catholic. Her church group and family were her major social supports. It was very important for her to discuss her spiritual beliefs with her physician.

Rebecca's faith was central to her life and was the basis of all her decisions. It was the way she coped with the effects of her chronic illnesses and with her dying. It was important for her to talk about her faith at every visit. She had an inner strength that was rooted in her religious beliefs and enabled her to withstand numerous physical and emotional challenges. In the end, it was her faith that probably gave her the will to live beyond what medical statistics would have predicted for someone as ill as she was. Daily prayer was so important to her that it also became an indicator for her well-being. At one point in her illness, she became very depressed. Although she denied symptoms of depression, she related that she was too tired to pray. She was then able to recognize symptoms of depression. Her church group was also a strong support. In fact, they were so present to her that they were clearly part of her extended family.

Case 4

Spirituality may be important in patient coping. Ronda was a 54-year-old woman with advanced ovarian cancer. Her husband, who was her major support, died unexpectedly. Ronda, who was Jewish, dealt with her suffering and depression through her faith in God. She also joined Jewish Healing Services for support and guidance.

Ronda was raised Jewish but was not observant throughout her adult life. She described herself as an optimist and saw that attitude as an inner strength. Her will to live was strong, and her fight to survive her cancer in the face of dismal odds gave her meaning in life. She spoke of her cancer as a gift in that it gave her a new perspective of life. She came to understand her life in a different, deeper way. She expressed a sense of gratitude for being alive each moment of the day and did not take anything, or anyone, for granted. During times of stress and loss, she relied on her inner strength as a resource. She reached out to support networks, such as the Jewish Healing Services. When her cancer metastasized, she looked at her religious roots for an understanding of death and of suffering. It was important for her to talk with her physicians about these issues and for her to be respected. For a physician to dismiss her will to live and try new therapies simply because of a statistical understanding of her disease would be to dismiss who she is as a person, a “statistic of one,” as she said. It was important for her to be able to talk with her physician about her will to live and also about her search for meaning in the midst of suffering. She made a “dream list” as to what was important for her to accomplish before her death. Therapy was adjusted around her ability to complete her dream list.

Case 5

Spirituality may be integral to whole patient care. Joe was a 42-year-old man with irritable bowel syndrome. He had major stressors in his life, including a failed marriage and dissatisfaction at work. He had signs of depression, including insomnia, excessive worrying, decreased appetite, and anhedonia. Overall, he felt that he had no meaning and purpose in life.

Joe did not respond to medication and diet changes alone. However, with the addition of meditation and counseling, Joe improved. In this case, the physical, emotional, social, and spiritual issues all interplayed and affected how he coped with illness.

SPIRITUAL HISTORY

The main elements of a spiritual history that has been developed for physicians and other health care providers can be recalled by using the acronym “FICA” (21).

F—Faith and Belief

“Do you consider yourself spiritual or religious?” or “Do you have spiritual beliefs that help you cope with stress?” If the patient responds “no,” the physician might ask, “What gives your life meaning?” Sometime patients respond with answers such as family, career, or nature.

I—Importance

“What importance does your faith or belief have in your life? Have your beliefs influenced how you take care of yourself in this illness? What role do your beliefs play in regaining your health?”

C—Community

“Are you a part of a spiritual or religious community? Is this of support to you and how? Is there a group of people you really love or who are important to you?” Communities, such as churches, temples, mosques, or a group of likeminded friends, can serve as strong support systems for some patients.

A—Address/Action in Care

The physician and other health care providers can think about what needs to be done with the information the patient shared—referral to chaplain, other spiritual care provider, or other resource.

FICA is not meant to be used as a checklist, but rather as a guide as to how to start the spiritual history and what to listen for as the patient talks about his or her beliefs. Mostly, FICA is a tool to help physicians and other health care providers know how to open a conversation to spiritual issues and issues of meaning and value. In the context of the spiritual history, patients may relate those fears, dreams, and hopes to their care provider. The spiritual history can be done in the context of a routine history or at any time in the patient interview, usually as a part of the social history. In addition to religious or spiritual beliefs and values and other aspects of the spiritual history, the social history should address lifestyle, home situation, and primary relationships; other important relationships and social environment; work situation and employment; social interests/ avocation; life stresses; and lifestyle risk factors (e.g., tobacco, alcohol, or illicit drugs).

The spiritual history is patient-centered. One should always respect patients' wishes and understand appropriate boundaries. Physicians and other health care providers must respect patients' privacy regarding matters of spirituality and religion and should avoid imposing their own beliefs on the patient (79).

The following case illustrates how FICA can be used. A patient who died of metastatic malignant melanoma was an Episcopalian. Her religious beliefs were central to her life, and in fact, were the means through which she came to be at peace with dying. During her last hospitalization, the house officers caring for her were apprehensive about discussing advance directives and dying. However, during the spiritual history, the patient told them how her religious beliefs helped her come to terms with dying and how she was ready to die naturally. She handed them her living will. She also asked that her church members be allowed to visit her often. She later told me that being asked about her beliefs helped her feel respected and valued by the physicians and that she felt that she could trust them more. The physicians stated that once they asked a spiritual history, the nature of the interaction between themselves and this patient changed. It felt “more natural, more comfortable, warmer and more honest.”

Another case illustrates the variability encountered in practice. When asked “if you have any spiritual beliefs that help you with stress,” a patient undergoing a routine examination answered that she found meaning and purpose while sitting in the woods near her house—that nature brought her peace. This was very important to her, as she noted that on days when she did not meditate there in the morning, she would become scattered and tense. Her community consisted of a group of like-minded friends who shared her beliefs. She asked that her medical record indicate that when she became seriously ill or dying, she wanted a room in her hospice overlooking the trees. She also asked to learn basic meditation techniques. In a subsequent visit many months later, she reported that she had stopped meditating, with negative results; resuming meditation helped her cope better with her stress.

ETHICAL ISSUES: PROFESSIONAL AND PERSONAL BOUNDARIES

Performing a spiritual history has been included in coursework on spirituality and medicine (21). The spiritual history emphasizes the practice of compassion with one's patients, and helps the clinician learn to integrate patients' spiritual concerns into the therapeutic plans. Given the data suggesting that spirituality may be beneficial for patients who are coping with illness, health care institutions should have written policies stating that the patient has a right to express his or her spirituality and religiosity in a respectful and supportive clinical environment.

Physicians should strive to discuss patients' spiritual concerns in a respectful manner and as directed by the patient. The spiritual history is patient-centered, not physiciancentered (Table 58-5). A physician should always respect patients' privacy regarding matters of spirituality and religion, and must be vigilant in avoiding imposing his or her beliefs on the patients. The relationship between physician and patient is not an equal one. There is an intimacy in the relationship, but it is intimacy with formality. The patient comes to the physician in a vulnerable time of his or her life, often looking to the physician as a person of authority. The physician should not abuse that authority by imposing his or her own beliefs, or lack of beliefs, onto patients. A vulnerable patient may adopt a physician's belief simply because the patient is fearful and assumes the physician knows more. In terms of spiritual intervention, physicians can recommend a variety of interventions, such as chaplain referral, meditation, yoga, prayer, or other spiritual practice. But the decision to recommend these comes from the patient. For example, physicians could recommend religious and spiritual practices to a patient if these practices are already part of that patient's belief system. However, an agnostic patient should not be told to engage in worship any more than a highly religious patient should be criticized for frequent church attendance. Thus, if a patient states that prayer helps with stress, the physician could suggest that prayer might help in dealing with a serious diagnosis. Or, if a patient finds meaning and purpose in nature, a physician might suggest meditation techniques focused on nature.

Spiritual history: patient-centered
Recognition of pastoral care professionals as experts
Proselytizing is not acceptable in professional settings
More in-depth spiritual counseling should be under the direction of chaplains and other spiritual leaders
Praying with patients:
Not initiated by physicians unless there is no pastoral care available and the patient requests it
Physician can stand in silence as patient prays in his/her tradition
Referral to pastoral care for chaplain-led prayer

TABLE 58-5. ETHICAL AND PROFESSIONAL BOUNDARIES

Patients sometimes ask their physician about the physician's beliefs. Given the unequal relationship between patient and physician, it is important that the question be handled carefully and with the same guidelines that are used when addressing other sensitive issues such as sexual history or domestic violence. Patients sometimes ask personal questions of their physicians to take the attention off themselves. Sometimes, it is to see if they can connect with the physician by reassuring themselves that the physician has the same beliefs as they. In general, if asked about his or her own beliefs, the physician could ask the patient why it is important for him or her to know that information. The physician can reassure the patient that the focus of the encounter is on the patient's needs and issues, not the doctor's. In some cases, patients still feel the need to know. A patient of a certain religious belief may want to work only with a doctor of that same religion. In some cases, it may not be possible to accommodate the patient, but at least the physician can explore with the patient the reasons for the request. Some patients want to know that their beliefs will not be ridiculed. A response from the physician that he or she respects and supports a patient's beliefs might serve to reassure the patient. In general, it is best to avoid sharing one's personal beliefs unless one already knows the patient and is comfortable that this sharing would not coerce the patient into adopting the physician's beliefs or intimidate the patient from sharing more about his or her own beliefs. A physician should not do anything that violates his or her own comfort level as well. Many physicians prefer to keep their private lives private in the professional context of the doctor-patient relationship.

Patients often ask physicians to pray with them. A physician need not worry that it is somehow inappropriate to allow a moment of silence or a prayer if the patient requests this. In fact, walking away and not showing respect for the request may leave the patient with a sense of abandonment by the physician. If the physician feels conflicted about praying with patients, he or she need only stand by quietly as the patient prays in his or her own tradition. Alternatively, the physician could suggest calling in the chaplain or the patient's clergyperson to lead a prayer. Physician-led prayer is generally not recommended, as that is usually the role of the clergy or chaplain. In addition, having the physician lead a prayer opens the possibility of having the prayer be of the physician's belief, not of the patient's. Furthermore, clergy and chaplains are trained specifically in techniques of leading prayer in ecumenical and health care contexts.

Appropriate referrals to chaplains are important to good health care practice and are as appropriate as referrals to other specialists. Chaplains are clergy or laypersons certified in a pastoral training program designed to train them as chaplains. Chaplains work in hospital settings, outpatient clinics, businesses, schools, and prisons. They are trained to be spiritual care providers working with people to explore meaning in life, cope with suffering, and use their beliefs to help them cope with illness or stress. Chaplains work with people of all faiths, as well as with nonreligious people. Clergy are trained to provide religious care usually only to people of their specific

denomination.

Where are the boundaries between what chaplains do and what physicians do? Some would argue that discussions with patients about spiritual matters should be initiated solely by chaplains (80). Physicians can use spiritual histories as a screening tool. By inquiring about a patient's beliefs, the physician can evaluate whether the beliefs are helpful or harmful to the patient's health and medical care. If a patient has beliefs that support him or her and give meaning and peace of mind, the physician can encourage those beliefs. In cases in which spiritual beliefs interfere with a patient's getting needed therapy—for example, a patient who thinks an illness is a punishment caused by God and therefore refuses medicine or treatment because of a feeling that the punishment is deserved—a referral to a chaplain would be very helpful. Patients have the right to refuse medical treatment. However, it is important that the choice be made with full informed consent. Therefore, if a patient refuses treatment based on a religious or spiritual belief, it may be appropriate to refer the patient to a chaplain so that the chaplain can explore these beliefs with the patient.

Sometimes, refusal of treatment is based on accepted religious tenets. Other times, the patient may attribute the reasons for refusal to religious beliefs when it actually stems from other concerns, such as lack of self-esteem or depression. The chaplain is trained to explore the beliefs with the patient further and help the patient differentiate between the two. The physician should be respectful of the patient's beliefs, but still explain the consequences of refusal of treatment without being coercive. This way the patient can have enough medical and spiritual information to make a fully informed decision. Physicians in general are not trained to explore the theological aspects of belief, although they can listen and learn about belief from patients. However, physicians can listen to and support patients as they make decisions for themselves. Sometimes, simply listening to a patient in a nonjudgmental fashion and asking a few open-ended questions, such as “tell me more about your belief,” can help patients resolve issues of belief and treatment for themselves.

Although many studies suggest that spirituality can be helpful, there are also circumstances in which spirituality can have a negative effect on health. It is important for health care providers to recognize this dynamic. For example, a person who interprets his or her illness as a punishment from God might attempt to refuse treatment. In such a scenario, a chaplain or other religious advisor could perhaps work with the patient's beliefs to help him or her work through the guilt issues. The patient might accept treatment or refuse it, but at least the decision wouldn't be motivated solely by guilt, and would be more of an informed decision. Some people who feel guilt in their relationships with God might also relate to others in their lives in a similar way. Counseling may also be helpful. Some religious beliefs forbid certain medical practices, such as Jehovah's Witnesses' refusal to accept blood transfusions. It is important to recognize the difference between refusing treatment based on an established religious principle versus refusal of treatment stemming from depression, unwarranted guilt, or a misperceived sense of punishment from God. Some patients may have complicated ethical and spiritual issues. Physicians need not feel that they must solve these dilemmas on their own. Chaplains, members of ethics committees, and counselors often work with physicians in the care of patients.

It is important to recognize that spirituality in the health care setting is not in any one person's domain. Physicians, nurses, social workers, and chaplains all can deal with patient spirituality. It also is true, however, that most physicians are not trained to deal with complex spiritual crises and conflicts. Chaplains and other spiritual caregivers are. Therefore, it is important that physicians obtain a spiritual history as a way of inquiry about spiritual issues that might impact a patient but that physicians also recognize when to make a referral to these specialists.

NEUROTHEOLOGY

Patients may talk about spiritual or mystical experiences, which might manifest as visions, feeling God's or a deceased loved one's presence, altered states of consciousness, locutions, or sensory experiences (unusual smells, sights, or sounds). From the clinical standpoint, there is a debate as to the difference between spiritual experience and psychopathology. Many patients close to death talk of seeing loved ones or angels in the room. Some physicians medicate patients if these experiences cause distress or agitation. This assumes that spiritual experiences are comforting versus psychopathological ones, which may cause agitation. Theologians would argue that, in fact, not all spiritual experiences are comforting, and that medicating people in the midst of a spiritual experience might be in conflict with patients' beliefs and religious traditions.

There are no clear-cut answers to this dilemma. But there is a new area of research and study called neurotheology, the study of the neurobiology of religion and spirituality. By using brain-imaging studies, scientists are attempting to identify the brain's spirituality circuit. Results indicate that certain spiritual experiences, such as deep meditation or intense religious moments in prayer, can be associated with distinct neural activity in the brain. However, this does not mean that such experiences are mere neurological illusions, nor do these studies establish cause and effect. Andrew Newberg, a physician who does this research at the University of Pennsylvania, notes that “there is no way to determine whether the neurological changes associated with spiritual experience mean that the brain is causing those experiences or is instead perceiving a spiritual reality” (81).

Theologians suggest that neurotheologians identify religion with specific experiences and feelings. Spiritual or mystical experiences may be part of a person's life, but those experiences have nothing to do with how well people communicate with God nor with the spiritual practices inherent in religions, such as prayer or virtue. Neurotheologians suggest that we may be “wired for God” (45) or that evolution has programmed the brain to find pleasure in transcending the self. But most mystics and spiritual leaders write not so much of pleasure from spiritual practice as of the perseverance of a spiritual practice, which at times can be difficult and seemingly empty. Most mystics, such as Teresa of Avila, have seen spiritual practices as leading them beyond themselves to the practice of charity and love of neighbors (82). Teresa of Avila and other mystics regarded spiritual or mystical experiences as special gifts of God but not essential to spiritual growth. Furthermore, spiritual experiences do not indicate the level of charity or love present in the heart of the person—only external acts of charity do.

Neurobiologists can correlate certain experience with certain brain activity, but it would be reductionistic to conclude that the brain is the only source of the experience. For example, science cannot measure the influence of spiritual grace. Thus, in the clinical setting, it is important to recognize the limits of science and to relinquish the need for reductionistic explanatory models for spiritual beliefs and experiences. Much of what happens to our patients may have no answers. Illness causes us to ask questions that are deeply spiritual and unanswerable scientifically: Who am I? Why am I suffering? What is the meaning of my illness and suffering? Illness, in and of itself, is a spiritual journey, which may include emptiness, joy, despair, hope, and mystical experiences. As physicians and caregivers, our job is to support our patients as they go through this journey.

Although it is critical to respect professional boundaries and not try to do the chaplain's job, there is a spectrum along which most physicians can operate. Some physicians elect to pursue issues of religion or spirituality with a patient in greater depth than would others. Consider as an analogy the treatment of depression by an internist. Some internists treat simple cases of depression, referring only the more complex ones to psychiatrists. Others refer a patient to a psychiatrist immediately on diagnosis of depression. Each physician must be honest in recognizing his or her own professional and personal limitations. Ultimately, the goal is to do what is best for the patient. If early referral to a chaplain or other support person is in the best interest of the patient, then that is the appropriate course of action.

CARING FOR OUR PATIENTS

Beyond the data, writings, and courses are personal stories from physicians and their patients. In my own experience as a physician who cares for patients with chronic and terminal illnesses, I feel privileged and honored to care for people who are facing death. Their strength and courage in the midst of suffering is inspiring. My patients are greater teachers to me and to my students on life than any philosophical text. The stories they share are ones of personal transcendence, courage, and dignity. My patients continually live with dying and in the midst of that are often able to face their losses, their fears, and their pain, and transcend to a place where they see their lives as rich and fulfilling. They reprioritize and thus are able to find a place of deep meaning and purpose in their lives. It is often humbling to me to recognize that what I place importance on in life now may have little or no importance in the end, when facing my own mortality. My annoyance at rush hour traffic when I am late, or my emphasis on academic success, pales by comparison to my patients' descriptions of a glowing sunrise or the deep love they feel for another. I would encourage all students reading this text to look on your patients as teachers and to approach dying patients not with trepidation and fear but with openness to all the joy and wisdom you can experience with them.

We should have systems of care that allow for people to die in peace, to die the way they want to, and to be able to engage in those activities that bring peace to them: prayer, meditation, listening to music, art, journaling, sacred ritual, and relationships with others. Our systems of care should be interdisciplinary, with physicians, nurses, social workers, chaplains, and other spiritual care providers all working together to provide spiritual and holistic care for our patients. It is then that health care systems will become caring communities rather than impersonal, technologically driven ones.

Our culture and our profession as a whole must look at dying very differently from the way it currently does. We need to see dying not as a medical problem but as a natural part of life that can be meaningful and peaceful. We can broaden and perhaps even enhance our lives now by knowing that one day we will die. By thinking about our mortality early in life, we will not be caught off guard and pressured by the dilemmas of choices at the end of life. We will have had a chance to think about some of those choices sooner and to come to peace with our mortality. This is where religious organizations can be particularly helpful. They can facilitate our discussions of dying and what that means to us. They can educate their members about the importance of preparing themselves for the choices, both spiritual and medical, that need to be made near the end of life. We, the interdisciplinary care team, can jointly assist the dying person come to peace in life's last moments.

All of us, whether actively dying or helping care for the dying, have one thing in common: We all will die. The personal transformation that is often seen in patients as they face death can occur in all of our lives. By facing our inevitable dying we can ask ourselves the same questions that dying patients face—what gives meaning and purpose to our lives, who we are at our deepest cores, and what the important things are that we want to do in our lives. By attending to the spiritual dimensions of our

personal and professional lives, however we express that, we can better provide care to our patients (83).

Wayne Muller has written:

> There are times in all of our lives when we are forced to reach deep into ourselves to feel the truth of our real nature. For each of us there comes a moment when we can no longer live our lives by accident. Life throws us into questions that some of us refuse to ask until we are confronted by death or some tragedy in our lives. What do I know to be most deeply true? What do I love, and have I loved well? Who do I believe myself to be and what have I placed on the center of the altar of my life? Where do I belong? What will people find in the ashes of my incarnation when it is over? How shall I live my life knowing that I will die? And what is my gift to the family of earth? (84)

Of all life's difficult yet important experiences, dying may be the most difficult one we will ever have. The moment of death, and the dying that precedes it, brings to a close the journey that each one of us has been on. We are the privileged persons who attend people while they are dying, be they our patients or our loved ones and friends. We are the persons who can bring hope and comfort to dying patients as they complete their lives. We need to ensure that our society and our systems of care preserve and enhance the dignity of all people, especially when they are made vulnerable by illness and suffering. We need to listen to the dying and to all our patients, and be with them, for them. The process of dying can be a meaningful one, one that we can all embrace and celebrate rather than fear and dread.

BEREAVEMENT CARE

J. WILLIAM WORDEN

DEFINITIONS

Bereavement: the situation of losing to death a person to whom one is attached.

Mourning: the process that one goes through adapting to such a loss.

Grief: the thoughts, feelings, and behaviors one experiences after the loss.

Bereavement care should be a part of any comprehensive palliative care program. The well-being of the family and of others who are close to a dying or recently deceased person is part of the health professional's responsibility. Health care providers and the institutions they serve must understand the impact of grief and be sensitive to the needs of the bereaved by offering both support and information (1). Included in the understanding of bereavement must be an awareness of the negative consequences that can accrue to survivors after a death. Bereavement is not in and of itself a pathological event. Quite the contrary, it is a normal human experience. However, for some the stress of bereavement may lead to pathological consequences, either physical or mental.

Bereavement may place some at risk for morbidity and mortality after a loss. There have been several investigations into the morbidity and mortality effects of bereavement, especially conjugal bereavement. The findings are mixed. To date, the evidence suggests that there may be a higher risk for mortality among men, especially those older than 75 years of age, but not among women. Remarriage seems to reduce the risk for men, but the reasons for this are not clear. It may be that only the fittest of men remarry (2). The first year after the death of a spouse seems to be the time when men are most at risk. Also during the first year of bereavement there is an increased risk of suicide, especially among older widowers and single men who lose their mothers.

The evidence for increased incidents of morbidity in the bereaved presents a mixed picture. Additional studies need to be done. It is clear, however, that there is a substantial increase in the use of alcohol, tobacco, tranquilizers, and hypnotics among the bereaved, both men and women. Investigators have looked at the stress of bereavement on various immune functions in an attempt to find such a relationship (3,4 and 5). These studies may help clarify possible relationships between some bereavement and morbidity.

In addition to issues of morbidity and mortality, there is the problem of complicated bereavement. Although most people make an adequate adjustment to bereavement, the adjustment becomes complicated in some, and they develop abnormal patterns of grief (6). Among the types of complicated bereavement are the following:

1. *Chronic grief* does not seem to end, and several years later the mourner has a sense of being stuck in the process. Although there is no timetable for mourning, it is the subjective sense of “stuckness” for the mourner that helps identify this phenomenon.
2. *Delayed grief* appears at the time of a later loss but is clearly linked to an earlier loss that was insufficiently mourned. Frequently this mourning is interrupted because the loss is negated or seems overwhelming to the person, or the grieving behavior is not socially supported by others in the mourner's life.
3. *Exaggerated grief* is present when a normal grief response is exaggerated to the point where the person becomes dysfunctional. For example, it is normal to experience dysphoria after a loss, but if this affect is exaggerated to the level of clinical depression, it becomes a type of exaggerated grief. Likewise, it is normal to feel anxious after a loss. If the anxiety rises to a clinical level, such as panic attacks, phobias, or another major anxiety disorder, this would also qualify as an exaggerated grief reaction. Dysfunctional experiences that arise in the course of bereavement often receive a *Diagnostic and Statistical Manual of Mental Disorders-IV* diagnosis. Frequently, however, there has not been a previous episode of the disorder, the patient sees a relationship of his or her affect and behavior to the loss, and the patient may never again experience such a disorder after treatment.
4. *Masked grief* is the fourth type of complicated bereavement. Grief that was absent at the time of the loss appears later under the guise of a psychiatric or medical symptom. When the unmourned loss is grieved, then the symptoms usually abate. Unlike exaggerated grief, wherein the mourner sees a relationship of the symptom to the loss, in masked grief the mourner does not see such a relationship.

TASKS OF MOURNING

The clinician who is interested in working with the bereaved needs to understand the process of mourning. Mourning does not involve clear-cut stages but rather certain tasks that need to be accomplished (6). These tasks (outlined in Table 59-1) do not require a specific ordering, but if they are not accomplished, the bereaved has not made a satisfactory adaptation to the loss.

To accept the reality of the loss
To experience the pain of the loss
To adjust to the environment in which the deceased is missing
External adjustments
Internal adjustments
Spiritual adjustments
To find a way to remember the deceased while moving forward with life

From Worden JW. *Grief counseling and grief therapy*. 3rd ed. New York: Springer, 2002, with permission.

TABLE 59-1. TASKS OF MOURNING

The first task of mourning is *to accept the reality of the loss*. Even in the case of an expected death from cancer, when the family may have observed the declining physical condition of the patient, there is a certain sense of unreality when the news comes that the person has died. This sense of unreality is heightened many times over when the death is sudden or violent. After a death, many survivors experience searching behavior, looking for the lost loved one, or they may misidentify people on the street and have to remind themselves that the person is dead and will not return, at least in this life.

Disbelief that the person is dead can range from a simple hope that one will wake up from a bad dream and that this couldn't be happening to a full-blown delusion that the person is not dead. Illustrating the middle of this continuum of disbelief is the mother whose daughter was killed in a house fire. Although she visited the cemetery every day to put flowers on her daughter's grave, she went around the house saying, “I won't have you dead; I won't have you dead.” This went on for 2 years until she was helped to acknowledge the reality of the loss—that her daughter was not coming back—as well as her own need to let her go and say goodbye to her.

Another form of thwarting this first task of mourning is an effort at “mummification,” i.e., keeping the room, clothes, and other belongings of the deceased undisturbed with the hope that one day the loved one may return. For most, the searching behavior and hope for reunion are short-lived, and people accept the reality that the

person is gone and will never again return as they once were.

The second task of mourning is *to experience the pain of the loss*. Most people do not like pain and attempt to cut short the pain of grief. Others around the mourner who are not comfortable with the pain may also try to thwart the task of experiencing the pain. Nevertheless, if the pain is not felt now it may return later, associated with another loss; alternatively, it may manifest itself as some kind of physical symptom or some form of aberrant behavior.

The negation of this second task of working through the pain is not to feel. People can short-circuit this task in any number of ways. Some try to stop their feelings and deny that the pain is present through substance abuse, removing reminders of the deceased, or moving to a different location. Others idealize the dead and only allow themselves pleasant feelings. Still others cut the pain by minimizing the relationship to the deceased: “He was not very important to me.” Moving after a death may be a way to cure the pain geographically. British psychiatrist John Bowlby has said, “Sooner or later, some of those who avoid all conscious grieving break down—usually with some form of depression” (7). One of the aims of grief counseling is to facilitate this difficult second task so people don't carry the pain with them throughout their lives.

Adjusting to an environment where the deceased is missing is the third task of mourning. Adjusting to the loss means different things to different people, depending on their relationship with the deceased and the various roles the deceased played. Widows and widowers may take time to realize all that they have lost when a spouse dies: friend, lover, bill-payer, gardener, bed-warmer, etc. The awareness of all that one has lost takes time, and this contributes to bereavement being a lengthy process. Six months after the death of her husband, one widow said, “If you had asked me before he died who was the social director in our family, I would have said we both were. Now I realize that he was the one who planned the weekend events and made the arrangements.” This was not the biggest loss she had sustained, but it illustrates how awareness of losses continues to come to the fore months after a death. Some survivors resent having to develop new skills after a death and thwart this third task by not adapting to the loss. They withdraw from the world, assume a helpless posture, and refuse to face up to environmental requirements. They are held in a state of suspended growth in which they are prisoners to a dilemma they cannot solve (7).

Adjustments can be categorized as external, internal, or spiritual. External adjustments refer to the more obvious changes such as living in an empty house, taking on the role of a single parent, learning to drive, and paying bills. Internal adjustments deal with changes in one's sense of self. Bereavement can lead to intense regression wherein the bereaved perceive themselves as inadequate, helpless, or otherwise incapable of functioning. Along with this may come the sense of being unlovable. Bereavement not only means the loss of a significant other but can also mean the loss of a sense of self, in which one's self-esteem and selfefficacy are severely challenged. In a 7-year study of widowed persons, Lieberman found that one-third of widows experienced some growth after the death and that this often included a revision of their self-image. Such persons tended to be those who felt that their own self was submerged in the marriage and who found a sense of liberation after the death (8).

Spiritual adjustment has to do with one's sense of the world and how the death has challenged one's fundamental life values and philosophical beliefs—beliefs that are influenced by families, peers, education, and religion as well as life experiences. Sudden and violent deaths frequently call for these adjustments as they challenge one's sense of God, the predictability of the universe, and why bad things often happen to good people (9).

The fourth task of mourning involves *finding a place in one's life for the deceased so that one can remember and appropriately memorialize the person, yet relocating that person so that one can move forward with one's life*. If a person tries to keep the relationship with the deceased just as it was before the death, the person may become stuck and not move forward with his or her life without the deceased, closing him- or herself off from new relationships and activities. A survivor's readiness to enter new relationships depends not on “giving up” the dead spouse but on finding a suitable place for the spouse in the psychological life of the bereaved—a place that is important but that leaves room for others (10). This task also applies to bereaved parents. A mother whose daughter was killed in a tragic accident was focused for months on that event and on her loss. It was her first thought on awakening every day. Then one day she was surprised when her daughter did not occupy her first waking thought. She then realized that her daughter was dead and was never coming back, even though she desperately wanted her to. She also realized that she was alive and needed to move forward with her life. Finding a way to remember the deceased while moving forward with life is the focus of this fourth task of mourning.

This task approach to mourning can be very useful to the clinician. First, it provides the clinician with an understanding of the process and supplies a focus for the types of intervention that may facilitate the process. Second, it offers a way to understand what is happening in the case of complicated bereavement—where and how a person is stuck, and ways to develop grief therapy strategies. Third, it offers the caregiver something to do for the bereaved that can help reduce the feelings of helplessness stimulated when the mourner wants from us the one thing we cannot give—namely, the dead person back.

MEDIATORS OF THE GRIEF RESPONSE

Although all persons who have sustained a loss by death need to accomplish the tasks of mourning, a wide range of behavior can be classified as normal grief. Not all people grieve the same way any more than all people die the same way. For some, grief is strong and overpowering; for others, it is a very mild experience. For some, grief begins on hearing of a death; for others, it takes longer to begin to grieve. For some, grief is a very brief experience; for others, it goes on and on and never seems to come to an end.

It is important for the clinician to understand that grief, the personal experience of loss, is a multidetermined phenomenon. No single mediator, such as type of death (sudden versus expected), can explain the variations in experience. An understanding of these mediators can be useful to the clinician who is trying to identify in advance how someone might grieve to offer preventive mental health intervention to those most likely to adapt poorly to the loss. Table 59-2 contains what seem to be the most important mediators of a grief response (6).

Nature of attachment
Mode of death
Historical antecedents
Personality variables
Social factors
Changes and concurrent stressors

From Worden JW. *Grief counseling and grief therapy*. 3rd ed. New York: Springer, 2002; with permission.

TABLE 59-2. MEDIATORS OF A GRIEF RESPONSE

The first mediator of a grief response is the *nature of the attachment*. The most intense and often most difficult grief responses occur (a) when the attachment between the bereaved and the deceased was very strong, (b) when the deceased was needed to support the survivor's sense of selfworth and self-esteem, (c) when the survivor was highly dependent on the deceased, or (d) when the relationship was a highly ambivalent one.

The *mode of death* can and does influence the grief response. A sudden death may be more difficult to grieve than one with advance warning. The natural death of an older person may be easier to grieve than the accidental death of a young child or the suicidal death of a teenager. Geographical distance at the time of death, multiple losses, and uncertain losses can all increase the probability of a poor outcome.

Historical antecedents are also important. How one handled previous losses and how well they were resolved can play a role in current loss. Also, a history of clinical depression may portend a more difficult mourning period.

Personality variables, such as age, gender, tolerance for pain and anxiety, personality structure, and ability to express feelings, also contribute to variations in grieving.

Social factors constitute another mediator of a grief response. Each person belongs to various social subcultures, such as ethnic and religious groups, which provide guidelines and rituals for grieving behavior. Social support is also an important factor in mourning. Those who feel supported by family and friends find it easier to grieve than those who do not or those whose social environment actively suppresses the expression of grief.

A final mediator is the *number of changes and concurrent stressors* experienced by the family as the result of the death. In the Harvard Child Bereavement Study of

bereaved families who had lost a parent to death, the strongest predictor of both the depression of the surviving parent and the functioning of the school-age children was the number of changes that the family experienced as the result of the death (11). Families who experience fewer concurrent stressors as a result of the death do better than families for whom stressors are many. Closely related to these family stressors are the family coping styles. Families who could engage in more active coping and who could redefine and reframe problems were less affected by these concurrent stresses than families that could not do this.

INTERVENTION PRINCIPLES

Given the tasks of mourning and the mediators of grief, there are certain implications for a comprehensive program of palliative care through which the bereaved can be helped (Table 59-3).

Facilitate anticipatory grieving
Before death, encourage communication between patient and family
At the time of death, encourage and provide for family presence
After death, encourage reminiscing
Help people deal with all of their feelings
Normalize grief behaviors
Identify complicated bereavement and make referrals to a professional for grief therapy
Be aware of the special features of the bereavement over the loss of a child

TABLE 59-3. INTERVENTION PRINCIPLES

First, recognize that both the dying patient and the family can and do grieve before a death. Being aware of this and helping the patient and family to understand this can help them to cope with the alienation that can occur when someone is dying.

Second, encourage families of the dying to say those things to each other that need to be said before the death. This can leave the survivor with less unfinished business to be dealt with after the death. Family members often need permission from the caregiver to do this. A sentence or two can go a long way to help the family members do what they inwardly want to do but may feel awkward doing.

Third, allow the family to be with the person as he or she is dying, and allow them to be with the body after the death. This can be very salutary in facilitating the first task of mourning—making the death real. There is nothing like the confrontation with the loved one's body to bring home the reality of the loss. A program that encourages this and makes provision for it can make an important contribution to bereavement.

Fourth, after the death, encourage conversations about the deceased. Nothing works better to bring home the reality of the loss than verbalizing about the deceased. The problem is that many families cut short this process because they don't want to hear about something they already know. An enlightened caregiver can encourage those who want and need to talk to do so. The mourner must first believe that the death happened before he or she can deal with the feelings that go with such a loss.

Fifth, help people deal with their feelings. Most do not have difficulty with sadness, but many do have difficulty with the anger, guilt, and anxiety that may follow a loss. Helping them to understand that a wide range of these feelings is normal and to find appropriate outlets for these feelings is all part of a comprehensive program of bereavement care.

Sixth, know what normal grief behavior is, and offer reassurance if family members are having experiences they have never had before and feel that they are going crazy. In our research and clinical experience we find that people seldom decompensate and go insane after a loss, but they may feel they are going crazy because of the unfamiliarity of these experiences. If the clinician knows that hallucinations, distractedness, nocturnal orgasms, sleep disturbance, appetite loss, and other anomalous experiences are normal, the appropriate reassurance can be given.

Seventh, the clinician should also know the signs of a complicated bereavement, and if these occur, should make a referral to a professional for grief therapy. The list of these signs and symptoms is too long for this report but can be found in detail in other places (6,12).

Eighth, know that pediatric oncology presents its own special features. Parents who lose children are among those with the most difficult grief to bear. To lose a child is not only to lose someone out of season but also to experience special strains on the whole family system. Much has been written on this subject, and support groups are available for bereaved parents, such as those sponsored by The Compas- sionate Friends. The concerned oncologist should be familiar with these resources.

BEREAVEMENT SERVICES

There are several considerations in the establishment of bereavement services as part of a palliative care service. They include such questions as these: Who should be served? Who should do the counseling? When should counseling begin and how long should it be continued? Where should this counseling be done? Let's look at these questions one by one.

Who should be served? There are basically three philosophies of grief counseling. The first is to offer such services to everyone who is bereaved. This, however, is not a costeffective approach, and not everyone needs grief counseling. Many, if not most, do very well on their own without the need for special intervention. A second and very common philosophy is to wait and see which people get into difficulty in their mourning and to offer intervention at that point. There is nothing wrong with this approach except that it requires a person to experience a high level of distress or poor coping before intervention is offered. A third approach is to screen individuals around the time of death to predict who among them will not be doing well a year or two later. Preventive mental health counseling can be offered to those who are predicted to be at risk to preclude later negative sequelae. This type of approach makes sense when valid predictors and risk factors have been identified and there is a high level of reliability in a set of predictors. Parkes and others have identified such risk predictors for conjugal bereavement, and Worden and Silverman have developed a screening instrument for high-risk children who have lost a parent to death (13,14,11).

The question of who should be counseled raises the issue of unit of care. Who in a family should be given counseling? When a spouse has died, the surviving spouse may prefer to be seen alone without other family members. When children die, the parents may prefer to be seen together. I prefer to have at least one session with the entire nuclear family, do an assessment of need, and make intervention referrals at that point.

Who should do the counseling? There are several possibilities. One involves a trained professional, such as a social worker, nurse clinician, psychologist, chaplain, or other mental health professional. The advantage here is the obvious training and experience of such personnel. Another possibility is the use of trained volunteers to intervene with or befriend the bereaved. Sometimes these volunteers have been bereaved themselves in the past and use their own experience to try and be helpful. Many hospice programs and groups like The Compassionate Friends use this type of volunteer. A third possibility is the use of nonprofessional volunteers with professional backup. Deci- sions regarding personnel need to fit the particular organization that is offering counseling, but the emphasis clearly needs to be on trained individuals.

When should counseling begin? There is a general consensus that the best time to start is between 3 and 8 weeks after the event (13). Earlier than that, the bereaved may be very involved with family, and the reality of the loss may not have set in. After 8 weeks, some have sealed off their feelings and may be hesitant to start the process all over again. For most bereaved individuals, at 2–3 months after the death, the reality of the loss and its consequences is setting in, pain is at a high point, and support that may have been there at the time of the funeral may be waning.

How long should counseling for individuals and families continue? There is no general agreement on this point. In the United States, hospice care programs usually follow-up with family members in one way or another for a year after the death. Such follow-up may be by phone, letter, or personal visit. This 1-year time frame was informally established and is not necessarily based on research. In fact, research shows that for some bereaved, the most difficult time, with the highest possibility for developing poor adjustment, occurs in the second year of bereavement. This argues for the need of a good screening instrument to predict the individuals who are at

most risk in the second year of bereavement.

Where should counseling take place? Some bereaved are hesitant to return for help to a hospital, a hospice, or to another place where the loved one died. This is especially true in the early months after a loss. Many people feel most comfortable in their own homes, and this may be the best place to see them in the early weeks after a loss. Some bereaved prefer to talk to someone on the telephone because of the anonymity, but face-to-face contact is usually preferable so that nonverbal communication can be assessed and used in the intervention. Later on it can be useful for the bereaved person to return to the place of death as a point of reality for that loss.

Groups for bereaved individuals can be very effective in facilitating the grief process. In a well-run group, mourners can find others who have experienced similar losses and can gain support from such individuals. Knowing that they are not alone in their loss, and knowing that others in the group will not be pushing them to finish their grieving, can be helpful to most people. However, not everyone wants to attend a bereavement group; women are more frequent attenders than men. Men are more likely to attend a group whose aim is education about the grief experience or one whose aim is addressing specific problems such as how to be an effective single parent.

CONCLUSION

Bereavement is one of life's greatest stresses and an experience from which none of us can escape. The clinician who learns from his or her own experience of loss can use this understanding to fashion interventions that can be helpful to the bereaved. Knowing what was and was not helpful to us in our time of need can direct us in making interventions, both verbal and programmatic, that are healing to the families in our care.

EDUCATION AND TRAINING IN PALLIATIVE CARE

DAVID E. WEISSMAN
JANET L. ABRAHM

Palliative care represents a new medical discipline in the United States. Although not yet a full-fledged medical specialty or subspecialty, palliative care is rapidly emerging as a topic of focused education for physicians and other health professionals concerned with care of the dying. Many studies have documented the poor state of palliative care education and palliative care educational resources in the United States (1,2,3,4,5,6,7,8,9 and 10). There is widespread agreement that all facets of the end-of-life experience have been neglected in health professional education, including (but not limited to) pain and symptom management, communication skills, ethics, personal awareness, and hospice care. This chapter focuses on physician education within palliative care, although much of the discussion is directly applicable to other health professional disciplines. Both the terms *end of life* and *palliative care* are used in this chapter. There is consensus among palliative care professionals that the term *end of life* represents a restricted vision of the broader concept of *palliative care*. As a cultural term, *end of life* is typically used to describe the near-dying experience, usually the last few weeks of life. In contrast, *palliative care* refers to the health care issues for patients and family facing any chronic, life-limiting illness, at any point in the disease trajectory.

REQUIREMENTS FOR PALLIATIVE CARE PHYSICIAN EDUCATION IN THE UNITED STATES

Until very recently, there were no mandated requirements for palliative care physician education. Not surprisingly, studies examining how and where palliative care is taught have found that teaching is uncoordinated, often elective, and mostly in lecture format, with limited patient contact (3). Although some U.S. medical schools have developed dedicated palliative care courses or comprehensive curricula, this has been the exception (11,12,13,14,15,16 and 17). In 2000, the Liaison Committee on Medical Education (LCME), the accrediting authority for U.S. medical schools, mandated that end-of-life care be part of every school's curriculum: “Clinical instruction should cover all organ systems, and must include the important aspects of preventive, acute, chronic, continuing, rehabilitative and end of life care” (18). Although this represents a major step forward in palliative care education, specific details from LCME as to what constitutes *end of life* remains to be defined.

Graduate education requirements for palliative care training are highly variable. According to the individual residency and fellowship program requirements listed by the Accreditation Council for Graduate Medical Education in 2000, only geriatrics, family medicine, internal medicine, neurology, and hematology/oncology have substantive requirements for palliative care training, and only geriatrics specifically mandates training via a clinical experience in hospice care (19,20,21 and 22). Recently, the Accreditation Council for Graduate Medical Education adopted six “general competencies,” applicable to all graduate training programs (23). Included are two domains of interest to the palliative care educator, *interpersonal and communication skills* and *professionalism,* domains that include topics of ethics, compassion, respect, and altruism. In the realm of testing, the National Board of Medical Examiners is working to expand end-of-life content on test questions administered to medical students and interns in the United States as part of the U.S. Medical Licensing Examination (24).

Although there is no national requirement for physicians already in practice to acquire new knowledge and skills in palliative care, the American Medical Association has encouraged all its member physicians to participate in *Education for Physicians on End-of-life Care* (25). One final training requirement comes via state law. Starting in 2000, California began requiring that all applicants for a medical license “successfully complete a medical curriculum that provides instruction in pain management and end-of-life care” (26). As with the LCME requirements, the exact criteria to determine what constitutes end-of-life instruction have not been defined.

Curriculum Guides for Palliative Care Physician Education

What should be included within the educational domain of Palliative Care? In the past 10 years, several groups have worked to define the components of a comprehensive palliative care curriculum. The *Canadian Palliative Care Curriculum* was developed as a guide to undergraduate palliative care education for Canadian medical schools (27). It contains a list of attitude, knowledge, and skill objectives for 22 different domains including symptom control, ethics, psychosocial issues, home care, cost containment, and quality assurance. In Great Britain and Ireland a curriculum was developed that includes specific palliative care curriculum goals for each training year (28).

One set of teaching objectives for U.S. physicians was published in 1994 by Schonwetter and Robinson (29). In 1998, a national consensus conference on U.S. undergraduate and graduate education was held, outlining curriculum features and opportunities for education across different educational venues (30). The outcome of this conference was a series of position papers outlining idealized curriculum and training opportunities (31,32,33 and 34). Although each of these discusses a somewhat different aspect of endof-life care education, there is broad similarity on the major educational domains (Table 60-1). Another consensus document was developed by participants from 11 U.S. medical schools participating in a medical school curriculum project sponsored by *Choice-in-Dying* with funding from the Greenwall Foundation. This document outlines goals and objectives for medical student education along with a discussion of potential student assessment measures and curriculum implementation strategies (35).

Educational domains
Pain assessment and treatment
Non-pain symptom assessment and treatment
Ethical principles and legal aspects of end-of-life care
Communication skills, personal reflection
Psychosocial aspects of death and dying
Death as a life-cycle event
Psychological aspects of care for patient/family
Cultural and spiritual aspects of end-of-life patient care
Suffering/hope
Patient/family counseling skills
Working as part of an interdisciplinary team
Care settings in which training should occur
Hospital
Palliative care consultation service or inpatient unit
Outpatient clinic
Home and home hospice
Residential hospice
Long-term care facility

TABLE 60-1. DOMAINS AND LOCATIONS FOR PALLIATIVE CARE PHYSICIAN EDUCATION

Curricula have been promoted for specific domains within palliative care. The American Association for Cancer Education published cancer pain management learning objectives for medical students and primary care residents (36). The American Society of Clinical Oncology published similar cancer pain objectives for medical oncology training and continuing education programs (37). Broad communication skills learning objectives (including objectives for end-of-life care) for medical students in the United States have been written by the Association of American Medical Colleges as part of its Medical School Objectives Project (38). More detailed objectives were compiled at the Medical College of Wisconsin in 1998 as part of an effort to outline specific communication skills objectives that should be mastered within each

year of medical school training (39).

For graduate education, the American College of Physicians and American Academy of Family Physicians have published curriculum guides for the care of the dying (20,22). For physicians already in practice, the American Academy of Hospice and Palliative Medicine developed a curriculum designed for “medical educators and practicing physicians” (40). This curriculum includes 22 modules, each containing a listing of learning objectives and core content for key domains in symptom control, communication, hospice care, and ethics. The American Academy of Hospice and Palliative Medicine curriculum was originally designed for physicians working as hospice medical directors, but can easily be adapted for other levels of physician education. The *Education for Physicians on End-of-life Care* project, designed for physicians in practice, contains a comprehensive palliative care curriculum including pain and symptom control, communication skills, ethics, and legal aspects of care (25). Again, this curriculum can be easily adapted for all levels of physician training. The newest comprehensive curriculum, developed in 2001 for medical oncologists and oncology trainees by the American Society of Clinical Oncology, includes 29 modules covering symptom control, communication skills, and related aspects of palliative care. Curriculum standards for palliative care fellowships are currently under development under the aegis of the American Board of Hospice and Palliative Medicine and the American Academy of Hospice and Palliative Medicine. An extensive listing of peerreviewed educational tools, curriculum guides, reference articles, and links in palliative care is available at the End-of-Life Education Resource Center, www.eperc.mcw.edu (41).

PLANNING A PALLIATIVE CARE EDUCATIONAL INTERVENTION

Needs Assessment for Curriculum Development

The first step in the design of an educational intervention is the performance of a needs assessment. The purpose of a needs assessment is to understand the gap between what is currently being taught and evaluated and the ideal (42). A needs assessment is used to understand and characterize the problem that needs fixing and how the problem impacts on different stakeholders, such as students, patients, or family members. A comprehensive needs assessment should be able to identify strengths and weaknesses in the current system of education along with barriers and opportunities for change.

To accurately understand the nature and scope of the problem, information needs to be obtained, ideally from multiple different sources, using different techniques. A key first step in the process is to understand what an idealized education plan should include. This information can be obtained by reviewing the literature, seeking consensus documents that define best educational practice, and conducting interviews with experts and colleagues who have undertaken a similar task (42). The next step is to obtain local data to understand how your current program is or is not achieving the best practice standards. Although abundant national data may be available, it is local data that are most useful in convincing change agents of the need for action. Data that can be rather easily obtained include surveys of attitudes, self-confidence, or knowledge of stakeholders; informal meetings soliciting information about current and desired curriculum and evaluation methods; and chart reviews (42,43). More sophisticated and laborintensive methods include formal focus groups, skills-based assessment (see the section Assessment of Learner Performance and Program Evaluation), and direct observation of clinical practice. The final step in the needs assessment process is to synthesize the information, prepare a report, and present the information to key stakeholders, individuals such as program directors or curriculum deans who can assist in making change happen.

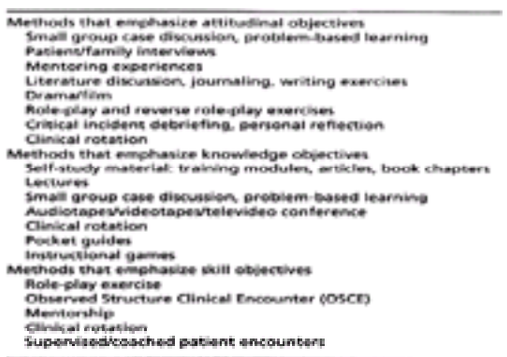
Different multidimensional palliative care needs assessments have been reported for different populations of learners. The Palliative Care Education Assessment Tool (PEAT) is a comprehensive “curricular mapping” tool, developed as a self-assessment tool to be used by medical schools (44). PEAT is used to assess curriculum across seven domains: palliative medicine, pain, neuropsychologic symptoms, other symptoms, ethics and law, patient/family/caregiver nonclinical perspectives on end-of-life care, and clinical communication skills. The successful application of PEAT, as a method to obtain needs assessment data and plan for curriculum reform, has been demonstrated in a cohort of New York medical schools (44).

Ury et al. reported their experience with a needs assessment process developed for one internal medicine residency (45). This process included distribution of a survey, focus groups, and topic rankings. Weissman et al. described a complex needs assessment process for understanding end-of-life education in a cohort of more than 150 internal medicine residency programs (43,46,47 and 48). This process includes (a) completion by the residency program director of a baseline assessment identifying their program's demographic characteristics, teaching content and methods, resident assessment methods, and perceived barriers and resources for end-of-life care and curriculum reform; (b) a separate but identical survey to be completed by a chief resident to assess for perceived differences in educational offerings between faculty and residents; and (c) surveys of self-confidence, concerns, and knowledge surrounding end-of-life care. Other focused assessment instruments have been described to assess attitudes and knowledge in various domains of end-of-life care (49,50,51 and 52).

Teaching Methods in Palliative Care Education

Teaching and learning are not the same; teaching is what the educator does, learning is what the learner acquires from the educational experience. The educators' attitudes, knowledge of the subject matter, skills, *and* educational techniques directly influence the relation between teaching and learning. Key to the success of a palliative care educational encounter is awareness of the key principles of adult learning. These include keeping the experience *learner-centered*, with relevant information keyed to the learners' *need to know,* and understanding that adult learners make choices about their participation (e.g., they leave the room if the information is not relevant to their needs). One way to obtain buyin from an audience of adult learners is to ask at the start of a teaching session, “Why are you here today? What do you hope to learn from this encounter?” Responses can be written on a flip chart or overhead projector, with the remainder of the education geared around the responses. Another suggestion is to start with a brief exercise that helps build a sense of *tension* for learning: Begin a teaching session by asking the learners two to three shortanswer or multiple-choice questions, holding back the answers until late in the teaching session.

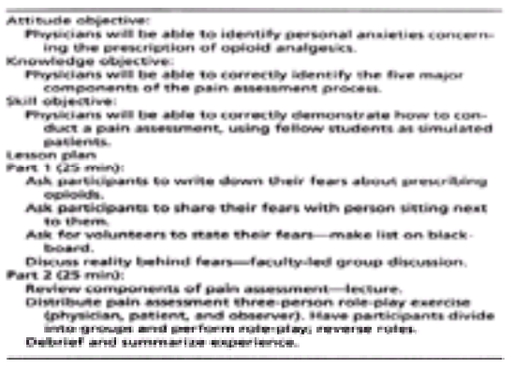
Table 60-2 details possible teaching methods for palliative care education, sorted by the type of desired learning objective. Delineating learning objectives is the first key step in planning any educational experience. Objectives communicate to the learner what is expected of the educational encounter and form the basis for evaluating the impact of training. Objectives are divided into one of three broad categories: Attitude objectives are concerned with values and emotions, knowledge objectives relate to acquisition of facts, and skill objectives relate to performance of a specific activity. Objectives should contain four discrete items: the *audience*, the *desired behavior*, the *condition* under which the behavior will be learned, and the *degree* to which the new learning will be demonstrated (53).



Methods that emphasize attitudinal objectives
Small group case discussion, problem-based learning
Patient/family interviews
Mentoring experiences
Literature discussion, journaling, writing exercises
Drama/film
Role-play and reverse role-play exercises
Critical incident debriefing, personal reflection
Clinical rotation
Methods that emphasize knowledge objectives
Self-study material: training modules, articles, book chapters
Lectures
Small group case discussion, problem-based learning
Audiotapes/videotapes/televideo conference
Clinical rotation
Pocket guides
Instructional games
Methods that emphasize skill objectives
Role-play exercise
Observed Structure Clinical Encounter (OSCE)
Mentorship
Clinical rotation
Supervised/coached patient encounters

TABLE 60-2. EDUCATIONAL METHODS FOR PALLIATIVE CARE EDUCATION

Given the pervasive and often negative attitudes that shape caring for the dying, it is advisable to include a mixture of attitude, knowledge, and skill objectives in all training experiences. Thus, it is also desirable to include a mixture of teaching methods in any one educational experience. Table 60-3 details an example of a 1-hour pain management teaching session that includes diverse teaching methods, including personal reflection, group discussion, lecture, and role-playing.



Attitude objective:
Physicians will be able to identify personal anxieties concerning the prescription of opioid analgesics.
Knowledge objective:
Physicians will be able to correctly identify the five major components of the pain assessment process.
Skill objective:
Physicians will be able to correctly demonstrate how to conduct a pain assessment, using fellow students as simulated patients.
Lesson plan
Part 1 (25 min):
Ask participants to write down their fears about prescribing opioids.
Ask participants to share their fears with person sitting next to them.
Ask for volunteers to state their fears—make list on blackboard.
Discuss reality behind fears—faculty-led group discussion.
Part 2 (25 min):
Review components of pain assessment—lecture.
Distribute pain assessment three-person role-play exercise (physician, patient, and observer). Have participants divide into groups and perform roleplay; reverse roles.
Debrief and summarize experience.

TABLE 60-3. SAMPLE OBJECTIVES AND LESSON PLAN FOR 50-MINUTE TEACHING EXERCISE ON PAIN ASSESSMENT FOR PHYSICIANS

In general, addressing attitudes is the most challenging feature of palliative care education. It is a truism of medical education that attitudes cannot be taught. Rather, a shift in attitudes requires that the learner feel safe and respected and be ready to give up one attitude (e.g., “I am afraid to use opioids for fear of causing addiction”) for another (e.g., “opioids rarely lead to addiction, are safe, and improve quality of life”). General principles of discussing attitudes are listed in Table 60-4.

How do attitudes form?
Imitation of others: positive and negative.
Direct instruction.
Observation of rewards and punishments.
Pressure to conform.
Cognitive dissonance: facts inconsistent with belief.
How do attitudes change?
Recognize that attitudes involve ego-involvement.
Shared group attitudes are more resistant to change.
There must be a willingness to change.
Individuals must be ready to change.
Exhortation, information, and rational argument have a limited role in the learning or changing of attitudes.
Effective teaching capitalizes on “teachable moments,” in which the learner is emotionally or intellectually aroused by a question, contradiction, or problem.
Attitudinal development is fostered in situations in which the learner can be active and can engage with others around real problems.
Attitudes are best learned/changed when:
The learner is able to examine personal feelings/attitudes in an open and nonthreatening dialogue with peers, and concrete knowledge and skills are taught that relate to the desired attitudes.
The learner has an opportunity to practice the new behavior, thus making a commitment.
The learner has the opportunity to reflect on the meaning, difficulties, and rewards of attitudinal change.
Role-playing and role-reversal encourages the learner to take an alternative perspective and may foster an empathic awareness of the other's experience.
Role models and mentors are crucial to the process of learning attitudes, especially when the learner is making a transition.
Feedback about the learner's progress toward explicitly desired attitudinal objectives can help promote self-reflection and self-learning.

Provided by Susan Block, M.D., with assistance from Lynn Wilkerson, Ed.D.

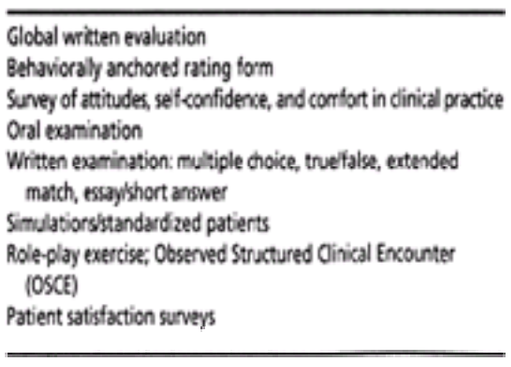
TABLE 60-4. TEACHING ATTITUDES

Knowledge objectives are the easiest to teach; perhaps that is why the traditional 50-minute lecture remains the most commonly used educational format in medical education. However, other modalities do exist, notably self-study guides, journal articles, video-and audiotapes, and use of games (e.g., *Medical Jeopardy*).

Teaching directed at skill objectives requires the learner to practice and demonstrate a defined skill such as patient counseling, calculating equianalgesic doses, or death pronouncement. Teaching sessions based on skill objectives requires preparation of case studies or role-playing scenarios, training simulated patients, or selecting and briefing real patients to be used in a training setting.

Assessment of Learner Performance and Program Evaluation

Table 60-5 lists commonly used assessment methods in palliative care. As with teaching methods, different assessment methods work best when appropriately matched to the learning objective. Attitudes are best assessed through personal interactions, directed questioning, and surveys. Knowledge can be assessed via oral or written examinations, and skills through direct observation or written problem solving (e.g., calculating opioid equianalgesic doses). Assessment techniques can also serve as a teaching tool. For example, asking physicians to take a multiple-choice examination and then reviewing the answers combines both learning and assessment. Another common example is to have learners practice communication skills with a simulated patient, who then gives immediate feedback to the learner.



Global written evaluation
Behaviorally anchored rating form
Survey of attitudes, self-confidence, and comfort in clinical practice
Oral examination
Written examination: multiple choice, true/false, extended match, essay/short answer
Simulations/standardized patients
Role-play exercise; Observed Structured Clinical Encounter (OSCE)
Patient satisfaction surveys

TABLE 60-5. LEARNER ASSESSMENT METHODS

Evaluating the impact of a teaching experience can be done at several different levels, depending on the desired information. At the most basic, learners can be assessed using a “happiness survey,” i.e., questions about the global quality of teaching, whether the learning objectives were met, the teaching skills of the educator, the quality of audiovisual material, etc. The next order of evaluation is to understand if learning occurred. Administering a series of questions using a prepost test design is a commonly used method of assessing the immediate impact of an educational experience. Unless a different set of questions is used in the post test, however, there is danger of test retest bias. Delayed post tests can be administered weeks, months, or years after a specific learning experience, to assess retention of information across time. However, interpretation of this data is fraught with hazard, as intercurrent learning activities distort the impact of the original teaching.

A different form of post test survey, the retrospective pre-post test, asks learners to rate their *change* in attitudes, knowledge, and skill at the conclusion of an educational program, compared to the beginning of the program (54,55 and 56). This is a very effective evaluation tool in palliative care, because it is common for physicians to think that they already know the facts of a given topic at the start of the teaching program, when in fact they only become aware of their deficiencies during the presentation.

The highest order of evaluation works to assess the impact of an educational experience on physician behavior and patient care (e.g., reviewing charts for written documentation of pain assessment information before and after a learning exercise on pain assessment). Other examples include chart audits for analgesic prescribing, videotaping patient encounters to assess communication skills, or asking patients to complete a survey rating their physician's communication skills.

EDUCATIONAL ISSUES IN SPECIFIC PALLIATIVE CARE DOMAINS

Pain Education

Pain must be controlled before physicians can assist patients with the myriad of physical, psychological, and spiritual problems at the end of life. Yet physicians frequently fail to apply currently accepted standards of care for acute or chronic pain management. Moreover, it is clear that despite a multitude of clinical guidelines, position papers, workshops, lectures, grand rounds, journal articles, and book chapters written about pain management, clinical practice is still far from optimal

(57,58,59 and 60).

The primary reason that conventional education formats fail to translate into a change in clinical practice is that physicians harbor a host of attitudes about pain and pain management that inhibit the appropriate application of knowledge and skills. These attitudes can be divided into two broad categories (57). First are physicians' attitudes about pain, which reflect societal views about the meaning of pain and pain treatment (61). A second category of negative attitudes relates to fears and myths about opioid analgesics: fears of addiction, respiratory depression, and regulatory scrutiny, along with the secondary consequences of these fears—malpractice claims, professional sanctions, loss of practice privileges, and personal guilt about potential culpability for causing death (62,63 and 64).

In addition to attitudes, deficits in pain knowledge and skills are widespread. Physicians generally do not know the clinical pharmacology of opioid and nonopioid analgesics, how to conduct a pain assessment, or how to use nondrug analgesic treatments (e.g., antineoplastic, anesthetic, and behavioral), and they lack skills in patient education and counseling regarding pain and pain treatment. Educational techniques and results from various pain education programs have been reported and reviewed extensively (59,60,65,66,67,68,69,70,71 and 72). Key findings include the following:

- Pain education must include attention to attitudinal issues along with knowledge and skills.
- Pain education must be longitudinal, not just part of a pharmacology course in the preclinical years.
- Pain education of physicians, together with nurses and pharmacists, can lead to significant empowerment and local change in practice.
- To most effectively impact pain management practice, education should be coupled to other elements of institutional change such as quality monitoring, development of routine assessment and documentation procedures, and standards development.

Ethics, Law, and Communication Skills Education

The specific content areas in ethics and communication skills necessary for palliative care education are listed in Table 60-6. There is considerable content overlap between ethics and communication skills. For example, to care for patients effectively, trainees need to understand the ethical and legal framework of advance directives *and* have the communication skills necessary to discuss these with patients. Similarly, trainees need to understand the ethical and legal background to make decisions about treatment withdrawal *and* to acquire the skills to discuss these issues with patients and families.

Ethics/law
Informed consent
Decision-making capacity
Advance directives, surrogate decision makers
"Do Not Resuscitate" orders
Treatment limitation and withdrawal
Medical futility
Assisted suicide and euthanasia
Cross-cultural care
Truth-telling
Communication skills
Empathic listening
Discussing advance care planning
Giving bad and sad news
Running a family conference
Discussing treatment goals
Discussing treatment limitation or withdrawal
Discussing hospice referral
Death pronouncement
Discussing autopsy and organ donation
After-death care/bereavement call/card

TABLE 60-6. ETHICS/LAW AND COMMUNICATION SKILLS DOMAINS

There is a rich literature on educational methods and outcomes in ethics and communication skills education (73,74,75,76,77,78,79,80,81,82,83,84,85,86,87,88,89,90,91,92,93,94,95,96,97,98,99,100,101,102,103,104,105,106,107,108,109,110,111,112,113,114 and 115). Although ethics is generally considered a preclinical course in medical school, it is advisable that training in ethics be incorporated throughout medical school, residency, and fellowship training. As the level of professional responsibility increases with each year of training, such responsibility imposes demands on the trainee to make increasingly complex and ethically challenging decisions. Such decisions often strain the trainees' personal understanding of professionalism and altruism and thus merit dedicated time for self-reflection and mentorship. Educational methods particularly suited to ethics instruction include case studies, small group discussion, mentorship, and narrative education. This is not to suggest that a lecture on the legal aspects of informed consent is not a valid educational tool, only that most ethical issues require active discussion and reflection to be incorporated into one's system of medical decision making.

For many communication topics, prior knowledge of the relevant ethical/legal framework is necessary before actually practicing the skill. Educational methods specific to communication skills training include demonstration and mentoring, role-playing, use of simulated patients, observed structured clinical encounter, and direct observation of clinical encounters. In addition, personal reflection and discussion, before and after patient encounters, is critical to allow the trainee an opportunity to debrief what are typically emotionally laden discussions.

Clinical Training Experiences

In the past 10 years, there has been increasing interest in developing clinical training experiences in hospice and palliative care. Hospital-based palliative care teams are thought to be a valuable venue for clinical education in palliative and end-of-life care (116,117 and 118). Trainees can learn how to work within a multidisciplinary group and can experience a truly collaborative process with the educational focus enlarged to include the physical, psychological, social, and spiritual dimensions of care. Two reports, one involving family practice residents and one involving hematology/ oncology fellows, have documented improvements in palliative care knowledge, comfort, and selected skills through a clinical palliative care rotation (119,120). The durability of the educational impact of these experiences on trainees has not been examined.

Clinical rotations that involve home or residential hospice experiences have been reported by several medical schools (13,14,15 and 16,121,122,123,124,125 and 126). The University of Maryland and the University of North Dakota School of Medicine and Health Sciences provide examples of clinical hospice experiences. In the junior year, Maryland students rotate through hospice sites for 1 half-day per week during the month-long ambulatory care block, receiving didactic instruction and reading and writing assignments, and participating as members of the multidisciplinary team in the care of three to six hospice patients (15,16). Students who were assigned this course scored 20% higher (p <.001) on a 60-item palliative medicine written examination than fellow classmates who did not. At the University of North Dakota, a 5-day hospice experience for junior students has been offered since 1995. Students engage in a combination of didactic presentations, home visits, interdisciplinary rounds, and personal journals (13). Significant pre-post test changes in attitudes were demonstrated.

Few reports of clinical end-of-life training experiences for interns and residents exist (127,128 and 129). Stanford University Medical School piloted a mandatory 4-week hospice and nursing home rotation for interns (128). Clinical time is spent caring for hospice and nursing home patients. At the end of the rotation, interns noted significant changes in their attitudes and knowledge about end-of-life care. Liao has reported early experience with a year-long, elective home hospice experience for third-year internal medicine residents (129). Residents reported improved comfort and self-confidence in dealing with end-of-life issues.

Hospice/palliative care rotations can have sustained effects. In one study, physicians who elected a 2-week clinical and didactic hospice/palliative care rotation during their fourth year of medical school completed a questionnaire 2–5 years after graduation. On a scale of 0–4, they gave the course a “4” on “how it affected my current communication with patients and knowledge of pain control”; 73% said it rated a “4” on understanding of quality-of-life issues in their current practice (126). The physicians also volunteered that the course improved their ability to help patients make decisions, and improved their knowledge and attitudes toward dying patients and the effect of disease on families.

Personal Awareness Training

Practitioners of palliative medicine and all clinicians who care for dying patients are likely to benefit from increased personal awareness of themselves, both as clinicians and as teachers (130,131). They are unlikely, however, to have received training in how to deal with the emotions that arise when caring for patients with progressive disease or with the dying patient. Physicians who do not receive such training may rely on detachment, and may not engage in the kinds of relationships that make practice feel worthwhile and that prevent burnout (132,133 and 134). These physicians are more likely to distance themselves by ignoring or paying selective attention to the cues patients offer that suggest they would like to talk about underlying concerns, trivializing those concerns by giving premature or false reassurance, or simply by changing the topic (134). Previous personal experiences with dying friends or relatives, lack of understanding of the impact of losses in their own lives and failure to grieve those losses, and lack of personal role models for how to cope effectively with emotional pain leave students and practitioners unprepared for the challenges such patients present. Without knowing why, physicians may find themselves either overinvolved or distant from terminally ill patients, and may feel a need

to continue to provide aggressive, cure-oriented care, long past the point of benefit to the patient.

Undergraduate course, residency, and fellowship directors have a number of options that can help trainees. A recommended curriculum to increase personal awareness of residents has been described (131). Settings for personal awareness training can include support groups, Balint groups, family of origin group discussions, meaningful experiences discussion, personal awareness groups, literature in medicine discussion groups, and psychosocial morbidity and mortality conferences (135).

As part of personal awareness education, students and trainees should examine their own death anxiety ("the fear of extinction, annihilation, obliteration, or ceasing to be").Trainees with significant death anxiety, who suffer stress from uncertainty, who are reluctant to disclose uncertainty, or who are anxious about attachment to patients, are more likely to have negative attitudes toward dying patients (136). Both death anxiety and uncertainty can be addressed in medical student curricula. The one controlled longitudinal study on this topic involved 99 medical students who participated in a course designed "to study the ethical, emotional, and cultural aspects of death and dying" (137). Students who took the course had significantly more positive attitudes immediately after completing the course and maintained them through their fourth year of school.

PALLIATIVE MEDICINE FELLOWSHIPS

Palliative medicine training is needed to prepare medical trainees for community or academic careers. Neither the knowledge and skills, nor the exposure to working with interdisciplinary teams needed for such a career, are found in any existing residency or fellowship training programs. As of April 2001, there were 18 U.S. programs offering physician fellowships in palliative care (138). In addition, starting in 2001, the Department of Veterans' Affairs will be providing support for physician fellowships in a limited number of training sites. Literature on the curricula and outcomes of current U.S. palliative care fellowships is scant (139,140 and 141). A consensus panel composed of the directors of the palliative care fellowships along with representatives from the National Hospice and Palliative Care Organization, the American Academy of Hospice and Palliative Medicine, the American Board of Hospice and Palliative Medicine, and the Department of Veterans' Affairs, is currently working on a document to define a core curriculum for palliative medicine fellowships.

FACULTY DEVELOPMENT

Faculty development is needed if goals in undergraduate and graduate palliative care education are to be met. A comprehensive faculty development program should include elements of professional, instructional, leadership, and organizational development (142). Several courses, typically multidisciplinary in design, have been developed in the United States, with the explicit goal of training academic faculty to become role models for palliative care education. *The Program in Palliative Care Education and Practice* at Harvard University includes didactic and experiential exercises in communication, pain and symptom management, ethics, cultural implications, teaching and learning styles, educational techniques, religious and spiritual concerns, personal awareness, organizational change, and grief and bereavement (138). Learners attend two 7-day intensive sessions, separated by 7 months, during which they work on projects at their home sites and continue education through casestudies discussed via email. The *Palliative Care Role Model program* is a 40-hour course given over 9 months, with physician, nurse, social worker, and physical therapist faculty from the Massachusetts General Hospital, Brigham and Women's Hospital, Dana-Farber Cancer Institute, and Harvard Pilgrim Health Care. The Mentorship program, sponsored by the *Network Project* at Memorial Sloan-Kettering Cancer Center is "an interdisciplinary, multimodality training program" that includes a 2-week observership in cancer pain management, psychosocial oncology, and cancer rehabilitation (143).

At the Medical College of Wisconsin, Weissman reported results of an 8-week, 12-hour faculty development program for academic physicians (56). Significant improvement in end-of-life knowledge and self-confidence and education skills was noted. A 1-week clinical experience for physicians, nurses, pharmacists, social workers, and chaplains has been offered at Northwestern University Hospital since 1995. Evaluations indicated that all participants felt it affected their practice in a positive way (144). In 1998, the Department of Veterans' Affairs implemented a project to help faculty in internal medicine training programs develop and implement state-of-the-art care for veterans at the end of life (145).

Perhaps the most innovate approach to faculty development was a report by Bruera et al. on patient-based learning offered through "bus rounds" (146). Participants used buses to take them on home visits to patients in palliative care home programs. During the bus ride between home visits, they discussed patients who they were to visit and reviewed relevant journal articles.

INTERDISCIPLINARY TRAINING

A common recommendation in palliative care is that education should take place in a multidisciplinary or interdisciplinary context. "A multidisciplinary field of study refers to an inquiry involving a plurality of disciplines in which disciplinary boundaries are maintained and the unique contributions of each are highlighted" (148). Clinicians who work in the multidisciplinary model are each representatives of a specialty, and they approach the patient's problems from their discipline's perspective. In contrast, interdisciplinary work can be thought of "as an inquiry involving a plurality of disciplines where disciplinary boundaries are often muted and the joint contributions of the synergy are highlighted . . . interdisciplinary activity emphasizes integrated, emergent approaches" (147).

It has been suggested that the *transdisciplinary* model should supplant the interdisciplinary. Transdisciplinary work has been defined as "a process by which researchers work jointly using a shared conceptual framework that draws together discipline-specific theories, concepts, and approaches to address a common problem" (148). Transdisciplinary education would seem an ideal model for palliative care. The evolving palliative care curricula provide the shared conceptual framework that could pull together the diverse fields of ethics, pharmacology, neuroscience, physiology, health services research, medicine, nursing, social work, psychiatry, chaplaincy, and clinical pharmacy to approach the relief of suffering.

These different models create uncertainties for educators in palliative medicine. To achieve the goal of collaboration with and respect for other disciplines, do physicians simply need training in how to work on a team composed of nonphysicians or should they have actual experience working as part of a clinical team? If clinical exposure is desired, is it sufficient to have a trainee (medical, nursing, social work) attend an interdisciplinary team meeting, or work with individual members of the team and then attend the meetings, or should trainees study together in a multi-, inter-, or transdisciplinary palliative care consult service, inpatient unit, or hospice?

In community and rural health delivery, interdisciplinary training has been effective in enhancing medical and nursing students' and allied health professionals' attitudes towards the professional range and competence of the other discipline (149,150). However, the authors of a Cochrane analysis of interprofessional education found only two intervention studies suitable for inclusion, although they are preparing a companion, less restrictive review (151,152 and 153). Despite the lack of data, the use of multi-, inter-, or transdisciplinary teams for training is often recommended in palliative care, and many of the courses described earlier (and others) are based on a model of multi-or interdisciplinary education (3,66,154,155,156,157,158 and 159).

STAFF STRESS AND BURNOUT

MARY L. S. VACHON

Caregivers strive to provide palliative care through the com-prehensive management of the physical, psychological, social, spiritual, and existential needs of patients and families facing incurable progressive illness. The stress caregivers experience can be both extremely challenging and very rewarding. Care-givers who begin their encounters with patients at earlier phases of illness, when there is still the hope for cure or pro-longed survival, may find themselves connecting at a deep level with patients and their families. These caregivers may experience a roller coaster of emotions that may be similar to those experienced by patients and their families if and when the disease progresses. Caregivers may find themselves engag-ing in anticipatory mourning, questioning the appropriate-ness of some treatment protocols, or pushing to do anything to ward off impending death. Caregivers entering into rela-tionships with patients and families at a later point in the ill-ness continuum may feel they do not have the time they need to develop the relationship they believe would be most benefi-cial to help patients deal with their rapidly approaching deaths. They may feel that patients and families have come to them out of the limitations of the health care system, rather than through choice. Both groups of caregivers may have dif-ficulty dealing with issues of financial constraints in today's health care system. There also can be controversy about who should be the primary caregivers of people with advanced dis-ease— oncology staff, or palliative care or hospice staff.

This chapter provides a brief historical overview of the lit-erature on occupational stress, burnout, and compassion fatigue; highlights the personal and occupational variables that may lead to stress, burnout and compassion fatigue in palliative care; elucidates some of the satisfactions associated with palliative care; and discusses coping in these fields. The emphasis is on research from the previous decade. Discussions of previous research have been published elsewhere (1,2,3,4 and 5).

INTRODUCTION AND HISTORICAL OVERVIEW

Caregiver Stress

Interest in the issue of professional caregiver stress dates from the late 1950s. The psychologist Herman Feifel (6) noted that physicians were found to have a greater fear of death than laypersons. In the same year, the sociologist Renée Fox (7) studied the stress experienced by physicians conducting pioneering work on the artificial kidney and kidney transplantation. Intervention to assist with the man-agement of stress began with nurses (8,9), moving on to teams (10), and then to physicians (11). Most of the early work was anecdotal in nature and made no attempt to define or measure the stress experienced by staff, much less to document ways of managing such stress.

The hospice/palliative care movement began in England in 1967 and in North America in 1974, and interest in the area of caregiver stress burgeoned (1). Gradually, work emerged that focused on measuring and managing staff stress in both hospice and oncology settings (12,13).

Concept of Burnout

As interest in caregiver stress increased, the concept of *burnout* was elucidated. The term is generally credited to Freudenberger (14,15). Burnout has been characterized as “the progressive loss of idealism, energy and purpose experi-enced by people in the helping professions as a result of the conditions of their work” (16, p. 14). Burnout has also been described as a syndrome of responses involving increased feelings of emotional exhaustion, negative atti-tudes toward the recipients of one's service (depersonaliza-tion), a tendency to evaluate oneself negatively with regard to one's work, and a feeling of dissatisfaction with accom-plishments on the job (17,18,19,20 and 21) (Table 61-1). Pines (22) suggests that “the root cause of burnout lies in people's need to believe that their life is meaningful, and that the things they do—and consequently they themselves—are impor-tant and significant” (22, p. 633).

Burnout is associated with:
Overfunctioning behavior and issues from childhood
Work overload
Role ambiguity
Role conflict
Time and staffing limitations
A stressful, discouraging work environment
Lack of advancement opportunities
Poor working relationships
Lack of chairperson and peer support
Poor head nurse leadership style
Increased demands by patients and families
A failure to do work the way one feels that it “should be done”
A lack of a sense of meaning from one's work
Frequent exposure to death and dying
A lack of existential significance

Modified from refs. 18–21.

TABLE 61-1. BURNOUT AND WORK ENVIRONMENT

The term *compassion fatigue* (23) has been used to describe a syndrome that shares some characteristics with burnout: depression, anxiety, hypochondria, combative-ness, the sensation of being on “fast forward,” and an inability to concentrate. Garfield states, however, that in contrast to one who has burned out, the caregiver with compassion fatigue can still care and be involved (5,24). Given that most of the research on these topics has been done using instruments to measure burnout, this concept is addressed in more detail than is compassion fatigue.

Burnout is generally seen to result from the interaction between the needs of a person to sacrifice himself or herself for a job and a job situation that places inordinate demands on an individual. The person prone to burnout is apt to have unrealistically high personal expectations for satisfaction in a given area of life. The phenomenon can occur not only in an individual but also within a system (16,25). Pines (19) proposed a social-psychological model of burnout positing certain characteristics of the work environment as contributing to burnout. According to her model, professionals with a high level of motivation can either achieve peak performance, if working within a positive environment, or develop burnout symptoms, if the individual continues to confront a stressful, discouraging environment. Individual differences determine how soon an individual develops burnout and how extreme the experience might be.

Pines (20) has also written about burnout from a psychoanalytic-existential perspective. Psychodynamic theory contributes the idea that people choose an occupation that enables them to replicate significant childhood experiences, and existential theory suggests that people attempt to find existential significance through their work.

Pines suggests that unconscious images from childhood influence one's career decisions. “People choose an occupation that enables them to replicate significant childhood experiences, gratify needs that were ungratified in their childhoods, and actualize occupational dreams and professional expectations passed on to them by their familial heritage” (20, p. 634). Given that the choice of a career involves such significant issues, caregivers enter their careers with very high hopes, expectations, ego involvement, and passion. If one is successful in one's career, then one derives a sense of existential significance and partially heals one's childhood wounds. When one feels that one has failed to do the work the way it “should” be done, or when work does not give one's life a sense of meaning, then individuals burn out. A lack of existential significance is the hallmark of burnout (20).

Grosch and Olsen (21) also posit an interplay between systemic factors and personal factors that produce burnout to understand burnout in clergy. Many of the same dynamics may be at play with health care professionals. Self-psychology provides an understanding of a faltering sense of self, the regulation of self-esteem, and the deep longing for appreciation that contributes to burnout. Finding healthy ways of maintaining a strong sense of self is necessary for effective helping as a professional. Self-psychology suggests that many helpers were sensitive and alert children who learned quickly to adapt to the needs of their parents (26,27). “They then were able to give their parents all the attention and affection that the parents themselves missed as children. Consequently, these children's own needs, programs, blueprints, or scripts were not allowed to develop. The ultimate outcome of such situations is a predisposition for diminished self-esteem and repeated attempts as adults to find the 'ideal parent' in their own children or partners” (21, pp. 20–21)—or patients. The emotionally vulnerable professional, craving admiration and appreciation, may develop an ever-increasing workload of patients and become dependent on the need to be needed that feeds the professional's sense of self-worth. This overfunctioning behavior often develops in childhood. Indeed, those who choose medicine have been found to have strong obsessivecompulsive personality traits that lead them to “choose a career in which long hours of study, heavy responsibility and devotion to work are required. In fact, the more these traits are exaggerated the more outstanding a student may be” (28, p. 647, references in original).

THE INDIVIDUAL AND THE WORK ENVIRONMENT IN ONCOLOGY

Demographic Variables

Younger caregivers have been found to report more stressors, more manifestations of stress, and fewer coping strategies (29). In a UK study comparing clinical oncologists (formerly known as radiotherapists), medical oncologists, and palliative care specialists, burnout was associated with being younger than 55 years of age (30). When this study was expanded to include other hospital consultants (gastro-enterologists, surgeons, radiologists, and oncologists), being 55 years of age or younger was identified as an independent risk factor for burnout (31). Increased job satisfaction was found to be associated with older age (32), although older staff members may be more sensitive to a gap between their real and ideal work situation and, if such a gap occurs, older caregivers might be more vulnerable to stress reactions (33).

Santos and Cox (34) compared intergenerational differences in pediatric nurses in the workplace and found difficulties with work adjustment amongst “Baby Boomers” (born between 1946 and 1964). When compared with “Generation Xers” (born between 1965 and 1981) and “The Matures” (born between 1909 and 1945), Baby Boomers had significantly higher mean scores on *role overload*, in which resources exceed demands, and *role boundary* issues involving conflicting demands and loyalties. The Matures had difficulty with *role insufficiency*, in which training and skills exceed job demands. Generation Xers had the highest mean scores on *physical environment,* in which the workplace itself provides extreme conditions. Boomers had more difficulty with *vocational strain* problems with the workplace and *interpersonal strain*, disruption with interpersonal lives. The stress and strain scales tended to be more negative on three of the four scales for Boomers. *Self-care,* personal activity to reduce stress and social support, and having others to support you were highest in the Matures. Boomers had the lowest, most negative scores.

It is interesting to compare the latter study with Vachon (29), in which those older than 45 years had the least stress and most successful coping mechanisms and those younger than 30 years had the most stress and fewest coping mechanisms. The group that would have been the youngest part of the sample and the middle part of the Vachon study would be the Boomers, who are now having the most difficulty in the Santos and Cox study. The fact that those older than 55 years in the UK study (30,31) were least likely to experience burnout also gives some credence to this hypothesis. This phenomenon may be worth further study to ascertain whether this is an age cohort issue.

In the Santos and Cox study, Boomers had severe conflicts with the Xers. The themes that emerged involved orientation toward work, length of service, and workplace behavior. The Boomers interpreted the Xers workplace behavior as reflecting slacker attitudes and a lack of commitment. In addition, the Xers were considered to be arrogant and self-absorbed, and too apt to leave the work situation. The Xers did not have the same feelings toward the Boomers. They voiced great commitment to the profession and organization, but many anticipated leaving the institution at some point in the future, and perhaps even leaving the profession entirely at some point in their careers to develop a more diversified job skill set. They felt that the arrogance perceived by the Boomers was not actually arrogance, but rather the self-reliance they have had to develop throughout their lifetimes.

Gender has also been found to influence response to stressors in the workplace. Female physicians were found to experience more role strain than their male counterparts (35), and in a Canadian study were more likely to report suicidal ideation (36). In a large study of almost 2000 British family practitioners (37), male physicians had higher anxiety scores than the norms and had less job satisfaction and drank more alcohol than their female counterparts. Dealing with death and dying was not a major source of stress; however, it was associated with excess alcohol use, especially for female physicians.

Female physicians have been found to report greater job satisfaction and greater well-being than matched controls (37). The latter finding was replicated in the more recent Physician Worklife Study (N = 5704) (38). Women were more likely than their male colleagues to report satisfaction with their specialty and with patient and colleague relationships, but less likely to be satisfied with autonomy, relationships with community, pay, and resources. Female physicians were also more likely to report less work control than their male counterparts regarding day-to-day aspects of practice, including volume of patient load. In addition, they were not paid as well. There is some evidence that female physicians may be more at risk of mental health problems (39). In The Physician Worklife study (38), women were 1.6 times more likely to report burnout than men. The odds increased by 12–15% for each additional 5 hours worked per week over 40 hours. Lack of workplace control predicted burnout in women, but not in men. Women with young children who received support for balancing their lives from their partner, significant other, and colleagues were 40% less likely to report burnout.

Contrary to other studies, male, but not female, oncologists were at more risk of burnout in a Finnish study of physicians from many specialties (40, adapted from 3,41). Being married and having more children was associated with better job satisfaction in a Swedish study (32). Being single was an independent risk factor for burnout in the study of consultants in the United Kingdom (31).

Personality Variables

In looking at the stress of those working in palliative care, the personal characteristics that professionals bring to their profession are relevant, as is the impact of professional training programs. Hospice workers have been found to ground their work in self-awareness and a clear personal philosophy (42). Working with dying patients has been found to shape one's attitude toward death and dying (43). Those who coped adequately with death were found to have a tendency to live in the present, rather than the past or future. They scored higher on inner-directedness, selfactualizing value, existentiality, spontaneity, self-regard/ self-acceptance, acceptance of aggression, and capacity for intimate contact (44, from 41).

Research on the personality of oncology nurses using the Personal Style Inventory (45), based on the 1923 work of Jung (46), showed that the most common personality type for oncology nurses was introvert, seeker, feeler, judger (ISFJ), in which feeling is introverted and perception is practical, so that helping others is both a responsibility and a pleasure. Caregivers with these personality characteristics. value interpersonal interactions and have great empathy. The strengths of this personality type include independence, ability to work alone, diligence, and attention to detail. Traits that could be a hindrance include the proclivity to work alone and the tendency to act on internal reasoning without consulting others. The latter personality trait could be a problem because oncology nurses play a pivotal role in collaborative groups in today's health care environment. The introvert prefers quiet time to concentrate and think before making decisions. This personality type also dislikes interruptions, which can be a problem in the busy oncology clinic or unit (47).

The personality of physicians and its association with possible job stress and burnout has been mentioned previously. Kash and Holland (28) have noted that the compulsive tendency of physicians, “when present in conjunction with other characteristics of overly controlled emotions and low need for relaxation and pleasure, makes the medical student, and later the physician more vulnerable than others to depression, alcoholism, psychiatric disorders, and suicide” (28, p. 647). Such problems have been found to be associated more with adjustment before medical school than to occupational adjustment (48). Physicians with the least stable childhoods and adolescent adjustments have been identified as being most vulnerable to occupational hazards (48). When a faulty sense of self-esteem develops in childhood, the adult may be emotionally fragile and have easily threatened self-esteem or a heightened sensitivity to slights, disappointments, or rejections (21).

The personality characteristic of hardiness, which consists of commitment, control, and challenge (49,50), has been found to be associated with decreased rates of burnout in intensive care unit (ICU) nurses and with improved coping in house officers at Memorial Sloan-Kettering Cancer Center (MSKCC) (28). Hardiness was also found to be associated with decreased burnout in Greek oncology nurses (18). The sense of control over things that happen in life and in the work environment was found to protect nurses from emotional exhaustion, depersonalization, and a lack of personal accomplishment. Nurses who experienced a higher degree of burnout reported a lack of a sense of control over external events. In an American study (51), nurses who were high in hardiness had a predicted mean burnout score 0.468

less than those low in hardiness.

In a study of 1925 white and blue collar university employees in Australia (52), *Cognitive Hardiness,* which assesses involvement, challenge and control (53), was found to be the best predictor of the ability to manage job stress, anxiety, daily hassles, and to maintain a healthy lifestyle. Hardy behaviors depend on both behavioral competence and supportive environments. These variables allow the individual to find the resources essential to coping, to make use of social networks when needed, and to transform stressful experiences into meaningful experiences (54). Stressors are seen as manageable by those who are hardy (51).

Closely aligned with the concept of *hardiness* is the *sense of coherence* (55,56). The sense of coherence is defined as ". . . a global orientation that expresses the extent to which one has a pervasive, enduring though dynamic feeling of confidence that one's internal and external environments are predictable and that there is a high probability that things will work out as well as can reasonably be expected" (55, p. 23). With a sense of coherence, the location of power is seen as being where it legitimately should be. That may involve the individual being in a position of power, or it may involve power being vested in someone else, but the sense is that power is where it belongs.

A sense of coherence is partly personality-related and partly developed through life experience. It refers in particular to personal resourcefulness. Those with a broad repertoire and good flexibility are better able to adjust to most life challenges than those with poor repertoires (57). "(T)he sense of coherence (SOC) construct is a generalized orientation toward the world which perceives it, on a continuum, as comprehensible, manageable, and meaningful" (56, p. 15). The strength of one's sense of coherence is a significant factor in facilitating the movement toward health.

Antonovsky (55) distinguishes between a sense of coherence and a sense of control that implies that "I am in control." He states that a sense of coherence does not imply that one is in control; rather that one is a participant in shaping one's destiny, as well as one's daily experience (29). In the case of palliative care staff, the sense of coherence implies that caregivers have some ability to influence the care that their clients receive—for some, their influence may be great and for others, it may be more minor because of circumstances beyond their control—but they are able to make a difference.

Organizations exert a strong collective influence on the values, beliefs, and behavior of individuals (58). If staff members, as individuals, do not have a strong sense of coherence; if they are working in a setting in which they consistently find themselves having a lack of control; and if they do not have the sense that those in positions of authority know what they are doing and understand the reality of the world of the palliative care practitioner, the stage is set for feelings of powerlessness (5).

Stressors in Supportive and Palliative Care

Florio, Donnelly, and Zevon (59) studied 59 oncology nurses using a transactional model of stress, which views stress as a transaction between the person and the environment that is mediated by two processes: cognitive appraisal and coping. They developed a work-related stress concept map for oncology nurses involving the spatial relationships among nine stress clusters. "Physician-Related Stress" and "Ethical Concerns" were in close proximity to one another and composed the larger dimension of role conflict. "Death and Dying" and "Observing Patient and Family Suffering" were in close proximity and represented the emotional. stress associated with oncology nursing. The personal impact of stress was represented by the clusters "Carryover Stress" and "Negative Self-Thoughts," which are very close together. Finally, "Organizational Factors," "Coworker Stress," and "Inadequate Resources" were in close proximity and related to stress from the work environment.

"Organizational Factors," "Death and Dying," "Observing Patient and Family Suffering," "Physician-Related Stress," and "Ethical Concerns" were the most frequently occurring stress clusters. "Organizational Factors," "Observing Patient and Family Suffering," and "Physician-Related Stress" were rated as the most intense stress clusters. The least controllable stress clusters were "Organizational Factors," "Physician-Related Stress," and "Ethical Concerns." The most controllable stress clusters were "Carryover Stress" and "Negative Self-Thoughts." The authors conclude that oncology nurses experience high levels of emotional stress.

Emotional Labor

Work in palliative care can be described as *emotional labor*, which is "the labor involved in dealing with other people's feelings, a core component of which is the regulation of emotions" (60, p. 15). This work is often performed by women. "Emotional labor is hard work and can be sorrowful and difficult. It demands that the laborer give personal attention, which means that they must give something of themselves, not just a formulaic response" (60, p. 19). Such work also involves the regulation of emotion between the carer and the person being cared for, which is one of the sometimes tremendous but rewarding challenges of work in oncology.

When Swedish nurses working in hospice and oncology were compared (61), the content and quality of the nurses' physical and emotional labor differed significantly. Hospice nurses spent significantly more of their time with patients and relatives (37%) compared with the oncology nurses (21%). When they were with patients, most of the nurses' care involved physical activities, such as helping patients with their daily activities in hospice and helping patients with needs in relation to investigations and treatment in the oncology unit. The emotional labor of talking with patients and providing emotional support consumed 9% of the hospice nurses' time and 4% of the oncology nurses' time. These figures compared favorably to those of Quist (62), who found that emotional labor consumed only 2.3% of nurses' time. The proportion of direct-care time taken up by emotional labor was 19% in the oncology nurses and 24% in the hospice nurses, compared with 5.5% of the time in Quist's study. The authors compare this study with observational studies in an oncology unit in Denmark (63) and an acute and long-term care unit in Sweden (64). In both of the studies, the investigators found a discrepancy between the nurses' thoughts and actions. In their communications, the nurses were dedicated to patient-oriented and holistic care, but in their actions they prioritized routinized task or social and professional interactions with colleagues. During quiet working days, rather than engaging in the emotional labor to which they were committed, the nurses used their time in other ways. It was hypothesized that this was a way for the nurses to maintain control. "By minimizing their social relations with patients and routinizing their work, by working according to an agreed rule for a 'busy day,' the emotional involvement stemming from being too close to a patient could be controlled" (61, p. 72). The authors acknowledge that one of the limitations of the study is that it is not always possible to separate emotional labor from physical labor.

In a Bavarian study (65) comparing 57 physicians and 91 nurses on cancer wards in 13 settings, nurses were found to report greater stress and to have a vulnerability to stress in areas involving the empathic component of their relationship with patients. Physicians had stress associated with decision-making and communicating diagnoses. Having to work with trainees was seen as a stressor for both nurses and physicians. Small hospitals engendered less job critique among nurses, but more stress through identification with patients. Doctors found such hospitals to be cramped. The variables in this study were not linked to gender, with the exception that females of both professions had a greater tendency to cry. With age, stress reduced for most stress areas, as was found previously (29).

Mount (66) delineated the stressors of oncologists as including exposure to death as an existential fact, emphasizing the finite nature of life; the cumulative grief associated with repeated unresolved losses; the pressures of a medical care system fueled by the medical information system; the inability to achieve the idealistic goals embraced by holistic medical care; the stressors inherent in working as a team; and the issues involved in treatment failure. In a large study of physicians in the United Kingdom, clinical oncologists, formerly known as radiation oncologists, reported that most stress of their stress evolved from treatment toxicity and errors and from dealing with patient suffering. Medical oncologists reported more stress from organizational responsibilities/conflicts. Palliative care specialists had the lowest mean percentage of items contributing "quite a bit" to "a lot" to stress (30). The palliative care physicians reported that feeling overloaded, and the effects of this on their home lives, made the greatest contribution to their stress. Compared with other physicians, palliative care physicians reported less stress from overload and more satisfaction from having good relationships. They also reported less stress and more satisfaction with the way they were resourced and managed—unless they were hospital-based, in which case there was more stress and less satisfaction from management and resources (39).

Role Overload

Role overload was identified as a major issue for oncology nurses in the 1990s (67). In a study involving a random. sample of hospice nurses throughout the United States, job pressure—involving on-call duty, the need to travel to patients, and repeated crises—was one of the least appealing aspects of hospice nursing (68). The pressures of practice and work overload were associated with stress and burnout (29). Grunfeld et al. (69) studied 681 physicians, allied health professionals, and support personnel in Cancer Care Ontario. High job stress was associated with having too great a volume of work, having inadequate time to do the job properly, feeling under pressure to make deadlines, having conflicting demands on time, and having home life disrupted because of working long hours.

Oncology nurses experience difficulty with excessive demands, negative expectations from patients/families, unexpected crises, poor staffing, overwork, inadequate time, patient deaths, and balancing work and personal life (47). In a Swedish study, hospital nurses' heavy workloads kept them from being able to attend continuing education courses to learn how to deal with the problems they were experiencing (32). In another study, the more patients for whom the oncology nurse was responsible, the greater was her burnout score (33). Heavy workload was the only job stressor associated with burnout with emotional exhaustion being a particular stressor, in a study of Greek oncology nurses (18, adapted from 5).

Hospice initially prided itself on having time to spend with patients and their families. However, with financial constraints growing increasingly tight, hospice nurses are finding themselves more and more stretched to provide the type of care they want to provide. Further role overload could result if the potential for palliative care were ever to be realized. In one section of the United Kingdom, it was predicted that an increase of around 65% of inpatient provision would be needed to accommodate all

patients with chronic, progressive disease (70).

Role Conflict

Role conflict in palliative care can evolve from a variety of sources when one's role as a team member is in conflict with what one thinks might be in the best interest of patients. Such issues include conflict about end-of-life care between nurses and physicians; conflict with patients who may not yet be ready to accept the reality of impending death, when the nurse feels it is time for them to stop aggressive treatment (71); “allowing” patients to maintain control, while feeling disappointed in not being able to fully discuss patients' expressed wishes to die; taking actions to help patients or families maintain a sense of control, while questioning the wisdom and morality of their decisions; dealing with the sometimes hazy distinction between patient autonomy and a professional ethic of care (72); and the decision to transfer patients from active treatment settings to hospice or palliative care programs primarily for economic reasons (73). Inexperienced nurses caring for very symptomatic palliative care patients in the community may feel role conflict between the patient's right to good symptom control and the nurse's fear of hastening the patient's death (74).

Hart et al. (72) used critical incidents from the practice of palliative care nurses to improve skills in psychosocial care. They found that in the practice incidents that nurses identified, they repeatedly related roles in which they were mediating in a conflict situation to restore harmony and control. “The conflict was experienced within themselves and with others; the sense of control related to themselves, their clients and involved family and friends. Despite the magnitude of the issues they faced and perceived organizational constraints, most of the nurses related a sense of personal responsibility to mediate a successful outcome to the situation. When they were not able to 'fix' a situation, they expressed feelings of professional inadequacy” (p. 253). The nurses reported difficulty with patients who chose not to communicate their feelings about death and dying with either staff or their families and those who chose not to take medications so that death might come more quickly. Patients' actions to take “personal control” of their situation and to refuse palliative care threatened the nurses' feelings about their role as palliative care nurses and made them feel they had not been good enough advocates for palliative care.

Staff can also feel conflicted with the increased use of technology in palliative care. Staff in a children's hospice were studied in the early years of the program (75), as well as more recently (76). Whereas in the first study staff felt a sense of impotence when they were unable to relieve the perceived needs or distress of patients, in the second study they had concerns about the increasing use of life support equipment for the children, and the balance between quality of life and technical support.

Issues of Power and Control

Issues involving power and control in palliative care can be significant. There is some suggestion that conflict between oncologists and oncology nurses has decreased, possibly due to changes in pain and symptom control management (67). However, the struggle around power, a lack of control, and decision making in the British context is reflected in the fact that hospice medical directors rated their relationships with matrons as being most problematic (77). Encountering difficulties in relationships with nurses was the only aspect of work in which palliative care physicians reported more stress than their colleagues in other specialties. This was hypothesized to derive in part from the lack of role clarity in the roles of consultants and senior nurses in palliative care, because historically some charitably funded hospices were run by matrons (39). These issues are also being experienced in North America, as trained palliative care physicians attempt to integrate into preexisting hospice programs

Nurses report being in situations both in the hospital and in the community in which they feel responsible for alleviating the pain of a palliative care patient yet do not have a physician willing to order the medication they believe will be sufficient to control the pain. In addition, with the earlier discharge of sicker patients, nurses with limited experience may be expected to care for seriously ill palliative care patients in their homes, without access to physicians skilled in effective palliative care and symptom management (5).

Team Conflict

Team communication problems have been a significant part of hospice, palliative care, and, to a lesser extent, oncology since the early days of these specialties. The research on this subject has been reviewed elsewhere (1,5,78). A lack of support from one's team members has been associated with high levels of depression (79). Organizational factors, such as personality issues and team conflict, were more commonly reported stressors than were problems in dealing with patients and families and issues related to death and dying (29). This finding has recently been replicated in a study by Florio et al. of oncology nurses (59) referred to in the section Stressors in Supportive and Palliative Care.

Is Stress Greater Among Those Providing Palliative Care?

In a British survey (30) sent to all consultant nonsurgical oncologists in the United Kingdom, the stressors of medical oncologists (N = 69), clinical oncologists (formerly known as *radiotherapists*) (N = 253), and palliative care specialists were assessed (N = 126). Sources of stress were segregated into four factors: feeling overloaded and its effect on home life, having organizational responsibilities/conflicts, dealing with the patient's suffering, and being involved with treatment toxicity and errors. Clinical oncologists were more likely to experience burnout. In addition, they reported significantly higher stress from treatment toxicity and errors, and dealing with patient suffering, than medical oncologists, who reported more stress from organizational responsibilities/conflicts. Palliative care specialists generally reported the lowest mean percentage of items rated as contributing “quite a bit” or “a lot” to overall job stress. The estimated prevalence of psychiatric disorder in the physicians studied was 28%, which was similar to that of British junior house officers. The percentage of clinicians reporting high levels of exhaustion on the Maslach Burnout Inventory (MBI) was similar to that of the normative sample (31% versus 33%) (80). Thirty-three percent of both the cancer clinicians and the normative sample reported low personal accomplishment. Significantly fewer of the UK cancer clinicians reported high levels of depersonalization compared to the U.S. sample (23% versus 33%, p <.0001).

When these figures are compared with the recent Cancer Care Ontario study (69), the comparable figure for physician exhaustion was a much higher 53.3% (allied health professionals, 37.1%; support staff, 30.5%). A much higher 48.8% of physicians reported low feelings of personal accomplishment (allied health professionals 54%, support staff 31.4%). The feelings of depersonalization in the Canadian group were similar to the UK sample, with 22.1% of physicians (4.3% of allied health personnel and 5.5% of support staff) reporting feelings of depersonalization. These figures may be unique to Ontario, or may indicate an increase in stress in oncology due in part to everincreasing workloads and limited resources. At the time of the study, and for a period of years before the study, Ontario has been experiencing limited resources and treatment delays that are no doubt at least part of the source of the stress being experienced by physicians.

With regard to nursing staff, Cohen et al. (81) reviewed the literature and suggested that when comparisons were performed, oncology nurses differed little from, or fared better than, other nurses in terms of stress levels and stressors identified. The data from the Ontario study would indicate, however, that there is concern regarding the low feelings of personal accomplishment being reported by more than half of the allied health personnel (including nurses, social workers, and radiotherapy technologists) in this study.

Van Servellen and Leake (82) compared 237 nurses from acquired immunodeficiency syndrome (AIDS) special care units, oncology special care units, medical ICUs, and general medical care units and found no significant differences in scores on the MBI. They found that greater job influence had a significant protective effect on emotional exhaustion and enhanced personal accomplishment, and that job tension was a significant predictor of exhaustion.

In a Greek study, Papadatou et al. (18) found no statistically significant difference in burnout scores between oncology nurses and nurses in general hospitals. Personal characteristics were found to predict a greater percentage of variability in the burnout experience than either occupational or demographic variables.

In a British study, Wilkinson (83) measured the anxiety of 65 nurses working on six units in two cancer hospitals. The Spielberger State-Trait Anxiety Inventory (84) was used. Oncology nurses were found to be no more anxious than other working women. Newly qualified nurses were more anxious than sisters and enrolled nurses. Nurses who never went to church had a higher state anxiety score than those who went to church weekly or occasionally. There was some difference in the level of state anxiety on different wards and the authors noted that the ward on which nurses worked appeared to influence the levels of stress and job satisfaction experienced—this was thought to be due in part to managerial style affecting ward climate.

When the team in a hospital-based home care unit (HBHC) working with severely ill cancer patients was compared with the staff working with a similar population of patients on three inpatient units, both groups showed a limited degree of continuous stress and a high degree of job satisfaction (32). However, there were differences between the two work environments. The HBHC group reported more freedom to make their own decisions, better cooperation between day and night shifts, a more reasonable workload, fewer problems in communication with patients, and fewer problems with tension and sleeping. These findings were felt to be due to the fact that the HBHC team was older, more often married, and had worked longer in health care. They were thus more experienced.

A German study compared 299 physicians and 592 nurses from 54 different hospitals and clinics (85). The staff worked in oncology, cardiac, intensive care, or surgical units. Although the groups experienced the same overall degree of work-related stress and physical complaints, the oncology group suffered more from feelings of emotional involvement and self-doubt. However, the oncology group suffered less from stress connected with institutional factors than did the comparison group,

despite few objective differences in their situations. The author hypothesized that the stress accompanying the care of people with cancer is no greater than that which accompanies the care of other medically ill people but is of a different quality. For oncology staff, institutional stressors move into the background when compared with the personal emotional involvement of working with patients.

In general, although the stress of those in oncology in the 1990s did not differ significantly from that of their colleagues in other medical and nursing specialties, it was generally greater than that of colleagues in palliative care. The Ontario study (69) may reflect an increase in stress in oncology with increasing workloads and limited resources. In a review of the literature on stress in palliative care (1) it was concluded that, whereas in the early days of the palliative care movement stress was a problem, later studies have shown that stress and burnout are by no means universal. As we move into the new millennium and workloads are increasing, further research is needed to assess whether palliative care practitioners are also feeling the strain of this change. Of course, comparisons would then also need to be made with health care practitioners in a variety of other specialties whose workloads have increased.

Stressors versus Rewards

Although palliative care can be stressful, some authors have also tried to measure its rewards. Papadatou et al. (18) suggest that the challenge of working with cancer patients may serve as a reward that counterbalances the stressful aspects of practice. Bean and Holcombe (47) point out the way in which the personality types of oncology nurses may be complementary to the stressors identified in the work setting (47,86), leading presumably to increased job satisfaction. Some of the satisfactions that may be received from working in palliative care include

- Valuing each individual; experiencing the reciprocity of giving and receiving in relationships; having a sense of interconnectedness and of mutual nurturing; being close to patients and sharing a part of one's self; having the chance to make a difference in people's lives (87)
- Helping patients achieve optimum health by enabling them to do all they are capable of doing; being able to give patients options, recognizing that patients are the directors of their own decision making; being able to personalize the hospital environment so patients can feel more at home (87)
- Assisting patients and families learn to cope with and adjust to caring for a dying relative at home; managing death at home; learning from patients and families (88)
- Experiencing positive feedback from patients and families; effectively relating with and communicating with patients and families (89)
- Witnessing the smooth termination of life; initiating innovative, effective intervention for the patients, involving the right decisions at the right times; and peace for the patient (89)
- Being able to provide families with good memories in the midst of difficult times (89)
- Helping patients to find meaning in suffering (90)
- Having an opportunity to learn skills and to develop as a person; having the ability to constantly learn (87); finding the challenge of working with cancer patients to be a reward that counterbalances the stressful aspects of the work (18)
- Experiencing positive relationships and support from colleagues (81,89,91)
- Deriving satisfaction from the essence of oncology nursing, including handling emergencies, preventing serious errors, helping with emotional distress, and empathizing with patients (86)
- Dealing well with patients and relatives (30)
- Having professional status and esteem, deriving intellectual satisfaction, and having adequate resources to perform one's role (30,91, adapted from 5)

MANIFESTATIONS

In a study of more than 2000 Canadian physicians, those under stress had more problems with patients, obtained less satisfaction from their medical practice, and rated their quality of care lower (92,93).

Physical

A strong association has been found between specific, situational stressors and reported psychosomatic complaints (65). Interpersonal difficulties, whether on or off the job, related to physical distress for nurses, whereas for physicians, dissatisfaction with the job and working conditions, including space problems involving the work environment and dealing with patients, related to a general malaise. Irregular working hours related to stress in both groups.

Nurses were more apt to report problems with headaches/pressure in head, tiredness, tendency to cry, loss of appetite, irritability, and neck/shoulder pain if their lives outside the work situation did not relieve the stress generated on the job. For nurses, there were three distinct phenomena associated with the stress of dealing with patients: interpersonal conflict (leading to irritability and headaches); physical distaste for certain tasks (leading to visceral pain and nausea); and physical strain, causing back pain, heaviness in legs, and neck/shoulder pain. Identification with the patient correlated most markedly with tiredness in its various forms. If the reported symptom level, rather than the reported stress level, was taken as an indicator of objective stress, then neither lack of satisfaction with the job and the surroundings nor proximity to the dying was linked to health-related concerns. Identification with the patient's suffering was itself principally tiring. However, the effects of interpersonal difficulties *(private life* and *dealing with patients)* were most worrisome (65).

The authors observe that for physicians the findings can be summarized in one over-simple phrase: “Stressed doctors are tired” (65, p. 1017). For the physician group, the authors described a subpattern of symptoms that “linked stress to loss of control, in the form of irregular heartbeat, diarrhea, discomfort in the throat, dizziness, and breathlessness. The doctors' stress may derive in part from lack of confidence when faced with their limited ability to alter the course of illness. Identification with the patients' suffering, which was linked to tiredness among nurses, had effects among doctors that suggest an almost physical rejection of the patient” (65, p. 1021).

Psychological

Compassion Fatigue

Whereas health professionals traditionally have been taught to maintain a boundary between themselves and their clients, very close relationships can and do develop in palliative care and oncology (94). This closeness and exposure to repeated difficult illness experiences and deaths can lead to the experience of secondary traumatic stress (STS) or compassion stress. *STS* is defined as “the natural consequent behaviors and emotions resulting from knowing about a traumatizing event experienced by a significant other—the stress resulting from helping or wanting to help a traumatized or suffering person” (23, p. 7). Secondary traumatic stress disorder (STSD) is a more severe manifestation of STS and “is a syndrome of symptoms nearly identical to PTSD (posttraumatic stress disorder), except that exposure to knowledge about a traumatizing event experienced by a significant other is associated with the set of STSD symptoms, and PTSD symptoms are directly connected to the sufferer, the person experiencing the primary traumatic stress” (23, p. 8). Compassion fatigue is identical to STSD and is the equivalent of PTSD (, from). Garfield (24) writes of the compassion fatigue that exists amongst AIDS/human immunodeficiency virus caregivers. He states that in contrast to caregivers heading for burnout who unconsciously begin to wall off more and more strong feelings associated with their work, those with compassion fatigue are able to monitor their decrease in empathy and feeling and remain emotionally accessible. However, they have greater and greater difficulty in processing their emotions, are anxiety-ridden or distressed, and have images that intrude on their days and nights and painful memories that flood their world outside the caregiving arena (from 5).

Multiple Grief and Loss

Mount (66) has reflected on the losses associated with working in oncology and notes that these losses become an integrated part of one's professional life. “Moreover, our losses do not occur in a vacuum. They interact with, modify, and often augment the other stressors in our personal and professional lives. Our reaction to loss may be repressed, only to surface later, associated perhaps with some other unrelated event” (66, p. 1127). He warns that the weight of these losses may lead to a burden that is increasingly intolerable and frequently difficult to define.

Papadatou (95) has defined the losses in oncology nursing as follows:

- Loss of a close relationship with a particular patient
- Loss due to the professional's identification with the pain of family members
- Loss of one's unmet goals and expectations
- Losses related to one's personal system of beliefs and assumptions about life
- Past unresolved losses or anticipated future losses
- The death of self

Constant exposure to death and loss may leave caregivers with grief overload and considerable distress. However, participating in the death of some patients has been found to result in some nurses having intense positive responses that promote professional development (96). Constant confrontation with the deaths of others causes

caregivers to repeatedly reevaluate their own mortality and to reexamine the meaning of life and living (66).

Nurses have difficulty with grief if they had not been able to help the patient die a good death, for whatever reason (96). When the symptoms of dying patients are not controlled, the nurses feel responsible and “wanting,” and if training and experience are lacking, this may well be the case (74). Staff members often experience difficulty dealing with their feelings of grief and loss at the time of death because of other responsibilities that must be attended to immediately. There is often a strong covert institutional message, as well as peer pressure, not to dwell on the loss (97).

Particularly since the AIDS epidemic, the concept of multiple loss has been increasingly recognized. The concept of multiple loss in AIDS caregivers reflected in part the reality that many caregivers were caring for dying patients, while partners, friends, and members of their social network were dying at the same time.

Chronic compounded grief, defined as cumulative responses to losses over a period of time, has been found to be a powerful factor that contributes to resignations and turnover among oncology nurses and the ability of individual nurses to care for patients effectively. Feldstein and Gemma (97) suggest that what others refer to as burnout is really chronic compounded grief. In a study of response to death in a Canadian continuing care and rehabilitation hospital, 42% of the staff felt themselves to have been “moderately” to “extremely” affected by patient deaths, had lost time at work due to patient death, had low morale, experienced strain in personal relationships, had a loss of efficiency at work, or had health problems they attributed to patient deaths (98, from 5).

Burnout

In a large study of the stress of oncologists (99), 56% of oncologist subscribers to the *Journal of Clinical Oncology* Burnout was measured using an author-constructed questionnaire, as opposed to one of the more usual instruments used to measure burnout (100). When asked to define the specific nature of their burnout, 56% mentioned frustration or a sense of failure, 34% mentioned depression, 20% mentioned disinterest in practice, and 18% mentioned boredom. Almost half felt that burnout was inherent to the practice of oncology. Institution or university-based oncologists on salary reported a lower incidence of burnout (47%) than those in private adult oncology practice (63%).

In the Ramirez et al. study of UK oncologists and palliative care specialists (30), *job characteristics* associated with burnout included “being overloaded and its effect on home life,” “dealing with patients' suffering,” and low levels of satisfaction from “not having adequate resources to perform one's role.” Depersonalization was associated with “being overloaded” and “dealing with patients' suffering” as well as low levels of satisfaction from “dealing well with patients and relatives.” Being a clinical oncologist, as compared with a medical oncologist or palliative care physician, and working part-time, were independent risk factors for depersonalization. “Low personal accomplishment was associated with stress from 'being involved with treatment toxicity and errors' and low levels of satisfaction from 'dealing well with patients and relatives' and from 'having professional status and esteem'” (30, p. 1268).

A large Finnish study of 2671 physicians (40) found that male oncologists were among those physicians most likely to report burnout; the same finding was not reported for female oncologists. The authors speculated that higher burnout is associated with the specialties involved with dealing with chronically ill, uncurable, or dying patients. They hypothesized that hope (and the lack of it) in medical work has important influences on feelings of burnout. As with the U.S. study (99), they found that those with a university position were less likely to report burnout.

In the Papadatou et al. study of oncology nurses (18), only the stress of a heavy workload, among all the job stressors studied, was found to be associated positively with burnout (and emotional exhaustion in particular). This finding is similar to that reported by oncologists (99), although the self-controlled aspects of workload (e.g., involvement in research and teaching) may be negatively related to burnout (18). Among house staff, hardiness was found to be negatively related to burnout and physical illness; negative work stressors were positively related to burnout, as was supervisor support (28).

The finding that self-controlled workload may be negatively related to burnout is interesting in view of the fact that in a large study of professionals from a variety of settings, those in oncology were most apt to mention developing the multiple roles of clinician, researcher, and teacher as one of their major coping mechanisms (29).

Coping styles can exert a protective influence on burnout. In a group of nurses (51), those using direct, active coping (changing the stressor, confronting the stressor, finding positive aspects in the situation) had the lowest burnout scores, and those using direct-inactive coping (ignoring the stressor, avoiding the stressor) had the highest scores. The lowest burnout scores were found in nurses with greater hardiness who used direct-active coping behaviors.

Depression and Burnout: Do They Differ?

Feelings of depression must be distinguished from those of burnout. Maslach states that one phase of the burnout syndrome involves a sense of reduced accomplishment and a loss of self-esteem, which is a central characteristic of depression. The loss may be that of early ideals or of “good people” to work with. A professional's sense of self-worth and self-esteem may be threatened by the inevitable outcome of patients' deaths and the physical, psychological, and social pain of terminal illness (101). Caregivers may also feel that they have failed at their work or have failed to live up to their original standards (17). Burnout is generally regarded as being associated with overinvolvement in any one area of life to the exclusion of all others. Usually this is the occupational role (102).

Although the burned-out person may be depressed, the symptoms are not primarily intrapsychic but are, at least partially, situationally induced. An appropriate evaluation of burnout requires that the possibility of a clinical depression be ruled out. A clinical depression might be suspected if the person has had a recent loss, has the vegetative symptoms of depression, has had a previous history of depression, or has a family history of depression (102). If the symptoms are worse in the work situation, associated with conflict or feeling misunderstood by colleagues in a person who tends to work long hours or always takes work home and has no time for outside interests or support from others, then the problem may well be burnout.

Ramirez et al. (30) attempted to distinguish between the phenomenon of burnout and psychiatric disturbance. They used the 12-item General Health Questionnaire (GHQ) (103). The GHQ has been used in a variety of studies of occupational stress (see 1 for a review of its use in palliative care studies). The estimated prevalence of psychiatric disorders from the GHQ was 28% and was not significantly different among the three oncology specialty groups, nor did their findings differ from other studies (30). They concluded that although clinical oncologists experienced the greatest amount of work-related stress and lowest satisfaction from work-related sources, they are not at any greater risk of psychiatric disorder than their colleagues.

No demographic or job characteristics predicted psychiatric disorder as measured by the GHQ. However, high GHQ scores indicative of psychiatric disorders were associated with high levels of stress from feeling overloaded, being involved with treatment toxicity and errors, and deriving low levels of satisfaction from having professional status and esteem.

In an Italian study (91) comparing oncologists, nurses, and radiotherapy technicians, 16% of subjects reported depression on an author-constructed instrument. Nurses, women, and younger respondents were most likely to report depression.

COPING WITH STRESS AND BURNOUT IN PALLIATIVE CARE

The research on coping with job stress is still limited. There have been few long-term longitudinal studies of coping. In a multidisciplinary, multispecialty study, caregivers were twice as likely to report personal coping strategies, rather than environmental strategies, as being helpful in dealing with and preventing occupational stress (29). Florio et al. (59) compared positive versus negative outcomes of coping strategies using problem-focused versus emotion-focused coping strategies. The coping strategies that were most effective in handling work stress were *emotion-focused/positive* (develop a growth perspective, positive reappraisal, affective regulation and balancing work stress) and *problem-focused/positive* (including positive involvement in treatment and coworker support). Less effective strategies included *emotion-focused/negative* (withdrawal, apathy, negative coping, catharsis/break room).

Personal Coping Strategies

On the basis of the findings of the subsample of 110 professionals in oncology, the most helpful personal coping strategies included developing a sense of competence, control, and pleasure from one's work; having control over aspects of one's practice; having a personal philosophy of illness, death, and one's professional role; managing one's lifestyle; and leaving the work situation.

A Sense of Competence, Control, and Pleasure in One's Work

A sense of competence, control, and pleasure in work is often associated with a sense of belonging to a team “that knew what it was doing.” Through team affiliation one may derive an ongoing sense of personal worth that survives even though individual patients die (29).

A sense of competence is very similar to the sense of personal hardiness found to be helpful in other studies (18,28), as well as to the sense of coherence (55,56 and 57). Hardiness protected oncology nurses from emotional exhaustion on the MBI. The personality factors that best predicted personal accomplishment on the MBI included a sense of mastery and control over the difficulties of life and a problem-focused coping style when faced with adversity. The role-related variables that predicted high personal accomplishment included a tendency to assume somewhat neutral expectations (neither high nor low) regarding job satisfaction at the beginning of one's career (18).

A sense of competence can also be associated with having a good person-environment fit between one's personal characteristics and the work environment (29). Bean and Holcombe (47) noted the ways in which the personality types of oncology nurses were complementary to the essence of oncology nursing identified by the nurses in the Cohen and Sarter study (86). The introvert's attention to detail could prevent serious errors, which was viewed as a part of the essence of oncology nursing. The critical incidences of “empathizing with patients and helping with emotional distress were consistent with feeling as the preferred way of making judgments” (86, p. 1484).

A sense of control included redefining particular situations as being a challenge instead of a threat, redefining one's role and involvement with people (e.g., “It is not my role to save people from their illness; rather it is my role to help people to lift the burden which is theirs”), developing more complex skills, and sharing decision-making and control with patients (29). Antonovsky (56) noted that participating in trying to change difficult situations can prevent damage to an individual's sense of coherence, can sometimes add strength, and in some cases can create the opening for the beginning of a major change in life circumstances.

A sense of pleasure in one's work evolved “from one's work with individual patients, from pleasure in the utilization of professional skills, or satisfaction with the indirect impact that one's work can have on groups of patients and families that one might influence indirectly through teaching or administrative roles” (29). Caregivers reported allowing themselves to feel pleasure at a job well done. This approach requires a certain maturity, as well as an ability to distance oneself from the pain of others and to derive satisfaction objectively from one's role in helping to alleviate at least some of this suffering. Some caregivers have difficulty in distancing in this way and feel guilty if they experience a sense of satisfaction that is associated with the suffering of others. When individuals participate in changing conditions and in the process of changing societal conditions, such as has happened in hospice and is now happening in palliative care, there is an improvement in their sense of self-efficacy and self (5).

Perry (87) has used nursing narratives to explore exemplary nursing practice in palliative care and oncology nursing. She uses the themes of the dialogue of silence, mutual touch, and sharing the lighter side of life to illustrate aspects of exemplary nursing practice and identifies joint transcendence as the essence of exemplary nursing practice. “When both care providers and care receiver are co-participants in caring, the release can potentiate self-healing and harmony in both. The release can allow the one who is cared for to be the one who cares, through the reflection of the human condition that in turn nourishes the humanness of the care provider. In such connectedness they are both capable of transcending self, time, and space. Neither stands above the other” (104, p. 132 in 87, p. 100). Hart et al. (72) suggest that the reconstruction of nursing intervention through narrative gives meaning to the experience and creates opportunities for challenge and affirmation.

Barnard et al. (105) have used the narrative approach to study the process of hospice and palliative care from the perspectives of patient, family, and professional and volunteer caregivers. Their research shows clearly the points of tension that develop when patients, families, and caregivers disagree on the goals of care and how these issues are and are not worked out to the benefit or detriment of all concerned.

A Personal Philosophy

The caregiver who is going to stay in oncology for an extended period often feels the need for something beyond the present role. A personal philosophy of illness, death, and one's professional role is an important coping mechanism for many (29). “Becker (106) believed that people's need to believe that the things they do are meaningful is their way of dealing with the angst caused by facing their own mortality. In order to be able to deny death, they need to feel heroic, to know that their lives are meaningful, that they matter in the larger 'cosmic' scheme of things” (20). Becker spoke of the need for people to become heroes (106). The way they become “heroes” depends on “their culture's prescribed 'hero system.' In previous eras, religion was the most commonly chosen hero system. Today, for many people, religion is no longer adequate. For people who have rejected the religious answer to the existential quest, one of the frequently chosen alternatives is work. People who choose this alternative are trying to derive from their work nothing short of a sense of meaning for their entire lives” (20, p. 634). Existential quests are a way of coping with the fear of death (20). For some, a religious philosophy centered around a commitment to serve others may be both helpful and key to deriving a sense of meaning in difficult times.

Heim (35) found that religion could be a helpful coping mechanism for a certain group of nurses. The religious beliefs of house staff were also found to be associated with lower burnout levels (28). However, when caregivers use their own personal religious beliefs to reach out to patients, this may or may not be helpful to the patients (107).

For many caregivers, the concept of the “wounded healer” is an integral part of their philosophy of practice (24,108,109,1 and 110). This concept derives from ancient universal shamanic stories of Paleolithic times. These stories are of tribal priests, “the original wounded healers, whose ability to heal others was seen as being directly linked to their having journeyed in depth into their own wounded selves” (109).

Successful caregivers are often “wounded healers,” with wounds sustained in childhood, adulthood, or both. “In many cases, in trying to heal their respective wounds, these caregivers were drawn, consciously or not, to healing others” (107). Sulmasy (110), a physician, philosopher and Franciscan friar, contends that, “All health care professionals are wounded healers. They cannot escape suffering themselves. Moments of pain, loneliness, fatigue, and sacrifice are intrinsic to the human condition. The physician or nurse's own bleeding can become the source of the compassion in the healer's art. From the physician or nurse's own suffering can come the wine of fervent zeal and the oil of compassion . . . The physician's or nurse's wounds can become resources for healing” (110). Sulmasy warns, however, that wounded healers must not become so overwhelmed with the suffering of others that they are unable to offer effective care. “Competence remains the first act of compassion. Wounded healers do not ask their patients for help, but recognize the unity between their own neediness and the needs of their patients. Wounded healers issue an invitation to patients to enter into the space of the healing relationship” (110). In this sense, the clinician offers hospitality.

Henri Nouwen (108) wrote of the minister as a wounded caregiver. His perspective provides interesting reflections for caregivers in palliative care. Nouwen quotes the Talmud as asking the question of how one might know the Messiah. “He is sitting among the poor covered with wounds. The others unbind all their wounds at the same time and then bind them up again. But he unbinds one at a time and binds it up again, saying to himself, 'Perhaps I shall be needed: if so I must always be ready so as not to. delay for a moment' (taken from the tractate Sanhedrin)” (108). From Nouwen's perspective, the caregiver must bind her own wounds carefully in anticipation of the time when she will be needed. The wounded healer must look after her own wounds, but at the same time be prepared to heal the wounds of others (from 5).

Inherent in a philosophy of practice is the right, and indeed obligation, to mourn for those who have died. Although not all patients touch caregivers equally, in many situations patient deaths and the ensuing staff grief deserve recognition. Acknowledging the deaths of individual patients can enable practitioners to avoid the accumulation of grief that comes from repeated, unresolved losses (66). However, at times, multiple losses can lead to a sense of grief overload that may need to be dealt with in a variety of ways, including memorial services, journaling, staff “wakes,” or funeral attendance. In addition, participating in a grief process can enable caregivers to assess gains that have been made and what one has gained from this relationship in a manner that may be helpful to future clinical practice.

Management

Although lifestyle management is certainly not a panacea for dealing with work stress, it enables one to have the energy to cope with stressors. It reflects acknowledgment of an individual's need to learn his or her body's response to stress to detect signals of significant overload. When one finds oneself experiencing symptoms of stress, such as headaches, gastric disturbances, increased infections, a lack of pleasure in one's professional roles and responsibilities, or feeling overwhelmed by responsibilities, it is often time to take a break before symptoms become more serious. This break may consist of a few hours away from one's desk to pursue another interest or a longer break of a few days or weeks. Oncologists have suggested decreasing burnout through time away from the clinical setting, including more vacation or personal time and sabbaticals (99).

Effective lifestyle management involves developing a balance between one's personal and professional lives. Job-home interaction has been found to be a significant source of stress in several studies (29,30,65). Controlling jobhome interaction can be very difficult, particularly for those who have developed multiple professional roles (e.g., clinician, researcher, and writer) while trying to maintain a healthy personal life. Certainly, there are times in which career demands must take precedence, but if one always bows to career demands at personal sacrifice, one may need to do some looking at one's sense of self-esteem.

Although lifestyle management and good health habits, including diet, exercise, and rest, are all helpful in stress reduction (Table 61-2), those in oncology often do not mention using these coping strategies (81). For caregivers who are prepared to do some reflecting on their occupational roles and the meaning it has in their lives, the questions contained in Table 61-3 are helpful.

Other lifestyle management techniques that have been shown to be effective include the following:
Recognize and monitor symptoms
Good nutrition
Meditation
Spiritual life
Grieving losses
Decrease overtime work
Exercise—aerobic, yoga, qi gong, tai chi
Energy work—reiki, healing touch, therapeutic touch
Maintain sense of humor
Seek consultation if symptoms are severe
Discuss work-related stresses with others who share the same problems
Visit counterparts in other institutions; look for new solutions to problems
Time in nature (5,28,111)

TABLE 61-2. LIFESTYLE MANAGEMENT TECHNIQUES

Treating career burnout addresses three questions:
Why, psychodynamically, did this person choose this particular career, and how was it expected to provide existential significance?
Why does this individual feel a sense of failure in the existential quest, and how is the sense of failure related to burnout?
What changes need to take place for this individual to derive a sense of existential significance from work (20, p. 633)?

TABLE 61-3. TREATING CAREER BURNOUT

Social Support Systems

The development of a personal social support system to help to sustain one through life and its vicissitudes, both on and off the job, is extremely important. The following is a personal “tried and true” approach to aspects of a social support system that can be helpful in facing stress on and off the job and helping one to maintain a sense of roots:

- A spiritual life that connects the individual with the transcendent, from which one can derive a sense of meaning and purpose in life that can be sustaining even when personal and professional stress is at a high level.
- A solid, supportive family system comprised of people who can listen and provide emotional support, emotional challenge, and practical assistance.
- A network of friends comprised of persons who are involved in various aspects of one's personal and professional life, with whom one has reciprocal relationships and to whom one can turn for help in a variety of ways, and who in turn can look to you for such help.
- Supportive colleagues at work, whether those be team members; colleagues outside of one's direct team with whom one can share the trials, tribulations, and joys of the workplace; or administrators who can understand the stress to which one is exposed.
- Colleagues with whom one may not work but who understand one's professional trials and tribulations, with whom one can share a similar professional value system and from whom one can receive support. The author belongs to a support group of oncology nurses who have met every 6 weeks for 25 years. A group that shares personal and professional life experiences together such as this is of inestimable value.
- A community of others reflecting one's religious beliefs or value systems.
- A mentor or supervisor who can provide support and challenge and with whom, ideally, one can reflect over the years (112).

Organizational Coping Mechanisms

Team Philosophy, Team Support, and Team Building

Although personal coping mechanisms are important, the work environment does have a role to play in helping caregivers provide effective care to those with cancer. A sense of team philosophy, support, and team building has been identified as an important organizational coping mechanism for both palliative care and oncology professionals (29). Improving interprofessional cooperation, team processes, and group support in nursing was found to provide the best protective or buffering approach to many health stressors, especially burnout (35). The perception of social support at work was also correlated with lower burnout in a study comparing hospice and oncology nurses (33).

Nason (113) notes that team development always involves tension and conflict. This may be viewed as the result of competition, lack of role definition, or poor leadership, but it can also be viewed as a reflection of contradictory institutional goals. Team members may become entrapped in conflicting relationships through the interaction of limited resources, competing demands, and unrealistic institutional priorities, and as a consequence may come to represent differing value systems within the organization. For example, team members of different disciplines may become involved in rivalry and “turf wars” in the current tight economic climate in which the roles of many professional groups are being challenged.

An effective team must have clear objectives, mission, and priorities that are shared by all team members. Role expectations should be realistic and well defined when they overlap. Effective decision-making and problem-solving processes should be in place to arrive at the “best” possible solution; environmental norms should exist that support the tasks of problem-solving. There should be a concern for each other's needs and an opportunity for individuals to enlarge their roles and optimize their chances for personal growth (114).

Papadatou et al. (115) studied the role of social support in pediatric nurses in oncology and critical care and found that over time the role of colleagues became increasingly important; for some nurses this was the only source of emotional support. There was an intimacy that evolved involving friendships and quasi-family relationships outside of work and even marriage.

The support in that group of nurses was sought at four levels: informational, clinical/practical, emotional, and meaning-making. The first two levels of support primarily benefited the patient, whereas the latter two levels of support helped the nurses cope with the dying process and the death of children. There were similarities and differences in the levels of support used by both groups. Both groups valued *informational support,* although in different ways. Critical care nurses preferred information addressing clinical issues, whereas oncology nurses valued information exchange about the progress and treatment of individual patients and about acquiring new scientific knowledge. Both groups were dissatisfied with the *level of clinical/practical support,* primarily because of difficulty in cooperation among team members. In oncology, this involved difficulties with role blurring between physicians and nurses; in the ICU, it involved rivalry and closed subgroups due to educational differences. The two groups were also different in the receipt of *emotional support.* In the ICU the ongoing presence of several colleagues provided emotional and clinical support, whereas the pediatric oncology nurses were more apt to be without a colleague or physician at night. The oncology nurses were more apt to share emotions and experiences openly when a child died, whereas the ICU nurses shared primarily in small groups or with “friends.” They tended to try to avoid focusing on issues of death and to focus their energy on saving other children (5).

Support Groups

The development of supportive, collaborative work relationships may be fundamental to enhancement of selfefficacy and self-esteem. It is important that organizations create the opportunity for ongoing support, and that nurses have the time to attend support sessions, especially for those working alone in the community. This may consist of support through team meetings, easy access to consultants, a buddy or mentor system for ongoing support, and the opportunity to debrief after critical incidents (5).

Although support groups are recommended almost as a panacea for either team stress or problems with patients, they were found in one study to be the least commonly mentioned organizational coping strategy (29). Horowitz et al. (116) reported on interdisciplinary “pizza rounds” held weekly on the Neurooncology Service at MSKCC. The purpose of the rounds is to “enhance patient care by improving interdisciplinary functioning and by providing staff with the opportunity to exchange ideas, solve problems involving difficult patients and families, develop consistent plans for patient management, and ventilate their emotional responses to job-related stress. Food is served as a means of increasing attendance and reducing hierarchical barriers between staff members” (p. 330). The group is led by a social worker and a psychiatrist. Although no formal evaluation of the meetings has been conducted, the authors feel that the fact that the group has endured for a period of years attests to its effectiveness.

Administrative Policies

The incidents that cause problems for caregivers often reflect how organizational policies and practices limited the flexibility of staff to implement effective care (72). To support patient autonomy, nurses need to experience professional autonomy within the work environment. When they do not have this professional autonomy, they need to work towards achieving it, or recognize the limitations of the system in which they work and not assume personal blame and responsibility when this is inappropriate (5).

Effective administrators and administrative policies can be extremely important in maximizing productivity and job satisfaction. Oncology nurses valued administrators who were able and willing to change the work environment for staff. “Competent, caring administrators provided leadership, were flexible and available, communicated with staff, fostered development, and allowed opportunities for growth and input into decisions . . . Nurses spoke about how important it was to 'have a voice in fixing' a problem at work” (81). In view of the stress experienced by those in oncology because of work overload, it is important to develop realistic workloads that recognize the needs of both caregivers and organizations. Effective administrative policies need to recognize the importance of the emotional labor of oncology and to recognize that this activity sometimes takes time away from other activities (60).

An environment should be provided in which the feelings generated in oncology care can be recognized and expressed. James (60) warns that although the repression of emotion at work may appear to lead to greater efficiency in production, it does not mean that emotions disappear, merely that they are concealed but will eventually be expressed elsewhere—that is, at home or possibly in leisure pursuits. It takes time to work through frightening or worrisome feelings, helping ill people and their families to work out a strategy that they can live with. Time needs to be worked in to provide job flexibility to deal with emotional labor in a highly technological environment (60). By making the expression of feelings in the workplace unacceptable, labor processes may affect not only how feelings are expressed in the workplace but also the emotional labor that is likely to be necessary at home. In a Swedish study, a home-based care program was able to provide very satisfactory work conditions, despite demanding work with cancer patients, by ensuring a continuous education program and providing an environment that stimulated the staff's own initiative but was also capable of supporting staff when necessary (32).

Recognizing the economic constraints of the current work environment, all professional groups need to work with administration to develop new roles. In addition, opportunities abound for the development of roles in a variety of settings (117).

Educational Interventions

The work of Florio et al. (59) on the work-related stress concept map suggested that specific interventions can be designed and implemented to target specific stress dimensions. They suggest, for example, that skills training in conflict resolution and assertiveness might be more helpful for oncology nurses in dealing with stressful interactions with physician contacts and less helpful when dealing with patient and family suffering. They suggest interventions for oncology nurses including skills training, relaxation training, job redesign, support groups, and policy changes.

Training in management skills appears to reduce the stress of overload and increase professional esteem. Equipping clinicians with these skills should increase personal competence in meeting the demands of the job and reduce levels of burnout and psychiatric disorder (30). Dealing with patients and families was generally seen as being the most important source of work satisfaction. Communication skills training has been suggested to reduce stress and enhance the satisfaction of dealing with patients, as well as reducing the stress of dealing with treatment toxicity and errors, and enhancing professional self-esteem (30). An educational and supportive intervention program showed that it was possible to reduce burnout in medical oncology house staff at MSKCC (28,118). Furthermore, the patients on the intervention unit perceived the house staff as being more empathic, sensitive, and compassionate.

CONCLUSIONS

The evidence shows that the stress and burnout caregivers experience continues to be an important issue among those engaged in palliative care. The evidence indicates that this may be increasing, especially in oncology. Clearly there is stress associated with the empathic relationship with patients and families, particularly those approaching death. However, much of the stress experienced by caregivers continues to come from the work environment. The increasing workload that is occurring due to the aging of the population, the aging of the nursing workforce, and the economic constraints imposed by health care changes (e.g., managed care) are significant issues that need to be addressed to provide the care that is needed by the vulnerable members of society.

Evidence from the United Kingdom has shown the greater risk of burnout in clinical oncologists whose work-loads are on average two and one half times that of their colleagues in major European countries and the United States (30). Additional evidence of stress in oncologists in Ontario, whose workloads have also significantly increased, also lends credence to concerns about burnout and work-load. To date, most studies have dealt with the perception of work overload that caregivers report, and have not attempted to document the actual work being performed. Future research needs to determine at what point increasing workloads jeopardize patient care, caregiver health, and home life. The evidence has shown that younger caregivers may be at particular risk of burnout. Programs to target this group have been shown to be effective (118), but more evaluation studies are needed. Further work on personality hardiness as a buffer in the work environment is also indi-cated. Perhaps those with hardy personalities and the ability to exert control in the work environment will have a role to play in helping to determine realistic expectations in the work setting.

With the current economic climate necessitating signifi-cant changes in models of care delivery, it is important to continue to assess the stress of oncology practitioners over the coming years to assure that optimal patient/family care is provided by practitioners who recognize the need to care for themselves to be able to care for patients within organi-zations that provide the necessary administrative support needed for a healthy organization with realistic workloads.

ASSESSMENT OF DECISION-MAKING CAPACITY

ARTHUR R. DERSE

In the practice of palliative care, patients face many important decisions. These decisions range from determining which possibly curative treatments to choose from among a range of available options to determining the appropriate point to forgo attempts at curative or life-sustaining treatment. These health care decisions are among the most important not only for the patient, but also for the patient's family and loved ones. At some point in the disease process, many oncology patients lose the capacity to make these decisions, yet these decisions need to be made. If the patient is unable to make these decisions, others will need to make them. If the patient has planned wisely, the decision will be made by an individual whom the patient trusts and who understands the patient's health care preferences. If not, those decisions will be made by others, who may not have any idea what the patient would have wanted.

When patients can no longer make health care decisions, they lose the ability to exercise a fundamental liberty, the right to self-determination. Additionally, the burden of making those choices then falls on the health care team and others, most often family members. Understanding the concept of decision-making capacity and determining whether a patient has decision-making capacity is important for another related reason. If the patient has executed an advance directive, this right to make health care choices may be exercised through a living will, the appointed agent, or a surrogate. The absence of decision-making capacity is the trigger for the activation of an advance directive (1). When there is no advance directive, many states have statutes that allow for automatic appointment of a surrogate. A patient's lack of decision-making capacity triggers the appointment of a surrogate decision maker (2). Thus, a determination that a patient is nondecisional has important legal, ethical, and social implications.

BASIS FOR MAKING HEALTH CARE DECISIONS: INFORMED CONSENT

Informed consent is a necessary component of the process of shared decision making between doctor and patient (3). Informed consent is also a central and fundamental tenet of bioethics and American law. The legal evolution of informed consent, based on the right to determine what shall be done with one's own body (4), began early in this century. It has been expanded to encompass the requirement that consent for medical procedures be informed with disclosure of risks (5). In some states, the risks disclosed should be those considered material by the reasonable person, rather than those that a professional might consider adequate (6). Informed consent encompasses the possibility that the patient may refuse the proposed intervention. The patient's legal right to refuse life-sustaining medical treatment is grounded in commonlaw respect for bodily integrity. The patient's liberty interest is protected by the Due Process clause of the Fourteenth Amendment of the Constitution. The most important expression of this principle was enunciated by the U.S. Supreme Court in the Cruzan case, in which the question, in part, was whether an individual has a constitutional right to refuse treatment (7). Other courts have affirmed this principle, which applies even in cases in which the patient does not have a terminal illness (8,9).

Refusals of proposed treatments must also be informed. Physicians must disclose information about the consequences of the refusal (10). Patients who are not decisional do not lose their rights to self-determination. Rights of nondecisional patients may be exercised by authorized surrogate decision-makers, such as an agent designated by a power of attorney for health care.

The basic elements of informed consent are as follows: (a) The patient's physician must disclose information appropriate to the decision (i.e., risks and benefits, alternative therapies, no treatment); (b) the patient must have the capacity to make health care decisions; and (c) the patient's decision must be voluntary, with a lack of coercion or undue influence by others on the patient while making the decision (11).

In palliative care, in which patients are facing the end of life, informed consent is important for two reasons beyond the fact that it is a basic legal and ethical requirement for all medical interventions. First, many patients and families who are facing treatment withdrawal may have not been fully informed of the risks and benefits of the therapy at the time it was begun. They may not have been told that treatment would be withdrawn if it was no longer effective. After being fully informed of the burdens of continued treatment, the patient or surrogate may elect to stop.

Second, patients and families who refuse further treatment should be told the consequences of the discontinuation of the treatment, just as they are informed of the benefits and risks of other interventions.

However, there are two circumstances in which informed consent may not be required. In an emergency, physicians are able to treat patients without obtaining consent under the *emergency privilege*, a legal exception to the requirements of informed consent. Emergency privilege requirements are as follows: (a) The patient must be unconscious, or without the capacity to make a decision, while no one legally authorized to act as agent for the patient is available; (b) time must be of the essence, in the sense that there is a risk of serious bodily injury or death; and (c) under the circumstances, a reasonable person would consent (12). However, this emergency exception does not pertain if the patient has decision-making capacity and is able to communicate his or her decision about medical care, or if the patient has authorized someone to speak for him or her, and that person is available to represent the patient's interests.

There is another rarely used exception to the requirement of informed consent known as *therapeutic privilege*. Under this exception, if a patient would become so emotionally ill or distraught on disclosure of information so as to foreclose a rational decision or pose psychological damage to the patient, the physician is not required to disclose the information. This therapeutic exception has been used extremely rarely and courts are careful to circumscribe the physician's privilege to withhold information for therapeutic reasons for fear that the exception might devour the duty to disclose entirely (13). Absent an emergency without a surrogate, or the rare circumstances of the therapeutic exception, the physician is required to obtain informed consent for testing and treatment.

DECISION-MAKING CAPACITY AND CONSENT

Central to the concept of informed consent is that patients who have the capacity to make medical decisions may accept or refuse treatment, even in circumstances in which the majority of reasonable persons would not make a similar choice, as long as the patient understands the implications of the choice (14). Thus, a determination of a patient's decision-making capacity is crucial to the patient's ability to make an autonomous choice and, in some cases, the patient's ability to exercise the right to refuse treatment.

In each instance that requires patient consent, health care providers must consider the patient's capacity to give consent. Not every medical encounter requires a formal determination of a patient's decision-making capacity. In fact, practitioners often assume the patient has decisionmaking capacity unless there are signs to the contrary. Questions of patient capacity in decision making typically arise only when a patient chooses a course other than the one the health professional finds most reasonable—often a refusal of treatment (15). However, in all medical encounters health care providers are making *some* judgment of this capacity, even if only by observing the patient and evaluating the appropriateness of the patient's responses to questions. For those encounters in which decision-making capacity is at issue, a formal judgment should be made. Physicians taking care of patients at the end of life should consider the patient's decision-making capacity before presenting the

patient with significant health care decisions.

DETERMINATION OF DECISION-MAKING CAPACITY

A court of law may determine a patient to be incompetent and appoint a guardian to make important decisions for the patient, including those concerning health care. However, many patients who have not been declared incompetent by a court nonetheless have problems with their ability to make health care decisions. Clinicians are often faced with patients who have never been declared incompetent by a court, and either have questionable decision-making capacity or, as in the case of the comatose patient, have no decision-making capacity at all.

Although courts routinely determine a patient to be incompetent based on the expert opinion of a physician or psychologist, appellate courts have rarely scrutinized the process or standards for determining decision-making capacity. Thus, the elements of decision-making capacity have been best delineated by health care professionals and ethicists rather than the courts. One formulation, based on the analysis of the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research (the Commission), is well recognized and is useful in clinical practice (16). Another analysis of decisionmaking capacity recognizes five increasing standards, including the ability to communicate a choice, the ability to make a reasonable choice, the ability to appreciate the circumstances of the decision, the ability to reason to consider consequences and compare them, and the ability to understand and paraphrase the meaning of the information disclosed (17). Each of these recognizes important elements of the patient's capacity to make medical decisions.

Elements

Simply put, in assessing a patient's ability to make a decision regarding health care, one must evaluate three elements of the capacity to make health care decisions. First, the patient must possess the ability to comprehend the information about the medical problem and to appreciate the impact of the disease and the consequences of various options for treatment, including forgoing treatment. Second, the patient must possess the ability to evaluate the options by comparing the risks and benefits of each option, to deliberate in accord with his or her own values, and to make choices that are not irrational. The patient should also be able to maintain a consistent choice over time. Third, the patient should be able to communicate his or her choice (18). A useful mnemonic for these elements of decision-making capacity may be to analogize the processes to those performed by a computer, with its ability to take in information, analyze it against an internal set of values, make a decision, and communicate it. Any break in the chain of processes may constitute a lack of decision-making capacity. Of course, the analogy is imperfect because a human being's thought processes are significantly more complex and nuanced than a computer's, and may be affected by important values besides logical analysis. Values may change over time or after consultation with physicians, family, and friends (Table 62-1).

TABLE 62-1. EVALUATING DECISION-MAKING CAPACITY

Each of these three basic elements of decision-making capacity can be delineated further. First, the patient must possess of a set of values and goals, including a framework for comparing options, and the ability to make reasonably consistent choices. Second, the patient must have the ability to communicate and to understand information, including the ability to give and receive information; the possession of linguistic and conceptual skills needed for at least a basic understanding of the relevant information; and sufficient life experience to appreciate the meaning of potential alternatives. Third, the patient must have the ability to reason and to deliberate about choices, including the ability to compare the impact of alternative outcomes on personal goals and life plans, some ability to employ probabilistic reasoning about uncertain outcomes, and the ability to give appropriate weight in a present decision to various future outcomes (19).

This analysis may at first look to be a daunting standard by which to be measured even for those who have full decision-making capacity. However, the Commission recommended that the measurement of decisional capacity not be absolute, but rather measured by a “sliding scale.” Generally, determination of the capacity to decide on a course of treatment must relate to the individual abilities of the patient, the requirements of the task at hand, and the consequences likely to flow from the decision. Thus, when the consequences for well-being are substantial, there is a greater need to be certain that the patient possesses the necessary level of capacity (20). When a decision to forgo treatment could result in death, the need to be certain that the patient has decision-making capacity is greatest.

A lack of decision-making capacity may be caused by any break in the chain of decision making: the ability to understand, to reason and evaluate, or to communicate a decision. Obviously, patients in a coma, infants, and the profoundly mentally disabled lack decision-making capacity for all medical decisions. Some other patients, such as those at the end of life who have metabolic abnormalities, disorientation, or early dementia, although impaired to a certain extent, may yet retain some degree of decision-making capacity.

Thus, decision-making capacity has two seemingly contrary characteristics. Decision-making capacity has characteristics of a continuum (21) (i.e., a sliding scale that relates to the complexity, importance, and consequences of the decision in relation to the patient's abilities)—the more grave the decision, the higher the standard. Yet in the final analysis, at a given point in time, for a given patient with a specific health care decision to make, it is all or nothing: A patient either has the capacity to make a specific health care decision or does not.

Role of Mental Status Examinations

A mental status examination may be a useful tool in determining decision-making capacity. A commonly administered test is either the Mini-Mental State Examination or a variation of it. The Mini-Mental State Examination establishes orientation, memory, attention, and reasoning ability through the use of vocal responses. It also tests the ability to name objects, to follow verbal and written commands, to write a sentence spontaneously, and to copy a complex polygon (22). This short test is foundational for demonstrating a normal mental status, but may not address some of the critical issues of determining decision-making capacity, e.g., understanding nature, risks, benefits, alternatives, and consequences.

For the mentally impaired by developmental disability and the elderly, there are other brief measurements of cognitive functioning, including the Dementia Rating Scale and the Alzheimer's Disease Rating Scale (23). There are also tests for the possibility of intercurrent depression, as well as tests for social function, including subjective well-being and coping skills (24). None of these is designed to measure the specific elements of decisional capacity, although they may be contributory to the overall evaluation.

There should also be a realization that a strict standard of comprehension of information does not reflect the reality of informed consent in the general population. Studies of the ability of persons with normal cognitive abilities show that patients often cannot comprehend or remember the information they are given during the discussion of a procedure and its benefits and risks (25,26). Additionally, because informed consent may evolve in relation or reaction to a new medical condition or situation, it should not be expected that patients will have perfect comprehension of the risks, benefits, and alternatives and that they will be ready to make an immediate decision without some reflection, consultation, and perhaps, vacillation.

Who Should Determine Decision-Making Capacity?

Clinicians already use a rough measure of decision-making capacity when examining or speaking with a patient. Most determinations of decision-making capacity do not rely on special expertise. Psychiatric or psychological consultation may be helpful for some difficult situations in which depression or mental illness may cloud judgment and might be treated. Additionally, mental health professionals have special expertise in analyzing patient thought processes. However, in most cases, any clinician should be able to determine decision-making capacity in a formal way using the standards described in the section Determination of Decision-Making Capacity.

Decision-Making Capacity and the Legal Consensus on Withdrawal of Life-Sustaining Medical Treatment

In the past two decades, federal and state courts have decided a number of cases that have established a consensus of important legal principles in end-of-life care. The first principle is that patients with decision-making capacity may refuse unwanted medical treatment, even if this could result in their death. This principle was stated by the U.S. Supreme Court in the Cruzan (27) case, in which the court recognized that an individual has a constitutional right to refuse treatment (in this case, nutrition and hydration for a patient in a persistent vegetative state). The court grounded this in both the common-law respect for bodily integrity and the liberty interest articulated in the Fourteenth Amendment to the Constitution (28). The second principle is that patients who lack the capacity to make medical decisions do not lose

their rights to refuse life-sustaining medical treatment. However, the manner in which these rights may be exercised is different. Authorized surrogate decision makers may make decisions to limit treatment for patients who lack decision-making capacity using standards discussed in the section Implementing the Patient's Wishes: Standards. The third principle is that courts have recognized that withholding or withdrawing lifesustaining medical treatment is considered neither homicide nor suicide. The fourth principle is that courts have drawn a distinction between intentionally causing a patient's death, which remains illegal, and allowing a patient to die as a result of the withdrawal of life-sustaining medical treatment, which is permitted under appropriate circumstances (29).

Thus, because patients have the right to refuse lifesustaining medical treatment, the determination of decisionmaking capacity can be a life-or-death key to differentiating between a legitimate refusal of treatment by a patient with the ability to evaluate the options, understand the implications, and communicate a choice that should be respected, and a refusal by a patient who no longer has this capability and whose refusal in some cases may be overridden.

SPECIAL POPULATIONS

Minors

By legal definition, minors (those younger than 18 years of age) may not make health care decisions. There are statutory exceptions for some specific medical problems— contraception, sexually transmitted diseases, and substance abuse, among others. However, minors can reach a status where they may be considered to be emancipated or mature for medical decision making; this may be determined by statutory recognition (e.g., those minors who are living independently, enrolled in the armed services, or are married) or by a court that determines that an individual minor is legally capable of making a medical decision. Bright line rules aside, adolescent minors who are undergoing supportive oncological care and who exhibit the essential elements of decision-making capacity should be given great latitude by parents and clinicians in medical decision making.

Patients with Dementia and Psychiatric Disorders

Because mental disorders such as delirium or dementia are common reasons that patients lack decision-making capacity, the presence of a psychiatric disorder should alert the clinician to take special care in determining decision-making capacity. Patients with delirium are rarely able to make health care decisions because of the inability to concentrate. Patients with dementia may be unable to make medical decisions because of cerebral frontal lobe impairments that affect abilities such as memory, insight, and judgment. However, a diagnosis of dementia alone is not sufficient to determine lack of decisionmaking capacity (30). Even the person with somewhat advanced dementia may have intermittent periods of lucidity that allow for significant decision making. As an example, some patients may be relatively lucid in the early hours of the day, but grow more confused as they tire. Presumably, because there is a consistent period of lucidity, this type of individual could still participate in decision making about medical care.

In addition, patients with psychiatric disorders such as schizophrenia may have diminished decision-making capacity due to delusions, denial of illness, or impairments in memory and concentration. Although approximately one-half of patients with schizophrenia have impaired decision-making capacity, another half may be able to make medical decisions (31).

It is also important to note that the presence of depression does not automatically interfere with decision making. Depression is a natural and rational response to cancer, and the depression may be ameliorated by antidepressants. The key question is the degree to which the depression affects the processes of decision making.

PROBLEMS IN THE DETERMINATION OF DECISION-MAKING CAPACITY

Vexing Problems in Determining Decision-Making Capacity

The Commission and others have cautioned against using the objective outcome of a decision process as a test of whether a patient lacks decision-making capacity (known as the *objectively correct standard*). Thus, just because the decision seems wrong or against recommendations does not mean that the patient who made it does not have decision-making capacity. Conversely, the Commission also recommends against using the patient's concurrence with recommendations as a similar test. Intuitive thought processes and feelings may lead patients to make medical decisions that seem to be wrong, or at the least, suboptimal (32). Physicians and others may deem these decisions irrational, retrospectively categorizing the patient's decision-making capacity as flawed (33).

It has been said that few problems in medical ethics are as intractable as that of patient decision-making capacity (34). In the most difficult cases, a patient may make a medical decision on reasoning that is not logical, but rather is based on intuition and feelings. Such decision making is not so foreign in other venues (e.g., refusing to board an airliner for a trip due to fear of flying, while being willing to drive the same distance without wearing a seat belt—a statistically far more dangerous choice), but when the refusal of what may be life-sustaining medical treatment does not seem to be based on a logical conclusion of a patient's expressed values, clinicians are understandably perplexed.

The few courts that have wrestled with these most difficult cases have found the patient to be incompetent when the patient is “incapable of recognizing facts which would be obvious to a person of normal perception,” such as the refusal to recognize a malady and its consequences (35). On the other hand, a patient with an abnormal mental status has been allowed to refuse treatment as long as the patient understood the nature and severity of illness, despite the fact that recovery without treatment was extremely unlikely, and treatment was almost uniformly effective (36).

Patients also make important health care decisions based on religious beliefs that may not be commonly accepted. The Constitution's First Amendment protects religious belief and practice from government interference, but unless the hospital is a government entity, the First Amendment would not apply as a bar to treating patients against their wishes when their refusal is based on religious grounds. However, appellate court precedent allowing a physician to override an adult patient's religious refusals of treatment (37) has given way to precedent that respects such refusals as competent (38). A patient's hope for a miracle while refusing indicated treatment does not automatically indicate a lack of decision-making capacity (39).

Pearls and Pitfalls in the Determination of Decision-Making Capacity

A recent survey of clinicians culled and ranked a number of common pitfalls in the determination of decisionmaking capacity (40). They encompass the most common misconceptions:

1. Legal competency is not synonymous with medical decision-making capacity. Legal competency, as determined by judicial proceeding, differs from clinical determination of decision-making capacity. Clinicians should be able to determine a patient's medical decision-making capacity.
2. Capacity is not all or nothing for all medical decisions, as individuals may have the capacity to make some decisions but not others.
3. A patient's capacity to make a particular medical decision is not static. It may change over time, caused by fluctuations in mental status.
4. The fact that a patient is able to communicate a decision does not necessarily mean that the patient has decisionmaking capacity. When assessing capacity, the clinician should give more weight to the process a patient uses to make a decision than to the final decision itself.
5. A clinician's agreement with a decision made by a patient does not necessarily indicate that the patient has decision-making capacity. The clinician should still assess a patient's decision-making capacity even when the patient agrees with the clinician's recommendations.
6. Patients who are given inadequate information may have the capacity to make a decision, but the clinician should ensure that the patient has been given relevant and consistent information about the proposed treatment so that the patient can make an informed decision.
7. Patients should not have to bear the brunt of decision making alone. The clinician should take steps to optimize the patient's capacity to make decisions, including time to make decisions, careful phrasing, teaching aides, use of personnel specially trained to bridge language and cultural barriers, and, where the patient permits, the enlistment of family members to help with communication.
8. Just because a patient has a psychiatric diagnosis does not mean that the patient automatically cannot make health care decisions. Patients with psychiatric disorders may still have the capacity to make medical decisions. Patients with schizophrenia and early dementia, for example, may have the ability to make medical decisions.
9. The fact that a patient is committed to a mental health institution does not mean that the patient cannot make health care decisions. Even patients who are committed to a mental health institution may retain the right to make health care decisions.
10. In most cases, mental health professionals are not necessary to determine a patient's capacity to make medical decisions. Clinicians of all stripes should be able to make a determination of patients' decision-making capacity, although mental health expertise may be helpful for the more difficult cases.

DECIDING FOR PATIENTS WITHOUT DECISION-MAKING CAPACITY

Legal Devices for Making Health Care Decisions

Once a patient has been found not to have decisionmaking capacity, how should medical decisions be made? Traditionally, if no other provisions have been made by the patient, the legal standard for making both medical and nonmedical decisions for patients determined by a court as incompetent has been to establish a guardianship. The guardianship process is often slow and costly for the patient or family, and the guardian is normally expected to make decisions using the traditional “best interest” standard, which does not always rely on the patient's previous expressions of preferences. In practice, in the interim before a guardian is appointed, clinicians have informally turned to a spouse or family member (one of whom would most likely be appointed guardian) for decision making. Even with a guardianship, withdrawal of life-sustaining medical treatment poses special problems in determining what a patient would have wanted under the circumstances. Advance directives were created to address these problems.

Advance directives give legal recognition to the previously expressed desires of the now incapacitated patient. Advance directives, which consist of directives for medical care made in advance of incapacity, act as expressions of patient wishes for the now nondecisional patient. Advance directives were recognized and encouraged in the Cruzan case and the Federal Patient Self Determination Act that followed it (41). As a result of the Patient Self Determination Act, each state must recognize at least one form of advance directive and hospitals are required to inform patients of their right to refuse medical treatment and to make advance directives. The two most common forms of advance directives are the living will and the power of attorney for health care. The living will is a document that directs physicians to withhold life-sustaining medical treatment if the patient is nondecisional and has a terminal illness (or, in many states, is in a persistent vegetative state). The power of attorney for health care is a document that appoints an agent to make health care decisions for the patient when the patient becomes incapacitated. Both documents are triggered when two physicians (or a physician and a psychologist) determine that the patient no longer has decision-making capacity for the health care decision at hand. Advance directives give immunity to physicians who follow the directive in good faith.

Despite the availability of these documents, the majority of individuals do not complete advance directives. As a result, a number of states have enacted surrogacy laws (42). Under a surrogacy law, patients without advance directives who become incapacitated may have a decision-maker appointed from a list of eligible individuals, including a spouse, family member, or others as prescribed by statute. Surrogacy laws give legal recognition to a process that many physicians have turned to in the past when no one had been appointed as guardian, namely, turning to the person most likely to be recognized as the appropriate representative of the patient (43).

However, until greater numbers of patients complete advance directives, doctors, family members, and others are faced with the task of making decisions about limitation of treatment without these legally approved expressions of patient preference in the majority of end-of-life decisionmaking cases in which patients do not have decision-making capacity. This task generally includes a process of either acting in what is perceived to be the patient's best interest, or, where state law permits, acting according to the previously expressed preferences of the patient.

Implementing the Patient's Wishes: Standards

Decisions to forgo life-sustaining medical treatment in the patient who no longer has decision-making capacity have been the subject of scrutiny by the U.S. Supreme Court and numerous state courts and legislatures. For nondecisional patients, state courts, for the most part, have recognized two criteria to measure whether the now nondecisional patient would forgo life-sustaining medical treatment. One test requires determination that treatment would not be in the “best interest” of the patient. This test is a similar standard to that which a guardian must exert on behalf of his or her ward, or parents on behalf of their child—namely, the patient's wishes aside, what would be best for the patient.

Another test allows a “substituted judgment” to determine what the patient would have wanted under the circumstances to justify treatment termination (44). This test takes into account the patient's subjective wishes. Depending on state law, withholding or withdrawal of life-sustaining medical treatment is permissible when the appropriate test is satisfied. When a patient has not made an advance directive that addresses the medical question at hand, a statepresribed surrogate or others who make decisions for the patient are faced with the task of making those decisions, relying on whatever evidence exists of the patient's wishes regarding end-of-life treatment.

States have different standards for determining the nondecisional patient's prior treatment wishes. When not stated explicitly, it is generally assumed that a preponderance of evidence is required (i.e., it is more likely than not that the patient would have made a particular health care decision). Some states require a higher degree of certainty (“clear and convincing” or “clear” evidence) that the patient would have chosen a particular course of action in health care decision making. The difficulty in relying on previous verbal expressions of the patient's health care preferences reinforces the importance of advance directives in adult end-of-life planning. End-of-life decision making for patients who were never decisional (e.g., adult incompetent patients who never had decision-making capacity) generally requires an individual who is legally able to act in the patient's best interest, such as a guardian.

Quality of life may arise as a factor to consider when deciding when to forgo life-sustaining medical treatment. Physician perception of poor quality of life can influence recommendations to forgo life-sustaining medical treatment (45), even in cases in which concerns about poor quality of life might not be shared by the patient. Physicians tend to underestimate patients' preferences for life-sustaining medical treatment in chronic illnesses, whereas family members may overestimate the patient's preferences in the same circumstances (46). Unless patients have stated in an advance directive or by other means how they would evaluate their present state, quality-of-life considerations in patients who are now nondecisional are extremely problematic. Nonetheless, without an advance directive that incorporates patient wishes, there seems no better choice than to rely on family and loved ones for expressions of patient preference. This reinforces the need for advance directives that appoint a surrogate while still providing important information about patient wishes.

Clinicians facing difficult decisions concerning patients at the end of life may be aided by consultation with their institutional ethics committee or ethics consultant. Health care institutions are mandated by the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) to have a mechanism to resolve ethical issues, and most health care institutions have established ethics committees or ethics consultants. The committees or consultants have developed processes to allow clinicians and others, including patients and families, to consult them for advice in resolving difficult ethical issues in patient care. Ethics committee deliberation and ethics consultation can provide a forum for discussing end-of-life decision making and making recommendations regarding ethically appropriate choices in a given situation.

SUMMARY

In the practice of palliative care, patients, their families, and their loved ones face many important decisions. At some point in the disease process, many oncology patients lose the ability to make these decisions, yet treatment decisions still need to be made. The elements of decision-making capacity serve as a standard to determine whether a patient is decisional or not. Mental status examinations may be helpful but not necessarily determinative of incapacity. In most circumstances, clinicians should determine decision-making capacity. Nonetheless, vexing problems arise in determining decision-making capacity that may require mental health expertise. Legal devices for making health care decisions for patients without decision-making capacity include guardianship, advance directives, and surrogacy laws. There are statespecific standards as to the test to be applied in deciding what a patient would have wanted under the circumstances. Ethics committee and consultants may be helpful in difficult cases.

ADVANCE DIRECTIVES

LINDA L. EMANUEL

Many oncology patients would like to have some control over their medical care, not only when they are alert but also when they are too sick to participate in decisions. Similarly, those who have to make decisions for patients who are unable to participate would like to be guided by the patient's wishes. Advance care planning evolved in response to these needs. Having discussions about goals in different types of scenarios and including both family and physician in that discourse are the key issues. For effective discussions, it helps to have the patient and family go through validated worksheets that walk them through the various considerations and result in expressions of preference that are clinically meaningful. This should usually be done on the patient and family's own time, with opportunities to check in with the physician and team to ensure coordination and agreement. Ideally, this can happen over time, integrated into the course of care.

TERMS, HISTORY, AND LAW

There are two main modalities by which a person can make preparations in anticipation of future incapacity (1). One is to appoint a proxy to speak in the place of the principal person. The other is to write down wishes in a directive. These two modalities are usually complementary, since written statements cannot provide for all eventualities, and proxy decision-makers cannot speak accurately on behalf of patients without the patient's guidance.

Proxy Designation

Physicians should be aware of three key issues on which to advise patients and proxies. First, patients, professionals, and the proxies themselves should understand the proxy's role. Speaking in place of the patient can take two distinctly different forms. In one form, the patient asks the proxy to represent the patient's prior wishes and to hold steadfast to these known prior preferences, extrapolating them if necessary to the situation at hand. In the other form, the patient simply chooses the proxy and lets him or her speak according to the proxy's own judgment (2). In this alternative role, the proxy remains more independent of the patient's stated prior wishes and tries instead to imagine what the patient would have wanted in the circumstances, judge the best interests of the patient, and balance other issues as he or she sees fit. These two modalities can be merged. For instance, a patient may tell a proxy to apply his or her prior wishes, albeit with latitude and taking particular types of unpredictable family issues into consideration (3).

Second, patients and proxies should know that studies have found that proxies often guess the prior wishes of patients inaccurately and, furthermore, that proxies often imagine that the patients' prior wishes are for more intervention than patients actually select (4). Even a proxy who has had a close relationship with the patient may not be able to make accurate judgments. It is possible that close relationships do not often include discussions about medical aspects of dying, or that patients do not even know their own preferences until they have discussed or faced a relevant matter. It is also possible that proxies face significant emotional issues that may hinder their ability to imagine the patients' wishes. Regardless, physicians must counsel patients to discuss relevant perspectives explicitly and well in advance of a deteriorating medical situation that may result in incompetence.

Third, patients should be aware that friends and family members have their own interests and issues, which may conflict with their role as proxy. Common examples include the difficulty of letting go of the loved patient, the great emotional burden of making life-and-death decisions, the difficulty of finding the extensive time it takes to perform the proxy role well, and the difficulty of choosing how to allocate limited family resources (e.g., to the patient's medical care versus the children's education) (4). Conflicting motivations are inevitable and need not prohibit the proxy role. Nonetheless, the proxy may need help distinguishing different motivations and abiding by those that are most suited to the proxy role.

Instructional Directives

The history of the development of instructional directives reflects the search for the most valid form of expressing prior wishes. The earliest commonly used instructional directive was the “do not resuscitate” (DNR) order, written by the physician after discussion with the patient and family (5). After its proposal in 1976, a set of studies and a culture evolved around the DNR discussion. It is still relevant and can be included in comprehensive advance planning discussions (6). A hazard of isolated DNR discussions is that they occur too late, either missing the patients who need them or occurring in such “out of the blue” conversations that patients get unintended messages, perhaps feeling that they are being abandoned (7).

An earlier modality for making instructional directives, which never achieved widespread use in the medical system, was the living will. This was introduced in 1968 by a lawyer, Louis Kutner. The living will attempted to express the widespread view that heroic levels of technological intervention should be avoided if the patient's prognosis was hopeless. The statements made in living wills were true enough to the sentiment, but in practice they were insufficient to guide the specific decision-making needed in real clinical circumstances. Different interpretations of what constitutes a heroic intervention and what constitutes a hopeless prognosis meant that this early type of living will was liable to bring as much confusion as clarity to the decisions.

Efforts to increase the specificity of living wills began, starting most notably with Sissela Bok's and Michigan's living will (8,9). Thereafter, developments began along two lines: one to better describe the general health-related values of the patient (values histories) and one to formulate ways in which patients could make very specific treatment preference statements (treatment-specific directives) (10,11). Empirical evidence that general statements cannot predict specific wishes has supported the more balanced view that these two modalities work best together (12,13 and 14). Some patients are inclined to write a free-prose letter encapsulating their wishes. Such letters can be worthwhile, but many patients do not have the writing skills or the specialized knowledge that ensures coverage of relevant decisions. In such cases, concurrent use of predrafted documents is to be encouraged.

More recently, efforts have been focused on the need to validate predrafted instructional directives, just as any other instrument that seeks to record subjective matters

needs to be validated (15). Specific forms that have been extensively validated are still few, and validated forms tailored to oncology patients are even fewer. One of the more studied forms, which is generic and adaptable, is reproduced in Appendix 63-1. Physicians should advise patients to use validated forms, since using nonvalidated forms risks misrepresentation of patients' true wishes and can confuse decisionmaking. Validated forms also provide a succinct method of ensuring that patients have considered the major areas that most people need to cover. The use of a validated form as a worksheet for thought and discussion can be as important as its use as a recorded document.

Statutory versus Advisory Documents

All states and the District of Columbia have statutes that endorse advance directives in one way or another. Some endorse the use of proxies, others endorse the use of instructional directives, and most now endorse both (16). Most state statutes have a corresponding document, which is often available from local health care facilities or state medical organizations. The fundamental purpose of state statutes is to allow physicians to follow the patient's wishes without fear of liability. The interests of the patient are served indirectly by protecting physicians who follow patients' wishes and rendering physicians vulnerable if they do not. Many states specifically honor the statutory documents of other states, although some differences exist, and frequent travelers may wish to have documents from their frequented state bound together with those from their home state.

It is part of common law that competent patients have the right to accept or refuse medical intervention, even lifesustaining intervention. Even casual statements have been honored as sufficient evidence, although written statements have been explicitly identified as desirable evidence of patients' preferences (17,18). Physicians can therefore be assured that patients' statements recorded in a fashion not specifically designed for local state statutes—they can be considered advisory documents—still carry legal authority. Distinctions between legal and “nonlegal” or “illegal” forms in this context are erroneous. A statutory form is legally binding, and a nonstatutory advisory document is also binding if it provides clear evidence of the patient's wishes. Since statutory forms are written to comply with legal criteria, they are often far less informative than advisory documents, which can address personal values and clinical issues.

Patient Self-Determination Act and Recommendations of the Joint Commission on Accreditation of Healthcare Organizations

In 1990, the U.S. Congress passed the Patient Self-Determination Act, which requires that patients be asked about the existence of an advance directive at the time of enrollment or admission to a health care facility. The intent of the law was to increase awareness and documentation of advance directives. In addition, the Joint Commission on Accreditation of Healthcare Organizations recommends that facilities have arrangements for counseling patients who wish to complete advance directives. Completion of advance directives is best done in the more stable setting of continuing outpatient care, but occasionally their completion in the inpatient setting is unavoidable. Thus, although minimal compliance with the Patient Self-Determination Act and the recommendations of the Joint Commission require relatively little from physicians, the spirit of both requirements involves thoughtful, longitudinal involvement of the physician in discussion with the patient.

CONCEPTUAL FOUNDATIONS, EMPIRICAL BACKGROUND

Honoring Patients' Wishes

The basic precept on which advance directives depend is somewhat confusing. The notion that autonomy can be extended into times of incompetence by recording wishes ahead of time is problematic. How can anyone know whether the wishes of an incompetent person are represented by previously recorded wishes? What about patients who are incompetent for decision-making but are awake and appear to be capable of feelings and wishes, and these apparent wishes differ from the prior wishes? Responding to these two questions, which motivated considerable criticism of the advance directive movement, depends on understanding two things. First, the justifying principle for advance directives is surviving interests, rather than the broader principle of autonomy. Second, the patient condition in which advance directives pertain is actually wishlessness, not the more general condition of incompetence (19).

Surviving Interests

Ordinarily, autonomy involves application of real-time wishes. But since it is impossible to create real-time wishes when there are none, autonomy can be extended only by applying prior wishes. A surviving interest constitutes a distinct form of autonomy and should not be confused with the more general autonomy. *Surviving interest*, ordinarily a legal term, refers to the right of the individual to determine decisions on matters in which he or she has an overriding interest even after losing the direct ability to act on these matters. The most common example is the estate will, in which individuals exercise their right to determine disposal of their property after death. A related arrangement that relies on a surviving interest concerns the funeral directions by the principal planning for his or her own death. Another example is the organ donor card. The important point is that arrangements predicated on surviving interests do not rely on real-time wishes; they rely on prior wishes. Advance directives rely on prior wishes in just the same way as these more traditional applications of surviving interests. Even when a proxy is instructed to make decisions without reference to the patient's prior wishes, the proxy's authority relies on the patient's prior wishes to designate him or her, and while proxies may make use of their own real-time judgments, there is no application of the patients' (nonexistent) real-time wishes. The question, “How can anyone know if the wishes of the incompetent patient are represented by the recorded wishes?” can now be answered— When there are no real-time wishes, it is prior wishes that must be represented.

Zone between Incompetence and Wishlessness

Patients who are in a state in which it is not possible to have wishes, such as occurs when there is complete absence of neocortical function, clearly meet the criteria by which advance directives can be activated. A problem arises when a patient is not wishless but is decisionally incapacitated, as is commonly the case after a stroke or in many types of dementia or debilitated states. Many such circumstances involve such a significant change in patients' personality or states of being that they are very different from the former selves who made out the directive. There is limited ethical imperative to apply the wishes of the former person to the current person if the latter is a significantly altered or truncated version of the former (20). Many patients fall into this “twilight zone,” and advance directives should be used as no more than one factor (the representation of prior wishes of the former person) in the assessment of what the current person's wishes and needs may be. Under these circumstances, advance directives may be said to represent a weak version of the surviving interests of the patients, and other factors must therefore be considered. Technical and legal statements as to when advance directives can be activated often fail to make this distinction. Nonetheless, physicians should be particularly careful to meet ethical standards as well as legal ones under these circumstances. The question, “How should one represent decisionally incapacitated patients who seem to have wishes that differ from the recorded wishes?” can now be answered—A combination of guidance by the advance directive and substituted or best interests judgment should determine the physicians' and proxies' decisions for patients in this circumstance.

Substituted Judgment and Best Interests Judgment

Whenever patients' surviving interests are unknown, decisions must be made by using standards of substituted judgment or best interests judgment. The application of prior wishes is not the same thing as using substituted judgment. Even when prior wishes are inferred from stated wishes to fit unpredicted decisions, this is a form of prior-preference– guided judgment that is justified by surviving interests.

Substituted judgment usually refers to attempts to judge as the patient would have if he or she could have. In the words of Justice Hughes, who wrote the opinion for Karen. Quinlan's case, “If Karen were herself miraculously lucid for an interval (not altering the existing prognosis of the condition to which she would soon return) and perceptive of her ... condition, she [would] decide upon ... [the decision of the court offered on her behalf]” (21). Substituted judgment is an intrinsically difficult concept and is just as difficult to implement in reality. Understanding what a person would want is hard enough in ordinary circumstances. Understanding what a person would want when the person is in a state that the proxy has never been in is even harder. When that state is such that the individual is incapable of having wishes, it is impossible. This last key difficulty centers on the fact that real-time wishes are being created when there are none. Commentators have noted that substituted judgment usually ends up being a version of best interests judgment. It may also end up being a version of priorpreference–guided judgment in that attempts are made to guess what the prior healthy person would have wanted if he or she could have anticipated the eventual condition.

Best interests judgment is somewhat easier conceptually, but still difficult to implement. The idea is to judge according to the best interests of the patient. It has this advantage: Not only is real time used, but also there need be no reliance on notions of the patient's wishes. The difficulty for this concept is determining what the best interests of the patient are, since this involves highly subjective value assessments. It may also be the case that the patient is so debilitated and “absent” that ordinary real-time interests do not exist. Despite these difficulties, it is the best guiding standard available when prior preferences cannot be used.

AUTHENTICITY OF WISHES

Cultural Differences

Advance care planning has evolved in the contexts of Western cultures and is often thought of in terms suited to social contexts in which individuals' rights have some priority. However, the idea of planning is not predicated on individualism and readily accomplished in cultures that emphasize extended families and community

responsibility. Other cultural differences can also invite special consideration, but, similarly, can usually be overcome. When the role of deciding for others traditionally falls to a particular role or person in a culture, it can be that advance planning may seem a threat to that role. Or, if there is distrust of those who seek to plan by those who will be affected, then planning may be counterproductive unless trustworthiness is established. But, perhaps the most problematic cultural issues has to do with cultural prohibitions against discussing dying. This taboo has been as strong in the Western cultures as elsewhere. Delegated decision making to family heads has been identified in families of Asian origins; trust concerns have been identified in African-American patients and families; and concerns over precipitating undesired outcomes if they are discussed has been identified among Navaho families (22,23 and 24). While cultural issues are powerful, generalizations are also problematic. Every case must be engaged on its own issues. The clinician who approaches people with genuine respect and, with an open mind, inquires about and honors cultural differences, should be able to accomplish advance care planning in forms that suit each case and setting. Three practical tips can help with many situations: If extended family decision-making may be desired, ask the patient how he or she would like decisions managed and include the relevant people in the process, perhaps suggesting designation of the decision-maker in the family as the proxy. If trust may be insufficient, spend longer establishing trustworthiness by explaining the nature of your thinking as a clinician, by including other members of the family or community and by avoiding arrogation of decision making and sharing information fully and carefully. If death is difficult to talk about, be extra sure that you are comfortable with the topic and approach it with simplicity and a listening disposition. Ask if there are ways of talking about dying that might be easier and try to accommodate any requests.

Informed Consent and Competence Standards for Advance Directives

Patients' prior wishes are articulated in real time and must be held to the same standards as any other real-time decisions, namely, to ordinary standards of informed consent. Informed consent has received considerable attention, and its standards can be read about elsewhere (25,26 and 27). Although standards may evolve, for the present, physicians should ensure that patients understand the nature of the decision, understand the alternatives, and understand the risks (common or serious) and benefits. Patients should be over 18 years of age, have decision-making capacity in the relevant areas, and give evidence of having made actual active decisions.

Informed consent specifically for advance directives can be considered in two parts. First, patients must consent to completing an advance directive. Patients must know what the basic procedures are (to discuss the issues and record preferences) and understand that traditional decision making (having physicians and legal next of kin use their best judgment) is the alternative. They must know that there are risks either way (e.g., careless advance directives can lead to unintended actions, but traditional decision making is known to correspond poorly to patients' wishes). To be competent in the use of instructional directives, patients have to be competent in the use of imagined scenarios. Otherwise, they will not be able to understand the intervention choices they are making for future potential situations. This is not as dissimilar as it may initially seem from real-time decisions, since real-time decisions are also based on how people think they will feel in the future while living with the consequences of the immediate decision.

Second, discussions of advance directives need to ensure adequate informed consent for any specific treatment decisions made. This can be difficult because of the large number of decisions included in some instructional directives and because of the sketchy nature of delineated scenarios in the advance directive. Many instructional directives specifically state that they are to be used as a guide to the patient's wishes rather than as a series of treatment decisions. For this reason, standards of informed consent can be relaxed to some degree. Nonetheless, the standards must be sufficient to provide an accurate picture of the patient's wishes. The use of well-designed brochures or other information packets that describe key interventions can help ensure informed consent standards. The key interventions should include mechanical respiration, resuscitation, chemotherapy or radiation therapy, dialysis, simple diagnostic tests, and pain control (including the potential side effect of respiratory depression). Whether or not information aids are used, physicians must ensure evidence of patients' comprehension.

Valid Expressions

The validity of prior preferences can be judged in essentially the same way that the validity of real-time wishes is judged. Validation of predrafted instruments for the articulation of subjective matters is a well-developed discipline in itself. Generally speaking, instruments must meet standards of content validity, construct validity, criterion-related validity, and test-retest reliability. The first requires that the instrument cover the relevant content matter, the second that items in the instrument be constructed to fit the concepts of the subject matter, the third that the items bear sensible relationships to existing relevant scales and to one another, and the fourth that if the same items were used over again at a different time a reasonably similar set of responses would be obtained (15). Predrafted advance directives should meet these standards, as adapted to the needs of advance directives (19).

An efficient way for physicians to assist patients in valid expressions and recordings of prior preferences is to provide them with a validated, predrafted, instructional directive and go through it. If patients have been able to complete such a directive, meeting standards of informed consent for the wishes they express, then the statements recorded must be considered valid.

HOW TO DO IT

Five Steps in a Continuing Process

The creation of recorded advance directives is one step in a longitudinal process that should be integrated into the totality of clinical care. Although five steps can be identified, they will rarely be so distinct in actual practice. First is raising the topic. Second, and most important, is structuring a core discussion to cover the main issues and start the patient thinking about his or her views. Third is reviewing the final document and putting it in the medical record. Fourth is updating the directive from time to time. Fifth is ensuring its availability and use, applying it to decisions that arise after the patient has become wishless (28).

Raising the Topic, Providing Background Information, and Advising on Proxy Choice

First, the topic must be raised. This may be the hardest part, although once expected and routinized, it is a surprisingly easy matter.

With whom should the topic be raised? Among oncology patients, everyone should have the opportunity for advance care planning, whether the prognosis for cure is excellent or poor. Occasionally, patients will have discussed advance care planning with their primary care or other physician. The oncologist can build on this foundation. The topic should not be avoided on the assumption that it has been dealt with. Patients who have completed advance care planning before receiving their oncologic diagnosis may have since changed their perspective. The extent and structure of the planning may not have been as good as that the oncologist can offer. Most important of all, the oncologist needs to know the substance of the patient's current health advance care planning.

In an oncology or a palliative care practice, the topic can be raised by the fourth or fifth visit, depending on the emotional and medical circumstances. Time should be allowed before advance care planning for confirmation of the diagnosis, exploration of treatment options, establishment of a solid therapeutic relationship, and some adjustment by the patient to his or her diagnosis. Earlier mention, say at the second or third visit, that advance planning will be a component of routine care (as should occur for all patients with or without cancer) can facilitate the process. In a long-term care facility, an analogous process is possible, with early mention that the discussion will occur, within the first 3 months of a patient's residency.

One fashion in which the topic can be raised is as follows:

> Ms/r. X, I want to talk with you about planning for future medical care. Many now recommend that people make plans whether or not they have an illness, and that doctors discuss these issues routinely with patients. There is even a federal law that aims to let people know that advance planning is available to all people. We should go through these issues together. It is part of getting to know your values and helping to ensure that you are cared for the way you would want to be even in times of life-threatening illness when communication may be impossible. There is nothing new about your health, and I am not hiding bad news that we have not already discussed; planning for the future simply is prudent. Is this something you have explored before?

It is helpful to be able to add, as is true for many oncologists:

> I myself have done this as a routine matter, despite being in good health.

Some issues for the patient to consider in selecting a proxy can be included at this point, in particular that being a proxy is a complex and burdensome task, and that family members and close friends may have interests that conflict with the patient's. Most people prefer to select someone close to them as a proxy nonetheless, and usually for good reason, but the possibilities of appointing a more distant friend or a professional, such as a social worker or lawyer, are worth considering. Some patients suggest appointing the physician as proxy. Since the idea of a proxy is to have someone to talk with the physician, this is not usually the best idea. The patient should be reassured that the physician will in any case be working to make the best decision for the patient and additional proxy powers are usually unnecessary; participation by the physician in creating a written directive, perhaps without a designated proxy, assists the aspiration.

Nonphysician health care providers can assist in the first step of raising the topic and providing background information. Brochures and predrafted forms and videos or

closed-circuit television programs can also be made available in patient information libraries and patient rooms.

Structured Discussion

Second, the topic must be discussed. This is usually done best by the patient and family on their own time, once they have been oriented to key features of the task. The proxy should be present at this discussion whenever possible. He or she can be advised to listen and ask for any needed clarification, in preparation for the potential role of speaking for the patient, and may even act as scribe, penciling down the patient's statements.

The most efficient way of structuring a discussion is simply to go through a validated blank directive, using it as a worksheet (19). The sections can be gone through systematically. Using a pencil rather than a pen to fill in the patient's wishes, and having the pencil in the patient's or proxy's hand, can help to emphasize explicitly that in this discussion the directive is being used as a worksheet and not a final document. When scenario-based documents are used, it is possible to start the discussion in something like the following fashion:

> Let's look at these standardized circumstances. You will go through one or two and then perhaps another one or two more. You can then do the rest later.
>
> Imagine this first case in the worksheet. You are in a coma with no awareness. Assume there is a chance that you might wake up, but it isn't likely, and recovery may involve serious disability.
>
> Some people would want us to withdraw treatment and let them die, others would want us to attempt everything possible, and yet others would want us to try to restore quality of life but stop treatment if it was not working. What do you think your goals for medical care would be?

Useful scenarios to have the patient and family go through include (a) a coma with a small chance of recovery (as above), (b) a persistent vegetative state, and (c) a moribund state with waxing and waning consciousness. In each scenario, the patient's goals for care are selected and then illustrated with some selected intervention preferences. The commonly considered intervention preferences are (a) resuscitation, (b) mechanical respiration, (c) chemotherapy or radiation therapy, (d) renal dialysis, (e) major surgery, and (f) artificial nutrition/hydration. In addition, preferences regarding (g) simple diagnostic tests and (h) antibiotics provide useful information. Finally, preferences should be discussed by the patient and family regarding comfort measures. Most people can also say whether pain control or being alert and unconfused to the last possible moment is more important to them. Although not a great deal of time need be spent on informed consent for each intervention, it may be wise to provide brochures on the interventions for patients to review on their own time. Nonetheless, emphasize that deciding on goals for care is more helpful than almost any other specific intervention decision (14).

The first three or so scenarios should be standard scenarios designed to cover the major situations commonly encountered when advance directives pertain. Then two or three additional scenarios can be used that are tailored to the patient. One may be created by the physician, based on the patient's illness and expectable circumstances (29). Another may be created by the patient if he or she wishes, based on what the patient considers to be a state worse than death that has not already been covered in previous scenarios (30). It can also be important to consider a scenario in which the patient is in his or her current health and acquires a new, life-threatening illness involving incompetence.

After these scenarios, patients can be asked what they would consider to be the best to be hoped for from the dying process. Most can say, for instance, that they want enough time to settle things with people they are involved with, that they want to have done one particular thing, or that they want to be in a particular place. Elicitation of these images of a good dying should not be construed as promises to fulfill them. Rather, the physician should tell the patient that the images may help in orchestrating care that frees the patient as much as possible to do as he or she wishes with the last stages of life, before unconsciousness or death occur.

There are certain key positions that patients should be encouraged to articulate during or after their consideration of the scenarios. One is their position on withholding versus withdrawing life-sustaining therapy. Some people have strong positions on the distinction or lack thereof between the two. It is well to have a specific indication whether or not an unwanted intervention, if in place already, should be withdrawn. Another topic that can be included in the scenarios is the place of pain control. Use of pain medications intended to control pain but with a known side effect of hastening death is generally considered morally acceptable. Physician-assisted suicide, while not generally accepted, is receiving wide attention, and it may be helpful to clearly articulate preferences and positions on this matter. Physicians who have patients requesting actions they cannot condone should advise the patients of the fact at this early stage. Similarly, the proxy should raise objections at this stage, if necessary.

Even if the physician is involved in structuring most of the discussion, the entire process need take no more than 15 minutes once the physician has gained experience with it. The intent is not to reach final resolution or to elicit extended narratives. Rather, it is to identify the key issues that patients should think about and to provide them with a good method for recording their preferences. Nonetheless, during these steps patients commonly communicate deeply held values. Witnessing such expressions can give physicians a strong sense of the privilege of caring for patients, and the knowledge that ensues about how health issues fit with the individual patient's sense of meaning in life can be of great practical importance. Reciprocally, patients can feel clearer, more understood, and confident.

Patients should be encouraged to absorb the informational materials and talk over all the issues with their family, friends, pastor, lawyer, counselor, or whomever they consider to be relevant. The patient can then prepare a statement, preferably in a fashion that includes a validated advisory form and a statutory form that can then be stapled together if they are not already combined.

Recording the Document

Once the patient has completed the essential personal discussions outside the physician's office, he or she can bring the document in for final review by the physician. At this point, the physician can check for medical misconceptions and major changes that may need inquiry. This should take only a few moments in most cases. It is useful to have a space where the physician can cosign the document (31). This signature should not be a requirement, but its presence fosters the physician's involvement and carries an important implicit message of partnership between patient and physician.

Updating the Document

Documents should be reviewed at routine intervals. For a patient who has undergone a cure or for whom the prognosis is good, this review should occur every 1 to 5 years and after major life changes such as childbirth, marriage, divorce, significant health status changes, bereavement, and important experiences of others' ill health. Most reviews will be rapid. Specific treatment decisions are about as durable as other major life decisions such as marriage (32,33,34 and 35). When a patient shows a particularly high level of instability, this may indicate incompetence for advance decision-making, and the physician should review the matter, perhaps advising simple designation of a proxy instead of instructional directives.

Applying the Document to Real Decisions

Certain patterns of decisions have high degrees of predictability. If a patient's prior directives do not cover the decision at hand, it may well be possible to extrapolate from the preferences that are provided in the directive. Such predictions can be far more accurate than unguided judgments. Decline of less invasive interventions predicts decline of more invasive interventions, and acceptance of more invasive interventions predicts acceptance of less invasive interventions. Acceptance of intervention in poor-prognosis scenarios predicts acceptance in better-prognosis scenarios, and decline in better-prognosis scenarios predicts decline in poorer prognoses. The use of simple calculations can even provide probability estimates of specific decisions, which, when very high or very low, can be a comforting guide to proxy decision-makers (36). This approach is illustrated and necessary reference statistics are provided in Appendix 63-2 and Table 63-2-1 and Table 63-2-2.

Pitfalls and Preventive Measures

A common pitfall is to omit advance care planning discussions altogether. Another variation on this theme is to mistakenly suppose that a “DNR discussion” is sufficient advance care planning. Discussing cardiopulmonary resuscitation and use of a DNR order in the absence of considering a range of scenarios and goals for care is often needlessly frightening for patients, considering as it does only the moment of death, and often yields unstable decisions and poor guidance to providers. If a clinician cares for a patient for whom a DNR order is written without comprehensive orders, such as are outlined in a Physician's Orders for Life Sustaining Treatment form, this should prompt a review of advance care planning with that patient.

As advance directives gradually come into more general use, common pitfalls are emerging (37). Assessment of a patient's competence to undertake advance care planning can be difficult if profound psychological issues or psychiatric diagnoses are involved. Occasionally, for instance, a patient will show major inconsistency in treatment plans or will ask for extremes of no treatment or undue intervention. These may be indications of ineffective emotional adjustment to medical circumstance. Although perhaps not strictly incompetent for completing advance directives, these patients may do better using proxy designation rather. than instructional directives to

preserve flexible decision making. As an alternative, advance care planning can be deferred or updated frequently until psychotherapy or other assistance has secured better emotional adjustment.

A further problem is noninclusion of relevant parties at early stages of planning. Noninclusion of the proxy or of family members or close friends who have divergent opinions can lead to fractured decision making. Noninclusion of the physician can lead to inadequate sensitization of the physician to the patient's thinking. For instance, a recent major study showed that when a nurse is the main communicator in advance planning, the physician's understanding of the patient's wishes is not improved (38).

Poor informed consent and documentation constitute another pair of pitfalls. For example, a patient may express a strong desire to avoid perpetual dependence on a respirator, but the wording of the advance directive may indicate that a respirator should never be used. In the event of reversible pneumonia, the patient may well want temporary use of a respirator. A properly validated directive should require this kind of distinction, and physicians should ensure this minimum level of patients' understanding. Physicians should check the document for improbable statements and ask patients to briefly state their wishes in free words, checking for correspondence with medical possibilities.

Perhaps the most common pitfall of all is activation of advance directives before patients have reached a wishless state and sometimes even before they have reached an incompetent state for the decision(s) at hand. A widespread tendency to avoid direct communication with patients appears to exacerbate this problem. Advance directives, as distinct from their predecessor, the DNR order, usually have no authority when they are first written and must not be activated until the patient is decisionally incapacitated and wishless.

A final, crucial pitfall is poor application of wishes to eventual decisions. Some studies have indicated that physicians rather commonly override advance directives (39). Whether this is because patients are decisionally incapacitated but not wishless, or because proxy opinions persuade physicians more than the patient's advance directives, or for other reasons, is not well studied. Nonetheless, if a patient has a validated advance directive that uses scenarios and specific intervention choices, extrapolation to unstated decisions can be accomplished with considerable accuracy in many cases.

BROADER USES

Structured Deliberation

An unforeseen benefit brought about by the idea of advance directives was a general increase in attention to the questions of how patients' health care values can be elicited, understood, documented, and used as the driving force behind therapeutic decision making. In a sense, the field emerged from a desire to move the medical question from, “What is the right decision?” to, “Who should make the decision?” with the intended answer being “the patient.” However, as the desirability of multilateral decision making became more accepted, the question has become, “What is the right kind of deliberative process for the decision?” This latter question is potentially relevant to a wide range of decisions and circumstances. In delineating a set of validated worksheets and structured deliberations for advance directives, the concept of structured deliberation for a wide range of medical decisions and approaches has emerged (40,41).

Structuring Other Care Plans

The use of care plans need not be limited to scenarios involving incompetence and wishlessness. Plans can usefully be made for situations involving no loss of competence as well. Nursing home and hospice facilities often make use of such plans. A common example is prior decision-making regarding transfer to a hospital facility in case of medical deterioration. Those who decline may have a written “do not hospitalize” order. Similar decisions about levels of medical care within the facility can also be made. For instance, some patients may elect comfort care only, whereas others may elect simple diagnostic maneuvers but no invasive ones, and others may elect full aggressive care. Corresponding orders and/or notes can be written in patients' records. Such decisions must always be subject to change if the patient wishes, just as advance directives are adjustable while the patient is competent. Nonetheless, such planning provides important communication and often streamlines decision making in the event of otherwise difficult decisions.

Intervention for Turbulent Thought Processes

Patients in difficult medical circumstances often face existential decisions. Turbulent emotions and turbulent thinking are common. For instance, a patient may understand that he or she has incurable cancer and, therefore, decline chemotherapy, but, when faced with the need to make a decision about resuscitation, may be precipitated into an emotional crisis by the sense of imminent death or impending abandonment and may decline a “DNR” order. Such decisions are often perplexing to providers, and discord between parties readily ensues. Discord over goals or treatment decisions should alert physicians to the likelihood that patients are facing emotional and moral turbulence. A structured dialogue can be very helpful. The preset scenarios in a validated, generic, advance directive provide an excellent structure. By going back over preset scenarios that the patient knows were designed independently and that cover questions likely to be relevant (because the document is validated), the physician may be able to discern the structure of the patient's nonturbulent moral thought. With the more stable structure returned, it is possible to reapproach a scenario that is tailored to the patient and, finally, the patient's current situation. Often, the patient no longer feels threatened by the sense of imminent mortality, and coherent thought processes and decisions can occur again. If these discussions are conducted in the presence of the proxy and other relevant care providers, there can be a refocusing of the entire group of providers on the retrieved coherent plan. Difficult personal interactions and time-consuming confusions can be put aside, allowing people to get on with the business of preparing for departure on a personally meaningful level.

Structured deliberations such as these can also provide an approach to patients who request euthanasia or physicianassisted suicide. Some patients may have firm and persuasive reasons for requesting such actions, but many patients are, in fact, seeking something else. Some seek control, some attempt to avoid pain, and some try to address concerns about being a burden or being abandoned. A structured path through scenarios allows patients to assert control and gain assurances that pain can be controlled in the great majority of cases, that there are ways of planning for burden and nonabandonment, and that there are ways to exit this world without active euthanasia or assisted suicide. Some physicians find active euthanasia morally defensible in some instances, and others do not. But all must agree that patients who request it erroneously, who are actually seeking care, should be identified and guided toward the actions they really desire. Structured deliberations can provide a sensitive, professional, and efficient method to help patients understand their own desires. They also provide the physician with a chance to communicate explicitly what their moral position is; physicians who do not find active euthanasia or physician-assisted suicide acceptable can make this clear in the supportive setting while simultaneously making clear what comfort care they can offer.

Limitations and Future Directions

As important as advance directives may be, they have clear limitations and should not be construed as a panacea for decision-making about life-sustaining interventions. Especially in the case of moderately demented patients or otherwise decisionally incapacitated but not wishless patients, advance directives offer no more than tangible evidence of one among other perspectives to be weighed in the decision. Even for wishless patients, advance directives provide a way to augment the honoring of surviving interests, but they do not offer perfect evidence of all relevant wishes.

No Evidence for Cost Savings

Some advocates have suggested that the use of advance directives can effect considerable cost savings. This perspective has been motivated by the assumption that their use would help avoid unwanted and costly interventions and, therefore, help reduce the costs of medical care. While end-of-life care is very costly, there is evidence that patients tend to opt for more treatment than physicians and nurses, and that proxies opt for even more intervention (42,43). In addition, although hospice and palliative care have traditionally been less costly than hospital care for dying patients, these populations are self-selecting. A randomized, controlled trial found no cost savings, perhaps indicating that patients, taken in the aggregate, may be getting more or less the degree of intervention that they want (44,45). Individual matches with patients' wishes are, however, found to be poor in many studies, and advance planning should continue with the goal of closing this gap. These motivations for advance planning have overwhelming, independent merit and should not be confused with false economic incentives.

When Patients Have No Advance Directive

About half of all patients have an estate will. If even this form of well-accepted planning for death is not used by more patients, it is likely that advance directives will also have a similar “ceiling.” To meet the objective of attempting to match decisions with patients' prior preferences, it can be helpful to have supplementary approaches (46). In circumstances when the patient comes from a population of patients whose preferences have been studied and documented, it is possible to refer to those data to help guide decisions for them. Thus, if it is known that the patients registered at the hospital in question declined resuscitation for the situation at hand in 85% of instances, the proxy may find this useful guiding information. In cases when the proxy has no idea how to speak on behalf of the patient, the physician may indicate that the greatest likelihood of matching the patient's prior wishes, if only the patient had had a chance to articulate them, will be by following the majority preferences of others. Naturally, these default guidelines should not be coercive or replace valid personal directives.

APPENDIX 63-1

THE MEDICAL DIRECTIVE

INTRODUCTION

As a part of a person's right to self-determination, every adult may accept or refuse any recommended medical treatment. This is relatively easy when people are well and can speak. Unfortunately, during serious illness they are often unconscious or otherwise unable to communicate their wishes—at the very time when many critical decisions need to be made.

The Medical Directive allows you to record your wishes regarding various types of medical treatments in several representative situations so that your desires can be respected. It also lets you appoint a proxy, someone to make medical decisions in your place if you should become unable to make them on your own.

The Medical Directive comes into effect only if you become incompetent (unable to make decisions and too sick to have wishes). You can change it at any time until then. As long as you are competent, you should discuss your care directly with your physician.

COMPLETING THE FORM

You should, if possible, complete the form in the context of a discussion with your physician. Ideally, this should occur in the presence of your proxy. This lets your physician and your proxy know how to think about these decisions, and it provides you and your physician with the opportunity to give or clarify relevant personal or medical information. You may also wish to discuss the issues with your family, friends, or religious mentor.

The Medical Directive contains six illness situations that include incompetence. For each one, you consider possible interventions and goals of medical care. Situation A is permanent coma, B is near death, C is with weeks to live in and out of consciousness, D is extreme dementia, E is a situation you describe, and F is temporary inability to make decisions.

For each scenario, you identify your general goals for care and specific intervention choices. The interventions are divided into six groups: (a) cardiopulmonary resuscitation or major surgery; (b) mechanical breathing or dialysis; (c) blood transfusions or blood products; (d) artificial nutrition and hydration; (e) simple diagnostic tests or antibiotics; and (f) pain medications, even if they dull consciousness and indirectly shorten life. Most of these treatments are described briefly. If you have further questions, consult your physician.

Your wishes for treatment options (I want this treatment; I want this treatment tried, but stopped if there is no clear improvement; I am undecided; I do not want this treatment) should be indicated. If you choose a trial of treatment, you should understand that this indicates you want the treatment *withdrawn* if your physician and proxy believe that it has become futile.

The Personal Statement section allows you to explain your choices, and say anything you wish to those who may make decisions for you concerning the limits of your life and the goals of intervention. For example, in situation B, if you wish to define “uncertain chance” with numerical probability, you may do so here.

Next, you may express your preferences concerning organ donation. Do you wish to donate your body or some or all of your organs after your death? If so, for what purpose(s) and to which physician or institution? If not, this should also be indicated in the appropriate box.

In the final section, you may designate one or more proxies who would be asked to make choices under circumstances in which your wishes are unclear. You can indicate whether or not the decisions of the proxy should override your wishes if there are differences. And, should you name more than one proxy, you can state who is to have the final say if there is disagreement. Your proxy must understand that this role usually involves making judgments that you would have made for yourself, had you been able, and making them by the criteria you have outlined. Proxy decisions should ideally be made in discussion with your family, friends, and physician.

WHAT TO DO WITH THE FORM

Once you have completed the form, you and two adult witnesses (other than your proxy) who have no interest in your estate need to sign and date it.

Many states have legislation covering documents of this sort. To determine the laws in your state, you should call the state attorney general's office or consult a lawyer. If your state has a statutory document, you may wish to use the Medical Directive and append it to this form.

You should give a copy of the completed document to your physician. His or her signature is desirable but not mandatory. The directive should be placed in your medical records and flagged so that anyone who might be involved in your care can be aware of its presence. Your proxy, a family member, and/or a friend should also have a copy. In addition, you may want to carry a wallet card noting that you have such a document and where it can be found.

MY MEDICAL DIRECTIVE

This Medical Directive shall stand as a guide to my wishes regarding medical treatments in the event that illness should make me unable to communicate them directly. I make this Directive, being 18 years or more of age, of sound mind, and appreciating the consequences of my decisions.

SITUATION A

If I am in a coma or a persistent vegetative state and, in the opinion of my physician and two consultants, have no known hope of regaining awareness and higher mental functions no matter what is done, then my goals and specific wishes—if medically reasonable—for this and any additional illness would be:

☐ prolong life; treat everything
☐ attempt to cure, but reevaluate often
☐ limit to less invasive and less burdensome interventions
☐ provide comfort care only
☐ other (please specify): _____

(Please check appropriate boxes)

	I want	I want treatment tried. If no clear improvement, stop.	I am undecided	I do not want
1. **Cardiopulmonary resuscitation** (chest compressions, drugs, electric shocks, and artificial breathing aimed at reviving a person who is on the point of dying). _____		Not applicable		
2. **Major surgery** (for example, removing the gallbladder or part of the colon). _____		Not applicable		
3. **Mechanical breathing** (respiration by machine, through a tube in the throat). _____				
4. **Dialysis** (cleaning the blood by machine or by fluid passed through the belly). _____				
5. **Blood transfusions or blood products.** _____		Not applicable		
6. **Artificial nutrition and hydration** (given through a tube in a vein or in the stomach). _____				
7. **Simple diagnostic tests** (for example, blood tests or x-rays). _____		Not applicable		
8. **Antibiotics** (drugs used to fight infection). _____		Not applicable		
9. **Pain medications, even if they dull consciousness and indirectly shorten my life.** _____		Not applicable		

SITUATION B

If I am near death and in a coma and, in the opinion of my physician and two consultants, have a small but uncertain chance of regaining higher mental functions, a somewhat greater chance of surviving with permanent mental and physical disability, and a much greater chance of not recovering at all, then my goals and specific wishes—if medically reasonable—for this and any additional illness would be:

☐ prolong life; treat everything
☐ attempt to cure, but reevaluate often
☐ limit to less invasive and less burdensome interventions
☐ provide comfort care only
☐ other (please specify): _____

(Please check appropriate boxes)

	I want	I want treatment tried. If no clear improvement, stop.	I am undecided	I do not want
1. **Cardiopulmonary resuscitation** (chest compressions, drugs, electric shocks, and artificial breathing aimed at reviving a person who is on the point of dying). _____		Not applicable		
2. **Major surgery** (for example, removing the gallbladder or part of the colon). _____		Not applicable		
3. **Mechanical breathing** (respiration by machine, through a tube in the throat). _____				
4. **Dialysis** (cleaning the blood by machine or by fluid passed through the belly). _____				
5. **Blood transfusions or blood products.** _____		Not applicable		
6. **Artificial nutrition and hydration** (given through a tube in a vein or in the stomach). _____				
7. **Simple diagnostic tests** (for example, blood tests or x-rays). _____		Not applicable		
8. **Antibiotics** (drugs used to fight infection). _____		Not applicable		
9. **Pain medications, even if they dull consciousness and indirectly shorten my life.** _____		Not applicable		

APPENDIX 63-2

EXTRAPOLATING STATED PREFERENCES

It is often necessary to infer a prior preference, since advance directives cannot foresee all possible decisions. In addition to using the general rules noted in the text of the chapter, it may be possible to use what a patient did state along with population preference data to calculate the probability that a particular prior preference would have been made if the patient had considered it. For many physicians and proxies, these calculations are reassuring.

Survey preference data from patients completing the Medical Directive provide prior odds for treatment preferences (Table 63-2-1). The same data allow particular preferences to be used as a “test” for other particular preferences. Each decision pair has a likelihood ratio that has been calculated from this data set. So, if the patient stated a prior preference that fits the test preference, the likelihood for all other decisions on the Medical Directive can be found (Table 63-2-2 and its accompanying explanatory footnotes). Together, the prior odds of a preference and the likelihood ratio of the relevant preference pair can be used to calculated the posterior odds that a patient would have had a particular preference (36).

Take the following example:

A patient who is unconscious and has a small chance of recovery has an advance directive stating that (s)he does not want artificial feeding in such a situation, but the question is whether to write a “Do Not Resuscitate” order. The family have no idea what the patient would have wanted. From Table 63-2-1 we see that the prior odds of declining resuscitation in this circumstance is 1.2 (55% of the population declined it). We also know from Table 63-2-2 that the likelihood ratio for this decision is 12.6. Therefore, the posterior odds are 1.2 × 12.6 = 15.1 that (s)he would have declined resuscitation. Therefore, the posterior probability that (s)he would have stated a wish to decline cardiopulmonary resuscitation in an advance directive is 15.1/(1 – 15.1) = 94%.

	Coma/chance		PVS		Dementia		Dementia/terminal	
Rx	Decline	Accept	Decline	Accept	Decline	Accept	Decline	Accept
abx	0.9	1.1	3.1	0.3	1.9	0.5	3.3	0.3
blood	1.3	0.9	4.2	0.3	2.5	0.4	4.8	0.2
cpr	1.3	0.8	4.8	0.2	2.4	0.4	4.7	0.2
dnr	0.8	1.2	3.7	0.3	2.4	0.4	4.2	0.2
dx	0.9	1.1	2.3	0.4	1.6	0.6	2.7	0.4
feed	1.2	0.8	4.8	0.2	2.7	0.4	4.2	0.2
iv	1.1	0.9	3.3	0.3	2.4	0.4	4.6	0.3
ommaj	1.6	0.6	5.1	0.2	3.0	0.3	5.3	0.2
ommin	1.2	0.8	4.1	0.2	2.2	0.5	3.9	0.3
dialysis	1.3	0.8	4.1	0.3	2.6	0.4	4.4	0.3
resp	1.2	0.8	4.0	0.3	2.7	0.4	4.8	0.2

abx, antibiotics; blood, blood transfusions; coma/chance, coma with a chance of recovery; cpr, cardiopulmonary resuscitation; dementia/terminal, dementia with terminal illness; dialysis, peritoneal or hemodialysis; dnr, invasive diagnostics; dx, noninvasive diagnostics; feed, artificial tube feeding; iv, intravenous fluids; ommaj, major operations; ommin, minor operations; PVS, persistent vegetative state; resp, mechanical respiration.
The prior odds for preferences are derived from population data that have been published elsewhere (47). The assumption is that prior odds of a given choice = (proportion of population with that choice)/(1 − proportion of population with that choice).
Some proxies or physicians will have reason to understand that the patient was not well represented by the population data. In these cases, if a calculation is still desired, a numerical estimate of the prior odds will have to be derived from whatever information is available.

WITHHOLDING AND WITHDRAWING TREATMENT: THE DOCTOR-PATIENT RELATIONSHIP AND THE CHANGING GOALS OF CARE

SHIRIN SHAFAZAND
LAVERA M. CRAWLEY
THOMAS A. RAFFIN
BARBARA A. KOENIG

Medical technology and sophisticated therapeutics have enabled physicians to prolong life—or, at the very least, to postpone death—in the face of serious illness. Patients thought to have terminal conditions less than a century ago are now living longer in our intensive care units (ICUs) and hospitals. This increased survival may not always translate into improved quality of life. Our technological capabilities have allowed us to adopt an aggressive approach to "curing" disease and maintaining life at all costs. And when our best efforts fail, we are ill-prepared as a society to deal with the lasting social and emotional consequences. It has become increasingly difficult for patients, families, and health care workers to decide when to stop "saving" a life and when to start the difficult process of preparing for death. What defines a "dying" patient? Must a patient actively decide to forego curative therapy to receive excellent palliative care? More and more often, these decisions are being made in hospital settings: 60% of deaths in the United States are in hospitals (1), and of these, up to 75% occur in the setting of decisions to withdraw or withhold life-sustaining therapies (2). The moment and timing of death is now managed, controlled, and negotiated, often by physicians who have had little formal training in the complexities of decision making or the clinical demands of end-of-life care.

This chapter begins by situating current debates about end-of-life care against the background of the dramatic social changes of the last decade. We then provide a review of the foundational ethical and legal framework governing decisions to withhold and withdraw life-sustaining therapies in the United States. The importance of the doctor-patient relationship in understanding (and enhancing) shared decision making on the trajectory to death is high-lighted. Increasing cultural diversity—a feature of much of the United States and many First World countries— provides a challenge to our fundamental assumptions about end-of-life decision making. Has the bioethics community been too insistent that patients make decisions requiring that they embrace death to receive first-rate palliative services? Finally, barriers to effective communication and approaches to improving end-of-life decision making are discussed. Although we have achieved significant progress as a result of increased attention to end-of-life care, the goal of translating the legal and ethical ideals described here remains incomplete.

SOCIAL AND HISTORICAL CONTEXT

Studying and commenting on death and dying has become a growth industry in the United States. But as little as 20 years ago, the words were rarely spoken outside of the medical "fringe"—for example, in the hospice movement, which developed outside mainstream medical practice and remained there until it successfully lobbied for the Medicare hospice benefit. In marked contrast, death is now defined as a major medical *problem* in need of a solution. And the problem has moved from the periphery of health care, a concern often delegated to nursing or social work, to a position closer to the center of medical practice. Evidence of this transformation—still incomplete—abounds. The Institute of Medicine (of the National Academy of Sciences) issued a major report on methods to improve care for the dying in 1997 (3), and a second report on the death of children appeared in 2002. The American Board of Internal Medicine has published an extensive series of recommendations and suggestions about best practice in the *Annals of Internal Medicine* (4). The American Medical Association conducted a nationwide education campaign to reach as many practicing physicians as possible in an effort to improve their practice in this area, and a similar effort exists within the nursing profession. Hospice and Palliative Medicine has become a recognized specialty in the United States. Major philanthropies have supported this work. The Robert Wood Johnson Foundation has established a national public relations campaign, titled "Last Acts," which aims to transform the culture of dying in the United States. George Soros' Open Society Institute created the "Project on Death in America," including a program to promote faculty scholars in U.S. schools of medicine (coauthors Crawley and Koenig have both received these awards). Perhaps of most symbolic significance, the National Institutes of Health have, for the first time, funded research initiatives in palliative care, primarily in symptom management, albeit on a small scale compared to its overall budget.

The primary solution to the problem of death and end-of-life care over the past three decades has been to institute bioethics practices that shift decisional authority from health care providers to patients. Patients must make concrete "decisions" about resuscitation, the transition from curative therapies to comfort care, and life-extending technologies such as ventilators and tube feeding. A key element in the tool kit of interventions is end-of-life planning, generally in the form of legal instruments like the durable power of attorney for health care. Perhaps not surprisingly, a $32 million, multisite, multiyear study—with the acronym SUPPORT—called into question the foundational bioethics paradigm (5). An intervention that included "state-of-the-art" procedures to elicit patients' preferences for care and to inform physicians of patient choices was deemed a failure. In spite of the results of the SUPPORT study, most of the national programs described continue to incorporate a fairly standard model of end-of-life decision making emphasizing patient choice. There is enormous reluctance to move away from the normative models developed over the past 30 years.

Our current practices are the result of careful ethical reflection by scholars in medicine, law, philosophy, and social science (6,7). These deliberations took place in dialogue with an important series of court decisions reviewed in the section Ethical Principles and Legal Standards. The result was a set of bioethics practices that now exerts enormous influence on clinical decisions at the end of life. The attention paid here to these seminal legal rulings should not lead to the conclusion that court intervention is necessary or desirable when difficult end-of-life choices emerge. Rather, in most instances decision making is best handled within the immediate clinical setting. Most bioethics scholars agree that courts should only be called on in the face of irresolvable conflict, and that even then a clear-cut resolution may not be forthcoming.

ETHICAL PRINCIPLES AND LEGAL STANDARDS

We argue that in the United States the interdisciplinary field of bioethics has come to dominate clinical practice about decision making in end-of-life care. Indeed, the issues associated with care of the dying have been central to the growth of bioethics, propelling its establishment as a field (8). Preserving patient autonomy has been the primary principle guiding many innovations, such as the use of advance directives to aid decision making for incompetent patients. Other foundational principles—beneficence, nonmaleficence, and justice—also influence decisions about withdrawing and withholding treatments in the United States (9,10). However, autonomy, or the right to selfdetermination, generally serves today as the cornerstone of ethical decisions in medicine. The principle of individual autonomy expresses the right of the competent individual to control decisions about his or her body. Although this includes the right to refuse life-sustaining therapies, it does not necessarily imply a complementary right to demand medically unnecessary, ineffective, or harmful therapy.

In the past quarter century, Western bioethics has emphasized the importance of the individual and individual choice (6). Qualities assumed to be present in the autonomous person include an ability to understand medical information, an awareness of individual preferences and values, and the capacity to communicate these values effectively. To facilitate the decision-making process by such competent individuals, physicians have a moral and ethical obligation to inform patients of their diagnosis and prognosis and to discuss available therapeutic options, including potential risks and benefits. Thus full disclosure of information or "truth-telling" by physicians is central to the principles of informed consent and informed refusal that have formed the basis for court rulings on withdrawal and withholding of medical treatment (11,12). It is clear from this brief description that informed decision making can be fraught with difficulties, chief among which is the lack of understanding and effective communication among physicians, patients, and their families. Speaking openly about death is challenging for all parties. We highlight some of these barriers to ideal communication later in this chapter.

In the United States, the legal justification for withholding and withdrawing treatments is based on the doctrines of informed consent and informed refusal (11,12). These principles state that except in emergency situations, all treatments should be initiated with the agreement of patients or their surrogate decision-makers, and that patients or surrogates have the right to refuse any or all treatments, even life-sustaining treatments. These fundamental rights are embodied in common law and legal statutes, and reflect basic protections provided by the United States Constitution (13).

The right to refuse medical treatment has so dominated recent discourse on end-of-life decision making that it is hard to remember that not long ago it was considered unethical and illegal for physicians and patients to terminate life-supporting therapies (14). The right of competent patients to refuse therapy was established in the 1984 case of *Bartling v. Superior Court* (15), in which the California Court of Appeals affirmed that mechanical ventilation could be discontinued at the request of the patient, despite objections by the physicians involved and the hospital providing care. Similarly, in *Bouvia v. Superior Court* (16), the California Court of Appeals established that a competent patient could refuse hydration and nutrition. Although the common law and statutory bases vary from state to state, a competent patient's right to refuse life-sustaining treatment is currently recognized by all American courts (12).

The ethical and legal considerations discussed have focused on the competent adult patient; but what if the adult patient lacks decision-making capacity? Assessment of decision-making capacity, sometimes called *competence*, is particularly complex when issues of withholding or withdrawing therapy are under review, because of the import and potential consequences of the decisions. (See Chapter 62, Assessment of Decision-Making Capacity.) In general, patients are not considered either globally competent or incompetent to make decisions; rather, the evaluation of capacity must be specific to the choice at issue. A patient who is unable to manage his or her financial affairs may be able to make informed choices about her personal care or other key components of palliative medicine. Patients who lack decision-making capacity continue to have the right to forego or limit therapy, if they have expressed this preference beforehand. However, a surrogate decision maker, rather than the patient, must exercise this right. In the ideal situation, a patient can exert control over these decisions by completing an advance directive, generally including the identification of a surrogate decision maker during periods of relative good health and clear thinking. In the absence of such a written directive or of an available and informed proxy decision maker, two standards are used to aid the decision-making process: the principles of “substituted judgment” and “best interest” (17).

The substituted judgment standard holds that decision makers, often family members or close friends, are not making choices based on their own values and beliefs; rather, their role is to “substitute” for the patient by expressing the patient's previously stated wishes. Because of widespread cultural reluctance to engage in active planning for one's death, friends or family members designated as legal surrogates often do not have clear-cut ideas of a patient's wishes. This occurs for many reasons. Frequently no discussion has taken place, especially if surrogates have been delegated through routine legal or estate planning, rather than in conversation with a health care provider. But even a surrogate who has a general understanding of the patient's values may find it difficult to translate stated preferences into clear-cut decisions once the patient is no longer able to decide for him- or herself. If the decisions of the surrogate are not in accord with previously stated patient wishes, or if there is disagreement among family members as to the best course of action, every effort should be made to reach a consensus. If a patient's wishes were not clearly stated or are unknown, then surrogate decision makers should rely on their knowledge of patient values and goals to determine what the patient would desire under existing circumstances. Finally, if the substitute decision maker is unable to make such choices based on the patient's prior statements or values, the “best interest” standard can be used to guide decisions. The surrogate decision maker, in collaboration with physicians and other health care workers, should balance the benefits of initiating or continuing a life-sustaining therapy with its perceived burdens to the patient. If the benefits outweigh the burdens, then the therapy should be continued; otherwise it should be discontinued (17,18). When incompetent patients do not have advance directives or substitute decision makers, the health care team (and rarely, the addition of a designated ombudsperson or courtappointed decision maker) should use the “best interest” standard to make treatment decisions. These principles echo the U.S. courts' rulings in various cases. Although theoretically forceful and legally sound in the clinic, these prescriptions and bioethics practices may be difficult to follow.

The legal principles of informed consent and informed refusal were applied for the first time to the care of incompetent patients during the 1970s in the *Quinlan* case (19). Here the New Jersey Supreme Court ruled that the patient, who was in a vegetative state, had the right to refuse continuation of mechanical ventilation. Because she could not exercise this right directly, her parents could act as surrogate decision makers and make a “substituted judgment” to guide her care. Similarly, in *Barber v. Superior Court* (20), the California Court of Appeals determined that two physicians charged with murder had not committed a crime when, with the permission of the patient's spouse and children, they discontinued artificial nutrition and hydration sustaining the life of the comatose patient. In its decision, the Court not only reinforced the substituted judgment principle set forth in *Quinlan* but also emphasized that all medical interventions should be evaluated according to benefits and burdens to patients. Based on the “best interests of patients,” if the burdens outweigh the benefits, then a particular treatment should be withheld or withdrawn.

Although the rights of incompetent patients to refuse life-sustaining treatments are now uniformly acknowledged in this country, the states vary in their regulations for selecting surrogates and determining what decisions surrogates can make. Some states have statutes that establish a hierarchy of decision makers among family members and relatives. For example, these guidelines specify who a clinician should turn to for assistance with decision making for an incompetent patient, specifying whether to give priority to a grown child or a spouse. There is general agreement that decisions should be based on patients' wishes and values; however, some states require a “high degree of certainty” before allowing surrogate decision-makers to withdraw or withhold treatment (12). The State of Missouri, for example, requires “clear and convincing evidence” of an incompetent patient's wishes before such end-of-life decisions. This position was established in the *Cruzan* case (21), in which the parents of a young woman diagnosed as persistently vegetative requested removal of the feeding tube from their daughter. The Missouri Supreme Court denied this request based on the facts of the case and the State's interest in the preservation of life. The U.S. Supreme Court, in its first consideration of the issue of withholding and withdrawing life-sustaining treatments, affirmed the decision of the Missouri Supreme Court, and by supporting the standard of requiring “clear and convincing evidence” of patient's wishes allowed states to restrict the role of surrogate decision makers. In effect, the Supreme Court allowed each state to decide how strong the evidence of patient wishes needs to be before proceeding with the decision to withdraw life support.

The *Cruzan* case is particularly important for its recognition of the principles of informed consent and informed refusal. In an opinion delivered by Chief Justice Rehnquist, the Supreme Court acknowledged prior rulings establishing the right of a competent person to refuse medical treatment under the Fourteenth Amendment to the Constitution: “The Fourteenth Amendment provides that no State shall 'deprive any person of life, liberty, or property, without due process of law.' The principle that a competent person has a constitutionally protected liberty interest in refusing unwanted medical treatment may be inferred from our prior decisions” (21).

The *Cruzan* ruling acknowledged decisions put forth by prior cases (19,20,22) and declared that the legal principles stated apply to all medical interventions, without distinguishing between “ordinary” and “extraordinary” treatments. Thus, in the eyes of the court, withdrawing and withholding of mechanical ventilation is no different from decisions to withdraw dialysis or nutrition and hydration.

One point discussed in the *Cruzan* case is worthy of mention: The general consensus among bioethicists and the U.S. legal system is that there is no legal and ethical distinction between withholding and withdrawing of lifesustaining therapies (17,22,23). Despite this agreement, health care workers and families have traditionally found it more difficult emotionally to withdraw life support rather than to withhold treatment. Religious and cultural views certainly influence this distinction. An awareness of these views is important in any end-of-life discussions with patients and their families.

Problems in Applying the Model

Although the ethical and legal principles discussed thus far appear clear-cut, making decisions for patients in practice, especially patients lacking clear decision-making capacity, is a difficult task. More and more, our technologies enable us to delay death in patients with advanced diseases. Many treatments offer only marginal benefit, and with a rapidly aging patient population suffering from multiple chronic and disabling illnesses, predicting which exacerbation will bring on a patient's final episode of ill health is possible only in retrospect. When these exacerbations occur, many patients lose the ability to make informed decisions about their own health care, or perhaps clear-cut preferences simply have never been voiced. The important responsibility of guiding treatment decisions falls on the shoulders of substitute decision makers. Surrogate decision makers do not make their decisions in a vacuum. Ideally, the patient's wishes and values should govern the decision-making process; however, the moral and religious convictions of the decision maker, family dynamics and cultural influences, and (rarely) possibilities of secondary gain undoubtedly play a role in these decisions. As stated in the *Cruzan* ruling, “There is no automatic assurance that the view of close family members will necessarily be the same as the patient's would have been had she been confronted with the prospect of her situation while competent” (21). A lack of clear and open communication between patients and their families and physicians is in part responsible for the difficulty faced by surrogate decision makers.

Many American families shy away from discussing death and the dying process openly (24). As a result, even patients who feel strongly about limiting life-sustaining therapies may fail to communicate these wishes to loved ones. The minority of adults who express their wishes through advanced directives do so in vague terms, often failing to provide clear guidelines for decisions regarding withdrawal or withholding of specific therapies such as nutrition, hydration, and mechanical ventilation. More important, patients do not discuss these directives with family members or their physicians, thus losing an opportunity to verbally express their values and beliefs and perhaps clarify some ambiguities. In a series of studies reported in 1997, Teno et al. noted that only 12% of patients with advance directives had talked to their physicians before completion of the document (25). Not surprisingly, only 5% of advance directives contained specific instructions about life-sustaining therapies (26). It is very difficult for anyone to select options from a list of imagined life-extending therapies, such as dialysis or intubation; patients often cannot express clear preferences about care in the abstract. In fact, the idea that all patients have clearly expressed preferences for specific interventions is conceptually flawed. More often, preferences emerge as patients interact with their care providers (27).

Given these uncertainties, surrogate decision makers are left with the difficult task of interpreting a patient's previous comments or using their understanding of the patient's goals to make decisions about a situation not previously experienced or considered by the patient. Empirical research using anthropological methods has shown that patients and families often have quite varied understanding of the nature of critical “decisions,” particularly in the ICU setting (28). Because events unfold under extreme time pressure, the medical profession and family members often find themselves at odds over decisions to withdraw and withhold therapies. One of the more challenging conflicts arises when surrogate decision-makers or patients themselves demand therapies that seem useless, unreasonable, or “futile” to the medical team. These conflicts are due in part to differences in treatment goals and values among patients, their decision-makers, the health care team, and the medical institution. Poor communication, uncertainties surrounding disease severity, and high expectations for the success of medical therapy serve to fuel frustrations and

create an environment of mistrust.

Based on the ethical principles of beneficence and nonmaleficence (providing benefit; avoiding harm) and distributive justice (using scarce health care resources fairly), a physician has no ethical obligation to provide treatments that he or she deems medically futile (29). The purpose of life-sustaining interventions is to benefit patients and promote their well-being. Theoretically, futile interventions are those that do not confer any benefit and thus have no intrinsic value. At an operational level, a straightforward definition of futile treatment has proven difficult to implement, because no objective measures of futility exist, and its application in particular cases is inevitably subjective and open to abuse. Arguments in favor of limiting or withholding futile treatments, even against the wishes of patients and families, are also made based on the principle of nonmaleficence. According to this reasoning, health care professionals have a moral obligation to protect the patient from harm; interventions considered futile may cause unnecessary pain and suffering and may have harmful side effects, thus justifying a decision to withhold certain interventions defined as futile, such as resuscitation attempts in seriously compromised patients. Furthermore, health care institutions sometimes limit life-sustaining therapies by establishing policies that restrict access to intensive care or coronary care units, a decision supported by the ethical principle of “distributive justice,” in which use of costly therapies unlikely to provide benefit is not justified from a societal perspective. It is important to remember that decisions about the just allocation of scarce health care resources are best made at the institutional or societal level, and not by any one physician or other health care provider faced with the care of a particular terminally ill patient. Even though this view is widely espoused, health care professionals still experience the troubling dilemma of providing care they deem futile. And some bioethicists have argued that clinicians do have an obligation to consider the “costworthiness” of the interventions they recommend (7).

As discussed, there is no clear definition of medically futile therapy. A narrow definition of medical futility focuses on the “physiological futility” of an intervention. Therapies that do not achieve their physiological goal are futile; withholding these therapies does not cause any harm and may benefit the patient by avoiding painful interventions. The physician's professional training and experience determine whether interventions are physiologically effective. In the ICU, for example, the continued use of vasoactive medication to treat hypotension, when it is clear that the medication has not been successful, is futile therapy using this narrow definition.

The American Thoracic Society statement on withholding and withdrawing therapy defines a life-sustaining therapy as futile if “reasoning and experience indicate that the intervention would be highly unlikely to result in meaningful survival for that patient. Here, meaningful survival specifically refers to quality and duration of survival that would have value to that patient as an individual”(29). This statement exhibits the many difficulties in defining futility; in the absence of explicit statements from the patient, determining the “quality of survival” that is valuable to any patient is a matter of judgment. Furthermore, a major obstacle to decisions based on the concept of medical futility is that, ultimately, physicians cannot predict death or prognosis in any one patient with absolute certainty (30). The best we can provide is an estimate of the probability of survival or treatment effectiveness based on studies in the literature or one's own clinical experience. This does not mean that physicians should be overly preoccupied with uncertainty, thereby ignoring their professional obligation to offer patients and families realistic predictions; Christakis argues that this is a key moral obligation central to medical practice, even if recently ignored in favor of an emphasis on therapeutics (30). Uncertainty contributes to physicians' tendency to delay engaging patients and family members in end-of-life discussions. In addition, family members who are desperately seeking a way to hold on to their loved one may see this uncertainty and hesitancy as a sign that a “miraculous” recovery may still be possible. Because of these difficulties, the concept of medical futility as a strategy for solving the complex debates surrounding appropriate care for terminally ill patients has lost its initial appeal. This strategy, particularly when instituted by health care institutions, may provide some guidance for clinicians, but is unlikely to be the panacea imagined when the futility debates emerged in the early 1990s.

Early and frequent communication between members of the health care team and the family is of paramount importance in reaching decisions to withdraw or withhold life sustaining therapies, particularly if these decisions are motivated by the clinical team's perception that further treatment is futile. When conflicts arise, physicians should make every effort to understand why patients or surrogate decision-makers persist in what is medically perceived to be futile therapy. Do their objections have an emotional overlay such as anger, denial, despair, or guilt? Are there cultural or religious beliefs that influence these decisions? Do decision-makers fully understand the prognosis and likelihood of poor outcomes? Has communication among all parties fostered trustworthiness, or is there a sense of mistrust? Are families and patients getting mixed messages from members of the health care team? Finally, members of institutional ethics committees, as well as religious and community leaders, should be consulted in the resolution of such conflicts.

Many policy makers and clinicians were hopeful that the ethical and legal reforms of the past few decades, translated into concrete bioethics innovations, would go a long way on the journey to improved end-of-life care. However, we suggest that an unexamined demand of the new practices— the requirement that patients embrace the idea that they are dying before making a transition from curative to palliative care—is one reason that the problem of managing death and improving end-of-life care remains unsolved. We became critically aware of the limitations of our clinical bioethics practices governing end-of-life decisions when confronted with California patients from varied ethnocultural backgrounds. The legal and policy reforms of the past decades served this population poorly. An extensive research program examining the challenges of end-of-life care for a diverse patient population has opened our eyes to limitations in the system more broadly (31). We now believe that the implications of our thinking about cultural issues are directly relevant to the care of all patients.

ETHNOCULTURAL DIVERSITY AND CULTURALLY SENSITIVE COMMUNICATION

Throughout this chapter, ethical principles and legal standards governing the withdrawal and withholding of life support have been described. The fact that these bioethics norms embody a Western philosophical viewpoint is rarely pointed out (32). Given the cultural diversity in the United States, physicians are increasingly involved in the care of patients with whom they are not familiar or who do not value the same principles. Given the history of racial discrimination in the United States, others may not trust that standards will be applied impartially when the boundaries between life and death are negotiated. Effective communication with patients and their families requires awareness of one's own values and cultural beliefs and an appreciation of cultural differences (33). In this section, differing cultural perspectives are presented using a case illustration. The case is a composite, drawn from previous research (34) and clinical experience.

Informed consent and informed refusal, which are paramount to respecting patients' rights to self-determination or autonomy, reflect dominant Western values, which privilege the individual. Many cultures, especially Eastern and Asian subcultures, value the family or other broader social unit over the individual. Also, other health care systems may place greater emphasis on the physician's role in protecting the patient from harmful information (beneficence), rather than on the clinician's duty to enable patient decision-making (and enhance autonomy). In a study conducted by Ruhnke et al. (35), Japanese and American physicians and patients were asked to complete a survey assessing their preferences in various end-of-life scenarios. In response to a vignette concerning a cancer patient, 80% of U.S. physicians and only 17% of Japanese physicians felt that the doctor should disclose a cancer diagnosis to a patient. A higher proportion of Japanese patients (42%) felt they should be told of the diagnosis; however, this number was still much lower than that of their American counterparts (81%). The majority of Japanese physicians (80%) and patients (65%) agreed that the doctor should tell the family and allow them to decide whether the patient should be informed. This is in contrast to U.S. physicians (6%) and patients (22%), where a minority chose family-centered decision-making over individual autonomy, although it should be noted that patients endorsed this option more often than physicians. Difference such as these are also found when comparisons are made among U.S. ethnic groups. Blackhall et al. found significant differences in how older Californians valued the concept of autonomy in advance planning for care at the end of life; patients from Korean and Mexican backgrounds gave it less prominence than white or African American elders (36).

In Western biomedicine, “full disclosure” is viewed as essential to the informed decision-making process; however, as illustrated in the Case Example below, not all patients and families value truth-telling equally.

Case Example

Mr. Jeong's cancer symptoms developed in China before he immigrated to the United States with his wife and two sons. Mr. Jeong (a pseudonym) does not speak English, but his older son, who speaks English well, accompanies his father to the clinic and serves as the translator. Since his arrival in the United States, Mr. Jeong has received chemotherapy for his metastatic colon cancer. He also is taking traditional Chinese medicines. The cancer has not been responsive and is rapidly progressing. The health care professionals taking care of Mr. Jeong wish to discuss his preferences for withholding and withdrawing treatments and end-of-life care, including resuscitation choices. On the assumption that the patient must be fully informed of the diagnosis, treatment, and prognosis to make important treatment and end-of-life decisions, they ask his son to translate direct information about his medical condition. The son insists that he should be the one to make these decisions for his father, and that Mr. Jeong would be harmed by the information the clinicians wish him to translate.

What would be required for Mr. Jeong to be truly informed about his diagnosis and prognosis to participate in end-of-life decision making? And more important, to what extent does Mr. Jeong wish to be involved in the decision-making process? By relying on family members instead of a professional interpreter for translation, these questions may not be answered in a straightforward manner. Although the ethical principle of autonomy supports a patient's right to make decisions about care, it does not imply that Mr. Jeong is *required* to make decisions himself. Competent patients should be given the opportunity to make these decisions, but health care workers must accept patient preferences for delegating the responsibility to other members of the family (34).

In conversations with Mr. Jeong's son, an important cultural preference was highlighted: “For us Chinese, we are not used to telling the patient everything, and patients are not used to this either. If you tell them, they can't tolerate it, and they will get sicker.” In fact, the patient's son was quite distressed when he was asked to translate discussions about withdrawal and withholding of treatments. “I did not want to do this, but the doctor found a social worker who speaks Cantonese, and she told my father everything.” When interviewed separately, the oncologist treating Mr. Jeong expressed dissatisfaction with the behavior of the older son: “He came to every visit and was always asking for more chemotherapy for his dad although it was completely unrealistic. He did not allow his dad to express his preferences and he certainly did not wish to discuss end-of-life care.” The end result of this failed communication affected Mr. Jeong dramatically. In response to the straightforward questions

posed by the translator asking if he wished to “limit” therapy, the patient refused to forego resuscitative efforts and asked for further experimental chemotherapy, precluding a referral to the local inpatient hospice where his symptoms could be better managed.

The frustration of the oncologist and the despair of the son are indicative of failed communication as well as differing cultural norms and values. The existing language barrier and absence of “cultural sensitivity” (37,38) were obstacles to effective communication in this case. Cultural sensitivity refers to an awareness of the impact of culture on a patient's values, beliefs, and worldviews. To achieve effective communication and resolve conflicts, physicians and health care workers need to acknowledge these cultural differences, remain nonjudgmental in the face of unfamiliar beliefs, and be willing to negotiate and compromise when differences arise. The reader may notice that this stance is wise in all clinical encounters, a point we endorse.

Table 64-1, based on previous work by Crawley et al. (37,39), reviews general strategies for culturally effective care. These strategies are relevant to all clinical decision making, including discussions about withholding and withdrawing life-sustaining therapies. Additional approaches specific to the end-of-life arena are reviewed by James L. Hallenbeck (see Chapter 47, Cross-Cultural Issues). Appreciation of the cultural diversity in our society today, accompanied by efforts to incorporate cultural sensitivity into day-to-day interactions, determines a good doctor-patient relationship. Needless to say, every relationship is unique and should be tailored to the situation and to the individual. To assume that all patients from a particular culture share similar beliefs and worldviews is to perform a grave disservice to patients. Indeed, stereotyping can be harmful, as well as indicative of disrespect. Cultural awareness serves as a generalized guide; physicians should use open-ended and empathic questions and comments to understand each individual patient's preferences and values.

Identified problems	Strategies
Communication	Be alert for problems, even when patients and physicians share the same language. Check explicitly that patients and physicians have understood each other.
Language barriers	Use trained medical interpreters. When possible, avoid using family or friends to translate.
Caring for specific populations	Increase knowledge of the cultural, economic, and sociopolitical contexts of interactions through guidebooks, community representatives, religious leaders, or professional colleagues.
Conflicting values	Elicit information of patient's or family's explanatory model of illness. Elicit patient's expectations for care. Identify shared values. Be willing to modify own position to reach a mutually acceptable solution. Seek consultation or assistance from other health care workers, institutional ethics committee, or community and religious leaders when necessary.
Mistrust	Respectfully inquire about past or present incidents that might have engendered mistrust. Listen to the patient's story and acknowledge the patient's experience. Address issues that patient identifies as important.
Negative attitudes of providers	Honestly examine your own value system and attitudes toward certain groups; identify and strive to eliminate discriminatory behavior.

TABLE 64-1. STRATEGIES FOR CULTURALLY EFFECTIVE CARE

Mr. Jeong's dilemma can also be attributed to a too-rigid adherence to bioethics norms, as well as to the assumptions underlying those norms. The oncologist was unaware that predicting a patient's imminent death is commonly assumed to bring it about; speaking of one's death is a strong cultural taboo in Chinese society. This may appear ironic in Buddhist societies in which the observant meditate daily about death; however, the *individual's* dying is not the focus of ritual practices (Dr. Craig Janes, *personal communication*, 2001). Mr. Jeong and his son, being recent immigrants, were unfamiliar with the biomedical expectation that patients actively accept that a transition in care is initiated by a patient's active choice. In the course of this transition, curative goals are set aside and palliative ends embraced.

THE DOCTOR-PATIENT RELATIONSHIP

A common theme emerging in our discussion thus far is the importance of effective communication between physicians and patients or their surrogate decision makers. Our values, beliefs, and virtues have an important impact on how we take care of our patients and how successfully we communicate with them. Beauchamp and Childress (40,41) identify four virtues for health care professionals: compassion, trustworthiness, discernment, and integrity. Compassion entails an active concern for the well-being of patients and an empathetic response to their suffering. Honesty and professional competency are necessary to foster a trusting environment. Patients are more likely to trust physicians who take the time to listen and respond to their concerns. The essence of discernment is “the ability to understand what needs to be done for patients, understanding how to do it, and then acting with sensitive and caring responses” (41). The final virtue, and perhaps the most important one, is integrity. Moral integrity is the ability to consistently apply ethical and moral norms to decisions, actions, and behaviors; this virtue should dictate every aspect of the practice of medicine. When patients seek care and medical advice, they entrust their health and often their lives to their physicians and other team members. Faced with such a heavy responsibility, physicians owe it to their patients to be strong advocates of their well-being and to approach each patient with the utmost compassion, professionalism, and integrity. Applying these ideals to end-of-life care presents unique challenges but offers considerable rewards.

Emanuel and Emanuel (42) have put forth four models of the physician-patient relationship: paternalistic, informative, interpretive, and deliberative. In the past century, U.S. medicine has seen the pendulum swing from a paternalistic model, in which physicians acting in the best interests of their patients unhesitatingly dictate therapeutic options, to a more informative model, in which patient autonomy is of paramount importance. The objectives of the informative model are to provide the patient or surrogate decision maker with all the information necessary for informed decision making. In its extreme form, the physician then merely carries out the intervention selected by the patient and does not bias the decision-making process in any way.

Somewhere in between these two extremes lies the essence of a good doctor-patient relationship. In the interpretative model, the physician informs patients and their families of the diagnosis, prognosis, and potential risks and benefits of treatment, but takes this interaction one step further by helping patients articulate their values. The physician can then determine which treatments best realize these values. The final decision is left up to the patient. The deliberative model goes further, allowing the physician to share his or her experience and recommendations with the patient. In this model, physicians suggest therapeutic options that recognize the patient's values, but also guide the decision-making process by suggesting what the patient should do (42,43). Depending on individual circumstances and the characteristics of each patient, the physician may use any one of these models at a given time.

Decisions to withhold or withdraw life-sustaining therapies are inevitably emotionally charged. Ideally, these discussions should be initiated early on as part of the overall goals of therapy, rather than abruptly when all attempts at a “cure” have failed (44). Early consideration allows the competent patient time to determine his or her goals and even encourage family discussions. Palliative care and relief of patient symptoms should be addressed in conjunction with “active” treatment. This also may help diminish the feelings of abandonment that occur when there is a sudden shift of treatment goals from “aggressive” measures to palliative care. Obstacles to this ideal are significant.

PREDICTING AND EMBRACING DEATH: A DILEMMA FOR BIOETHICS

The progress in the technical dimensions of palliative and supportive care highlighted in this textbook is contingent on a set of “decisions” or “choices” made in the course of a patient's uncertain trajectory toward death. Although some argue for and practice “mixed models” of care, in which palliative goals are incorporated into management early in the course of aggressive treatment for cancer or other lifethreatening disease, physicians on the whole do not initiate comprehensive end-of-life care until the patient is defined as “terminal.” Cure remains the clinical focus and the patient's goals and values do not guide decision making; rather, they are often secondary to curative efforts.

Considerable empirical research documents the powerful institutional forces that lead to serious delay in assigning a particular patient the label “dying.” Patients may not be defined as terminal until all imaginable therapeutic options have been tried and shown to fail (45). Similarly, patients one knows well or who are highly engaging may not be defined as in need of palliation, because of the powerful symbolic commitment to cure (45). Emanuel and colleagues have shown that fully one-third of cancer chemotherapy prescribed could be classified as “futile” (46). Most hospice referrals are delayed until the patient is in the last week, or even days, of life (47). Physicians overestimate the likelihood of survival to hospital discharge after resuscitation attempts, estimating that 40% of patients survive when the actual figures range between 10% and 20% (30). The SUPPORT study revealed that “do not resuscitate” orders were not written until the critically ill ICU patients studied were facing imminent death, in spite of an overall prognosis of less than 6 months (5). Callahan calls this “technological brinkmanship”: engaging in active and aggressive treatment until the last moment, and only then pulling back, hoping one has not gone too far in prolonging the dying process (48). Christakis emphasizes how the demands of institutions, as well as characteristics of both physicians and patients, shape professional resistance to predicting death (30).

These observations suggest why end-of-life care remains a significant social and economic challenge. In spite of significant progress in educating health care professionals and the public about the importance of palliative care, powerful countermessages abound. On the one hand patients are exposed to national campaigns to endorse the positive ideal of end-of-life care. On the other hand they are inundated by a different sort of media message. Large, full-scale advertisements seem to suggest that patients need only surf the Internet to find the right clinical trial, the right experimental drug to “cure” them. Cancer centers generally tout their success stories, not their excellent palliative care services.

A further flaw of the “choice” model is the presumption that health care providers offer their patients real and meaningful choices. Given the power differentials separating patients from providers, as well as varied access to medical knowledge, a neutral presentation of information is unlikely. Ethnographic research with cancer patients reveals that “decisions” leading to specific alternatives are often not recognized by patients or acknowledged by physicians. In describing a patient's “decision” to accept recommended surgery, a physician informant stated, “Well, there were decisions but it wasn't like there was any choice involved” (34).

The acceptability of the autonomy paradigm in the clinical arena is not due to its inherent or intuitive acceptance as the “right thing” to do; in fact, it was actively resisted when introduced in the 1970s. The seemingly simple “principlist” approach of much clinical bioethics—autonomy, beneficence, nonmaleficence, and justice—has been accepted in the clinical arena in part because of the profound time compression clinicians face. There is little opportunity for timeconsuming moral reflection in the everyday encounter; when a difficult situation cannot be ignored, clinicians prefer maxims to memorize, rules to apply, and, if at all possible, an algorithm to follow to resolve the situation. Although the autonomy paradigm was initially resisted because of its inherent challenge to professional authority, its procedural approach has been easily adopted as the quick “ethical fix” to the challenges presented by the clinical demands of end-of-life care, symbolized most clearly by the availability of new technologies. In spite of strong critiques of principlism in general, and the over-weighting of autonomy in particular, bioethics practices have been accepted as dogma in the clinical setting (31).

Rather than decision-making algorithms, effective communication among health care providers, patients, and their families is key to the success of compassionate end-of-life care. For certain patient groups this goal is more easily achievable. Cancer patients often have a predictable trajectory, allowing physicians to make accurate predictions about declining health status; such predictions are much harder in end-stage organ disease and the dementias, conditions that account for a significant percentage of mortality. Those with insurance and full access to health care resources are better served by current models of decision making than the poor or disenfranchised. Our analysis of focus groups conducted with African American physicians in four geographic regions of the United States revealed that palliative and end-of-life care are not considered top priority issues (Crawley, *unpublished data*, 2001).

CONCLUSION

Technology and medical therapeutics serve to prolong life and postpone death, at times at the expense of a good quality of life as patients near death. Patients and families are encouraged, in spite of general reluctance, to make decisions about withdrawing and withholding life-sustaining therapies. These decisions occur in highly charged emotional settings in which the strength of the doctor-patient relationship is put to the test. When providing care for patients from diverse cultural backgrounds, the Western emphasis on patient autonomy and active decision making needs to be balanced with the views and cultural beliefs of individual patients. The considerable challenges of caring for patients from societies in which death is not openly embraced point to the limits of abstract decision-making models for all patients, not just those ethnically distant. Current practices create a fiction, the illusion that patients may simply choose *not* to die (31). A more realistic model of care would not require that patients actively embrace death to receive excellent palliative care. Joanne Lynn, among others, promotes a strategy of identifying a narrow range of truly meaningful options that can be built into systems of care, while at the same time structuring a health care system that focuses on excellent practices (e.g., pain and symptom management) that do not need to be “chosen,” that instead become embedded in clinical practice. The “choice points” built into the current bioethics-driven end-of-life practices, in particular the complete fetishizing of decisions about resuscitation, would be a welcome casualty should Lynn's approach be adopted.

We have argued that a focus on discrete individual choices as key signposts on the pathway to death is descriptively invalid, and is resisted by both care providers and patients. It provides only the illusion of control and distracts from needed reforms. Paradigms of clinical care shaped only by utility calculations ignore the existential and unavoidable suffering of the sick and their families. True engagement and open communication is too easily avoided when decision-making is the sole focus. Clinical practices and procedures derived from this model deny the inherent uncertainties of medical treatment; they are based on a false hope that the inevitable failures of the body can be controlled.

ACKNOWLEDGMENTS

We wish to thank the following for generous support of our work in bioethics and decision making, end-of-life care, and cultural issues in health care: The Greenwall Foundation, the Robert Wood Johnson Foundation, the Open Society Institute, and the Nathan Cummings Foundation. PALLIATIVE CARE AND PHYSICIAN-ASSISTED DEATH

BARBARA A. SUPANICH

During the past 10 years, a thoughtful and intense debate regarding physician-assisted death has been occurring. In the United States, the debate has involved the U.S. Supreme Court (1,2), multiple physician, patient, and public surveys (3,4,5,6,7,8 and 9), and many discussions in communities and state legislatures. Broadly, the issues have focused on the morality, ethics, and legality of physician-assisted death. In 1997, the U.S. Supreme Court made a unanimous decision to uphold the right of states to prohibit physician-assisted death. The decision also allows states to permit it (1,2,10,76,77).

For those involved in hospice and palliative care, there are special concerns and challenges related to the issue of physician-assisted death. This chapter will review some of the major ethical arguments, look more specifically at the challenges posed for palliative care professionals, and propose ethically sound clinical strategies for responding to the challenges of a patient's or family member's request for physician-assisted death.

DEFINITIONS

It is important to begin a discussion of physician-assisted death by clearly defining ethical terms used in conversations about end-of-life care treatment options. *Withdrawing or withholding life-sustaining treatment* refers to decisions to stop or not initiate certain medical therapies, with the anticipated outcome that the patient will die from the underlying disease. Common examples include withdrawing a ventilator from a patient in end-stage emphysema, forgoing the use of antibiotics in a patient with terminal cancer and suspected pneumonia, and refusal of tube feeding by a patient with an end-stage neuromuscular disease.

Active euthanasia refers to the direct administration of a lethal agent to the patient by another party with a merciful intent. As commonly practiced today in the Netherlands, this might involve the physician injecting intravenously a quick-acting sedative followed by a paralytic agent to halt respiration. Active euthanasia may be voluntary, involuntary, or nonvoluntary, depending on whether the patient has freely chosen it, has freely rejected it, or has offered no opinion. This chapter considers only *voluntary active euthanasia* because that is the only form being seriously advocated in the United States today.

Assisted suicide refers to the patient intentionally and willfully ending his or her own life with the assistance of another party. This assistance may include different levels of involvement—merely providing information about how to commit suicide, providing the means to commit suicide, such as a lethal quantity of pills, or actively participating in the suicide, such as being present at the scene and inserting an intravenous line through which the patient may then administer a lethal dose (11). The widely publicized actions of Dr. Timothy Quill (12) and Dr. Jack Kevorkian (13,14) provide examples of the second and third levels of involvement, respectively.

For this chapter, *assisted death* refers jointly to the practices of voluntary active euthanasia and assisted suicide. Most of the ethics literature has focused on the special problems of the physician's role, that is, the practice of *physician-assisted death*. In a hospice context, the roles of the other health professionals and the family are extremely important and, in some cases, the patient may request assistance in dying from one or more of them as well as (or instead of) from the physician.

It is also important to be clear about what is *not* assisted death. As noted, it is *not* an assisted death if a competent person decides not to initiate a specific therapy (e.g., further chemotherapy, antibiotics for a pneumonia or another septic process, renal dialysis, or artificial nutrition or hydration). It is not an assisted death to withdraw any of these options from the terminal patient. The use of high-dose opioids when the intent is to relieve pain and not to hasten death is *not* physician-asssted death. Although many still believe that high-dose opioids pose a serious risk of fatal respiratory depression, palliative specialists know that this very seldom occurs with proper titration of analgesic doses, even when very large doses of opioids are administered in terminal illness. (15,16). Even if respiratory depression is a foreseen (but unintended) consequence of adequate analgesia, administering the analgesic is not considered to be physician-assisted death.

Withholding and withdrawing life-sustaining treatment is widely accepted today both in ethics and law as appropriate and compassionate care. This clinical practice is ethically and legally acceptable only when the competent patient is fully informed and freely chooses this option or has clearly documented these choices in an advance care plan document. Some, notably Rachels and Dixon (16,17), have argued that there is no morally relevant difference between this practice and the practice of assisted death. Dixon argues that fairness requires that if we legalize physician-assisted death, we should also make active euthanasia legally available (17). In this chapter, without giving detailed arguments, I will assume that if assisted death can be justified, it must be justified on its own merits and not merely because it shares some ethical features with the relatively uncontroversial practice of withdrawing or withholding life-sustaining treatment (18,19,20 and 21).

ETHICAL ARGUMENTS

Patient Integrity

Patients who are living with a life-limiting disease want their personal values and goals maintained and respected. For many patients, the most important personal values are autonomy and personal integrity. From the patient's perspective, this means that one's belief system, personal values, and life goals will be honored and respected and that they will play a vital role in treatment plans and palliative care planning. Most patients have the expectation that their suffering will be moderated, their pain will be controlled, and they will have the opportunity to have meaningful discussions with their physicians and family concerning the type and extent of their treatments (9,10,22,23 and 24). A recent report of the Oregon Health Division (36,77) confirms that 67% of the 26 persons who experienced a physicianassisted death in 1999 identified loss of autonomy, an inability to participate in activities that would make life meaningful, and loss of control of bodily functions as reasons for seeking an assisted death.

Proponents of assisted death would argue that they are honoring the personal integrity and personal autonomy of the person by being willing to discuss and assist the patient with *all* treatment/care choices for the patient, including assisted death. Proponents also claim that physician-assisted death minimizes harm to the patient and others. They argue that the patient should determine what counts as harm and may legitimately decide that ongoing life with severe suffering is a greater harm than a painless death (25,26).

Opponents claim that however important the moral value of patient autonomy, it is insufficient to justify the practice of assisted death (10,17,18,27,28,29 and 30). Autonomy may justify withdrawing or withholding treatment because that constitutes a negative right of noninterference, which is strongly grounded in the concept of respecting personal bodily integrity. But it cannot justify a positive right to demand that others take specific actions to promote one's own idea of one's welfare—especially when those actions cause death. Some opponents also make the claim that causing a death is one of the greatest harms that a clinician could inflict on a patient. The basic principle of “do no harm” should be understood as requiring a healing relationship between the physician and the patient and, thus, is in

direct conflict with respect for patient autonomy when assistance in dying is requested.

Compassionate Response to Suffering

For some physicians, a request by a patient for death assistance is viewed as a plea to release the patient from intolerable suffering. From this perspective, such assistance is understood as an act of compassion. Quill and others (31,32 and 33,40) have argued that a willingness to discuss this option with the patient often may act as a suicide preventive because once the patient's concerns and fears have been fully discussed, the physician may be able to propose alternative means of relieving suffering short of death (8,10,34,35 and 36). By contrast, if physicians refuse to offer assistance, suffering patients may avoid these searching conversations and instead commit suicide in a manner that actually increases their own and their family's suffering.

It is a serious mistake to equate suffering narrowly with pain and other unpleasant physical symptoms. Suffering is defined through the experiences of the individual, which includes a personal sense of impaired quality of life, and is understood as a fundamental threat to one's wholeness as a person. Suffering is ultimately tied to one's personal belief system. It reflects how those beliefs define the reality of the human person and how one experiences an illness in the overall context of one's life journey and personal expectations for the future. Two patients may report similar symptoms but have vastly different experiences of suffering (35,37,38,39 and 40,70).

Proponents of assisted death point to the multifaceted and complex nature of suffering as a defense for the individual's right to choose a quicker death because no one can really comprehend the severity of anyone's suffering. The challenge for those who provide palliative care and hospice care is to develop a plan which applies the breadth and depth of palliative care, that is, to attend to the physical, emotional, and spiritual needs of patients and their families within the context of each patient's belief/value system. We are faced with unique challenges when a patient has seemingly lost all hope for relief of his or her suffering. Although excellent palliative care and hospice care should greatly reduce the number of patients who may request death assistance, it would not negate the need for this option in some cases.

By contrast, opponents claim that proponents have a shortsighted and simplistic approach to the relief of suffering. Precisely because suffering is multifaceted and intimately tied to personal meaning, there are numerous options to offer suffering individuals to assist them in restoring a sense of meaning in their lives. To relieve suffering by eliminating the sufferer must always be viewed as an inadequate response. Attending adequately to loneliness, fear of death, depression, unresolved conflicts, lack of forgiveness, anger, and hopelessness is harder work but ultimately will allow a better personal resolution. This is especially important because physicians and families may tend to project their own suffering onto the patient and therefore conclude that a premature death is actually the merciful choice from the patient's perspective (8,10,40,41).

Safeguards

Both proponents and opponents of physician-assisted death agree that safeguards are needed to protect the patient's safety and integrity and to protect society from physicians who might abuse the end-of-life choice (10,25,30,31,42,43). Table 65-1 lists some commonly proposed safeguards and guidelines for discussing the choice of assisted death (31,42).

The patient must have a condition that is incurable (not necessarily terminal) and is associated with severe suffering without hope of relief.
All reasonable, comfort-oriented measures must have been considered or tried.
The patient must express a clear and repeated request to die that is not coerced (e.g., emotionally or financially).
The physician must ensure that the patient's judgment is not distorted—that is, the patient is competent to make a rational treatment choice.
Physician-assisted death must be carried out only in the context of a meaningful physician-patient relationship.
Consultation must be obtained from another physician to ensure that the patient's request is rational and voluntary.
There must be clear documentation that the previous six steps have been taken and a system of reporting, reviewing, and studying such deaths must be established.

From Quill T, Cassel C, Meier D. Care of the hopelessly ill—proposed clinical criteria for physician-assisted suicide. (Sounding Board) *N Engl J Med* 1992;327:1380; and Miller F, Quill T, Brody H, et al. Regulating physician-assisted death. *N Engl J Med* 1994;331:119, with permission.

TABLE 65-1. SAFEGUARDS AND GUIDELINES FOR THE DISCUSSION OF ASSISTED DEATH

As previously discussed (see the section Compassionate Response to Suffering), proponents believe that patients are the best judge of their own suffering and should have the option of discussing their situation with their personal physicians and developing a mutually agreeable plan for control of their pain and suffering (71). Proponents also believe that repeated and compassionate conversations between the patient and the primary physician over time will build the trust and rapport necessary for honest and uncoerced conversations among the patient, physician, and family members. Many proponents also believe that consultation with at least one other physician is a vital safeguard. A parallel safeguard is the assurance of accurate and clear documentation that all of the guidelines have been followed.

Most opponents would agree that patients are the best judge of their own suffering and that all reasonable comfort measures should be considered and tried. They would agree that the more open and frank discussions between the physician and the patient should occur on topics such as pain control and the patient's perception and experiences of suffering. In the opponents' opinion, these types of discussions and the subsequent individualized plan of care for the patient would negate the need for the option of assisted death. Opponents see the potential for coercion as very real and often quite difficult to ascertain so that the proposed guidelines would be inadequate in practice. Opponents are also concerned about the erosion of the physician-patient relationship occurring when physicians start providing the means of death for their patients. They see flaws in the consultation and documentation guidelines. They think that a physician could and would choose another physician of like mind to serve as consultant and are skeptical that any documentation system could assure consistency and compassion among physicians and guarantee safety and sensitivity for patients (10). Proponents are encouraged by the processes, documentation, and safeguards developed in Oregon (36).

Professional Integrity

Opponents of physician-assisted death often argue that causing death is inconsistent with the moral integrity of the physician, who should always strive to be a healer and never a killer (62). In this view, even if society deemed it appropriate to permit assistance in dying, ethical physicians would be obligated to refuse to provide such assistance. Some other group of professionals or technicians would have to be appointed by society for that role (44,45). Similar arguments of integrity have been made on behalf of nurses, pharmacists, and other health care professionals (29,46,47,48 and 49).

Some proponents of physician-assisted death claim that the opponents rely on too narrow a conception of the moral goals of medicine. Healing in the usual sense, they claim, is but one of the goals that define the content of the physician's professional integrity. Relief of suffering, respect for the patient's voluntary choices, and aiding patients to achieve the most peaceful and dignified death possible are also worthy aims. Therefore, suffering that has been unrelieved by excellent palliative care in a patient who has made repeated voluntary requests for death assistance would constitute an exception to the general prohibition. In such narrowly defined cases, a physician could assist death while maintaining ethical integrity (so long as assisting death did not violate any of that physician's personal ethical, moral, or religious values) (50).

Slippery Slope

Concern about a “slippery slope” is one of the main arguments raised by opponents. They contend that once the legal barriers to physician-assisted death are broken, there will be little justification for limiting this practice to only the terminally ill. What is today an *option* to choose assisted death might become an *obligation* to choose it, especially under pressures of cost containment and biases toward vulnerable populations such as the aged, the HIV positive and persons living with AIDS, minorities, and the disabled (51).

In particular, Miles (41) has raised the concern that vulnerable populations will be subtly pressured into choosing death by messages that they are not worth saving. Many family members and physicians who care for persons with chronic illnesses may become exhausted and exasperated and therefore might be driven to go along with or even encourage the suicide request.

Proponents respond that proper attention to safeguards will prevent many problems and concerns raised by the “slippery-slope” argument. Typical of the dispute between proponents and opponents of assisted death are sharply divergent interpretations of the current debate and discussion of the Oregon statutes and experiences. One side argues that this is the manifestation of our worst fears regarding physician-assisted death (10,30,35). The other suggests that published reports from the public health department in Oregon confirm that the safeguards are working, palliative care and hospice care have markedly increased, and in reality very few

patients over the past 2 years have requested and carried out an assisted death (36).

Substituted Judgment

Opponents worry that society will extend physicianassisted death to incompetent patients. Most proposals for physician-assisted death in the United States today specifically exclude the option of choosing physician-assisted death by an advance directive. The slippery-slope argument, however, claims that this barrier will become impossible to maintain once physician-assisted death is legally permitted (20,51). In 1997, the U.S. Supreme Court made a unanimous decision to uphold the right of states to prohibit physician-assisted suicide (10). The debate was not ended by this decision. It moved into the arena of state debates and referenda (10,52,53,54 and 55).

IMPLICATIONS FOR PALLIATIVE CARE AND HOSPICE

Official Policies

Both the National Hospice and Palliative Care Organization (NHPCO) and the American Academy of Hospice and Palliative Medicine have position statements opposing the legalization of assisted death (56,57). The American Academy of Hospice and Palliative Medicine statement is brief and states that competent palliative care usually relieves the pain and suffering of terminally ill persons and their families. This statement calls for policy reforms to ensure comprehensive hospice services for all. The NHPCO position paper (Table 65-2) is considerably more detailed and reviews all of the major points discussed. In summary, the NHPCO statement maintains that allowing unpreventable death to occur with dignity and comfort is quite different from accepting death as an expeditious way out of difficult situations for individuals or society.

In November 1990, a resolution was adopted rejecting the practice of voluntary euthanasia and assisted suicide.
These practices are counter to the National Hospice and Palliative Care Organization's core principles of relief of suffering, coordination of palliative and support services for the patient and family, a focus in maintaining the quality of remaining life, and a commitment to affirm life and neither hasten nor postpone death.
Hospice offers competent, appropriate, and compassionate palliative care to patients and their families as an effective choice for the care of dying patients and their families.
Aggressive palliative care can improve the quality and quantity of remaining life, as defined by the patient's life goals and choices.
Patients and their families need to be given the opportunity to discuss the accuracy, prognosis, and range of palliative treatment options appropriate for their personal situation and lifestyle.
The administrative and financial requirements of developing and maintaining assisted death as a component of the health care delivery system could competitively diminish the support needed to increase access to appropriate palliative care.

From Statement opposing the legalization of euthanasia and assisted suicide. Arlington, VA: National Hospice and Palliative Care Organization, with permission.

TABLE 65-2. MAJOR POINTS OF THE NATIONAL HOSPICE AND PALLIATIVE CARE ORGANIZATION'S POSITION STATEMENT ON ASSISTED DEATH

Both organizations see hospice as an ethically sound model of compassionate, cost-effective, patient- and familyoriented care. They also would argue that hospice care should be available to all and affordable for all who would opt for palliative care, and that all health care professionals should possess basic knowledge of palliative care and hospice management principles.

Attitudes

As one might expect from official policy statements, there is a marked difference in attitudes toward physician-assisted death among hospice workers in general. A slight majority of physicians in the states of Washington and Michigan favor a policy that would permit the option of physicianassisted death; other surveys have shown that from 33% to 40% of physicians favor such a policy (3,58,59). By contrast, surveys of hospice physicians, nurses, and volunteers show only a minority in favor of allowing physician-assisted death, and about two-thirds strongly opposed to it (29,61).

It is natural for those who devote so much of their energy to relief of symptoms and who see the vast majority of their patients “living well until they die” to view the occasional patient who chooses physician-assisted death as either a failure or a threat. Some of these patients may have had prior exposure to hospice, and the current decision for assisted death can be experienced as a rejection of the hospice philosophy. Even patients who had never experienced organized palliative care may seem to be saying by choosing assisted death that they do not value what is offered by palliative care. So, there are understandable philosophical and emotional reasons for hospice caregivers to react negatively to physician-assisted death.

Hospice professionals' approach to care of the terminally ill and dying emphasizes that each person will be supported through a variety of personal and professional resources to live well and be well supported in his or her death experience. At first glance, physician-assisted death would seem to be inappropriate, unnecessary, or both in every case (51). The philosophy of some hospice professionals is consistent with the views of proponents of assisted death. Both have in common a rejection of the dominant mode of dying that seems to characterize the American hospital setting—a death prolonged by excessive use of technology inadequately attended by concern for amelioration of symptoms and a depersonalized and deindividualized death, as patients' true choices are routinely ignored and human relationships and human caring are given short shrift in a world of machines. Both hospice professionals and assisteddeath advocates agree that there are much better ways to die and that the direction lies in more appreciation of human needs and of individual choices and values. Most hospice professionals would disagree with assisted-death advocates, however, by choosing improvements in the approach to caring for the dying in contrast to advocating for assisteddeath methods.

Success of Palliative Care

Advocates of physician-assisted death assume that palliative care modalities, while normally highly successful, cannot work in 100% of patients. There will of necessity be a few patients whose unpleasant symptoms, personal suffering, or inability to achieve personal needs or goals will not be ameliorated by even the most highly skilled palliative interventions. Many advocates of physician-assisted death would favor restricting the option of assisted death to that small percentage of patients who cannot be assisted effectively by palliative care treatments. This suggestion angers some palliative care specialists who contend that their treatment modalities are much more effective than physician-assisted death advocates appreciate. Knowing full well how often the average U.S. health professional underestimates the effectiveness of quality patient-centered palliative technology—and how often a so-called failure of palliative care is the result of an untrained practitioner either undertreating or choosing suboptimal treatment strategies—palliative care specialists may confidently predict that if they could only offer all needy patients in the United States the best quality hospice care, then the demand for physicianassisted death would soon be nil (55,56,73,74 and 75).

But both well-designed studies and common sense would lead to the conclusion that no medical therapy, however marvelous, can always succeed (33,59). Thus challenged, palliative care specialists sometimes suggest that they can indeed effectively treat all terminal patients with distressing symptoms. Even the 3–5% or so of patients whose physical suffering does not respond well to current treatment options and modalities (traditional and complementary) can be offered terminal sedation (59,72). Because the intent is to relieve symptoms and not to shorten life, pharmacologically induced coma does not constitute physician-assisted death but instead is an acceptable, if extreme, use of palliative treatment options (60).

Defenders of physician-assisted death have offered two rebuttals to this argument. First, they have argued that in many instances in which pharmacologically induced coma might be used, death follows so surely and within so short a span of time that it is a semantic quibble not to view this as physician-assisted death from a *moral point of view* (while recognizing of course that from a *legal point of view,* sedation to the point of coma is quite acceptable even in jurisdictions where physician-assisted death would be a crime).

To understand these ethical and legal nuances, it is important to discuss the application of the ethical principle of double effect to high-dose opioids for analgesia and to pharmacologically induced coma. To opponents of physicianassisted death, the two instances are quite analogous. In both cases, one intends relief of symptoms, not death. One foresees the risk that the means used to relieve symptoms could cause a hastened death, but hastening death is not one's true intent. Thus, death is a foreseen but unintended consequence of an action that is ethically defensible, and so the use of that means is ethically justified despite the risk.

To proponents of physician-assisted death, however, the two cases are quite different. Very few patients actually suffer respiratory depression from properly administered opioids in terminal illness. By contrast, in most instances of pharmacologically induced coma (most commonly with barbiturates), death follows with near certainty and within a much shorter period. Moreover, if one sees respirations being depressed, one would not lower the dose because the patient's awakening would mean the cruel reinfliction of the intolerable suffering that one sought to avoid by inducing the coma in the first place. More to the point, the question of intent is more

clouded in the case of induced coma. The fact that one elects to use this extreme measure, which often results in death within days or even hours, means that one has decided that any prolongation of conscious life is incompatible with this patient's true interests. If, by chance, the coma persists for many days or weeks, the palliative care professional will seldom regard this as a good outcome. Indeed, this may make the death an even more poignant tragedy for the family as well as for the caregivers.

A second rebuttal is that some terminally ill patients who have demanded the right to physician-assisted death have claimed that a drug-induced coma typifies the loss of control and dignity that it is their overriding goal to avoid. For at least this small group of patients, palliative care experts might relive unpleasant physical symptoms but only at the cost of violating the patient's own deeply held values regarding quality of life.

Pain versus Suffering

Suffering is a much broader concept than is pain or any set of unpleasant symptoms. The best available study of patient attitudes in a setting where physician-assisted death is openly practiced and legally tolerated reveals that only about 10% of patients requesting euthanasia suffer principally from pain and only about 50% suffer from any physical symptoms of the sort that can be easily relieved by palliative medical interventions. A significant number of requests to die arose from those who state that they are merely tired of life or whose general level of functioning has deteriorated below their personally acceptable minimum (60,77). Recently published reports from Oregon states that the most common reasons for asking for assisted death include loss of autonomy, loss of control of bodily functions, an inability to participate in activities that make life enjoyable, and a determination to control the manner of death (36,77). A recent study, which examined physician attitudes regarding physician-assisted suicide and AIDS patients, revealed that 48% of the physicians would assist the patient in the survey's case scenario and 53% had positively responded to a patient request in their own practices.

Possibly many or even most patients would be aided by emotional and/or spiritual counseling to the point where they would no longer request assisted death. A more sensitive and patient-centered approach, including the use of spiritual histories, would assist the hospice professional and the patient to gain a deeper understanding of the meaning that the patient attaches to his or her individual circumstances and not merely the assumption that palliative care treatments have been underused (22,24,28,60).

Funding for Palliative Care

One recurring argument against allowing physician-assisted death is that hospice and palliative care have been historically underfunded in the United States. According to this argument, as soon as physician-assisted death is a legal option, patients will be steered toward a quick, painless, cheap death and will be discouraged from seeking potentially expensive hospice care. The net result will be the serious underfunding of all types of palliative care programs, and the option to choose palliative care will be an option on paper only for most U.S. patients. Many U.S. hospice professionals charge that palliative care has been very slow to develop in the Netherlands and that country's euthanasia policy is directly to blame. Hospice professionals have experienced the problems and challenges of chronic underfunding and of working with physicians and administrators who were often ill-informed about hospice care. Understandably, they are skeptical of any proposal that assumes that palliative care has arrived and that adequate funding is on the horizon (61).

Defenders of the assisted-death option have argued in reply that a properly regulated and legalized option for physicianassisted death could actually support the expansion of hospice. The recent report on the Oregon experience with physicianassisted death would support this argument (36,77).

Many such proposals include the stipulation that no patient will be granted the request to die until palliative care experts have concluded that the patient cannot be effectively helped by appropriate treatments. In effect, the proposals would require that every patient requesting physicianassisted death undergo a trial of palliative care (31,42). Proponents further assume that in the vast majority of cases, the patients would be so impressed with the success of the treatment that they would elect to remain in the hospice program rather than be put to death. The result, they argue, will be additional political support for hospice programs and for palliative care training and research, such as the American Medical Association's Education for Physicians on End-of-Life Care program (48).

It is possible, of course, that health care professionals might merely rubber-stamp requests for assisted death rather than engage in detailed conversations with their patients. Ironically, this outcome would be more likely if the nation moves toward legalizing physician-assisted death and if (as opinion polls now suggest) the best trained palliative care specialists refuse as a matter of conscience to have anything to do with the assisted-death program, even to the extent of screening patients and consulting on available palliative care alternatives (29,61).

CLINICAL MANAGEMENT OF REQUESTS FOR ASSISTED DEATH

Although the debate between opponents and proponents of assisted death is complex and apparently intractable, many aspects of the practical management of patients who request direct assistance in dying will be the same regardless of the clinician's moral or ethical stance. There are clinical approaches that should fit both ethical positions comfortably. A few areas of practice must differ, however, to remain consistent with the clinician's own ethical or moral commitments (Table 65-3).

The clinician should listen to the request for assisted death in an open and sympathetic manner and evaluate the issues underlying the request.
The clinician should share her personal stance with the patient in an open and professional manner, always assuring the patient that he will be supported throughout the experience of his personal decision-making process.
All clinicians should take appropriate steps to process their personal emotional reactions to the patient's request, e.g., hospice team meetings.
The clinician should have a continuing dialog with the patient and appropriate family members or support persons concerning the development and implementation of therapeutic treatment plans, including a request for assisted death, in a manner consistent with the clinician's ethical values and personal belief system.

TABLE 65-3. SUGGESTED STEPS FOR THE CLINICAL MANAGEMENT OF A REQUEST FOR ASSISTED DEATH

Reactions to Patient Request

As noted above (see the section Attitudes), a hospice patient who requests physician-assisted death may well trigger intensely negative emotional reactions among members of the care team. It is very important that those emotional reactions be validated by other team members but not be allowed to derail the necessary conversations with the patient that will support the patient's values and choices, as well as assess future care needs. Ideally, the patient's request will be received sympathetically but matter-of-factly. The patient may be told that he or she is hardly alone among patients facing death in making such a request and that the clinician very much appreciates the trust shown by the patient in stating the request openly. The clinician would then continue the dialog with the patient regarding underlying reasons for this request and come to mutual agreement that this request will be discussed at his or her next care meeting.

Alternatively, a patient may confide this request or the fact that she is seriously considering suicide to only one member of the palliative care team with whom she may experience a deeper personal trust. In that event, the team member ought initially to respect the confidence but state that he or she feels a very strong obligation to share that information with all other team members so that as a team they can discuss how best to offer future assistance to the patient. The clinician should persist in seeking the patient's permission to share the disclosure with the rest of the team members. If the selective disclosure indicates that there are unresolved issues of distrust between the patient and other team members, the most therapeutic approach may be to address those issues head-on as part of the negotiations about the disclosure. If the patient continues to refuse permission to share this information, then the clinician is faced with the very difficult conflict about when it is justifiable to violate a patient's confidence (64). One must balance the goal of preventing harm to the patient against the possibility that violating a confidence (or threatening to do so) may lead to even less disclosure of key information and therefore a lessened opportunity to help the patient in the future.

If the clinician on balance thinks that the secret ought to be revealed to colleagues, the justification would be that the clinician is at the patient's bedside not as a solo practitioner but as a representative of the team, and not to allow the team to function cohesively is in a sense to reject the clinician's care. This justification will be most plausible when the team aspects of care and the sharing of information in the team have been fully disclosed to the patient as a part of the admission process. Also, in order to minimize further loss of trust, the clinician who feels obligated to reveal secret information should frankly inform the patient of this and the reasons for

disclosure.

Some requests for death assistance are transparently a result of a temporary stressor mood change and are very unlikely to represent the considered, enduring posture of the patient. The clinician may deal with such requests by validating the emotional state of the patient and responding with appropriate brief counseling.

All patients should be informed at this stage that it is the practice of the team to take all requests for death assistance very seriously. The patient should be informed that it is the experience of the team that the concerns and problems that prompt such requests can usually be ameliorated once the team has carefully assessed the patient's situation and further care options. The clinician should promise speedy attention to the concerns that the patient raises and full communication of the team's planning processes.

At this point in the inquiry, the clinician or the organization will take different approaches depending on their moral/ethical position on physician-assisted death. A clinician (or team) who is morally opposed to this practice in all cases should share this information with the patient lest the patient entertain unrealistic hopes of later assistance. The statement of refusal to consider the option of assisted death should be coupled with the promise to stand by the patient until the moment of death and to continue to search exhaustively for any means other than death assistance to ameliorate the patient's suffering. The clinician may wish to add that a moral distaste for the action of assisting death does not equate with a moral condemnation of the suffering individual who is making the request.

The clinician (or team) who is morally/ethically willing to consider the permissibility of assisting a patient's death in carefully selected cases may at this point share that stance with the patient. The clinician should next point out the procedure the team has agreed to following to be sure that the patient is making a voluntary, considered choice and is suffering in ways that cannot be relieved by any other means. The estimated amount of time needed for this determination, and to consider and suggest alternatives, should be shared with the patient. In any event, the patient needs to be told that no quick and easy acquiescence is contemplated. The clinician may wish to inform the patient of the statistical chances that the patient will select an alternative means of addressing his suffering and will in that event no longer request a quick death.

Possible Scenarios

After this initial discussion around the patient's first request for assisted death, the palliative care team should engage in a careful inquiry to determine the nature and origin of the patient's suffering, taking at face value that if the patient was prompted to ask to die the suffering must be more severe than the team had previously appreciated. The inquiry will be aided by understanding some common scenarios observed among patients making such requests (63). The categories developed by Quill are very useful (33,34); the following six scenarios illustrate situations in which all observers agree that the best option lies not in assisting death but in providing some other type of care.

Inadequately Treated Physical Symptoms

The easiest category to deal with is the patient who seeks death because of suffering caused by inadequately treated physical symptoms. The palliative care team may have missed the onset, duration, or severity of a symptom. The patient may have felt compelled for a variety of emotional reasons to deny or minimize the symptom. Or, a previously prescribed treatment may be producing unpleasant or intolerable side effects that the patient similarly feels obligated to deny or minimize, possibly to avoid hurting the feelings of the clinicians. In any case, a searching discussion in which physical symptoms and treatment side effects are explicitly explored should reveal the source of the problem, or other family members may be able to enlighten the hospice team on the nature of the complaint. A trial of an improved treatment strategy to show the patient that the troublesome symptom can be relieved to tolerable levels will also be successful in helping the patient experience and believe that his or her symptoms are able to be relieved.

Depression

Untreated depression can cause a patient to wish to die and to consider the future hopeless. A team member skilled in the differential diagnosis of depression should interview the patient with this possibility in mind. In an elderly patient, special expertise in geropsychiatry may be required both to distinguish the signs of depression from the side effects of aging or chronic illness and to determine a type and dose of antidepressant medication that can be successfully and safely administered to the patient (64,65).

The diagnosis of depression does not necessarily lead to the successful treatment of depression soon enough to preserve the terminal patient's quality of life. Thus, it is of no benefit to label him or her as depressed. As always in palliative care, the treatment of depression in the terminal patient should be aimed at the actual relief of troublesome symptoms rather than cure of a disease. This may require flexibility and creativity in combining medication with emotional support.

Family Dysfunction or Conflict

A patient's wish to die may grow out of conflict within a troubled family relationship. A patient may wish to die because of a fear that painful and dissatisfying family relationships are not going to improve. In other cases, a request may be a manipulative counteroffensive aimed at punishing other family members. Most hospice teams have social workers and chaplains as well as family practice physicians and nurses who are capable of evaluating family dysfunction and developing an appropriate management plan.

Spiritual Crisis

A request for assisted death may signal the fact that whatever belief system that previously provided the patient with a sense of meaning in his or her life is no longer experienced as supportive or meaningful, and the patient now feels that further existence would be without meaning. It may also suggest that this patient had been able to cope with previous life stressors without invoking any spiritual belief system and is now belatedly confronting the fact that he or she has no such resource to draw upon in looking at impending death.

Spiritual counseling may help to resolve the crisis and to restore a sense of meaning to the patient's life in the context of the illness and impending death. To be effective, the counseling will have to be tailored to the patient's beliefs and current needs. A careful assessment of the patient's sense of the nature of the current conflict and of why previously helpful spiritual or emotional supports no longer seem to be working is essential for identifying the type of counselor who would be most helpful. Human beings often assign meaning to events through the construction of narrative. Engaging the patient in telling or writing stories about his or her past life or present illness or about hopes for his survivors may facilitate the process of restoring hope and meaning (22,28,37,56,60,66,67).

Unremitting Suffering Despite Adequate Support

This category, which with high-quality palliative care will include relatively few patients, presents the starkest contrast between those morally opposed to and morally accepting of physician-assisted death. It is the patient who has failed to achieve adequate relief of suffering through appropriate trials of palliative treatments, with proper attention to emotional, social, and spiritual factors, and the patient who has been shown to be competent and persists in requesting death who presents a major ethical challenge to most palliative care clinicians. Supporters of physician-assisted death would argue that it is precisely this setting in which we as a society should support assisted death (63).

A problem will arise for the clinician opposing physician-assisted death if the patient has refused to try an offered mode of therapy or has ceased treatment before full therapeutic benefit occurred because of unpleasant side effects or fear of them. In some cases, the clinician will judge that the side effects were truly severe and debilitating or that their likelihood of occurring was exactly as the patient predicted. In such cases, the clinician might in good conscience proceed to assist death. But, in other cases, the clinician may judge, fairly or unfairly, that the patient's reasons for refusing the offered therapy were inadequate or insubstantial and that in effect the patient was so intent on receiving assistance with death that he was not really trying to achieve relief of suffering by any other route. This presents a serious dilemma for supporters of physician-assisted death. It is evident, however, that only patients can truly know how much they are suffering and that judgments by third parties that their reasons for refusing an offered therapy are flawed or inadequate seem to undermine the respect for free choice that motivated support for assisted-death policies in the first place. On the other hand, if patients may receive assistance in dying after refusing all offered therapies for any reason whatsoever, then we have in fact created a policy of death on demand in which all so-called medical safeguards are spurious.

It is important for clinicians to recall in such cases that it is much harder to make the case that assistance in dying is a *right* of the terminally ill patient than that such death assistance is *permissible* in rare, selected circumstances. If patients have no moral right to death assistance, then physicians can refuse to assist death in all dubious cases. This effectively places the burden of proof on the patient rather than on the physician—a negative situation if one adopts a strongly libertarian posture but a positive one if one is concerned about the ease with which any policy of assisted death may be abused to the detriment of vulnerable persons.

Those morally opposed to assisted death who are facing patients with unremitting suffering will again wish to affirm their commitment not to abandon patients and to always stand by them in their suffering while continuing to try new approaches and new combinations of treatments despite the waning likelihood of success. Spiritual counseling becomes critically important at this juncture because even patients who may continue to have some suffering before death may be helped to attach new and profound meanings to that suffering so that the suffering becomes personally more bearable. If heavy sedation or induced coma has not previously been considered, they should be reviewed with the patient and the family at this time. Knowing that these treatments and spiritual and emotional supports are available may help the patient find the strength to endure.

Hastening Death by Withdrawing Nutrition and Hydration

A policy proposal (65) and case report (69) awakened interest in a legally permissible strategy allowing patients to hasten death, even in jurisdictions proscribing physicianassisted suicide. The patient refused to eat and drink and the physician provided palliative support to prevent any discomfort of dying by dehydration. Clinicians may legitimately differ over the moral assessment of this practice. For some, it will seem a clear-cut case of providing compassionate symptom relief while patients exercise their legal and ethical right to refuse medical interventions, including artificial nutrition and hydration. For others, it will seem an obvious subterfuge in which one stays on the right side of the law while engaging in an act that is morally indistinguishable from physician-assisted suicide. After all, the patient refuses artificial nutrition and hydration not because of an inability to drink or eat in the regular manner and not because artificial administration is excessively painful or burdensome but because the patient has determined that future life is not worth living and that an early death is preferable. Thus, such cases are easily distinguishable from the more usual hospice case in which symptom relief is offered and artificial nutrition and hydration are seldom used because they would add no comfort and merely prolong the dying process.

Palliative care professionals and organizations may be divided on this strategy. Some who favor physician-assisted death will regard prolonged death from dehydration, even if symptoms are well controlled, as an undignified travesty of what could otherwise have been a quick and painless death had more direct means been used. However, some physicians who advocate physician-assisted death but fear the legal repercussions may find this an acceptable temporary solution. In that event, they could mention it as an option to patients who repeatedly request assistance in dying and whose suffering has not been adequately relieved by other means.

Considerable patient and family education is helpful and necessary because few health professionals and laypersons are aware that such a death can be relatively painless and comfortable (22,68,69). Some patients or families may still find the prospect unacceptable even after several conversations. For those patients who might elect to use this method, it will be important to allow for changes of heart along the way as well as to provide the promised symptom relief promptly and adequately throughout the process.

CONCLUSIONS

The foregoing sections have explained the ethical (moral) issues, the professional implications for hospice professionals, and the clinical management of requests for assisted death from hospice patients. Commentators on these issues (10,22,31) emphasize that there needs to be a stepwise approach to requests for assisted death, which should include assessment of decision-making capacity and lack of depression, excellent discussions regarding advance care planning, evaluation for treatable causes of symptoms and treatment if possible, proper utilization of professional resources (including spiritual), a network of caring (both family and professionals), and a death that expresses personal dignity and values (10).

PALLIATIVE CARE:ETHICS AND THE LAW

MARY E. BALUSS

Practitioners of palliative care face both legal and ethical imperatives. Those two realms usually overlap reasonably well because law is, at its base, a consensus on ethics of the place and time (1). There is tension—the laws may lag the ethics, and sometimes ethics lag law. At any given time some will feel that the law goes too far to impose an ethic, while others are impatient for it to do more. However, these tensions tend to exist at the edges and not at the core of law or ethics.

Lawyers and ethicists approach some issues differently and therefore reach somewhat different conclusions. Most important, perhaps, law varies from state to state. Ethics do not follow neat jurisdictional outlines. Ethics require good pain management; fear of legal sanctions restricts it. Ethics reach high; law is the lowest common denominator of behavior. For some practitioners, legal concerns have acquired unsupported mythic qualities that may stand in the way of ethical practice. This chapter will dispel some of the more common myths and highlight emerging tort issues that will bring legal pressure on risk managers to emphasize palliative care.

The chapter (a) gives the reader an overview of the important areas where law and palliative care intersect, (b) demonstrates that the law does not hinder good palliative care, and (c) highlights the importance of knowing your own state's legal requirements. It will review the facts underlining fears that treating pain leads to regulatory or criminal sanctions. Although those do happen, this chapter's message is that a practitioner who pays attention to good communication, is familiar with the clinical standards of practice, and documents his or her decisions can safely conform to the ethical obligation to provide palliative care.

INFORMED CONSENT

All content in this chapter presumes the patient has given informed consent. Failure to obtain informed consent risks claims of battery and malpractice, discussed below.

State statutes and judicial precedent define informed consent. Generally, they codify good medical practice. A practitioner must provide information on the risks, benefits, and alternatives to a particular course of treatment in sufficient detail that a reasonable person could rely upon it to make an informed decision. Palliative care requires special attention to informed consent because the emotional stakes are high, and the patients may not be at the top of their listening form. There remains a serious ethical debate in the palliative care community about truth telling at end of life (2).

Some, but by no means all, states recognize the ambiguities of informed consent at life's end. For example, they would permit a defense to failure of informed consent on the basis that professional judgment was exercised and informed consent adapted to prevent emotional suffering or loss of hope in a dying patient. Unfortunately, no consistent precedents guide the practitioner in making these judgments. The balance between paternalism and the “deplorable practice of truth dumping” (2) probably argues for sensitive truth telling rather than truth withholding. There is a broad area between “dumping” dire information and obtaining truly informed consent. The practitioner who opts for protecting the patient from grim facts should assure him or herself that it is a mature and careful decision, not a failure of will.

WITHDRAWING AND TERMINATING LIFE-SUSTAINING TREATMENT

When and how to stop aggressive curative care is a vital ethical issue. The ethical question is, however, infused with legal provisions that run from the highest areas of constitutional law to the minutia of state requirements defining who may make the decision to forgo care and when and how the decision is made. The state laws are not complicated and are designed in significant part to *protect* conforming practitioners from liability.

ATTENDING PHYSICIAN DECIDES WHO IS COMPETENT

Only a patient with decisional capacity may give informed consent. The Uniform Health Care Decisions Act (“Uniform Act”) § I (2) defines capacity as “an individual's ability to understand the significant benefits, risks, and alternatives to proposed health care and to make and communicate a healthcare decision” (3). All states give the attending physician the right and the responsibility to determine whether the patient has capacity. This is a legal obligation of the physician and a duty owed to the patient. In practice, ethical and psychiatric consultations can help form the decision, and there is leeway for sensitive discussions with family members. If family members disagree, they must to take their concerns to probate court.

COMPETENT PATIENTS CALL THE SHOTS AFTER BEING INFORMED

Competent adults have an almost unlimited right to refuse medical treatment and to withdraw from treatment. The Tenth Amendment to the U.S. Constitution reserves to the people fundamental rights not otherwise enumerated in the Bill of Rights and protects them against federal encroachment. The Supreme Court has held that one of those “penumbral rights” is an interest in personal privacy on matters of importance such as reproductive rights and health care decisions. The Fourteenth Amendment's “liberty” interest protects the individual against state laws that might encroach on the right to privacy. State constitutions vary in their language, but all offer competent adults the ability to withdraw from or refuse medical care.

Competent patients do not have to be terminally ill to refuse or withdraw treatment. The decision does not have to make sense to the medical team or be in the patient's best interests. The family does not have to agree and, unless the patient is a minor, does not even have a legal right to know. In some jurisdictions, there is a

“mature teen” exception so that some minors can call their own shots.

The practitioner's legal duty is to fully inform the patient, make sure the consequences and risks are understood, and then either respect the patient's instructions or refer the patient to another doctor who will. The last obligation is important. No state requires a practitioner to physically take the acts necessary to withdraw treatment if he or she has an ethical objection. The obligation to refer is clear but the statutory language allows an inference that if there were no other practitioners available, the provider's moral concerns would trump the patient's right.

PATIENT LACKING DECISIONAL CAPACITY MAY ALSO REFUSE LIFE-SUSTAINING TREATMENT

Incompetent patients retain rights to refuse or authorize treatment but the state has considerably more control. The seminal case from the U.S. Supreme Court is *Cruzan v Director, Missouri Department of Health* 497 US 261 (1990). In that case, Nancy Cruzan was in a persistent vegetative state, kept alive by artificial feeding and nutrition. Her parents and doctors advocated removing the feeding tube. The hospital refused. The Supreme Court refused to require the tube's withdrawal. The opinion affirmed the right of incompetents to have expressed treatment decisions honored but also held that the right may be limited by the states to serve legitimate state concerns. These include protection of life, preservation of the medical profession's integrity, prevention of potential abuse by surrogate decision makers, and prevention of suicide (4). In some states, there is also a limited consideration of family circumstances. All such state restrictions will be strictly scrutinized by the courts for legitimacy. Against that framework, the Supreme Court upheld Missouri's requirement that in the absence of written directives, advocates for treatment withdrawal would have to show by “clear and convincing evidence” that the patient would have wanted treatment to be withdrawn. It further found that the evidence presented by the Cruzan family was not sufficient.

Cruzan highlights the need for practitioners to know what the state standards and procedures are. All states allow a competent person to express his or her wishes for treatment if he or she becomes unable to make those decisions. These laws establish various forms in which the decision can be expressed, usually through either an advance directive for health care (“advance directive”) or a health care power of attorney (“power”). If no such document exists, which is the case for over 80% of terminally ill patients, then state law defines who may make the decision for the patient and what standards will be applied.

A practitioner who conforms to the statute will be protected from civil or criminal actions stemming from withdrawal of treatment. Following a hospital protocol that does not reflect state law is not good enough. A nonconforming hospital protocol has no legal effect and does not offer the practitioner legal protection otherwise available under state laws.

ADVANCE DIRECTIVES AND HEALTH CARE POWERS OF ATTORNEY

Until very recently, there was no legal mechanism that a competent person could use to direct what care he or she wanted in the way of medical treatment if he or she lost decision-making capacity. In common law, only a testamentary will, with the formalities of witnesses and signatures, survived a person's incompetency and death. Testamentary wills, however, have no legal effect until after death and therefore cannot be used to effect health care directives. Other common law powers of attorney were ineffective because they were not “durable.” They lost all effect if the principal lost decision-making capacity.

Advance directives and durable health care powers of attorney were created by statute to bridge this decisional gap between legal competency and death. The two instruments have similar purposes and legal significance but different limits. Advance directives (living wills) record the wishes of competent patients for their care—and most specifically their desire to refuse care—if they become terminally ill or permanently unconscious. The advance directive is essentially self-executing once the qualifying criteria are met. It binds the health care providers once they become aware of it—and they must inquire. A federal statute, the Patient Self-Determination Act (5), requires hospitals and nursing homes to advise patients on admission of their right to accept or refuse medical care and to execute an advance directive. Compliance with the act is a condition for Medicare and Medicaid reimbursement. Very few patients take advantage of the advice although studies show that the compliance rate increases when physicians encourage their patients to create an advance directive (6).

A health care power of attorney achieves the same effect, but operates differently. It delegates the patient's own decision-making right to someone else as of the time that the patient becomes incompetent. It is not self-effectuating: the agent has to act. A well-drafted power will include instructions to guide the agent's decisions, but is not required to do so. Moreover, unlike advance directives, a patient need not be terminally ill or permanently unconscious for the power to be exercised, although the surrogate's options in some states may be limited if the patient is not terminally ill or if the power is not sufficiently specific. The most common limitation is on the agent's power to demand withdrawal of artificial feeding and hydration.

Generally Applicable Requirements for Advance Directives and Health Care Powers of Attorney Formalities

Because they may hasten the death of a then-helpless person and are conceptually extensions of the testamentary will, *written* directives or powers of attorney must be formally executed. They are invalid if they do not meet the prescribed formalities. Most commonly, two adults must witness the documents. Their signatures attest that the patient was “of sound mind” at the time of execution. Statutes generally provide that the agent may not be a witness. They also prohibit the patient's health care providers or their employees from being witnesses and they also may not be the appointed agent. Concerns about conflict of interest or coercion are otherwise too strong. Exceptions in some states permit practitioners to be agents for patients who are close family members.

Effective Only on Incompetence

Although patients must be competent to make directives or appoint agents, their directive becomes effective *only* when they lose decisional capacity as determined by the attending physician. In addition, advance directives are only effective if the patient is terminally ill or permanently unconscious. (States vary in the precise formulation.)

Validity in Other States

There is a widespread but outdated belief that directives or powers executed in one state will not be honored elsewhere. In fact, such documents are statutorily presumed valid in other states and the practitioner may rely on them unless actually informed that the document is invalid. The only exception to the rule of presumptive validity is when an out-of-state power or directive requires some action that is illegal in the practitioner's state. In those circumstances, state law limits the practitioner although the instrument remains valid and effective to direct decisions that are legal in the practitioner's state.

May Be Orally Made or Revoked

Contrary to common belief, most states allow a power of attorney or advance directive also to be made orally by a competent patient. Rules vary about how oral statement must be witnessed and recorded in the patient's chart. In addition, most states allow a patient to *revoke* a written or oral directive or power of attorney orally. An oral revocation must be documented in the patient's chart and is not binding on the practitioner until that happens. Many states impose penalties if a person who hears an oral revocation fails to bring it promptly to the attention of the attending physician. Some states provide that an oral revocation must be made directly to a health care provider. Many states make it a criminal offense to conceal or destroy a power or directive.

Most state laws do not specify that the patient must be competent to effect revocation. A number of states actually specify that the patient does *not* have to be competent to revoke an advance directive or appointment of a surrogate. Nonetheless, oral revocation by an incompetent patient is problematic particularly if the family is not united. There are not enough precedents to generalize about liability risks when an oral revocation is challenged. Prudence dictates that the revocation be well documented by identifying the person who heard the statement, additional witnesses if any, and the date, time, and context of the statement. The witness statement should be written and confirm the substance of the statement. The practitioner should be cautious to make sure that the state's formulation is followed. For example, if only health care practitioners can witness an oral revocation, respecting a family member's statement alone would not be appropriate.

Emergency Exceptions

Emergency room personnel do not have to spend time searching for an advance directive (7). However, they must honor an advanced directive or do not resuscitate (DNR) order that is brought to their attention. In most states, wearing an approved DNR bracelet is recognized by law as a way to notify emergency providers that a DNR is in effect.

Emergency medical technicians have traditionally been unable to honor an advance directive even if it is presented to them. Recently, however, many states have initiated programs under which emergency medical technicians may honor DNR or other orders if the patient is identified, usually by a bracelet, as having an active order or directive.

WHO ACTS FOR THE PATIENT?

Advance Directive

A valid advance directive trumps all other notions about what care should be offered if the patient's condition reaches the stated criteria. If an advance directive is coupled with a health care power of attorney, the agent is bound by the directive (8).

Health Care Power of Attorney Unaccompanied by Directives

A validly appointed health care proxy has virtually the same authority to act as the patient would have if competent. An exception in some states prevents proxies from authorizing withdrawal of artificial feeding and hydration unless the patient is terminally ill or permanently unconscious or has expressly provided consent in an advance directive or in the document appointing the agent. Missouri does not allow a proxy to withdraw feeding or hydration at all (10). This restriction and, in fact, the more common restriction on removal of feeding and nutrition where the patient did not specifically authorize its withdrawal in an advance directive or power of attorney, may violate both the federal and state constitutions. Courts have consistently held that artificial feeding and hydration are forms of medical treatment. They have not indicated that there is a justifiable difference between forgoing other life-sustaining treatments and forgoing or withdrawing artificial feeding and nutrition and at least one state has held such a limitation unconstitutional (11). Courts have also held that federal statutes requiring nursing homes to provide feeding and hydration do not limit the right to refuse or withdraw from treatment (12).

When the Patient Has No Directive or Appointed Health Care Agent: Surrogacy

Although much is written about advance directives and health care proxies, most adult patients have neither. When the physician decides that his or her patient lacks capacity, state law identifies a person, or class of persons, to act as decisional surrogate. In most states, there is an order of surrogacy or surrogacy classes: the spouse (legally separated and exspouses excepted), an adult child, and then to an adult sibling. Some states continue the list of classes to more remote relatives—grandchildren, cousins, and the like. Increasingly, states are recognizing that patients' families can be fragmented, scattered, or simply unknown. These states add a category of persons who have “exhibited special care and concern for the patient, who is familiar with the patient's personal values, and who is reasonably available” (13). A very few states give domestic partners the same status as spouses. Colorado permits the entire group of relatives and those friends with a good idea of the patient's wishes to reach a consensus as to who the surrogate should be (14). In all states, if no surrogate of any level is available, a guardian appointed by the probate court must authorize withdrawal of treatment for the incompetent patient.

Almost all states also have some form of “surrogate tie breaker.” If the members of a surrogacy class, such as adult children, cannot agree, state laws usually require the practitioner to honor the wishes of the majority. If the majority deadlocks, the decision may have to be referred to a court or to the next lower priority group.

In every state, the surrogate is obligated to follow the patient's wishes to the extent those are known. If they are not known, every state requires the surrogate to act in good faith and in the “best interest” of the patient. Most states have procedures by which a surrogate not acting in the patient's best interests can be removed or instructed by a court. In those cases, the challenger has the burden of proof and will have to show by “clear and convincing” evidence (a high standard of proof) that he or she knows better what the patient would have wanted. Some states provide that a health care provider has standing to bring an action to have an agent removed. In others, that is less clear.

Statutes Absolve Practitioners Who Act on Best Information

A major purpose of surrogacy laws is to clear the practitioner's way and protect him from liability if he relies on apparently valid instructions from the patient or a surrogate. Statutes generally permit any practitioner to rely on a properly executed written or oral advance directive or health care proxy until informed that it is not valid. The statutes do not require the practitioner to resolve the issue of validity—that is for the courts. Similarly, the practitioner must make “reasonable efforts” to identify potential surrogates, but that does not entail a broad search. The practitioner must ask present or known and reachable kin and friends about other potential members of surrogate classes. A few statutes provide that the practitioner can rely on the notified kin and friends to locate and tell others.

The protection is broad. A practitioner who reasonably relies on a directive or surrogate's instructions is exculpated from both civil and criminal liability if the instructions cause or hasten death. There has *never* been a successful case against a doctor for withholding or withdrawing treatment under the post-*Cruza,*, advance decision-making statutes.

TREATING PAIN: HASTENING DEATH?

Americans fear unrelenting pain as death nears far more than they confess to fearing death itself. Studies also show that despite significant advances, the fear is entirely reasonable. Undertreated and untreated terminal pain remains exceedingly common as are treatable symptoms such as anxiety, depression, and dyspnea.

Undertreatment continues although palliative care experts urge that 95% of terminal pain can be treated. (With terminal sedation, there is no reason why that figure would not be 100% if the patient or surrogate so chose.) It persists despite significant literature on the physiology and methods of pain management and the exhortations of leading medical and governmental organizations.

This failure is unethical: “Physicians have an obligation to relieve pain and suffering and to promote the dignity and autonomy of dying patients in their care. This includes providing effective palliative treatment even though it may foreseeably hasten death” (15). Patients near the end of life must continue to receive emotional support, comfort care, *adequate pain contro*l, respect for patient autonomy, and good communication (16).

Although there is no direct authority, legal hindrances to treating the pain of the dying may violate the U.S. Constitution and may also be illegal under state constitutional theories (17). That suggestion was certainly made in various opinions by Supreme Court justices in the context of finding no federal right to physician-assisted suicide. States have taken legislative action to improve the treatment of pain. California's Pain Patient's Bill of Rights requires physicians to treat pain or refer the patient to a pain management expert. In 2001, California began to require that every health care licensee receive treatment in pain management as a condition to being allowed to renew his or her professional licenses (18). In 2000, Florida required health care providers to treat pain on request (19). In Oregon, failures to treat severe pain caused a physician to incur sanctions and license limitations (20). Other license board complaints by families who watched loved ones die in pain and fear are pending and are becoming increasing more frequent.

Physicians' fears are the leading cause of undertreated pain. A recent survey of nearly 400 physicians found that more than 25% were concerned about their patients becoming addicted to pain medication, and a significant number were afraid of investigation by a drug regulatory agency (21). The same survey found that 30% of physicians would be reluctant to provide opioid therapy to patients with severe and intractable pain, and 10% would provide opioids only to patients with 1 year or less to live. A survey of members of the American Pain Society found that undertreated pain is the major ethical concern of the respondents (22). Yet, where pain is documented and treated within well-known guidelines that are no more than good medical practice, those fears are dramatically overstated.

The number of patients who have experienced excruciating pain because of a practitioner's over-perception of criminal or civil risk is shamefully large. Cases finding criminal or civil liability for medical personnel who document and treat pain intelligently are almost nonexistent. The use of opioids for cancer pain is virtually enshrined in medical board guidelines.

CRIMINAL SANCTIONS FOR HASTENING DEATH: INTENT IS EVERYTHING

Intending to treat pain and ease suffering is palliative care even if it causes or hastens death. Intending to cause death, even with a merciful intent, is not legal anywhere in the United States (23). Physician-assisted suicide is legal only in Oregon (24). Even there it is used infrequently (25). Identical acts, identical results; the *critical* difference is the practitioner's *intent*.

The concept of intent in palliative care scares medical practitioners. “How would they know what I intend?” “We can't have laymen judging what's in a doctor's mind!” Intent, however, is the cornerstone of much of our criminal law. Courts are accustomed to dealing with proof of subjective “intent”; the phrase has significant legal meaning. In general, the intent proven must be intent to accomplish the specific illegal act charged. The state has the burden and it must prove intent “beyond a reasonable doubt.”

Criminal intent can be proven directly (a confession) or indirectly (circumstantially) by inferences reasonably drawn from all the facts and circumstances. However, when intent is proven circumstantially, the evidence *must* be consistent with the inference drawn and *may not* be consistent with *any* innocent intent. This is a very high

hurdle when palliative care is involved. Motive is also a problem for prosecutors. Medical practitioners have nothing to gain by a hastened death. Since 1980, no practitioner has been ultimately found to have the requisite intent for a criminal conviction when the defense claimed that the motive was palliative care. Dr. Kevorkian's case is no exception because he admitted an intent to cause death (26). Several cases illustrate the respect that courts have developed for aggressive palliative care.

State v Naramore

In 1996, a Kansas jury convicted Dr. Stanley Naramore of attempting the murder of an elderly cancer patient (27). Her family asked for better pain control. Dr. Naramore detailed the risks and administered a first dose of morphine. Her family interpreted a later ambiguous remark to mean that he actually intended to hasten her death. There was conflicting evidence as to whether Dr. Naramore had injected or prepared to inject the patient with Naloxone, which the prosecution took as an admission that he had consciously "gone too far."

Dr. Naramore was also charged with murder after a diabetic patient with heart disease refused blood thinners and suffered a serious stroke. After extensive efforts, Dr. Naramore and a second doctor determined that the man was "brain dead." He was extubated and died. The prosecution claimed that the patient was actually legally alive at the time but paralyzed by a drug. They claimed that extubation caused his death.

Dr. Naramore flatly denied any intent to cause death in either case. The state's proof of intent was entirely circumstantial. Its experts' testimony that Dr. Naramore's actions were outside the standard of care, and therefore presumably not intended to palliate, was rebutted by equally credentialed defense experts.

The Kansas Supreme Court summarily reversed both convictions. Its reasoning is important to any practitioner and accordingly is quoted below at some length. It held that the trial court erroneously failed to instruct the jury on the ambiguities and difficulties of palliative care. More important, it held that no reasonable jury could have found guilt "beyond a reasonable doubt" when medical experts so substantially disagreed.

> When there is such strong evidence supporting a reasonable, noncriminal explanation for the doctor's actions, it cannot be said that there is no reasonable doubt of criminal guilt. This is particularly true … where the only way the defendant's actions may be found to be criminal is through expert testimony, and that testimony is strongly controverted in every detail.
>
> We do not say that a physician can always escape criminal conviction for reckless or purposeful homicidal behavior through friendly medical testimony on his or her behalf. *But there is a reason why there has yet to be in Anglo-American law an affirmed conviction of a physician for homicide arising out of medical treatment based on such highly controverted expert evidence as here.*
>
> All three amicus briefs acknowledge the appropriateness of criminal responsibility where a practitioner's actions are clearly reckless or purposefully homicidal. However, they note that if criminal responsibility can be assessed based solely on the opinions of a portion of the medical community which are strongly challenged by an opposing and authoritative medical consensus, we have criminalized malpractice and even the possibility of malpractice.
>
> The instant case is a very good example of this. With no direct evidence of criminal intent, it is highly disturbing that testimony by such an impressive array of apparently objective medical experts, who found the defendant's actions to be not only noncriminal, but medically appropriate, can be dismissed as "unbelievable" and not even capable of generating reasonable doubt.
>
> —*State v Naramor*e, 965 P2d 211, 223–24 (Ks 1998)

United States v Wood

The reasoning in *Naramore* was subsequently applied to reverse the involuntary manslaughter conviction of a Veterans Administration doctor. The doctor injected a patient he believed to be "drowning in his own fluids" with potassium chloride. Two nurses refused to give the injection and warned the doctor that the rate of injection exceeded hospital policy. All agreed that some amount of the drug was appropriate.

The Court concluded that a rational jury could not infer from the evidence that the doctor acted with malice (intent) or in a manner that was wanton, reckless, or in gross disregard for accepted standards of care (28). The court reasoned that "[the doctor's actions] involved a choice between several courses of action, some of which were more risky, but perhaps more efficacious than others. *A physician cannot be convicted of murder simply for adopting, in an emergency setting, a risky course of action intended to prolong life that, when carried out fails to forestall or even hastens death*." (202 F3d. 1222 [10th Cir. 2000] at 1232)

The reversals of *Naramore* and *Wood* stand for the proposition that intent cannot be inferred circumstantially where credible medical experts disagree. Even involuntary manslaughter, which does not require malicious intent, requires evidence of care that is so substandard recklessly low that it denotes indifference to human life. This standard is far more demanding than the proof required to demonstrate medical malpractice.

TERMINAL SEDATION IS NOT CRIMINALIZED

Supreme Court Carefully Distinguished between Assisted Suicide and Terminal Sedation

The law recognizes terminal sedation as a palliative approach even when death might be hastened or caused by the sedating medication. Terminal sedation is distinguished from murder, euthanasia, and assisted suicide. All states that explicitly criminalize physician-assisted suicide carve out palliative care when there is no intent to cause death, even when the care might hasten the death (29).

The Supreme Court's assisted suicide cases explicitly distinguished between terminal sedation and assisted suicide on the basis of the practitioner's intent. Writing for the majority in one of the cases (30), Chief Justice Rehnquist conceded that the line might be fine, but affirmed the states' freedom to draw it.

> Just as a State may prohibit assisting suicide while permitting patients to refuse unwanted lifesaving treatment, it may permit palliative care related to that refusal, which may have the foreseen but unintended "double effect" of hastening the patient's death.
>
> —521 US 793, 808 n.11

(No federal or state court has since addressed terminal sedation in any context.)

Do patients have a legal right to receive palliative care up to and including terminal sedation? Justice O'Connor's concurring opinion in *Quill* suggests at least that states may not be free to infringe on access to palliative care.

> The parties and *amici* agree that … a patient who is suffering from a terminal illness and who is experiencing great pain has no legal barriers to obtaining medication, from qualified practitioners, to alleviate that suffering, even to the point of causing unconsciousness and hastening death.… In this light, … I agree that the State's interests in protecting those who are not truly competent or facing imminent death, or those whose decisions to hasten death would not truly be voluntary, are sufficiently weighty to justify a prohibition against physicianassisted suicide.
>
> —521 U.S., at 736–736, internal citations omitted

Justice Souter added:

> I do not believe … that this Court need or now should decide whether or not a … [a right to assisted suicide] is "fundamental." That is because, in my view, the avoidance of severe physical pain (connected with death) would have to constitute an essential part of any successful claim and because, as Justice O'CONNOR points out, the laws before us do not force a dying person to undergo that kind of pain. [They] … do not prohibit doctors from providing patients with drugs sufficient to control pain despite the risk that those drugs themselves will kill.
>
> —Id. at 785, internal citations omitted

These justices thereby uncoupled the state's right to forbid physician-assisted suicide from a right of patients to have their pain controlled even if death is thereby

facilitated.

In sum, the practitioner who intends to treat pain and does so with a decent respect for the standards of care has no reason to fear legal sanctions in the palliative context. A wise practitioner dealing with a seriously ill patient will assess and document pain and treat it aggressively. Except under Oregon's procedures, a physician who is asked to help a patient die by providing or administering a lethal dose of any medication *must* decline. However, ethically the physician *must* also make and keep a promise that pain and other symptoms will be treated even up to the point of sedation if that is what the patient or surrogate wants. If the physician cannot keep that promise, referral or consultation are not only appropriate but also required.

Physician-Assisted Suicide Is Presently Legal Only in Oregon

In all states but Oregon (31), assisted suicide is either specifically illegal (32) or presumptively illegal (33). In states where there is no statute at all, the act is regarded as illegal and punishable as a “common law felony.” [These deeds were felonies at the time the state constitutions were created but were never formally reenacted by statute. These “saved crimes” are now lumped together as minor felonies (34).] Relying on the “saved crimes” concept, the Michigan Supreme Court held that Dr. Kevorkian could be indicted for assisting a suicide even though the state had no assisted suicide statute on the books. Physician-assisted suicide is also a specific violation of federal law when conducted on a federal property, and federal funds may not be used in any jurisdiction to support physician-assisted suicide (35).

The Oregon statute is quite limited. The patient must be legally competent, a legal resident of the state, and have a life expectancy of 6 months or less. The patient must make an initial request both orally and in writing. An attending and a consulting physician must independently certify to the diagnosis and prognosis and that the patient is competent, not depressed, and has been informed of available options such as hospice, comfort care, and pain management. After certification the patient must again request assistance orally and in writing and then must repeat the request orally after a 15-day waiting period. The patient must also be physically able to take the medication without help. If all these conditions are met, the participating physicians are exempt from any penalties relating to suicide or murder and the patient's death does not constitute suicide for insurance purposes (36). Oregon's statute remains controversial. There have been several efforts to pass federal legislation that will preclude the use of federally controlled substances in assisted suicide. In 2001, the U.S. Attorney General instructed the DEA the department would not consider assisted suicide as a “legitimate medical purpose” under the Controlled Substances Act even if state law permitted the practice. Oregon promptly sued and a federal court enjoined implementation of the Attorney General's interpretation.

PALLIATING CHRONIC INTRACTABLE PAIN REQUIRES CLOSE ADHERENCE TO GUIDELINES

Untreated, chronic, intractable pain is epidemic in the United States and worldwide. The failure to treat it in the United States is directly a product of the fear of criminal and license sanctions. This should not be. The ethics of treating chronic pain are the same as for terminal pain. All but five U.S. jurisdictions (37) currently have state medical board guidelines and/or statutes that explicitly encourage treatment of chronic pain with opioids when other analgesic methods are not effective. The statutes and guidelines also set out standards for practitioners. There is no indication that the remaining five jurisdictions are more stringent.

If the state guidelines are followed, the guidelines assure the practitioner that there will be no licensing sanctions. If the state has passed an Intractable Pain Act, the practitioner is also protected from prosecution when guidelines are followed. These guidelines, as represented by the model guideline of the Federation of State Medical Boards, have the informal approval of the U.S. Drug Enforcement Administration.

A physician who prescribes opioids should strictly follow his or her state guidelines, which, in any case, make good medical sense in terms of history, examination, documentation, plan of care, and supervision. Maintaining a patient on opioid therapy without evidence that the patient is functionally better off with the medication than he or she is without, or in disregard of evidence of dysfunction or diversion, should be strictly avoided. Doctors who are subjected to medical board sanctions or investigated criminally almost always have failed to document their examinations, treatments, progress, and plan of care or have been indifferent to evidence of diversion or abuse.

PRACTITIONER LIABILITY FOR INADEQUATE PALLIATIVE CARE

Practitioners need to realize (and communicate to their risk managers) that *undertreatment* of pain is becoming legally risky. It will become more so as the public is educated by palliative care advocates to understand that most pain can be treated. Inadequate palliative care can be malpractice. It can invoke liability for battery, elder abuse, and infliction of severe emotional distress. Patient advocates are pushing hard to focus state medical boards, accreditation organizations, and the “fraud and abuse” investigators of Medicare/Medicaid bureaucracies on inadequate palliative care.

RISK OF MALPRACTICE LIABILITY IS SUBSTANTIALLY INCREASED BY NEW GUIDELINES AND STANDARDS FOR PAIN ASSESSMENT AND MANAGEMENT

Medical malpractice is a specialized branch of negligence law. To show malpractice, a plaintiff must prove by a preponderance of the evidence: (a) a legal duty of care, (b) a breach of the duty by the defendant, and (c) damages that are proximately caused by the breach. Each of the required elements has an accretion of law.

Duty of Care

As relevant here, duty is established by proof of a doctor (nurse)/patient relationship or a hospital/patient relationship. It is a given in cases that involve failure of care in most institutional settings.

Breach of Duty

A practitioner breaches the duty of care by falling short of the standard of care “in the community” for whatever treatment or decision is at issue. Both the existence of the standard of care and failure to meet the standard *must* be shown through expert medical testimony. If the practitioner is a specialist, the testimony must show that he fell short of the standard of care for the specialty, which might be higher than the standard applicable to a general practitioner. The jury must believe that the care fell culpably short of what a hypothetical “reasonable practitioner” faced with the same patient in the same condition would have been expected to provide. The standard of care never requires perfection. Finally, the plaintiff has to show that the practitioner's negligent acts proximately caused a cognizable injury.

The critical hurdle for malpractice actions based on inadequate control of pain and other symptoms of the terminally ill has been the “standard of care.” A practitioner cannot breach a standard of care until one exists. Until very recently, there was no medical consensus on clinical management of pain, or even agreement that a practitioner had a responsibility to relieve pain and suffering. Physicians were not well educated in pain management, and there were few resources available. “Not very good” *was* the “standard of care.”

That has changed (38). A consensus on good pain management practice has been building strongly for 10 years and has existed at least since the mid-1990s in a form sufficiently official to be useful in litigation. The pain management standards made applicable to every facility accredited by the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) are clear evidence that there is a standard for pain assessment and treatment (39). JCAHO hardly stands alone. The American Medical Association's program for Education for Physicians on End-of-life Care provides concise information on pain management with many references. It is being made available to every American Medical Association member. Similarly, a consensus has developed on chronic pain management that encourages use of opioids as a legitimate part of pain management. The Federation of State Medical Boards, after long study, published model guidelines for physicians treating chronic pain with opioids. They have been adopted as law or guidelines in 38 states (40).

Injury and Damages

The final ingredient in a malpractice case is proof of injury and entitlement to damages for that injury. This remains a difficult burden because it requires a different analysis than other medical injuries. In the classic malpractice case, harm is done by a practitioner's inept treatment or failure to be aware of what treatment is called for. Therefore, pain and suffering related to that failure is a separate cognizable component of the damage (41), not the injury itself. Pain alone, without a physical manifestation, was not considered an injury. Not providing pain medication does not increase costs. If a patient died, it was due to the underlying disease, not the treatment or lack of it. Pain was just part of the overall sad circumstance.

This analysis is no longer justified. The fact that pain can be treated separately from the disease and even can be treated when the disease is beyond treatment changes the analysis. It is also clear that untreated pain itself can cause more pain and do long-term physical and emotional damage (42).

In 1993, a North Carolina jury found a nursing home liable for pain and suffering experienced when a nurse, concerned about “addiction,” substituted weak analgesics

and a mild antidepressant for morphine ordered by the physician to treat the pain of end-stage prostate cancer (43). After extended testimony on the duty to treat pain and the standard of care for pain management, the jury awarded $15 million in compensatory and punitive damages. In approving a later settlement, the trial judge noted that the claim was for pain and suffering alone, not for wrongful death or some other harm to the patient (43).

Shortly thereafter, the Sixth Circuit affirmed a “pain only” injury under Tennessee law. The plaintiff and her husband were admitted to a hospital following a car accident. They were officially discharged (for transfer to another hospital as arranged for by the defendant) at midmorning. Due to transportation delays, they did not leave the hospital until the next evening. While they waited, hospital staff refused to give any pain medication, and medical records did not reflect visits from the doctor. As part of a larger judgment, plaintiff was awarded $25,000 in compensatory and punitive damages for the pain and suffering the plaintiff claimed had resulted from the doctor's abandonment and negligence (44).

INADEQUATE PAIN MANAGEMENT MAY CONSTITUTE “INFLICTION OF SEVERE EMOTIONAL DISTRESS”

The law recognizes two different kinds of infliction of emotional distress—negligent and intentional. Either of these could apply to a patient or to the family of a patient who has been subject to inadequate pain treatment.

A successful plaintiff in an emotional distress case is entitled to damages for mental distress or emotional disturbance that result from either purposeful or willful conduct by the defendant (intentional infliction) or indifferent and negligent behavior (negligent infliction). The difference is a matter of degree. Both require actions that cause actual consequences for the victim's physical or emotional health (45). Most states require that the plaintiff show that the emotional distress suffered had physical consequences such as sleep disruption, headaches, or gastrointestinal problems (46). However, 14 states allow recovery for emotional distress without requiring any physical manifestation (47).

Intentional infliction, a more serious complaint, has four elements. The defendant must act intentionally or recklessly, the conduct must be extreme or outrageous, the conduct must be the cause of the emotional distress, and the distress must be severe (48). The outrageousness of the defendant's conduct can be proven by the plaintiff's testimony. The severity of the distress must usually be proven by expert testimony. A physician, for example, might testify to treatment of the plaintiff for insomnia, nightmares, anxiety, or depression. Courts have held that “[p]hysical manifestation of emotional distress … may serve as proof of serious mental injury. Moreover, evidence that a plaintiff has suffered from nightmares, insomnia, and depression or has sought psychiatric treatment may support a claim of serious mental injury” (49). It also appears that next of kin of terminally ill patients are almost by definition in a precarious emotional state so that they are more easily distressed by callousness or negligence (50).

Emotional distress has a long-standing application in medical lawsuits. A physician can be held liable for mental and emotional anguish suffered by a patient due to negligent care or reckless misconduct. Some jurisdictions also employ a bystander rule that allows family members to recover for the emotional distress caused by watching a relative suffer negligent medical treatment. For example, parents have been allowed to sue for the negligent treatment of a newborn infant who was presumed dead by the hospital staff but turned out to be alive (51), for the negligent mishandling of a deceased child's body (52), and for observing the death of a newborn child due to alleged negligence by the obstetrician and staff (53). The same approach should also apply to those who watch loved family members suffer due to failure to treat pain. The analogy to the labor and delivery cases is clear in the hospital or nursing home setting where the patient is obviously suffering. The doctrine is “arguably applicable to any instances of intractable pain and its poor management in extreme cases” (54).

INADEQUATE PAIN MANAGEMENT MAY BE ABANDONMENT OF THE PATIENT

When a doctor agrees to treat a patient, that doctor has a duty to give the patient all necessary attention for as long as the patient needs it (55). A physician who leaves a patient at a critical stage of treatment without giving the patient adequate notice and time to choose another caregiver has abandoned the patient (56). Abandonment of a patient by his or her physician is a tort (57), and a physician who does it is liable for damages.

To prove abandonment the patient must show four things: Abandonment cannot take place without an established physician-patient relationship (58). The physician must have terminated his or her relationship with the patient or neglected the patient. The termination must have been done without reason or without sufficient notice to allow the patient to choose another physician, and the patient must have been injured as a result (64).

A physician who promises to help manage a patient's pain and then fails to do so may be found to have abandoned the patient. In one case (60), the patient's obstetrician promised to provide anesthesia for the patient's labor and delivery. The patient went into labor while the physician was away on a fishing trip, and the substitute obstetrician refused to give her any anesthetic. The patient sued for abandonment, arguing that she had not been given adequate notice or time to choose her own substitute obstetrician and that she had been injured by being deprived of the promised anesthesia. The court found that so long as the patient had not been given adequate notice, she had been abandoned, and the lack of help managing her pain during delivery was an injury. *Lynch v Bryant*, discussed above (see the section Injury and Damages) in the context of severe emotional distress, is also an abandonment case.

TREATMENT IN EXCESS OF PATIENT DIRECTIVES CONSTITUTES MEDICAL BATTERY

Medical battery occurs when the medical treatment given to a patient exceeds the patient's consent (61). It requires proof of an unwanted touching (medical care) but does not require physical harm and, in fact, the touching can be relatively trivial or even arguably beneficial. It is well established that failure to honor DNR orders or advance directives constitutes battery. In *Leach v Shapiro* (62), for example, an Ohio Court of Appeals found that there had been harmful contact when a woman in a chronic vegetative state was placed on life support without her consent. Similarly, a Michigan jury awarded surviving family members approximately $16 million for mental anguish and past and future expenses for medical care after life-sustaining procedures were performed in direct violation of a surrogate's instructions pursuant to a durable power of attorney for health care. A limited number of state statutes go further to create a specific cause of action when a practitioner fails to honor an advance directive or a living will (63).

TREATMENT IN EXCESS OF PATIENT DIRECTIVES MAY NOT BE “MEDICALLY NECESSARY” FOR PAYMENT PURPOSES

When a health care provider submits a request for insurance or Medicare/Medicaid reimbursement, he or she certifies that the service was reasonable and necessary (64). The federal program is required by law to deny payment for inappropriate services (65).

The legislative history of Medicare/Medicaid shows the importance Congress placed on a physician's certification that the care given is necessary. “The physician is to be the key figure in determining utilization of health services…. It is a physician who is to decide upon admission to a hospital, order tests, drugs and treatments, and determine the length of stay. For this reason the [Medicare statute] would require that payment could be made only if a physician certifies to the medical necessity of the services furnished” (66).

There are several ways that the certification's validity could be questioned in terminal care. If an advance directive precludes resuscitation, charges for life-prolonging resuscitation may not be necessary. Similarly, there is a reasonable argument to be made that any aggressive curative care to a patient who is terminally ill is legally unnecessary unless the patient is also advised that hospice care is an available alternative form of treatment. Although hospice issues are outside the scope of this article, a physician's failure to fully explain the hospice alternative to Medicare and Medicaid beneficiaries is a severe detriment to quality of life in terminally ill patients who might choose to take advantage of it if properly informed.

ELDER ABUSE STATUTES AND FAILURES OF PAIN MANAGEMENT

Older Americans are disproportionately represented in the sick and dying. Older Americans who are sick and dying receive less medication for pain than younger people (67), and demented older people receive less pain management than their competent contemporaries (68).

Almost every state has some form of elder abuse or adult protective services statute that defines elder abuse and provides a remedy for abusive actions. Most of the statutes protect disabled adults of any age. Combining these facts with the JCAHO pain standards applicable to hospitals and nursing homes and the American Geriatric Society's guidelines for the management of chronic pain (69), health care providers should be alert to the potential that failure to manage an elderly or incapacitated person's pain will be labeled elder abuse.

In June 2000, a California jury awarded $1.5 million to the family of an elderly man with a metastasized lung and bone cancer (70). He was prescribed low levels of pain medicine while he was in the hospital. Hospital records showed that throughout the hospitalization his pain was rated between 7–10 on an assessment scale. On discharge, although his pain was still rated a 10, he was prescribed oral acetaminophen/hydrocodone, which he could not swallow, supplemented later with a low dose of transdermal fentanyl and a meperidine injection. His doctor flatly refused to prescribe anything stronger despite his continuous pain. After several days, another

doctor prescribed higher doses of morphine, which brought immediate relief.

The physician defended his actions on grounds that he was not sure of the diagnosis as of the time of discharge and feared respiratory depression if morphine were administered. At trial medical experts testified on both sides. However, unlike criminal statutes, civil cases do not have to be proven “beyond a reasonable doubt.” Rather, they are judged on a much less stringent “preponderance of the evidence,” and the jury was free to weigh the expert testimony and find for the plaintiff.

This case is significant because it directly addresses pain and because the California elder abuse statute (71) requires proof (by a preponderance of the evidence) of reckless and malicious behavior to find liability. Many states have a lower standard in their elder abuse statutes and appear to require less stringent evidence of neglect or pain. They impose liability without the heightened “malicious and reckless” standard used in California. In addition, elder abuse statutes often permit punitive as well as compensatory damages and provide that the cause of action will survive the abused adult rather than terminate at his or her death (72). It is reasonable to expect that this cause of action will become far more common in the near future.

CONCLUSION

Both law and ethics require health care providers to walk a middle ground, treating pain and other symptoms aggressively to ease the process of any serious illness but to be wary of prescribing practices that might increase dependence and diversion in predisposed patients. Although some physicians have, understandably, characterized this middle ground as “between a rock and a hard place,” it is far more realistic to think of palliative care as good medicine: you want to deliver it, not deny it. No legal or ethical barriers exist that will hinder a good practitioner from providing palliative care. “Physicians should base treatment decisions on the scientific and medical evidence that is available from many sources. It is time for physicians, nurses, pharmacists, other health care professionals, system administrators, and regulators to come together to ensure improved function and good quality of life for all persons in pain” (73).

HEMATOLOGIC SUPPORT OF THE CANCER PATIENT

DAVEY B. DANIEL
EILEEN M. JOHNSTON
JEFFREY CRAWFORD

Cytopenias are a frequent and sometimes dangerous complication of malignancy and its treatment. The mechanisms causing these are numerous and are sometimes difficult to determine in an individual patient. Originally only armed with transfusion products and time, oncologists now have additional tools to deal with cytopenia. However, the appropriate use of transfusions and growth factors requires both an understanding of the literature and much clinical discretion.

ANEMIA

Etiology

Anemia is a frequent finding and a major factor in morbidity in many oncology patients. More than half of all cancer patients will be anemic regardless of treatment received, and approximately 20% of all patients undergoing chemotherapy will require red blood cell (RBC) transfusion during their treatment course. Patients with lung cancer, lymphoma, genitourinary tumors, and gynecological malignancies have the highest transfusion rates, perhaps due to the higher frequency of myelotoxic therapy to treat these tumors. Anemia within the hematologic malignancies is almost universal.

The etiology of anemia in cancer patients is usually multifactorial and is frequently a complication of both the cancer itself and its treatment. Tumor cells can invade the bone marrow, as in breast and prostate cancer, or can suppress marrow and erythropoietin production by cytokine production. Tumor necrosis factor has been shown to decrease marrow responsiveness, whereas beta interferon is thought to inhibit erythropoietin production within the kidney. Anemia of chronic disease, blood loss, shortened red cell survival, nutritional deficits, and underlying infection (again causing cytokine-related suppression) can be sources of anemia. Less common are acute hemorrhage from the malignancy itself and hemolytic states such as disseminated intravascular coagulation associated with promyelocytic leukemia and sepsis, immune hemolytic anemias from chronic lymphocytic leukemia, and medication-induced hemolysis. Anemia of chronic disease is the most frequent cause and is characterized by normocytic and normochromic morphology on peripheral and bone marrow exam, low serum iron and iron binding capacity, normal or increased marrow iron stores, and blunted erythropoietin levels and response. Finally, the continued bombardment of the marrow by myelotoxic regimens, including the newer combination regimens, can cause significant and prolonged anemia with repeated cycles causing a cumulative injury to production.

Chemotherapy can cause both transient and sustained cytopenia. The storage compartment of the marrow contains enough maturing cells to maintain peripheral counts for approximately 8–10 days after stem cell production ceases. Thus, the effect of cell cycle–specific chemotherapy will be notable by the tenth day after treatment, nadir counts are manifest between days 14 and 18, and recovery occurs between days 21 and 28. In contrast, G_0 active agents are characterized by delayed nadir counts (4 weeks) and prolonged recovery time (6 weeks) owing to the preferential effect on resting stem cells. Repeated dosing of chemotherapy, especially during early marrow recovery, may result in sustained toxicity and persistent pancytopenia. This effect is perhaps most notable with the alkylating agents owing to cumulative DNA damage. Likewise, radiation therapy further contributes to the anemia, particularly when the marrow is already suppressed.

Role of Erythropoietin

Erythropoietin plays a key role in RBC production and in the anemia due to cancer. An obligatory growth factor and regulatory molecule, erythropoietin affects RBC production by stimulating the burst forming units–erythroid (BFU-E) and the colony forming units–erythroid (CFU-E). The BFU-E cells are early cells within erythropoiesis, which proliferate rapidly and have a low number of erythropoietin receptors. Therefore, a higher level of erythropoietin is necessary to stimulate entry into the cell cycle for BFU-E cells. The later CFU-E cells have a high number of erythropoietin receptors and require a constitutive level of erythropoietin for continued survival, growth, and production. Erythropoietin thus shows a keen regulatory mechanism for red cell production. In the adult, approximately 90% of erythropoietin is produced within the peritubular fibroblastoid cells of the inner cortex of the kidney, and the remainder are produced in the liver. Within the peritubular intersitial cells, erythropoietin production is constitutive and inducible, with baseline levels produced from each cell and additional cells recruited to increase production for hypoxic states. As arterial PO_2 levels decrease and tissue hypoxia increases, erythropoietin levels increase, acting as a key regulatory mechanism. Thus erythropoietin has been shown to be responsive to hypoxic states, and as seen in the setting of decreased hemoglobin levels, it increases committed red cell progenitors and the rate of maturation of the reticulocytes. The erythropoietin level is fairly constant for an individual with stable hemoglobin level. It does not vary with gender or age, and has no biologically inactive precursor or stores.

Cancer can affect erythropoietin by decreasing the marrow responsiveness to erythropoietin or by decreasing erythropoietin production, as tumor necrosis factor and some nephrotoxic agents can. In both a rat model and in a group of lung cancer patients, cisplatin was shown to cause depressed erythropoietin levels from the expected compared to controls with similar levels of anemia (1). These patients did not mount the usual increased erythropoietin response levels to anemia after receiving cisplatin but were capable of producing increased levels once cisplatin treatment had been completed and renal function improved. Although this study suggests that patients are unable to support sufficient erythropoietin production, others show that cancer patients are unable to respond to the physiologically increased levels in response to cancer. In a study of 35 patients with lung cancer before initiation of treatment, Dowlati et al. showed that even when anemic cancer patients have increased production of erythropoietin, they have lower ratios of erythropoietin to serum soluble transferring receptors. This ratio is a marker of erythropoiesis and is elevated with increased production. This lower ratio shows that the marrow is not appropriately responsive to the stimulation by erythropoietin (2).

Usually, a decrease in oxygen-carrying capacity results in elevated erythropoietin levels. In fact, Finch (3) found erythropoietin levels increased as hemoglobin levels

dropped below 12 g/dl. However, cancer patients are often resistant to or incapable of producing increased levels of erythropoietin. In a study of 81 solid tumor patients, Miller et al. (4) showed that compared with a group of iron deficient controls matched for hemoglobin levels, cancer patients had significantly lower levels of erythropoietin regardless of cisplatin therapy.

Symptoms

Cancer patients often are fatigued and a major treatable component of fatigue is anemia. In a study of 1171 patients, fatigue was identified as the leading complaint of cancer patients—greater than pain, nausea, or emesis (5). Indeed, this study found that although physicians' major focus was treating pain, patients noted that fatigue was a greater concern. In addition to fatigue, anemia may be associated with other symptoms: shortness of breath, tachycardia, chest pain, dizziness, headache, claudication pain, colonic angina, and even depression. The pattern of symptoms and the individual's ability to tolerate them is significantly dependent on the rapidity of onset of the anemia, the patient's baseline functional status, and comorbid conditions. Although anemic patients may show pallor, orthostasis (if insufficient volume expansion has occurred), and hypoxia, these are usually patients with large acute hemorrhages who have not had sufficient time for volume expansion. It is the gradual onset of anemia that is much more characteristic of oncology patients and is more often associated with the insidious symptoms of fatigue, decreased exercise tolerance, and, in the elderly, sometimes confusion. Indeed, elderly patients have a lower reserve capacity and may display any of these symptoms at higher hemoglobin levels. A number of patient self-assessment scales have been created in the past decade by Cella to assess the effect that anemia has on the quality of life (QoL) in the individual patient (5). These scales concentrate on both the fatigue related to anemia with measurements of weakness, energy level, social limitations, and nonfatigue-related symptoms including difficulty walking, dizziness, headaches, dyspnea, chest pain, libido, and difficulty with motivation.

With laboratory testing, the diagnosis of anemia is rarely difficult. The history and examination clarifies how well a patient is tolerating the anemia. Physical examination findings are highly variable. Pallor can be difficult to recognize and is very dependent on pigmentation but mucosal membranes, nail beds, and palmar creases are often areas where pallor is more consistently noted. The decreased volume of anemia may cause widened pulse pressure, a hyperdynamic precordium, and systolic flow murmurs loudest at the apex with radiation along the sternum to the neck. Finally, patients with severe anemia can show signs of high output cardiac failure with peripheral edema and an S_3 gallop.

Transfusion

Despite a decade of debate, the question remains: What level of anemia is clinically significant? Oxygen delivery is maximized at hematocrits between 30% and 40%, but observational studies have shown no difference in morbidity and mortality in patients with hematocrits as low as 10%, provided sufficient intravascular volume is maintained. In the intensive care medicine literature, there remains a debate over what transfusion threshold should be used. A recent multicenter randomized trial of 838 intensive care unit patients showed that a restrictive transfusion strategy, using 7 g/dl of hemoglobin versus 10 g/dl in the control, yielded similar 30-day mortality rates and had statistically significant lower inhospital mortality (6). In a later subgroup analysis, those patients with coronary disease also had similar mortality rates within the two transfusion regimens (7). Reasons for equivalent mortality despite increased oxygen delivering capacity at higher hemoglobin levels may relate to a theorized immunosuppression that some have noted with transfusions, as well as the risks of transfusion reactions and complications.

This intensive care population is very different from the patients usually seen in oncology. The cancer patient often has a chronic anemia, and the focus is generally not on shortterm mortality but rather on QoL and symptom management. It has been thought that chronically anemic patients fare better than others through compensatory mechanisms of maintenance of plasma volume, maintained cardiac output, and shifts in the oxygen-hemoglobin dissociation curve from 2,3-diphosphoglycerate production. This has been the general teaching for some time. However, there is now mounting evidence that oncology patients with chronic anemia may significantly benefit from hemoglobin levels near normal, which are far greater than that we have sought to maintain in the past or in other patient populations.

The decision to transfuse a patient with blood products must take into consideration the degree of physiologic stress from the anemia, comorbid illness, the potential of recovery without transfusion, and finally, transfusion risks. Traditionally within oncology, anemia was noted but not treated. Due to reactions and infectious risks, transfusions were reserved to those times when patients were thought to substantially benefit from exposures to these risks. Transfusion thresholds varied but were often carried out only when hemoglobin levels dropped substantially, sometimes below 8 g/dl. New data suggest that QoL may be better maintained at much higher hemoglobin levels, and that some patients may be undertreated.

Immunologic Effects of Red Blood Cell Transfusion

The effect of transfusion on immunologic function has been debated for three decades. In 1973, Opelz et al. described an improvement of allograft survival in patients who had previously received transfusions (8). Allogeneic transfusions have also been shown to improve disease response in patients with inflammatory bowel disease. Each of these suggested a potential immunomodulatory effect of allogeneic transfusions. However, this enthusiasm has been tempered by concern for the impact this may have on those requiring transfusions for hematologic support, particularly in oncology patients undergoing surgery with curative intent.

In the 1980s, a number of retrospective analyses suggested that patients who received blood products perioperatively for cancer-related surgery had increased incidence of tumor recurrence. There were also several conflicting studies that did not support an immunosuppressive theory. These were retrospective studies, many of which are plagued by multiple confounders. A meta-analysis by Chung et al. (9) compiling over 5000 patients undergoing colorectal carcinoma surgery concluded that there was an increased risk for adverse outcome (death, cancer death, or recurrence) in transfused patients (odds ratio of 1.69). In a similar meta-analysis, transfused patients with colorectal carcinoma had a relative risk of recurrence or cancer-related death of 1.37 (10). Again, these analyses were limited by the data of the individual studies, which could not sufficiently correct for confounders such as comorbidities.

There have been two randomized trials that evaluated allogeneic transfusions and the risks for infection and tumor recurrence. Busch et al. (11) randomized 475 patients to autologous and allogeneic transfusion perioperatively for colorectal carcinoma resection. There were no substantial differences between the two groups for postoperative mortality, infectious complications, recurrent disease, or disease-free survival, but there was an increase in disease-free survival in patients receiving no transfusions (73% vs. 59% in those receiving transfusions). However, 28% of those assigned to the autologous group also received allogeneic transfusions because a two-unit limit was set for autologous transfusions. This may have diluted the power to detect changes due to allogeneic transfusions. A second study also failed to show a difference in survival due to transfusion (12).

The mechanism behind a hypothetical immunosuppression from allogeneic transfusions has not been fully explained. It may involve an alteration in the cytokine milieu, with down-regulation of cell-mediated immunity accounting for the enhanced tumor survival as well as the improvement that has been noted in inflammatory bowel disease (12). Heiss et al. confirmed that allogeneic blood transfusions do indeed alter cytokine production in a study of 52 patients undergoing colorectal surgery who required transfusions. Patients receiving allogeneic transfusions had increased levels of interleukin-2 (IL-2) and IL-2 receptors, lower levels of tumor necrosis factor, and significantly elevated IL-10 levels. This again supports an immunomodulatory role of transfusions, which may place patients at increased risk for infection and tumor recurrence through a less vigilant immune system following transfusion.

Erythropoietin

There has been rapid progress during the last two decades as biotechnology has changed our options for treatment of anemia. It was only in 1985 that recombinant human erythropoietin (rHuEPO) was purified and cloned. In 1987, it was approved for treatment of anemia related to renal disease and then, in 1990, it was approved for human immunodeficiency virus (HIV)–related anemia. A number of small phase I and II trials in the early 1990s showed efficacy in the treatment of anemia related to chemotherapy. Ludwig et al. (13) showed in a phase II trial of 13 patients with multiple myeloma–related anemia an 85% response rate to epoetin alfa treatment with at least a 2 g/dl increase in hemoglobin and relief from transfusion dependence. Similarly, in a phase I–II trial of 21 patients receiving cisplatin with hemoglobin levels less than 11 g/dl, patients were randomized to 100 units/kg or 200 units/kg five times per week and the overall response rate was greater than 50%, with a mean rise in hemoglobin of 2.5 g/dl (14).

In a randomized trial of erythropoietin, Abels (15) studied 413 patients with a variety of advanced malignancies (excluding myeloid malignancy) and hematocrits less than 32%. Patients not receiving chemotherapy were given erythropoietin at 100 units/kg subcutaneously three times weekly while patients undergoing chemotherapy were given 150 units/kg three times weekly, with each group titrated to keep hematocrit less than 38%. In the nonchemotherapy group, 32% of those treated with erythropoietin had an elevation in hematocrit of six or more points, after 8 weeks, compared with 10% in the placebo group. Those undergoing nonplatinum-based regimens had a higher response rate (58% vs. placebo 13%) compared with cisplatin-treated patients (48% vs. placebo 6%) at 12 weeks. No increased rate of adverse effects was noted in erythropoietin groups, and QoL parameters showed improvement in all patients responding to erythropoietin regardless of chemotherapy treatment. At the end of the first month, transfusion requirements for rHuEPO patients had already decreased again regardless of the chemotherapy regimen.

Based on the data from these phase I and II trials, erythropoietin was approved for treatment of chemotherapyassociated anemia in 1993. However, it had not yet been shown to be effective in large trials with a large variety of tumor types. Three large community-based, observational studies were completed during the last 5 years (Fig. 67-1). Each prospectively examined the open-label use of erythropoietin in anemic cancer patients undergoing chemotherapy and recorded change in hemoglobin, transfusion requirements, and QoL measurements. All three studies reached similar conclusions regarding the effectiveness of erythropoietin in increasing

both hemoglobin levels and QoL scores.

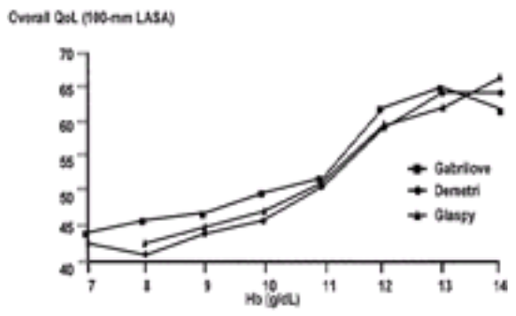

FIGURE 67-1. Community-based trials. Overall quality of life (QoL) associated with hemoglobin (Hb) levels (cross-sectional). LASA, Linear Analog Scale Assessment, also known as Cancer Linear Analog Scale (CLAS). (From references 16,17 and 20, with permission.)

Demetri et al. (16) examined 2370 patients with nonmyeloid malignancies, the majority (78%) of whom had solid tumors (24% lung, 17% breast, and 13% gynecological). Roughly one-fourth of these patients received a platinum-based therapy—a regimen known to cause significant anemia. Each had a hemoglobin level less than 11 g/dl, with an overall mean hemoglobin of 9.3 g/dl, and were given 10,000 units of epoetin alfa three times weekly with increased doses to 20,000 units if unresponsive at week four. Sixty-three percent of patients responded by an increase of at least 1 g/dl after 4 weeks of treatment. At 4 months, the mean hemoglobin had risen by 2 g/dl, and the transfusion rate had decreased from 29% the month before treatment to 5% at month four. Also, patients showed an improvement in QoL as measured by visual analog scales and by the Functional Assessment of Cancer Therapy-Anemia, self-report instruments. The difference was statistically different ($p < .001$), with those with the greatest increase in hemoglobin showing the most improvement. Those with a less than 2 g/dl response had improvement in QoL measurements if the disease was stable or responsive to chemotherapy. As might be expected, patients did not have an improvement in QoL if hemoglobin level did not increase or if they had disease progression. However, those with progressive disease and a greater than 2 g/dl response showed a much less severe decrease in QoL compared to similar patients that had no improvement in hemoglobin level.

These results were consistent with a similar study by Glaspy et al. (17). This open-label, nonrandomized study enrolled more than 2352 patients with hematologic or solid tumor malignancy under the care of more than 500 community-based oncologists. Epoetin alfa was well tolerated, with only a 3% discontinuation rate from side effects. More than half of those patients evaluable had an increase in hemoglobin level of greater than 2.0 g/dl. There were insufficient data to determine if there was survival benefit in those receiving epoetin alfa therapy and to fully differentiate QoL improvements by tumor response, although trends showed improvements in those with complete, partial response, or even stable disease. This study also showed decreased transfusion requirements (by 50%) and again no easily identifiable predictors for response. Some studies have shown that early changes in the transferrin receptor protein level, reticulocyte count, and hemoglobin may be the most effective way to identify those who are responding early in the course of treatment, but these have not yet been shown to be an effective clinical tool (18). Other measurements of endogenous erythropoietin levels and ferritin levels have had inconsistent abilities to predict response.

The three-times-weekly regimen for epoetin alfa administration is somewhat restrictive. Patients or their caregivers must either learn to administer injections or make frequent visits to the clinic, increasing the cost of care. There is clinical evidence showing efficacy of a once weekly dosing schedule. In a study of 62 healthy, nonanemic male volunteers, Cheung et al. (19) administered several doses and dosing regimens, including a study randomizing patients to either 150 IU/kg 3 times a week for 4 weeks or 600 IU/kg once per week for 4 weeks. Results from these trials showed that epoetin alfa's pharmacologic response is dependent both on the dose and dosing regimen. Both the three times weekly and the once weekly dosing regimens maintained elevated serum erythropoietin levels and reticulocyte percentages (1–2%) (19). This finding suggested that weekly dosing, which is more convenient and likely more cost-effective, may be an option in the treatment of patients with cancer-related anemia.

Gabrilove et al. examined this issue in the third of the large community-based trials of erythropoietin (20). Patients were dosed at 40,000 units per week with a dose escalation to 60,000 units/week if unresponsive. Again, weekly epoetin alfa offered significant improvements in QoL, hemoglobin level, and transfusion requirements, which was identical to the results in the two previous, community-based trials using three times a week schedule. This large study provided reassuring clinical data that once weekly dosing is a reasonable alternative, and it has now become the community standard in the United States.

Prevention of Chemotherapy-Induced Anemia

Although the above studies all showed that it was possible to treat anemia resulting from chemotherapy treatment, none examined the outcomes associated with the prevention of anemia. In 1997, a blinded study randomized 27 patients with small cell lung cancer receiving treatment with cyclophosphamide, doxorubicin, etoposide, and granulocyte colony-stimulating factor (G-CSF) to receive placebo or epoetin alfa (at 75 units/kg/day beginning on day 1 continuing through six cycles) (21). Crossover to the treatment arm was allowed for placebo patients who became anemic. This chemotherapy regimen had previously resulted in a 100% anemia rate and 80% transfusion dependence. In this study, those randomized to erythropoietin had a mean time to anemia of 3.7 cycles compared to 1.5 cycles of placebo patients. Time to transfusion was 96 days for those treated with epoetin alfa compared with 43 days for placebo patients. Although impressive differences in time to transfusion were seen, because of crossover, further effects of epoetin alfa may have been blunted. Similar preventative results were found in a trial of 36 patients with head and neck carcinoma receiving neoadjuvant chemotherapy with paclitaxel and carboplatin. The mean hemoglobin of the erythropoietin group fell 0.5 g/dl while those receiving no treatment had a decrease of 3.3 g/dl (22).

Anemia and Treatment Response

A number of studies have shown that tumor hypoxia reduces the tumor responsiveness to radiation therapy. It is thought that oxygen is required to prevent cellular repair of DNA damage from hydroxyl ions produced from radiation. These oxygen molecules fix the damaged areas, preventing repair of sublethal damage from radiation. Not surprisingly, the radiation dose required to kill cells in a hypoxic environment is significantly higher than those with an adequate oxygen supply. Brizel et al. have shown that patients with head and neck tumors treated with radiation therapy have lower, 2-year survival (70% vs. 31%) and 2-year local tumor control (82% vs. 41%) if the PO_2 within the tumor site is less than 10 mm Hg (23). Likewise, differences in survival based on hemoglobin level have been shown in non–small cell lung cancer (hgb >13), and in bladder, prostate, head and neck, and anal cancer (24). Although no current trials have been published showing that using epoetin alfa to increase hemoglobin levels will increase tumor responsiveness to radiation therapy, the above studies suggest that it is fertile ground for further investigation. A recent trial of erythropoietin in the treatment of chemotherapy-related anemia included survival as a secondary end point (25). This trial confirmed other studies showing correlation between improvement in hemoglobin levels and QoL scales. It also showed a trend towards improved survival in its study of 375 solid and hematologic cancer patients randomized to epoetin alfa or placebo. Although not reaching clinical significance, mean survival in the epoetin alfa group was 17 months, compared to 11 months in those patients treated with placebo ($p = .13$). This must be tested further before adding survival to the list of epoetin alfa's benefits.

Novel Erythropoiesis-Stimulating Protein

Novel erythropoiesis-stimulating protein (NESP) (darbopoietin alpha) is an analog of erythropoietin with two additional oligosaccharide chains; it is a larger molecule (38,500 daltons vs. 30,400 daltons) with a slightly different amino acid structure. With the increased glycosylation, its half-life is far greater. Intravenous administered NESP's half-life measures 25.4 hours, and the subcutaneous halflife is even longer at greater than 48 hours (26). Although its affinity for the erythropoietin receptor is somewhat less than rHuEPO's affinity, this does not seem to affect its effectiveness. Two small multicenter studies have shown NESP's efficacy in dialysis patients when given either intravenously or subcutaneously. Weekly administration and three-times-weekly administration (with same total dose) were compared, with no difference in responsiveness between the two arms; the mean change in hemoglobin in the subcutaneous arm was 1.08 g/dl at 4 weeks. The optimal dose was 0.45 µg/kg given weekly based on a dose escalation phase of the study (27). In preliminary studies, Glaspy et al. has compared NESP given weekly to epoetin alfa given three times weekly with no significant difference between the two regimens in oncology patients (28). In a dose escalation trial (29), the highest dose of 4.5 µg/kg gave a mean increase in hemoglobin level of 2.6 g/dl at the trial's end. Further trials are ongoing to determine the optimal dose and schedule of this new agent, and randomized trials comparing NESP to epoetin alpha in the oncology patient are eagerly awaited.

In the future, blood substitutes may play a role in the management of the oncology patient. At present, however, they have not been sufficiently studied, continue to have significant barriers to use, and remain only an intriguing promise. As safety and efficacy improves and use begins in other disciplines, such as surgery, we will begin to see more investigation in the use in oncology patients.

NEUTROPENIA

One of the most common, dose-limiting toxicities of chemotherapy regimens remains neutropenia and its associated complications. Febrile events during neutropenia may be as high as 10% per day for neutropenic patients. Mortality as a consequence of neutropenia may still be as high as 3% in patients with solid tumors (30). Although supportive care for neutropenia continues to be aggressive, with broadspectrum antibiotics and hospitalization for those at moderate to high risk, newer outpatient oral antibiotic regimens have been shown to be appropriate in certain lowrisk populations (31). In addition to the infectious risks, neutropenia often further complicates treatment by requiring dose reductions and dose delays, the consequences of which are difficult to discern.

There are three growth factors with demonstrated efficacy currently available, and a fourth, promising, secondgeneration growth factor is currently awaiting approval in the United States. Filgrastim *(E. coli* derived G-CSF), sargramostim (yeast-derived granulocyte-macrophage colonystimulating factor [GM-CSF]), and molgramostim (*E. coli* derived GM-CSF) all enhance proliferation and maturation of myeloid cells. G-CSF is a lineage-specific growth factor that hastens maturation and release of the committed progenitor pool and prolongs circulation of released granulocytes. The growth factor also enhances neutrophil efficacy through increases in chemotaxis and phagocytosis and primes granulocytes for respiratory burst. With stimulation by growth factors, progenitor cell production and maturation of neutrophils may occur within a single day, compared with the usual 5-day maturation process.

GM-CSF is a lineage-nonspecific factor that acts synergistically with other cytokines to enhance erythroid and multipotent colonies, with resulting broader hematologic effects. Clinical effects include expansion of the myeloid, eosinophil, and monocyte/macrophage pools as well as increased neutrophil activity similar to G-CSF's effects.

G-CSF and GM-CSF are administered subcutaneously at standard doses of 5 μg/kg/day and 250 $\mu g/m^2$/day, respectively; lower doses of G-CSF are now being studied and may lead to more cost-effective administration. Use of these growth factors concomitantly with radiation and chemotherapy is not recommended due to potentially increased toxicity. The optimal timing for initiation and duration of therapy is not completely clear, but typically, growth factor is begun 1–3 days after completion of chemotherapy and discontinued after post-nadir neutrophil recovery. Toxicity related to G-CSF is generally mild. Up to 40% of patients complain of medullary bone pain. Infrequent reactions include allergic reactions, Sweet's syndrome, infection site reaction, and reduction in platelet counts. GM-CSF has a broader range of side effects; patients may note fever, nausea, headache, bone pain, diarrhea, thrombosis, and anorexia.

The data examining the role of growth factors in oncology patients are quite substantial. The American Society of Clinical Oncology (ASCO) periodically reviews the literature and updates its evidence-based recommendations for clinical practice (32). Although there is much variation in the use in individual cases, these guidelines help form a basis of clinical practice. The use of G-CSF in cancer treatment must be considered in three individual circumstances— primary and secondary prophylaxis of neutropenia and treatment of neutropenic fever (Table 67-1).

Primary prophylactic use should be reserved for those patients with expected incidence of febrile neutropenia of >40%. Primary prophylaxis should not be used in most patients receiving most standard chemotherapy regimens.
Special populations: Certain populations that are at higher risk for infectious complications because of bone marrow compromise or other complications may be considered for primary prophylaxis.
Secondary prophylactic use: Dose reduction can be considered rather than CSF use in those with previous febrile neutropenia or prolonged neutropenia.
Treatment: CSFs should not be used to treat afebrile neutropenia or in cases of uncomplicated febrile neutropenia. Those high-risk patients with profound neutropenia, sepsis, or documented infection may benefit from adjuvant treatment with CSFs.
Acute myeloid leukemia: CSFs can be used to decrease the duration of neutropenia following induction chemotherapy and possibly following consolidation.
Radiation: CSF use should be avoided in those receiving concomitant chemotherapy and radiation.

TABLE 67-1. AMERICAN SOCIETY OF CLINICAL ONCOLOGY GUIDELINE HIGHLIGHTS FOR COLONY-STIMULATING FACTOR (CSF) USE

Primary Prophylaxis

Several large prospective trials have shown the ability of G-CSF to reduce the incidence of febrile neutropenia in regimens with rates of neutropenia approaching 40% (33,34 and 35). In these studies, febrile neutropenic incidence was reduced by half in patients receiving growth factor support. Additional studies have confirmed the efficacy of growth factors in preventing neutropenia but unfortunately no study thus far has shown improvement in disease-free or overall survival in patients receiving growth factors. Bokemeyer et al. (36) showed that high-risk patients with testicular cancer were able to tolerate the full course of chemotherapy with G-CSF support, but there was no difference in overall survival. Similar results have been shown in non-Hodgkin's lymphoma, small cell lung cancer, and in breast cancer. ASCO recommends primary prophylaxis for regimens that have neutropenic fever rates of greater than 40%. However, few routinely prescribed chemotherapy regimens lead to this degree of myelosuppression. This recommendation was based on original data that showed cost effectiveness at neutropenic fever rates of 40%. More recent data from Lyman et al. suggest that a lower threshold of 20% may be considered when all costs of care are considered (37). Regardless of the threshold considered, it is important to not only consider the regimen being used but also whether or not the patient being treated is at higher risk for febrile neutropenia and its complications.

Special Populations

Although few standard regimens induce neutropenia at sufficient rates to warrant primary prophylaxis, there are a number of populations whose risk may warrant special consideration. Elderly patients, HIV patients with lymphoma, and those with significant comorbidities have been cited as special populations for whom primary prophylaxis should be considered. Rates of neutropenia in treatment regimens for non-Hodgkin's lymphoma varied between 21–47% in a number of studies of elderly patients. Even more important, risk for infectious death can be up to 30% in these patients with the majority occurring following the first cycle of chemotherapy. Therefore, a less stringent standard may need to be considered for older and sicker patients. Other populations recognized by the ASCO committee that may benefit from prophylaxis are those with extensive previous chemotherapy or radiation and those in whom there may be significant increased risk of infection. Indeed, the ASCO guidelines recommend that clinical discretion prevail in cases in which the clinical risk of neutropenia is judged to be substantial.

Secondary Prophylaxis

Because of the difficulty in identifying high-risk patients for primary prophylaxis, the most common current clinical practice is secondary prophylaxis. This is a population of patients who have already proven themselves to be at high risk for neutropenic fever and its adverse effects by a first episode of neutropenia. In a study of patients receiving cyclophosphamide, doxorubicin, and etoposide for advanced small cell lung cancer, Crawford et al. showed that in patients with previous febrile neutropenia, the use of G-CSF reduced the duration of febrile neutropenia in subsequent cycles (from 6 days to 2.5 days) and the rate of this complication (from 100% to 23%), even when maintained on the same dose (31). Thus, prophylaxis allows for maintenance of dose intensity, which may or may not yield improvements in outcome. Although the concept that maintaining dose intensity and schedule leads to improved survival seems reasonable, is suggested by retrospective studies, and is consistent with current strategies, there have been no definitive studies that prove this. Because of this lack of data, the ASCO committee on growth factor use has suggested that dose reduction also be considered as an alternative to secondary prophylaxis with colony-stimulating factors (CSFs) in the absence of evidence that dose intensity improves outcome (32). The relationship between dose and outcome will continue to be an area of clinical investigation and clinical decision making for years to come.

Treatment of Febrile Neutropenia

Thus far, a number of well-designed prospective trials have examined the use of CSFs to treat those who already have febrile neutropenia. Although a number have shown a decrease in the duration of neutropenia, none has shown a decrease in infectious consequences and mortality. A pediatric study by Mitchell et al. showed a mean decrease of 2 days in hospitalization and neutropenia, and 1 day in antibiotic therapy in those receiving G-CSF (38). A study of 68 febrile neutropenic patients by Ravaud et al. (39) suggested that GM-CSF reduced the duration of neutropenia, hospitalization, and antibiotic use. However, the mean decrease in hospitalization was only 1–1.5 days.

Despite evidence that CSFs can shorten febrile neutropenic episodes, it is unclear if those with uncomplicated neutropenic fevers should receive this support. However, the ASCO guidelines do recognize that there are populations that are at risk for a particularly poor outcome and should obtain CSF. These include those with profound

neutropenia (absolute neutrophil count £100/µl), sepsis, invasive fungal infection, pneumonia, and uncontrolled disease.

Use of Colony-Stimulating Factors in Hematologic Malignancies

There was much initial concern over the use of CSFs in leukemias because of possible stimulation and regrowth of leukemic cells. These patients have the highest incidence, and frequently the longest duration, of neutropenia, and CSF, if safe, would presumably have the greatest potential benefit through decreasing hospitalization time, antibiotic use, and neutropenic complications. A number of studies have now shown the safety and efficacy of CSFs in patients with acute myeloid leukemia (AML) (40,41). Although only one study (42) has shown improvement in response rates due to CSF use, there is consensus that CSF use can improve time to recovery of neutrophil counts without enhancement of leukemic growth. A study from the Southwest Oncology Group study randomized 234 patients with AML who were over the age of 55 to placebo or G-CSF (400 µg/m^2) daily until recovery (43). The G-CSF treated group had a 15% reduction in duration of neutropenia (for a mean reduction of 3 days), 2 fewer hospital days with fever, and 4 fewer days of intravenous antibiotics. However, as in the previous studies, there was no significant statistical difference in response rates, documented infections, or overall survival. Therefore, use of CSF is safe and may be indicated in certain patient populations at high risk for complications from febrile neutropenia.

Pegylated Filgrastim

Although efforts are still under way to better define the appropriate uses of G-CSF, several difficulties with its administration still exist. The daily administration of G-CSF in the clinic setting can be both expensive and inconvenient to patients. A longer-acting form of granulocyte stimulating factor has been developed and tested. A conjugate with a 20 kilodalton polyethylene glycol attached to the N-terminus of the standard recombinant human G-CSF molecule, SD/01 has a prolonged half-life with no apparent change in its pharmacodynamics. Due to the elimination of renal clearance of this larger molecule, SD/01 levels at the neutrophil remain elevated until absolute neutrophil count levels begin to rise and are then cleared by receptors on the neutrophil itself. This self-regulation allows dosing once per chemotherapy cycle, reducing inconvenience and, hopefully, overall health care costs. Several early clinical trials have confirmed this promise. In a trial of patients with non–small cell lung cancer, patients were randomized to G-CSF or SD/01 at one of three different doses. Results were comparable between standard G-CSF and the pegylated version, and a dose-response was seen (44). In a recent blinded and randomized phase III trial of 310 patients with breast cancer, SD/01's efficacy was compared with that of filgrastim in the primary prevention of neutropenia (45). The duration of neutropenia was similar in each group—1.7 days in those treated with SD/01 vs. 1.6 days in filgrastim patients. The incidence of febrile neutropenia was 9% in SD/01 patients and 18% in filgrastim patients.

THROMBOCYTOPENIA

Platelet Transfusions

Decreased platelet counts are common in the cancer patient; the causes include invasion of the marrow by tumor, nutritional deficiencies, myelosuppression due to cytokines from the tumor, and myelosuppression/myeloablation from intensive chemotherapy regimens. Thrombocytopenia was originally a common complication of acute leukemias and their treatment, but it is now an increasing complication of solid tumor treatment as multiagent chemotherapy is adopted in a variety of malignancies, including lung and lymphoma.

Although mortality from major hemorrhages in an oncology patient is increasingly rare, thrombocytopenia is a frequent concern for the oncology patient. Complications vary from harmless ecchymoses and petechiae to disruptive epistaxis and gingival bleeds, to life-threatening gastrointestinal and intracranial hemorrhages. There is a perception that diffuse mucosal hemorrhages are frequent in patients with severe thrombocytopenia. However, Chu et al. (46) showed in a study of 133 patients with various levels of thrombocytopenia that specific sites (either unifocal or multifocal) were usually responsible for hemodynamically significant bleeding. This indicates that thrombocytopenia often unmasks areas of bleeding rather than causes diffuse mucosal bleeding (it should be noted that this study is somewhat dated and may or may not apply to patients undergoing bone marrow transplantation).

Whether the patient has simple petechiae or a major hemorrhage, the treatment for thrombocytopenia is still the same: prevent or treat the hemorrhage by supplementing the platelet level. More than 9 million platelet units were transfused in 1997, and oncology patients consumed as much as one-third of these transfused platelets. While most platelets transfused in the surgical patient are one-time transfusions in direct response to bleeding episodes and increased consumption of platelets, much of that used in the oncology patient is given for prophylaxis, with multiple transfusions required over longer periods of time. Prophylactic platelet transfusions are common, frequent, and are now considered the standard in the care of oncology patients. However, the standard at which one should transfuse has shifted over the last decade. As late as 1992, 80% of physicians sampled were using a standard threshold for prophylaxis of 20,000/µl (47). Based on recent studies, the last ASCO committee on platelet transfusions now recommends the new threshold of 10,000/µl at which to transfuse oncology patients (Table 67-2).

10,000/µl should be the prophylactic threshold for adult patients with adult leukemia and most solid tumors.
20,000/µl should be considered for some tumors that, due to tumor necrosis, are particularly at risk for bleeding. Examples include melanoma, bladder, gynecological, and colorectal tumors.
Platelet counts greater than 50,000/µl should be reached before surgery.
To reduce alloimmunization, leukoreduced blood products should be used in patients who will require continued platelet transfusions.
Patients refractory to platelet transfusions should be treated with HLA-matched platelets.

From Schiffer CA, Anderson KC, Bennett CL, et al. Platelet transfusion for patients with cancer: clinical practice guidelines of the American Society of Clinical Oncology. J Clin Oncol 2001;19(5):1519–1538, with permission.

TABLE 67-2. AMERICAN SOCIETY OF CLINICAL ONCOLOGY CLINICAL PRACTICE GUIDELINES FOR PLATELET TRANSFUSIONS

The earliest data came from Gaydos et al. (48), who showed an inverse relationship between bleeding episodes and platelet levels. At 20,000 platelets/µl, the percentage of hospital days with hemorrhage was 4%; with 10,000/µl, the percentage was 8%, and even greater levels of bleeding were observed at <5000/µl. While not finding an absolute cutoff at which bleeding occurs, Gaydos et al. did note multiple risk factors that make bleeding more likely. These included infection, fever, the underlying disease process, and drugs that interfere with platelet function (including aspirin, which was used as an antipyretic in many of these patients). Despite little evidence to show that 20,000 platelets/µl was indeed the level at which bleeds became more common, it was eventually adopted as such. Since then, there have been one retrospective and two prospective trials of prophylactic transfusions comparing 20K to 10K as the threshold for transfusion.

Gmur et al. (49) retrospectively examined 102 patients with leukemia over a 10-year period. Patients received transfusions at a threshold of 5000/µl. Those with a fever or minor bleeding had a threshold of 10,000/µl, and those who required heparin or an invasive procedure had a threshold of 20,000/µl. There was little difference in significant bleeding episodes between the three groups. There were three episodes of fatal hemorrhagic episodes, but these occurred at higher platelet levels. Again, a threshold below which bleeding was more likely was still not clearly identified.

More recently, Heckman et al. (50) randomized 78 acute leukemia adult patients to prophylactic transfusions at either 10,000/µl or 20,000/µl level during induction chemotherapy. Patients all underwent 1 of 3 different chemotherapeutic regimens, with exclusion criteria of uncontrolled infection, history of bleeding diathesis, disseminated intravascular coagulation, acute promyelocytic leukemia, AIDS, and platelet refractoriness. There were no statistically significant differences between platelet refractoriness or bleeding episodes. No fatal bleeding events occurred in either group during the study, but there were eight transfusion reactions in the 20,000/µl threshold group compared with none in the 10,000/µl group ($p = .005$). Patients with the lower threshold did receive more prophylactic and total transfusions [mean of 10 vs. 6 transfusions for prophylaxis and mean of 11 vs. 7 for total transfusions (nearly statistically different)]. The study was powered to show a difference of 25% increase in bleeding episodes with a standard incidence of 70%; the actual bleeding incidence was 90%. Thus the study should have adequately noted any differences in bleeding events.

A larger multicenter trial was soon performed, which confirmed this earlier data. Rebulla et al. (51) used similar thresholds in 255 adolescent and adult patients with AML (excluded acute promyelocytic leukemia). During episodes of fever to 38°C, active bleeding, or invasive procedures, the high threshold was used (this occurred 22.6% of the time). Major bleeding episodes were similar in the two groups with 21.5% (10,000/µl group) and 20% (20,000/µl) of patients having episodes greater than petechiae, mucosal, or retinal bleeding ($p = .41$). One fatal bleed, a cerebral hemorrhage, did occur in the lower threshold group, but this event occurred when the platelet count was 32,000. Platelet transfusions were 21.5% lower in the 10,000/µl threshold group ($p = .001$). Gastrointestinal bleeding did occur twice as often (12

episodes vs. 5 episodes) at the more restrictive threshold, but there were no differences in the number of red cell transfusions required due to this.

Procedures

Bishop et al. (52) showed that the thrombocytopenic patient can undergo major surgery provided that adequate transfusion support is given. The retrospective analysis of 95 patients with acute leukemia requiring a variety of surgeries showed that, provided counts exceed 50,000, blood loss is usually minimal. Seven percent of those undergoing surgery had >500 ml of blood loss, and only 7% required more than four units of packed red cells. There were no surgically related fatalities. As many as 66% of the patients in the 167 operations performed were neutropenic at the time of surgery, but there were no postoperative infections attributable to the surgical intervention. Based on this, the ASCO committee recommended a threshold of 50,000/µl before major invasive procedures (53). There is little guidance in the literature regarding the appropriate levels before lumbar puncture or bone marrow aspiration. Several retrospective studies of no more than 20 adult patients have recommended transfusions before lumbar puncture for levels of less than 20,000, but this has not been examined in larger trials.

Refractoriness

Refractoriness to platelet transfusion is a common and significant effect of repeated transfusions and may be as high as 35% in patients with AML (54). Refractoriness to platelet transfusion is thought to be due to platelet-reactive alloantibodies against histocompatibility antigens. These antibodies consume large numbers of transfused platelets and leave little to show for the transfusions.

It is now recognized that leukocytes contaminating the platelet transfusion play a role in immunization. Because platelets lack class II histocompatibility antigens, another agent must serve as a costimulant along with its class I antigens. Several methods are used to reduce leukocytes within a transfusion. Filtration is the older process but varies in its ability to filter leukocytes; it usually results in a three log reduction in the volume of leukocytes. Newer methods have used ultraviolet light to reduce antigenicity of transfusions. In the Trial to Reduce Alloimmunization to Platelets, over 600 patients were randomized to receive either pooled, filtered, single-donor filtered, or pooled irradiated platelets. Each of the methods to reduce the number of viable leukocytes transfused led to a reduction in the production of antibody formation compared with simple transfusion with pooled platelets (17% vs. 45%). Leukocyte-depleted transfusion products (both RBCs and platelets), therefore, should be used in leukemic patients receiving induction and consolidation. The data behind those with solid tumors who require platelet transfusions are not as clear, mostly because these patients rarely require the prolonged transfusions common in the treatment of leukemic patients. Little research has been done in this population. Leukodepleted transfusions are also less likely to cause transfusion reactions, which are thought to be mediated by cytokines from leukocytes. However, both methods of leukocyte reduction are inefficient, costing a loss of up to 25% of platelets and driving up the costs of transfusions.

Although patients who received repeated transfusion often develop antibodies, other factors also play a role in a poor response to an individual platelet transfusion. Fever, infection, and an active bleeding source all consume additional platelets and may be reflected in a less than expected response to a transfusion. The ASCO committee has recommended that following transfusions, platelet counts be measured again to determine an adequate increase in platelet counts. If a patient fails to have adequate increases in posttransfusion platelet counts in at least two ABO-compatible transfusions, the clinician should consider alloimmunization and other causes of platelet destruction such as disseminated intravascular coagulation, sepsis, and immune thrombocytopenia purpura. One can measure platelet antibody titers, but it is often not clear how this will guide clinical decision making. Often patients with alloimmunization can be transfused with HLA-matched platelets with good response (up to 50%), but it is critical that further transfusion be coordinated with blood bank personnel. If HLA-matched platelets fail to produce adequate responses, cross-matched or familymember donated platelets may then be used.

Thrombopoietic Agents

Platelet transfusions are costly, at times ineffective, and place the recipient at risk for transfusion reactions and infectious exposures. Given the promising responses of anemia and neutropenia to growth factors, it is hoped that a pharmacologic alternative to platelet transfusion will soon be found. Early efforts using cytokines to stimulate platelet production showed significant toxicities, including fevers and hypotension (IL-1) and headaches, fatigue, and fevers (IL-6), but little clinical benefit. However, IL-11 has been approved as a thrombopoietic agent based on promising data in breast cancer patients. IL-11 was originally derived from stromal cells and was found to stimulate proliferation of a murine plasmacytoma cell line. It has multiple effects on both hematopoietic cells and other organ systems such as intestinal and bronchial epithelial cells. IL-11 either alone or in concert with other cytokines has been shown to increase megakaryocyte maturation markers, megakaryocyte polyploidy, and platelet size. *In vitro* studies showed little activity alone, but *in vivo*, it has been shown to promote megakaryocytopoiesis and increase platelet production. In a study of 93 breast cancer patients, platelet transfusions were reduced in 30% of patients (55). However, side effects are significant and include edema, fatigue, myalgias, and cardiovascular events. This has limited use in general clinical practice and fueled the drive to find other agents to stimulate platelet production.

It has been less than a decade since the c-MPL ligand was identified and cloned. From this development, two variants of the c-MPL ligand have been produced and studied, showing mixed results in clinical trials. RhTPO, an intact recombinant thrombopoietin, and PEG-rHuMGDF, a truncated and pegylated human recombinant megakaryocyte growth and development factor, showed early promise in phase I trials. PEG-rHuMGDF was shown to improve platelet recovery by 1 week in patients undergoing treatment with carboplatin and paclitaxel for lung cancer (56). However, neither rhTPO or PEG-rHuMGDF has since had the remarkable clinical results seen with growth factors for other hematopoietic lineages. PEG-rHuMGDF's potential in preventing thrombocytopenia in acute myelocytic leukemia patients was examined but failed to show a decrease in days to recovery of platelet counts in patients receiving PEG-rHuMGDF following induction chemotherapy (57). Likewise, studies in autologous bone marrow transplantation and stem cell transplantation patients have also failed to show any significant reduction in the length of severe thrombocytopenia or platelet transfusion requirements. Furthermore, there has been concerning evidence of antibody production to the pegylated MGDF when injected subcutaneously. In one study, 8.9% of patients given three doses of PEG-rHuMGDF developed significant thrombocytopenia. These antibodies are thought to inhibit native thrombopoietin's effects as well by a cross-reaction, thus worsening a thrombocytopenia (58). For this reason, the manufacturer halted further U.S. clinical trials of PEG-rHuMGDF in September 1998.

The story of thrombopoietin continues. A recent phase I trial of 33 patients with breast cancer receiving autologous bone marrow transplant showed both safety and tolerance to rhTPO without any signs of neutralizing antibodies (59). This study, however, again failed to show a dose effect for escalating doses of rhTPO or improvement in time to recovery of platelet counts when compared to previous study populations.

COMPLICATIONS OF BLOOD PRODUCT TRANSFUSIONS

Transfusions of blood products are obviously a necessary component in the support of the oncologic patient. However, they are not without consequence. Hemolytic transfusion reactions occur infrequently but may be responsible for as many as 1.0–1.2 deaths per 100,000 patients transfused. A total of 34 deaths in the United States may have occurred secondary to hemolytic transfusion reactions in 1990.

Alloimmunization is the most frequent complication, with estimates of rates varying from 7–30% (60). In a retrospective analysis of 564 patients with myeloproliferative or lymphoproliferative disorders from 1987–1996, Schonewille et al. found an overall immunization rate of 9% of patients receiving long-term transfusion support, with the risk of immunization of 0.5% per each RBC unit transfused. As seen in the previous section, platelet alloimmunization is a major problem in the treatment of oncology patients. However, there is some suggestion that those undergoing chemotherapy may not produce as active a response to incompatible transfusions as others requiring transfusions, thus lowering actual alloimmunization rates in oncology patients.

Transfusion Reactions

Acute reactions occur during and immediately after transfusion and vary from the discomfort of an allergic reaction with urticaria to the life-threatening hemolysis and multiorgan system dysfunction associated with acute hemolytic reactions. Due to strict and thorough cross-matching, acute hemolytic reactions are infrequent, less than 1 per 200,000 units transfused (61), but up to 16 deaths per year may be attributable to this immunologic response to an incompatible blood product. Symptoms occur early in transfusion, often within the first 5 minutes of beginning the transfusion. However, reactions can occur several hours after transfusion. Fever, chills, and hypotension typically dominate the presentation, but reactions can include such nonspecific complaints as flushing, low back pain, dyspnea, nausea, chest pain, or abdominal pain.

The pathophysiology of this reaction is the best described of transfusion complications. Hemolysis is initiated by the action of preexisting IgG or IgM alloantibodies against major blood group antigens. IgM antibodies, usually to the ABO blood group, will fix C9 to the RBC surface, activating the complement system and causing intravascular hemolysis. IgG antibodies, often binding to the Kell or Kidd blood group antigens, lead to extravascular hemolysis with removal of affected cells by the spleen, liver, and bone marrow. The initial hemolysis is just the beginning of a cascade created as macrophages phagocytose transfused cells and release of a breviary of cytokines, including tumor necrosis factor, IL-8 and IL-1, causing the symptoms mentioned above. The reaction is actually a systemic process and effects on coagulation and renal function are often seen. The balance of the coagulation system is upset as cytokines and byproducts of RBC hemolysis are released. Platelet activation and factor XII activation from antigen-antibody interaction further increase coagulation activity. Disseminated intravascular coagulation can occur with its resulting effects, and renal dysfunction is frequent. The causes are multifactorial but may be due to microthrombi from disseminated intravascular coagulation,

hypotension from cytokine effects, such as bradykinen, or intrarenal shunting creating renal ischemia.

Laboratory evidence of acute hemolytic transfusion reaction (AHTR) includes early and rapid decrease in serum haptoglobin levels and increases in serum bilirubin, plasma hemoglobin, and urine hemoglobin peaking around 6 hours after initiation of reaction. With prompt attention and discontinuation of the instigating transfusion, AHTR need not be fatal. The transfusion must be stopped immediately, intravenous saline continued, and both the transfusion sample and the patient's serum sent for investigation. Intravenous furosemide and fluid can diminish some of the effects of the intrarenal shunting. Hemolysis can also occur due to nonimmunologic mechanisms including mechanical forces, osmotic pressure (e.g., contact with nonisotonic fluid or in G6PD-deficient transfusions in patients receiving reducing agents).

Some reactions occur up to weeks following transfusion. These are frequently asymptomatic and are usually noted by a falling hematocrit associated with positive direct Coombs, elevated bilirubin, fever, hemoglobinuria, and varying degrees of renal insufficiency occurring one to weeks following transfusion. These outcomes are usually secondary to an amnestic response to RBC antigens, but may be due to *de novo* development of IgG antibodies to non-ABO antibodies. Kidd and Duffy system antibodies are more likely to result in symptomatic reactions. Treatment is usually supportive, but in cases of trauma-related massive transfusions, additional transfusions may be warranted.

Delayed hemolytic transfusion reactions tend to be less fulminant and manifest by falling hematocrits with elevated bilirubin, fever, hemoglobinuria, and a positive Coombs test seen 5 to 10 days following transfusion. Usually asymptomatic and undetected, some prospective work has shown that the actual incidence may be as high as 0.5%. More significant reactions may lead to renal failure, jaundice, and further deterioration of an already ill patient. The likely precipitating event of the reaction is an amnestic response to RBC antigens or *de novo* development of non-ABO antigens. Anti-Kidd and Duffy antibodies may play a role in those clinically significant reactions, but these are difficult to detect. Management is symptomatic support.

Transfusion-Related Acute Lung Injury

Transfusion-related acute lung injury (TRALI) is a rare but life-threatening acute noncardiogenic pulmonary edema with symptoms similar to adult respiratory distress syndrome. Patients experience tachypnea and dyspnea and exhibit bilateral pulmonary edema. Differing from cardiogenic edema and cases of fluid overload, the etiology is thought to be donor HLA antibodies reacting with recipient neutrophils. These activated granulocytes are sequestered in the pulmonary vasculature, where they wreak havoc, releasing proteolytic enzymes that damage the microvasculature. Pulmonary leak then occurs, allowing fluid and protein to fill the alveoli. TRALI often occurs early in transfusion, within 2 hours, but has been reported much later. Respiratory compromise typically lasts several days, and most recover without lasting sequelae. However, some patients require short-term ventilator support. Mortality rates have been reported as high as 6%. There is no method of predicting which transfusions will result in TRALI, although multiparous women may have an increased frequency of antibodies due to exposures during pregnancy and delivery.

Febrile Non-Hemolytic Transfusion Reactions

Febrile non-hemolytic transfusion reactions, the most frequently seen of transfusion reactions, is a cluster of symptoms similar to AHTR but without the specter of fatality. Patients complain of fever, chills, nausea, emesis, and/or malaise and often have a rapid increase in body temperature of 1–2°C. Although originally attributed to antileukocyte antibodies, it is now recognized that recipient's immunologic system may also contain antiplatelet or antigranulocyte antibodies that create these symptoms. In some cases, no precipitating antibody is found at all, and cytokines are thought to play the key role. As the number of leukocyte-depleted blood products transfusions have increased, the frequency of these reactions has declined. Patients can be treated with antipyretics, usually acetaminophen, for symptomatic relief.

Platelet transfusions much more frequently cause febrile reactions than other blood products. Although some are attributable to antibodies, cytokines likely play a role. Transfusions of stored platelets more frequently cause reactions perhaps due to the production of cytokines during storage. If donor-end, leukodepleted platelet transfusions are used, the incidence of febrile non-hemolytic transfusion reactions is dramatically reduced.

Anaphylaxis and Allergic Reactions

Anaphylactic reactions are infrequent, but rapid death can occur as laryngeal edema, bronchospasms, and hypotension develop from mast cell degranulation. The majority of these reactions are seen in immunoglobulin A (IgA)-deficient patients who have anti-IgA antibodies and are then transfused with products from an IgA donor. Treatment is just as in other anaphylactic reactions with corticosteroids, antihistamines, and support measures. Future reactions can be prevented by transfusing components from IgA-deficient donors or by washing packed RBCs and platelet products to reduce the possibility of transfusing IgA. Benign allergic reactions are fairly common with any transfusion product. Antigens present in the transfused products can cause urticaria. Treatment is again antihistamines, but routine prophylactic treatment is not recommended. Patients who have had previous reactions, however, are commonly treated prophylactically with each transfusion.

INFECTIOUS RISKS AND COMPLICATIONS

Bacterial Infections

Despite likely underreporting, bacterial infection accounts for approximately 15% of reported, transfusion-related mortality. Contamination generally occurs at the time of collection from skin flora of inadequately prepared donors or from asymptomatic bacteremia from the donor. Platelets have a higher incidence of contamination because storage and increased exposure from the multiple donors of pooled platelets. These units are frequently contaminated with skin flora, which then replicates with storage at room temperature. For this reason, platelet storage is limited to 5 days. Because RBCs are stored at cooler temperatures, contaminants in these products are frequently *Yersinia*, *Serratia*, *Pseudomonas*, and *Enterobacter* species, which can survive cooler temperatures. Patients frequently present with symptoms of sepsis at the time of transfusion. Hypotension and shock can develop rapidly as accumulated endotoxin is released into the recipient. Symptoms may later develop as bacteremia occurs within the host. Efforts at prevention are largely focused on improved sterile collection techniques.

Viral Infections

The safety of the U.S. blood supply has improved over recent years such that the risk of transmission of a serious viral pathogen is approximately 29 per million units (63). Yet fear of this complication is often the greatest concern of blood product recipients. Failure to detect the presence of virus in the contaminated units is largely the result of donation and testing during the “window period” shortly after the donor has acquired the infection and before serologic conversion.

The screening of blood products for the presence of HIV-1 antibodies began in the United States in 1985; in 1992 antibody testing for HIV-2 was also applied routinely. More recently, since March 1996, products have been screened for the presence of HIV-1 p24 antigen with a consequent decrease in the duration of the window period from 55 days in 1985 to 16 days in 1996. The current estimated risk of transmission of HIV via blood product transfusion is estimated to be <1 in 493,000 (63).

Infection with human T-cell lymphotrophic virus (HTLV-1) is associated with the clinical syndromes of adult T-cell leukemia/lymphoma and tropical spastic paraparesis. There is no clear clinical disease imparted by infection with HTLV-2 virus, but there is suggestion of a neurological condition similar to that of HTLV-1 infected persons. Transfusion-related tropical spastic paraparesis has been described with an incubation period of approximately 3 years. Recipient seroconversion following transfusion of a cellular component seropositive for HTLV is approximately 40% and is diminished with increasing age of the transfused component.

Hepatitis B infection becomes chronic in approximately 10% of infected patients, usually with no symptoms. A percentage of these asymptomatic carriers have undetectable levels of hepatitis B surface antigen (HBsAg) and anti-hepatitis B core antigen (anti-HBc), such that their donated units will escape detection with an estimated risk of post-transfusion hepatitis B of approximately 1 in 63,000 (62). It is possible that this represents an overestimate and that many of these infections are acquired independently of the transfusion given the high seroconversion rate in the general public.

Hepatitis C virus was first characterized molecularly in 1989; current immunoassays are directed against various viral epitopes and provide a 70-day window for detectability. Newer screening tools, such as viral polymerase chain reaction, are now available and may decrease the window following infection to several weeks. Transfusion with an infected unit of blood results in a 90% seroconversion rate, with at least 65% of patients developing chronic infection. The majority of those infected with hepatitis C go on to develop chronic liver disease. An estimated 300,000 people in the United States may have contracted hepatitis C in the 1980s through transfusion (62). Risk of transmission with transfusion is currently estimated at 1 in 103,000 transfused units that have been screened for hepatitis C antibodies.

Many other clinical infections have been related to blood transfusion, including common pathogens such as Epstein-Barr virus and parvovirus, as well as rarer illnesses such as Chagas' disease, Creutzfeldt-Jakob disease, leishmaniasis, malaria, babesiosis, and syphilis. Fortunately the transfusion-related incidence of these diseases is uncommon. Cytomegalovirus (CMV) deserves special note because of the high seroprevalence in the United States (35–80% varying by region) and the potentially devastating effects on the immunosuppressed host who acquires the infection. CMV is a leukocyte-associated virus; thus any blood product contaminated with white blood cells is capable of transmitting infection. Several studies have shown decreased rates of CMV infection in patients receiving leukodepleted blood products, but prospective trials comparing leukocyte reduced versus CMV seronegative transfusions are limited. Thus CMV-negative donors are still used as the standard of care for

those patients in whom CMV infection could be devastating, including seronegative bone marrow transplant patients.

Other Late Complications

Secondary hemosiderosis is rarely a complication in the oncology patient requiring transfusions but can frequently occur in patients with hemoglobinopathies, aplastic anemia, or severe myelodysplasia who are transfusion dependent for years. Each unit of packed RBCs contains approximately 200 mg of iron and significant hemosiderosis usually requires more than 2 g of iron surplus (100 units of transfusion products in the absence of continued bleeding). Clinical manifestations of iron overload are the direct result of iron deposition in the affected organs and most commonly include skin discoloration, gonadal failure, liver dysfunction, and diabetes. Less frequently, patients may have cardiac failure, arrhythmias, arthropathy, and even personality changes.

CONCLUSION

The discovery of the hematopoietic growth factors and their introduction into clinical practice has dramatically changed our understanding of hematopoiesis. In addition, the clinical consequences of anemia, neutropenia, and thrombocytopenia in the cancer patient have become much better characterized. Clinical practice guidelines have been developed and are continually being revised as our knowledge base increases. Meanwhile, the areas of transfusion medicine and infectious diseases have clarified the appropriate settings for transfusion support and antibiotics and the risks and benefits of these approaches. In addition, economic studies and outcome research have focused on this critical area of supportive care to help us understand the best approaches to be used for our patients. With the advent of second generation hematopoietic growth factors, further benefits are anticipated, including trials that may shift emphasis from treatment of cytopenias to more preventive strategies. In this rapidly changing area, readers are encouraged to follow the results of ongoing randomized clinical trials as well as the updates of evidence-based, clinical practice guidelines to best incorporate the use of hematopoietic growth factors, transfusions, transfusion support, and antibiotics in the clinical care of their patients.

NUTRITION SUPPORT

POLYXENI D. KOUTKIA
CAROLINE M. APOVIAN
GEORGE L. BLACKBURN

Malignant disease is frequently accompanied by profound weight loss and malnutrition. In fact, cancer patients have the highest prevalence of malnutrition of any hospitalized group of patients (1). In its most severe form, weight loss due to malignancy is termed the *anorexia-cachexia syndrome* and is characterized by anorexia, skeletal muscle atrophy, tissue wasting, and organ dysfunction (2). Malnutrition associated with malignancy is a poor prognostic indicator. It is associated with a higher mortality rate (3) and a higher perioperative morbidity rate in patients who have lost greater than 5% of their body weight and have a reduction in some of the indices of nutritional status (4). The indications for implementing nutrition support in cancer patients—and its safety—have been established (5,6,7,8,9,10 and 11). But the possible benefits of nutritional therapy are still contentious.

This chapter will address the following questions: What is the effect of nutrition support on the outcomes of cancer patients undergoing various treatment modalities? What is the role of nutrition support in the treatment of cytokine-mediated cancer anorexia and altered host metabolism? Are there specific nutritional supplements that take on a pharmacological role by modulating tumor cell growth? Finally, is preservation of quality of life by reduction of fatigue and other effects of malnutrition an adequate outcome of adjuvant nutritional therapy? Because of the ongoing controversies associated with these issues and ethical issues regarding nonvolitional feeding guidelines, nutrition support of the cancer patient should be emphasized in the clinical setting. Nutrition support is an integral component of comprehensive cancer care in patients who are carefully selected through the use of nutritional screening tools and for whom appropriate goals of treatment have been established.

MALNUTRITION IN THE CANCER PATIENT

Malnutrition in the cancer patient results from several mechanical and metabolic processes. The cachexia of malignancy is a complex metabolic disorder characterized by involuntary weight loss which, if not treated, often leads to death (3). Certain tumors predispose individuals to cancer cachexia. Table 68-1 depicts the frequency of weight loss among approximately 3000 cancer patients studied by the Eastern Cooperative Oncology Group. Breast cancer and sarcomas rarely resulted in significant host weight loss compared with cancers involving digestive organs such as stomach and pancreas. Patients with lung cancer or prostate cancer also demonstrated significant weight loss and malnutrition. The Eastern Cooperative Oncology Group survey demonstrated a lower morbidity and longer survival in patients without weight loss, except in cases of pancreatic or gastric cancer. Preventing weight loss by nonvolitional feeding does fully restore the difference in outcomes (12,13).

Tumor type	Number of patients	Weight loss in the previous 6 mo (%)			
		0	0-5	5-10	>10
Favorable non-Hodgkin's lymphoma	290	69	14	8	10
Breast	289	64	22	8	6
Sarcoma	189	63	21	11	7
Unfavorable non-Hodgkin's lymphoma	211	52	20	13	15
Colon	307	46	26	14	14
Prostate	78	44	27	18	10
Lung, small cell	426	43	23	20	14
Lung, non-small cell	550	39	25	21	15
Pancreas	111	17	29	28	26
Nonmeasurable gastric	179	17	21	32	30
Measurable gastric	138	13	28	29	30
Total	2918	42	23	18	16

TABLE 68-1. FREQUENCY OF WEIGHT LOSS IN CANCER PATIENTS

Causes of Malnutrition

Table 68-2 lists the potential etiological factors in the development of cancer anorexia. The development of malnutrition in the individual patient is usually the result of a combination of these mechanisms (14).

Direct and indirect tumor effects
Change in taste
Dysphagia
Pain
Gastrointestinal tract obstruction
Early satiety
Anorectic factors (cytokines) produced by tumor or host
Antineoplastic therapy
Chemotherapy
Radiotherapy
Anorexia/anosmia
Nausea
Mucosal/ulcerations/infections

TABLE 68-2. ETIOLOGY OF THE ANOREXIA-CACHEXIA SYNDROME

Anorexia of Malignancy

A decrease in food intake and weight loss that occur without an overt cause is referred to as the *anorexia-cachexia syndrome*. Several factors, including changes in the central nervous system, changes in taste perception due to tumor, and depression and its associated reduced physical activity, have been implicated as causes of cancer anorexia. The regulation of appetite is complex and is mediated by blood nutrient levels, host nutrient resources, liver function, gastrointestinal (GI) capacity, and environmental cues, such as smell and sight, all of which are processed by the brain (15). Recently, considerable attention has been directed to the role of various cytokines as mediators of the anorexia-cachexia syndrome, particularly tumor necrosis factor (TNF). Cytokines are discussed in detail later in this chapter under mediators of cancer cachexia.

NUTRITIONAL EFFECTS OF CANCER TREATMENTS

Radiation

The site, magnitude, and duration of radiation therapy all influence the severity of nutritional injury. This injury may be associated with both acute and late effects of radiation therapy (16,17,18 and 19).

After radiotherapy of the oral cavity and pharynx, patients can experience both heightened and suppressed taste sensation. Loss of taste is severe and rapid after oropharyngeal irradiation, as measured by quantitative tests of sensitivity to sour, sweet, and bitter substances. Fortunately patients often regain preirradiation taste sensitivity 60–120 days after therapy is completed.

Radiation to the head and neck may inhibit adequate salivation, leading to changes in eating habits. Also, patients may experience increased sensitivity of their teeth to extreme temperature and sweetness. In a study of weight loss during a 6- to 8-week course of external beam radiation therapy to the head and neck regions, 93% of 114 patients lost an average of 3.7 kg. In addition, approximately 9% of individuals lost more than one-tenth of their body weight during their 6- to 8-week course of radiation (17).

Radiation to the gastric area and small and large intestine is associated with various complications that may influence nutritional status. Low doses of gastric irradiation reduce gastric acidity whereas higher doses may induce ulcer formation. Nausea, vomiting, and diarrhea are common in individuals undergoing radiation to the small and large bowel. In addition, chronic diarrhea or bowel obstruction may develop due to radiation-induced enteritis following high-dose GI irradiation.

Upper abdominal radiation may produce radiationinduced hepatitis, characterized by anorexia, nausea, vomiting, and abdominal distention. This disorder is usually temporary. Radiation to the pancreas may similarly result in acute anorexia, nausea, and vomiting.

Chemotherapy

Chemotherapy can affect host tissue in addition to the targeted neoplasm and thus cause short-term nutritional defects. Almost every major class of compound used in chemotherapy and immunotherapy products can produce nausea and vomiting (20) accompanied by anorexia. This often results in reduced dietary intake, electrolyte imbalance, weakness, and progressive weight loss (21).

Mucosal toxicity, manifested as oral ulcerations, cheilosis, glossitis, and pharyngitis, may be inevitable with the use of some chemotherapeutic agents. This often leads to odynophagia and anorexia. Specific agents, such as actinomycin D, cytarabine, 5-fluorouracil, hydroxyurea, and methotrexate, can produce ulcerations of the entire GI epithelium (22,23). Therapy itself does not induce malabsorption but, because of its side effects, can aggravate the effect of tumor-related malabsorption syndromes (22). Small intestinal absorptive function with either a single agent or combination chemotherapy remains well preserved in most instances. Nutrition support is usually unnecessary in the initially well-nourished patient if the ill effects of chemotherapy are significantly limited in time and intensity.

Many major organ systems are affected by chemotherapeutic agents, resulting in decreased efficiency of metabolism. The liver is especially vulnerable, and hepatic injury is commonly associated with anorexia. Diffuse hepatocellular damage often results in hypoalbuminemia. Several agents affect other organ systems. Hydroxyurea may cause renal impairment. Doxorubicin may cause cardiac toxicity leading to congestive heart failure, water retention, and electrolyte imbalance. Ohnuma and Holland (20) and Carter (24) provide extensive discussions of the nutritional consequences of chemotherapy and immunotherapy.

Surgery

Nutritional depletion can be attributed to surgical intervention in many cancer patients. Nutrition support can be a beneficial tool, as a patient with good nutritional status develops fewer postoperative complications. If nutritional assessment reveals protein calorie malnutrition, elective surgery can even be delayed until nutritional status improves (25). Yamada et al. (26) analyzed the association between nutritional parameters and postoperative complications in 440 patients with gastric cancer. The frequency of postoperative complications was highest in patients with stage IV gastric cancer. A strong interrelationship was found between nutritional status and postoperative complications.

Certain surgical procedures require nutritional intervention. Radical resection of the oropharyngeal area often necessitates postoperative tube feeding (27). Conditions associated with esophagectomy and esophageal reconstruction may include delayed gastric emptying secondary to vagotomy, malabsorption, and the development of a fistula or stenosis. Gastric surgery may result in dumping syndrome, malabsorption, and/or hypoglycemia.

The site and extent of intestinal resection can result in a variety of nutritional complications. Jejunal resection can decrease the efficiency of absorption of many nutrients. Ileum resection commonly results in vitamin B_{12} deficiency and bile salt losses. With extensive small bowel resection, malabsorption leading to malnutrition is common, as reported in jejunoileal bypass (28). Abnormalities in sodium and water balance are commonly associated with ileostomy and colostomy formation. In addition, gastric and intestinal bypass surgery to relieve obstruction can result in a blind loop syndrome with specific nutritional deficiencies.

Individuals with pancreatic cancer should be nutritionally assessed because they frequently lose weight before their diagnosis and surgical intervention. After pancreatectomy, malabsorption and endocrine as well as exocrine insufficiency are common problems that may require insulin and pancreatic enzyme replacement. Cancer patients undergoing ureterosigmoidostomy may experience hyperchloremic acidosis and hypokalemia in addition to other more common postoperative problems.

If it is anticipated that nutritional intervention will be required postoperatively, a nasoenteric feeding tube can be placed intraoperatively. With patients in whom a longer recuperative course is anticipated, placement of a gastrostomy tube or jejunostomy tube may be more appropriate.

Energy Metabolism in the Cancer Patient

Altered metabolism of nutrients is common in cancer anorexia. A wasting of 100 nonprotein calories per day in futile pathways can contribute to major losses in both total weight and lean body mass over the long term. Abnormalities in carbohydrate, protein, and lipid metabolism are common. The inability of cachectic cancer patients to gain lean body mass despite adequate nutrition support is likely due to the effect of the tumor on host metabolism. The Pancreatic Cancer Task Force reported that 80% of 924 patients with pancreatic cancer had weight loss before diagnosis (29). Whereas 50% of the pancreatic cancer patients studied had experienced weight loss longer than 2 months before diagnosis, only 26% of these patients reported anorexia during this period.

Carbohydrate Metabolism

Abnormal glucose metabolism, a major source of caloric wasting, is a hallmark of cancer cachexia (30). Both increased glucose production and utilization as well as insulin resistance are characteristic. Glucose intolerance may be attributable to a reduced tissue sensitivity to insulin (31). There may be decreased pancreatic b-cell receptor sensitivity in cancer patients as well, leading to inadequate insulin release in response to a glucose load. Such abnormalities in peripheral glucose metabolism

simulate a type II diabetic state but also share elements similar to the stress state (32,33,34,35 and 36).

An increase in gluconeogenesis in the liver of the cancer patient is a common finding. This can be the result of an increased release of glucogenic fuel substrates, such as lactate and alanine (34,36), as well as an increased induction of hepatic gluconeogenetic enzymes (33). The energy drain created by increased hepatic gluconeogenesis leads to host depletion of protein and calories. Elevation of hepatic glucose production in a tumor-bearing host requires energy; three moles of adenosine triphosphate is necessary to convert each mole of lactate to glucose. Therefore, abnormal glucose kinetics can result in calorie-consuming futile metabolic cycles, with a drain on host energy. Cancer patients who lose weight may exhibit increases in glucose flux and glucose oxidation rates. This mechanism is central in the development of host depletion in cachexia, although the energy expenditure involved in these processes suggests that they are more likely associative than causative (37,38).

Protein Metabolism

Cancer anorexia is accompanied by wasting of host protein mass, leading to fatigue, weakness, and altered host cellmediated immune response. Clinical signs include skeletal muscle and visceral organ atrophy, hypoalbuminemia, and anergy. Host protein wasting results from alterations in total body protein turnover, muscle protein synthesis and catabolism, hepatic protein metabolism, and plasma secretory protein levels. Several studies have shown that cachectic cancer patients have elevated rates of protein turnover and that the normal adaptation of reduced protein metabolism (i.e., protein sparing) in the setting of starvation does not occur (39). With nutritional depletion, patients with cancer anorexia continue to manifest elevated rates of skeletal protein mobilization rather than the normal response of decreased protein turnover and protein sparing. Protein turnover rates in cachectic cancer patients are significantly higher compared with similarly malnourished control patients without cancer. A loss of less than 100 g of protein nitrogen or 625 g of body protein equal to 2.5 kg of lean body mass can produce mild protein malnutrition, fatigue, weakness, and altered immune response (40). Explanations for this phenomenon of increased nitrogen turnover remain controversial. However, the findings suggest an injury response to cancer with the tumor acting as a “nitrogen sink.”

Lipid Metabolism

The most common impairments in lipid metabolism seen in cancer patients are hyperlipidemia and depletion of fat stores (41,42 and 43). Abnormal lipoprotein lipase activity alters the ability of fatty acids to be utilized as protein-sparing energy fuels and is a major cause of protein malnutrition. The hyperlipidemia seen in cancer patients is significant and may play a role in disease outcome. Elevated lipid levels may have an inhibitory effect on monocytes and macrophages. The combination of increased lipolysis, fatty acid recycling via very low density lipoprotein, and the impairment of lipoprotein lipase enzyme activity leading to decreased lipid clearance can be immunosuppressive.

Suppression of lipoprotein lipase occurs in cancer patients, but the mechanism is different from that which occurs in starvation. In the latter, lipid mobilization occurs despite a decrease in lipoprotein lipase activity because of a 50% decrease in plasma insulin levels. Vlassara et al. (44) have shown that cancer-associated reductions in plasma lipoprotein lipase are accompanied by normal or even increased insulin levels. This represents a maladaptive host response, since insulin promotes lipid storage, not fat oxidation. Impaired glucose and fat oxidation provide a sink for loss of gluconeogenic amino acids, thus producing an energy deficit and malnutrition.

Biochemical Mediators of the Anorexia-Cachexia Syndrome

The anorexia-cachexia syndrome incorporates a group of symptoms and signs such as inanition, anorexia, weakness, tissue wasting, and organ dysfunction (2,14,45,46 and 47). Potential etiologies of cancer anorexia are listed in Table 68-2. Cachexia was previously thought to be the result of increased energy demanded by the growing tumor mass. Recent research has demonstrated that it is primarily due to major metabolic abnormalities, such as profound lipolysis and loss of skeletal and visceral proteins, both of which are caused by immune mediators (e.g., TNF and interleukin-6), and tumor byproducts (e.g., lipolytic hormone). This means that anorexia, an almost universal characteristic of cachexia, should be interpreted as the result of metabolic abnormalities rather than the main cause of cachexia (48).

There has been much interest in the possible role of cytokines in cancer anorexia. Prominent cytokines include TNF, interleukin-1a and b (IL-1), interleukin-6 (IL-6), interferon-a (IFN-a), and differentiation factor, also known as leukemia inhibitory factor (49). The peptides are pyrogens, and their administration, with the exception of IL-6, can produce many of the systemic vascular effects seen in sepsis and shock. For example, IL-1 and TNF-a share the capacity to up-regulate gene transcription of endothelial cell adhesion molecules, increase procoagulant activity, promote the transendothelial migration of leukocytes out of the vascular component into the pulmonary epithelium, and activate the release of toxic superoxide and other enzyme products from neutrophils (50).

Cachexia-anorexia syndrome is characterized by progressive weight loss, lipolysis, loss of visceral and skeletal protein mass and profound anorexia (51). Cachexia is characterized by dramatic loss of triglycerides from adipose tissue and proteins from skeletal muscles (52). Weight loss decreases a patient's chance of survival, and patients with cachexia experience more complications after surgery, radiation therapy, and chemotherapy. In addition, cachexia reinforces the weakness associated with anorexia and chronic nausea and is a source of psychological distress for patients and their families.

Features of cancer cachexia can be reproduced by cytokine administration. For example, IL-1 (53) and, to a lesser extent, TNF-a (54) and IFN-a (55) are potent anorexia-producing agents. Some cytokine effects are mediated through the hypothalamus (56), and others act directly on the GI tract, causing decreased gastric emptying (54). Other cytokines may promote cachexia by increasing resting energy expenditure. Warren et al. (57) reported that cancer patients receiving cytokines as antineoplastic therapy had a dose-dependent increase in resting energy expenditure.

A mechanism proposed by Kern and Norton (2) to explain the anorexia and metabolic derangements of the anorexia-cachexia syndrome is shown in Figure 68-1. Some cancers incite a paracrine-induced systemic host response with production of cytokines such as interleukins or cachectin/TNF. These are secreted by immune cells and may be part of the host defense in an attempt to destroy the tumor. However, cytokines have negative secondary effects on host organs, resulting in anorexia and abnormalities in carbohydrate, protein, and lipid metabolism. Mobilization of nutrients from fat and skeletal muscle during the acute phase of sepsis or in trauma patients rapidly provides a physiological source of nutrients to the liver so that it can synthesize acute injury proteins. In the cancer patient, the low-grade release of cytokines persists because of the metabolic activity of the tumor and eventually causes severe depletion of host cell mass. The anorexia of chemotherapy, radiotherapy, or surgery only exacerbates this process, adding to the net effect of host depletion. The “at-risk” cancer patient can be identified by a rapid weight loss of greater than 10% of usual body weight.

FIGURE 68-1. Proposed mechanism of the cancer anorexia syndrome. Tumor–host interaction results in production of metabolically active cytokines that cause anorexia and abnormalities in host intermediary metabolism. FFA, free fatty acids. (From Kern KA, Norton JA. Cancer cachexia. JPEN J Parenter Enteral Nutr 1988;12:286–298, with permission.)

Cancer cachexia is a syndrome of progressive wasting which also has been suggested to be mediated by TNF-a, IL-1, IL-6, IFN-g, and leukemia-inhibitory factor (58,59). Recently a novel, tumor-derived cachectic factor was identified in the murine MAC16 colonic adenocarcinoma model of anorexia. This factor, provisionally named proteolysisinducing factor, was subsequently identified in the urine of weight-losing patients with cancer but not in the urine of weight-stable patients with cancer or weight-losing controls with benign disease (58,60).

Fordy et al. reported that patients with significant weight loss from colorectal liver metastases required a large tumor volume (61). This weight loss was not explained by changes in diet, quality of life, or hormones, but activation of the innate immune systems and incomplete activation of the acquired immune systems were likely to be involved. Agents that attenuate either the acute-phase inflammatory response or T lymphocyte IL-2 receptor up-regulation might reduce weight loss in patients with

metastatic disease (61).

Preventing malnutrition is easier than reversing it. Reversing malnutrition in a patient with advanced cancer is nearly impossible. Patients with cancer often lose weight and become malnourished at a time when they most need nutrition support (62). Current pharmacological therapies as well as complementary and alternative methods may be recommended for patients with cancer cachexia (63). In recent years, medications such as corticosteroids and progestational drugs, have proven effective in relieving symptoms of cancer cachexia. Corticosteroids have a limited effect (lasting up to 4 weeks) on symptoms such as appetite, food intake, sense of well-being and performance status, but none of the studies proved that patients had weight gain (48). Recent studies involving terminally ill patients have shown that progestational drugs improved the symptoms of fatigue and anorexia even in the absence of weight gain. If abruptly discontinued, both megestrol and medroxyprogesterone could induce thromboembolic phenomena, breakthrough vaginal bleeding, peripheral edema, hyperglycemia, hypertension, Cushing's syndrome, alopecia, adrenal suppression, and adrenal insufficiency. However, in most clinical trials, the adverse effects rarely led patients to discontinue these drugs (64).

ADJUNCTIVE NUTRITION SUPPORT DURING ANTINEOPLASTIC TREATMENT

The goal of nutritional care in the cancer patient should always be considered supportive whether the aim of primary therapy is cure or palliation. Nutritional therapy should be aimed at improving metabolic status, body composition, functional status, and, ultimately, quality of life. Nutrition support can prevent further deterioration in all of these parameters. However, because of the metabolic derangements of cancer cachexia, attempts to reverse severe nutritional depletion are almost universally unsuccessful.

Concerns also exist over the risk of disproportionately stimulating tumor growth as well as the ability to replete the malnourished cancer patient (65). Animal studies have been inconclusive concerning this issue. Undoubtedly in a cachectic noncancer patient receiving either total parenteral nutrition (TPN) or enteral feeding, nitrogen balance, wound healing, and outcome are improved. However, controversy continues about the role of nutrition support in cancer patients. The use of nonvolitional feeding, particularly intestinal feeding tubes and TPN, is designed to prevent the nutrition-related complications of cancer therapy (5). In the setting of chemotherapy, the risk of providing nutrition support inappropriately must be foremost in clinical decision making. TPN is not indicated for patients with advanced metastatic cancer who are not receiving antineoplastic treatment, and the routine use of TPN in cancer patients who can tolerate enteral nutrition is unjustified. The potential adverse consequences of nutrition support in the setting of cancer make it important to establish the therapeutic benefits before the initiation.

“If the gut works, use it” has become the motto of most nutrition support teams around the country. The use of the GI tract is encouraged whenever possible because it is safe, physiological, and cost effective. There is also evidence that enteral nutrition may improve visceral protein synthesis. In addition, enteral feeding is superior to TPN in supporting GI mucosal growth and function. This may be important for critically ill patients in whom the gut mucosal barrier may become compromised.

Nutrition Support in the Perioperative Setting

Prospective randomized clinical trials evaluating the clinical efficacy of nutrition support in cancer patients undergoing surgical therapy were recently reviewed (66). Twenty-seven trials were identified evaluating TPN in cancer patients who underwent surgery (67,68,69,70,71,72,73,74,75,76,77,78,79,80,81,82,83,84,85,86,87,88,89,90,91,92,93 and 94). Only five trials found statistically significant differences in clinical outcomes (69,74,78,79,86). One study reported fewer postoperative complications and decreased mortality in patients with GI carcinoma receiving preoperative TPN (74). Two other trials (69,79) reported decreased postoperative complications in patients receiving preoperative TPN. However, a large multicenter Veterans Affairs cooperative study (86) found similar rates of complications in the TPN and control groups. In addition, the study observed a statistically significant increase in the infection rate in patients receiving preoperative TPN and concluded that routine use of TPN in the perioperative setting is not indicated. Seven trials evaluated hospital length of stay (69,78,82,84,85,87,94), and only one (78) reported a significantly shorter length of stay in patients given TPN perioperatively. There were two meta-analytic reviews of prospective and mixed clinical trials published recently (95,96). Both reviews found that the combined rate of complications or mortality in patients receiving perioperative TPN was one-half to two-thirds that of the control group. Klein and Koretz et al. (66) report that data from studies providing at least 7 days of preoperative TPN suggest that the rate of preoperative complications can be decreased by approximately 5%, but that this result may not be justified economically.

Seven trials (92,97,98,99,100,101 and 102) investigated the use of enteral nutrition in surgical patients with cancer. Perioperative mortality and length of hospital stay were similar in both enterally fed and control patients. A study looking at the effect of postoperative jejunostomy tube feeding with a formula enriched with arginine, ribonucleic acids, and omega-3 fatty acids in cancer patients reported fewer complications and shortened length of stay compared with patients receiving a standard formula (103).

Nutrition Support in Patients Treated with Chemotherapy

In recent studies evaluating the use of TPN in patients undergoing chemotherapy (104,105,106,107,108,109,110,111,112,113,114,115,116,117,118,119,120,121,122,123,124,125,126,127 and 128), there was no advantage in overall survival in those receiving nutrition support. Only one trial in patients with squamous cell lung cancer reported an increase in survival of patients given TPN (125). Other trials in patients with colorectal cancer (98) and adenocarcinoma of the lung (128) reported decreased survival in the TPN-treated groups. Two meta-analytic reviews (95,129) concluded that TPN provided no added benefits in terms of survival, tumor response, or chemotherapy toxicity. However, TPN did seem to increase the infection rate.

Studies evaluating enteral nutrition in patients receiving chemotherapy were difficult to evaluate due to differences in composition, timing, and duration of nutritional therapy (66). However, no therapeutic benefit was reported in these trials in terms of survival, tumor response, or chemotherapy toxicity (130,131,132,133,134 and 135).

Nutrition Support in Patients Treated with Radiation Therapy

Four prospective and mixed controlled trials evaluated the effect of TPN in patients undergoing radiation therapy for cancer, with no difference in survival reported between TPN and control subjects (136,137,138,139 and 140). Moreover, the rate of infection was greater in patients receiving TPN than in controls in one study reporting infection rates (139).

Seven trials reported the outcome of enteral nutrition in patients receiving radiation (141,142,143,144,145,146,147 and 148). There was no difference in survival noted in the two studies that reported survival rates. Side effects were fewer in nutritionally treated patients receiving radiation for abdominal and pelvic cancer (142,143 and 144) but were greater in one study looking at head and neck cancer patients (146).

Nutrition Support in Patients Treated with Bone Marrow Transplantation

Two studies investigated the use of nutrition support in patients treated with bone marrow transplantation (BMT). BMT requires intensive chemotherapy and often radiation, leading to esophagitis and enteritis, resulting in severe nutritional depletion. In one study, Weisdorf et al. (149) reported increased survival in patients who received TPN as compared with controls. In a study by Szeluga et al. (150), patients received either TPN or enteral nutrition post-BMT, and survival did not differ between the two groups. However, the infection rate was higher in patients receiving TPN as compared with those given enteral therapy.

Several studies have evaluated the efficacy of glutamineenriched TPN in patients undergoing BMT. Glutamine is an important intestinal fuel that attenuates mucosal damage, thereby potentially decreasing bacterial translocation and bacteremia. Glutamine-enriched TPN is hypothesized to decrease the occurrence of systemic infection in those patients who are predisposed. In one study (151), Ziegler et al. reported similar survival but decreased infection rates and shortened length of stay in patients receiving glutamine-TPN versus thoose receiving standard TPN. However, Schloerb et al. (152) reported similar rates of survival, infections, and length of hospitalization when involving patients with both hematological and solid tumors.

In conclusion, most clinical trials have failed to demonstrate the clinical efficacy of providing nutrition support to most patients with cancer. However, nutrition support during treatment for cancer should not be denied in patients judged to have life-threatening malnutrition, as is provided for patients with benign disease (153).

GUIDELINES AND RISK FACTOR ASSESSMENT FOR NUTRITION SUPPORT

Global Assessment Tools

The implementation of nutrition support teams as well as proper guidelines and protocols for surveillance are the first steps in ensuring that malnourished patients are identified through nutritional screening (Table 68-3). Three simple assessment measures discussed below can be used initially to screen for protein calorie malnutrition: height and weight to determine body mass index (BMI) (154), percent of regular weight lost, and serum albumin levels. These measures are sensitive enough to identify most patients with protein calorie malnutrition. Other indicators from the Nutrition Screening Initiative level II screen (155) include midarm muscle

circumference, triceps skinfold, and serum cholesterol. In addition, clinical history, drug use, eating habits, living environment and income, and functional status, as well as mental and cognitive functioning, need to be assessed.

	Standards
Initial evaluation	
Body mass index (kg/m²)	(see Table 68-5)
Rate weight loss (% weight loss/time)	(see Table 68-6)
Serum albumin (g/dl)	≥3.5 g/dl
Comprehensive evaluation	
Anthropometrics	
Triceps skinfold (mm)	(see Table 68-8)
Arm muscle circumference	(see Table 68-8)
Biochemical indices	
Urine	
Creatine height index	
Urine urea nitrogen	6–7 g/24 h
Nitrogen balance	0–1 g/24 h
Catabolic index	(see text)
Serum	
Transferrin (g/dl)	≥170 g/dl
Total lymphocyte count	≥1500 cells/mm³
Prealbumin	18–45 mg/dl
Immune function: delayed hypersensitivity	
Skin tests	
Candida	≥5 mm induration
Mumps	≥5 mm erythema/induration
Tetanus toxoid	≥5 mm induration

TABLE 68-3. NUTRITIONAL ASSESSMENT PARAMETERS

Other indicators are also available (156,157,158,159 and 160). Buzby et al. (156) developed a Prognostic Nutritional Index (PNI) evaluating serum albumin, serum transferrin, triceps skinfold, and delayed hypersensitivity as a multiparameter index of nutritional status for preoperative nutrition support.

The PNI is defined as

$$PNI\ (\%) = 158 - 16.6(Alb) - 0.78(TSF) - 0.20(TFN) - 5.8(DH)$$

where *Alb* is serum albumin in g/100 ml, *TSF* is triceps skinfold in mm, *TFN* is serum transferrin in mg/100 ml, and *DH* is cutaneous delayed-type hypersensitivity reactivity to any three recall antigens and is scored as 0 (nonreactive), 1 (<5 mm induration), or 2 (>5 mm induration) (19). A PNI of less than 40% is categorized as low risk, 40–49% intermediate risk, and greater than 50% high risk.

Another index, the Nutritional Risk Index, was developed by the Veterans Affair TPN Cooperative Study Group (11). This index approximates the degree of malnutrition based on a specific constant, serum albumin levels, and percent weight loss.

Perhaps the most beneficial tool for nutritional screening in the oncology patient is the Subjective Global Assessment (SGA) (Table 68-4) modified by Ottery (161,162) for the practicing oncologist and other health care providers. The original SGA (163) estimates nutritional status on the basis of medical history (i.e., weight and weight history, dietary intake, GI symptoms with >2 weeks duration, functional status, and metabolic demands) and physical examination (five determinations of muscle, fat, and fluid status) (164). On the basis of these features, the patient is categorized as (a) well nourished, (b) having moderate or suspected malnutrition, or (c) having severe malnutrition (165). Two modifications of the SGA have been developed specifically for use in oncology patients (161,162). Figure 68-2 demonstrates an algorithm for optimal nutritional oncology intervention based on the SGA (166).

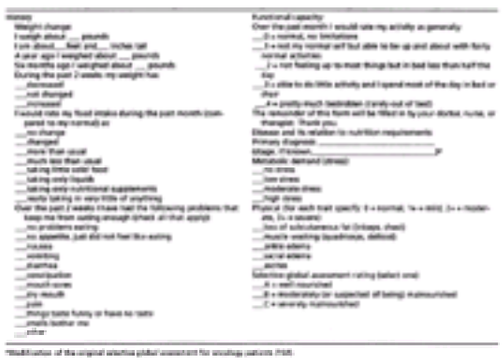

TABLE 68-4. PATIENT-GENERATED SUBJECTIVE GLOBAL ASSESSMENT OF NUTRITIONAL STATUS

FIGURE 68-2. Algorithm of optimal nutritional oncology intervention: baseline nutritional status (SGA). “Risk” refers to nutritional risk. GI, gastrointestinal; SGA, subjective global assessment; SGA-A, well nourished; SGA-B, moderately malnourished; SGA-C, severely malnourished. (From Kern KA, Norton JA. Cancer cachexia. JPEN J Parenter Enteral Nutr 1988;12:286–298, with permission.)

Individual Screening Tools

Body Mass Index

The BMI (144) may be a useful tool to identify individuals at risk for protein calorie malnutrition (Table 68-5).

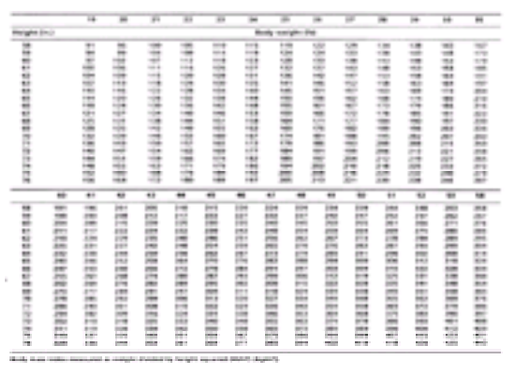

TABLE 68-5. BODY MASS INDEX TABLE

$$BMI = \text{weight (kg)}/\text{height (m}^2\text{)}$$

A BMI of less than 22 may be indicative of possible protein calorie malnutrition, especially among cancer patients.

Weight Loss

Documentation of the patient's weight history is an important and easily obtainable index for the suspected presence or progression of malignancy. There are several parameters available to interpret weight measurements including the weight/height index and the percentage of weight lost. Because the patient's height remains essentially constant, the weight/height index remains a reliable tool for estimating nutritional status. An index less than 90% of standard would suggest moderate nutritional risk whereas a weight/height index less than 75% of standard suggests severe malnutrition.

Table 68-6 focuses on the percentage of regular weight lost. This too can be a good indication of the severity of nutritional deficiency. For example, “severe” weight loss should be considered with a 5% loss of body weight in 1 month or a 10% loss within 6 months (167).

	Significant weight loss (%)	Severe weight loss (%)
1 wk	1–2[a]	>2
1 mo	5	>5
3 mo	7.5	>7.5
6 mo	10	>10

[a]Percent weight change, usual weight – actual weight divided by 100 x usual weight.
From Blackburn GL, Harvey KB. Nutritional assessment as a routine in clinical medicine. *Postgrad Med* 1982;71:46, with permission.

TABLE 68-6. EVALUATION OF WEIGHT CHANGE

Fluid balance or degree of hydration also affects the accuracy of the change in weight. Fluid retention or loss can account for significant weight shifts rather than changes in body cell mass or protein content. Therefore, fluid balance should be closely monitored.

Serum Albumin

Serum albumin concentration is a commonly used index of nutritional status. Albumin, synthesized in the liver, has a half-life of approximately 20 days with normal serum concentrations of greater than 3.5 g/dl (Table 68-3).

As a nutritional marker, serum albumin concentrations may be beneficial for detecting malnutrition. Table 68-7 demonstrates that, in hospitalized patients, hypoalbuminemia is associated not only with anergic immune status but with increased morbidity and mortality, and is a poor prognostic indicator (168).

	<10%	<25%	50%	>75%	>90%
Anergy	5.2	4.2	3.2	2.2	1.2
Sepsis	4.3	3.7	3.1	2.5	1.9
Death	4.9	4.0	3.2	2.3	1.5

From Langstein HN, Norton JA. Mechanisms of cancer cachexia. *Hematol Oncol Clin North Am* 1991;5:103–123, with permission.

TABLE 68-7. PROBABILITY ESTIMATES USING SERUM ALBUMIN

There are, however, limitations to the use of serum albumin concentration as a nutritional index for stressed and critically ill patients. During an acute illness or stress, such as injury, infection, or surgery, serum albumin synthesis decreases and hypoalbuminemia ensues. In addition, due to the long halflife, serum albumin does not respond on a daily or weekly basis to nutrition support. Finally, serum albumin concentrations can be affected by fluid status and volume repletion.

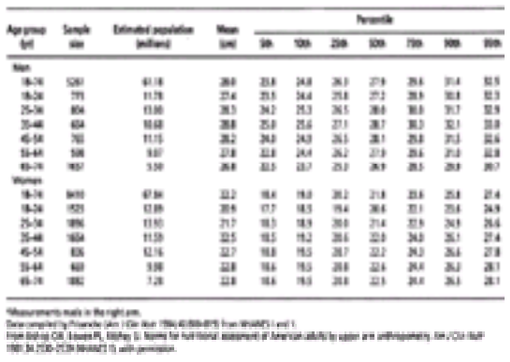
Anthropometrics

Anthropometric techniques are tools that may be beneficial in defining fat stores in the patient with cancer. One of the major sites of fat deposition in the human body is the subcutaneous space (19). Subcutaneous fat represents approximately 30% and 33% of total body fat in men and women, respectively; these numbers vary according to age, level of obesity, and measurement techniques (12).

A useful anthropometric assessment of body fat mass is the triceps skinfold measurement (TSF). This is performed by using large calipers at the upper left arm. Knowing the TSF, one can derive the more valuable arm muscle circumference (AMC):

$$AMC = \text{arm circumference} - TSF$$

The AMC is compared with standard tables (Table 68-8), and values less than 60% of standard are consistent with protein depletion (19). As with all anthropometric techniques, interobserver and intraobserver variation ranges from 15% to 20%, and the exact correlation between upper arm circumference and total body protein stores is unknown.



Age group (yr)	Sample size	Estimated population (millions)	Mean (cm)	Percentile						
				5th	10th	25th	50th	75th	90th	95th
Men										
18–74	5261	61.18	28.0	23.8	24.8	26.3	27.9	29.6	31.4	32.5

TABLE 68-8. MIDARM MUSCLE CIRCUMFERENCE IN ADULTS (18–74 YEARS), UNITED STATES[a]

Transferrin

Transferrin is a 90-kd globulin that binds and transports iron. The half-life of transferrin, which is primarily synthesized in the liver, is 8–10 days. Visceral protein depletion is reflected with transferrin levels less than 170 g/dl. This makes it more sensitive than albumin as an index of improvement in nutritional status. There are, however, two instances when transferrin levels are unreliable for nutritional status: in iron-deficient or iron-overloaded patients who tend to show high and low transferrin levels, respectively, and in patients who have had multiple transfusions (7).

Delayed Hypersensitivity

Assessment of the function of the cellular immune system through delayed hypersensitivity testing to common skin antigens can be a marker of nutritional status. Anergy has been correlated with an increased incidence of postoperative morbidity and mortality (169). The common recall antigens used are *Candida*, mumps, dermatophytes, or tetanus toxoid. After 24–48 hours, 5 mm or greater of induration is considered a positive response. Cellular immunity is most sensitive to malnutrition, but protein deficiency also reflects leukocyte function, particularly immune cell activation and cytokine release.

Evaluation of Ongoing Nutrition Support

Patients undergoing administration of nutrition support require assessment of several parameters to tailor daily requirements of specific nutrients. Many of these parameters, notably serum albumin, AMC, and BMI, are not sensitive enough to detect the short-term effects of nutrition support. In addition to daily electrolyte determinations, physical examination, and accurate body weights, other parameters, such as nitrogen balance, may be more beneficial in assessing the impact of nutritional therapy on a short-term basis.

Health care providers must, however, differentiate an increase in weight caused by fluid retention from lean body mass. Malnourished patients who are suddenly overfed can develop an increase in intravascular volume, congestive heart failure, and electrolyte abnormalities, which can be fatal (170).

Nitrogen Balance

The nitrogen balance determination is a dependable measure that can reflect the influence of nutrition support on lean body mass. Nitrogen balance reflects the difference between nitrogen intake versus output over a 24-hour period. With 1 g of nitrogen representing 6.25 g of protein, the nitrogen balance is calculated as

$$\text{Nitrogen balance} = \text{protein intake (g)} \div 6.25 - (\text{24-hour urine urea nitrogen} + 4\ \text{g})$$

The principal form of urine nitrogen is called *urine urea nitrogen*, which can be easily measured. Urea excreted in the urine reflects protein degradation. In addition to urea, other forms of nitrogen are excreted, including nonurea urine nitrogen, fecal nitrogen, and integumental nitrogen. These are lost at a fairly constant rate except when diarrhea is present. In calculating nitrogen loss, 4 g is added to the nitrogen output as an estimate of fecal and integumental losses.

NUTRITION SUPPORT

Parenteral Nutritional Requirements

Caloric Requirements

The “gold standard” for estimating basal energy requirements was derived by Harris and Benedict around the turn of the century (171). Basal metabolic requirements (BMRs) can be calculated using the following Harris-Benedict equations:

$$\text{BMR for males} = 66.4730 + (13.7516W) + (5.0033H) - (6.7550A)$$

$$\text{BMR for females} = 65.5095 + (9.563W) + (1.8496H) - (4.6756A)$$

where W is weight in kilograms, H is height in centimeters, and A is age in years.

The primary goal of parenteral and enteral nutrition support is to supply adequate protein and nonprotein calories to prevent further catabolism and promote the accrual of protein. The use of parenteral nutrition, although controversial in some settings, has been accepted as an effective means of sustaining life and promoting recovery in critically ill patients incapable of ingesting, absorbing, or assimilating nutrients. TPN has also proved appropriate for similar noncritically ill patients who have preexisting malnutrition and for nonstressed but hospitalized patients who can take nothing by mouth for 5 to 7 days. These goals of parenteral nutrition remain supportive: (a) improving wound healing, (b) bolstering immune function, (c) influencing acid-base and mineral homeostasis, and (d) minimizing obligate nitrogen loss in the catabolic postinjury state. These goals are achieved by (a) providing substrate (protein, carbohydrate, lipid, electrolytes, minerals, and vitamins) for ongoing metabolic functions, (b) improving cardiac and respiratory function by restoring glycogen stores in cardiac and diaphragmatic muscle, and (c) potentially modifying the systemic inflammatory response (167,170,172).

All critically ill patients require a thorough nutritional assessment to determine who is likely to benefit from nutrition support and whether nutrition is to be provided via an enteral route, parenteral route, or a combination. Three principal factors predict the need for nutrition support: current nutritional status (i.e., body composition) and recent weight loss, the anticipated duration of inadequate nutrient intake, and the presence and degree of the stress response. A nutritional assessment begins with a thorough history and physical examination. The BMI is often a useful indicator. Defined as weight in kilograms divided by the square of height in meters, it normalizes body weight for height and is independent of sex. A value less than 18 is consistent with significant malnutrition. Weight alone may be a poor indicator of nutritional status, as short-term fluctuations in total body water may account for changes in weight. Temporal and peripheral muscle wasting may occur, signifying probable malnutrition even in the face of weight gain. Upper arm anthropometry is a useful tool for assessing malnutrition. A value below the fifth percentile is consistent with a loss of approximately 30% of normal lean body mass and is an absolute indication for nutritional intervention. Serum levels of visceral protein markers such as albumin, prealbumin, retinol-binding protein, and transferrin, have commonly been used as indicators of nutritional status (167,170).

Choosing the appropriate route of nutrition support for a critically ill patient is an important decision predicated on the patient's clinical situation. Although enteral feeding is always the preferred route for patients with a functional GI tract, many patients have relative or absolute contraindications to enteral feedings. Patients with severe diarrhea, abdominal distention, high nasogastric tube output, pancreatitis, or unobtainable safe access to the GI tract are poor candidates for enteral nutrition. The complications of enteral nutrition include pulmonary aspiration, diarrhea, and intestinal ischemia or infection. Owing to the seriousness of intestinal ischemia, hemodynamically unstable patients with low cardiac outputs and patients on moderate to large doses of alpha agonists should not be fed by the enteral route. In addition, many patients are difficult to feed safely enterally, because of either feeding intolerance or respiratory failure with aspiration risk.

The mild to moderately stressed patient usually requires 25–35 kcal/kg and 1.5 g of protein/kg of ideal body weight in order to maintain positive nitrogen balance.

Nonprotein calories are supplied by both carbohydrates and lipids, with glucose being the major energy source for the central nervous system, red blood cells, and renal medulla. These organ systems require a minimum of 100–150 g/day (19). The maximal infusion of dextrose given should be 5 mg/kg/minute. Exceeding this rate may lead to hepatic steatosis and excess fat synthesis and carbon dioxide production (19). The caloric density of glucose is 3.4 kcal/g; approximately 60–70% of nonprotein calories should be provided as dextrose (172).

Lipid Requirements

Fat emulsions, derived from soybean or safflower oil, provide 2.0 kcal/ml in standard 20% solutions. The usual dose of lipid is 0.5–1.0 g/kg/day, with the maximum of 2.5 g/ kg/day (173). Lipid emulsions are usually formulated to provide approximately 30% of total nonprotein calories. However, a minimum of 0.5 mg/kg/day is sufficient to prevent essential fatty acid deficiency.

Protein Requirements

The protein requirements for a mild to moderately stressed patient may be estimated at 1.5–2.0 g protein/kg based on ideal body weight. Although nonprotein calories may spare nitrogen in the nonstressed state, patients with cancer usually require an infusion of 0.2–0.3 g nitrogen/kg/day to maintain a positive nitrogen balance (174).

Fluid Requirements

Fluid requirements depend on baseline requirements, losses, and fluid deficits. Fluid status is dynamic and should be monitored on a constant basis by physical examination and accurate daily weights. The average fluid requirement varies from 1250 to 3000 ml/day, depending on body habitus. The average semistressed patient requires approximately 35 ml/kg/day. A wide array of fluid abnormalities can be seen in cancer patients due to the disease process and therapies such as surgery, radiation therapy, and chemotherapy.

Electrolytes

Electrolytes are included in all parenteral nutrition solutions. Electrolyte requirements for patients with cancer are essentially the same as for patients with nonmalignant forms of disease. The electrolyte composition of TPN will be dependent on the hormonal milieu, GI, and pulmonary losses, disease state, and renal and hepatic function (19). In addition, treatment modalities (i.e., amphotericin B administration) can alter electrolyte requirements. Daily serum electrolyte measurements are important to customize the patient's daily nutritional prescription. Limitations exist for calcium, phosphorus, and magnesium in parenteral nutritional solutions. Calcium and phosphorus can form a precipitate if they are not compounded properly or if excessive amounts are added to the solution (175). The pH, temperature, and type of amino acid solution will also affect the compatibility of calcium and phosphorus (176). Hypophosphatemia may result from hyperalimentation without adequate supplementation. A minimum of 20 meq of potassium phosphate per 1000 kcal will usually prevent hypophosphatemia (177).

ENTERAL FEEDINGS

If the GI tract is intact and functioning, liquid formula diets are preferred. Oral supplements provide an excellent source of calories and protein to bolster a modest oral intake or as an adjunct to hyperalimentation. Unfortunately, cancer patients often suffer from anorexia, nausea, oropharyngeal obstruction, or central nervous system pathology and cannot meet their caloric needs despite a functioning intestinal tract. These individuals can benefit from tube feeding. Small pliable nasogastric tubes are available and well tolerated by most patients. Delivery methods can be by either bolus feeding, gravity, or mechanical pump systems. In the critically ill patient, the literature supports the use of continuous rather than intermittent tube feeding. In this population, continuous tube feedings have been associated with positive nitrogen balance and weight gain as compared to intermittent tube feedings (178). Continuous tube feedings require less energy expenditure because of diet-induced thermogenesis and have been shown to be effective in the prevention of stress ulceration (179,180).

Although most patients' needs can be met with one or two enteral formulations, there are a myriad of diseasespecific products available. Slow rates should be initiated at 10–20 ml/hour and then increased 10 ml every 8–12 hours until full flow rates are obtained. There is usually no reason to dilute low-fat, well-tolerated formulas such as Peptamen, Vital, or Vivonex. The patient's head should be maintained at a 30° elevation with nasogastric and nasoduodenal feedings to avoid aspiration. For patients needing chronic enteral feedings, surgical or endoscopically placed gastrostomy or jejunostomy tubes may be beneficial.

Nutritional Adjuncts

Insulin has been investigated as an anabolic agent in the treatment of cancer cachexia because of the tumor-associated alterations in carbohydrate metabolism and insulin resistance demonstrated in cancer patients. Studies have shown that parenteral nutrition administered with insulin to cancer patients results in improved skeletal muscle protein synthesis and whole-body protein net balance compared with standard TPN (181). The use of insulin as an anabolic adjunct to TPN appears promising, but further trials examining clinical outcomes are needed.

Growth hormone has been shown to attenuate the loss of body protein when administered to patients without cancer (182). There has been little study of growth hormone as a nutritional adjunct in patients with cancer because of the fear of stimulating tumor growth. In animal studies and *in vivo* human tumor studies, no increase in tumor volume has been reported (183,184). Further studies will be needed to outline a potential role for growth hormone in the nutritional therapy of cancer patients.

Glutamine is a nonessential amino acid that has been noted to be depleted in patients with cancer. Standard TPN solutions do not contain glutamine because of instability issues. Addition of glutamine to TPN formulations has been shown to improve nitrogen balance and promote protein synthesis without stimulating tumor growth (185). Ziegler and colleagues in a double-blinded prospective trial found that patients receiving glutamine-enriched TPN had an improved nitrogen balance, fewer infections, and short-ened length of hospitalization compared with controls (186). Further clinical studies using glutamine are ongoing, as it may be potentially beneficial as an adjunct to conventional TPN in cancer patients.

Immunonutrition in Cancer Patients

Over the past several decades, our appreciation of the importance of feeding patients who are unable to take in calories adequate for metabolic requirements has increased extensively. Better techniques for providing nutrition intra-venously have improved the survival of patients with prolonged or permanent loss of GI tract function (187). Special enteral diets have been formulated to contain high amounts of arginine together with omega-3 fatty acids, nucleic acids, and sometimes glutamine (188). All these substances have been shown to enhance or preserve host immune responses and/or to reduce harmful and exaggerated inflammatory responses. This therapeutic approach has been termed immunonutrition (189).

Artificial nutrition support after major surgery should be considered an essential part of postoperative care. In particular, in patients undergoing pancreaticoduodenectomy or gastrectomy for cancer, early postoperative nutrition support is needed because, in these subjects, adequate post-operative oral intake is reached late, and preoperative protein-energy malnutrition is often present (190). Hochwald et al. reported in a randomized, prospective trial, that early postoperative enteral feeding led to a decrease in fat oxidation and protein catabolism. These findings were associated with hyperinsulinemia, which correlated with positive protein net balance. By significantly impacting on protein loss, early postoperative enteral nutrition may potentially contribute to a decrease in postoperative morbidity and mortality in upper GI cancer patients (191).

Since 1990, standard enteral and parenteral preparations have been modified by adding immunonutrients (192,193,194,195 and 196). This new category of dietary compounds has peculiar properties. Among the most interesting and carefully investigated immunonutrients are the following: (a) arginine, which improves macrophage tumor cytotoxic effects, bactericidal activity, and vasodilatation through production of nitric oxide; stimulates T-cell proliferation, natural killer cell cytotoxic effects, and generation of lymphokine-activated killer cells; and modulates nitrogen balance and protein synthesis (197,198); (b) omega-3 polysaturated fatty acids, derived from fish oil, which are potent anti-inflammatory agents through pathway of coagulation, and up-regulate the immune response; and (c) glutamine, which is known to facilitate the transport of nitrogen between organs, reduce the skeletal and intestinal protein waste during stress, enhance macrophage and neutrophil phagocytosis, and preserve the intestinal permeability by being the major fuel for different cell types (199,200). Glutamine administration helps minimize atrophy of intestinal mucosa associated with TPN, and intestinal mucosa damage due to chemotherapy and radiation therapy (201,202). Supplementation of the amino acid glutamine, by the enteral or parenteral route, as either the free or dipeptide form, appears safe and efficacious in patients undergoing BMT (203,204).

Prebiotic bacteria, such as *Lactobacillus plantarum,* seem not only to preserve key nutrients, such as omega-3 fatty acids, but also increase its content during storage conditions. *L. plantarum* competes with gram-negative potential pathogens for receptor sites at the mucosal cell surfaces, eliminates nitrate and produces nitric oxide; this may help recondition the GI mucosa. To produce a *L. plantarum*–containing formula, a treatment policy is regarded as an extension of the immunonutrition program, and is called *ecoimmunonutrition.* Patients with radiation therapy or cancer are candidates for ecoimmunonutrition (205).

The conception of immunonutrition has gained a great deal of clinical attention, and studies have been performed in an attempt to demonstrate clinical outcome benefits (189). In cancer patients undergoing elective surgery, Daly et al. reported, in two different studies, a significant reduction of postoperative infections in patients who were given immunonutrition early after surgery (206,207). A multi-center study from Germany showed a slight reduction in overall postoperative complication rate in the immunonutrition group (22% vs. 31% in the control group) (208).

When the authors grouped complications occurring before or after postoperative day 5, the immunonutrition group had significantly lower incidence of late postoperative complications, whereas no difference was found in the early postoperative complication rate. These results seem consistent with the hypothesis that some days of feeding are necessary to improve the host defense and subsequently to reduce infections (209).

A second study performed by Senkal et al. was more compelling (210). Patients were randomized to receive 5 days of preoperative and 5 days of postoperative immunoenhancing diet (IED) and standard-enhancing diet (SED). For the evaluable patients, there was a trend toward a significant reduction in overall combined infections and wound complications (IED = 13% vs. SED = 24%, p = .08) and significant reduction in late (>3 days) complications (IED = 9% vs. SED = 21%, p = .04). The number of early complications was low (210). Heslin et al., who studied 195 patients undergoing elective cancer surgery, did not find a significant difference in postoperative infectious and noninfectious complications by comparing groups treated with either an early postoperative immunoenhancing diet or simple crystalloid fluid replacement (211). However, in the immunonutrition group, the average postoperative energy intake was 60% of the nutritional goal and only 30% was given with the immunoenhancing diet.

Kemen et al. reported that postoperative immunonutrition improved immune response late after surgery, probably because the amount of immunonutrients given in the first days after operation was too small to stimulate a prompt burst of immune response and, consequently, to improve outcome (212). The early postoperative administration of enteral immunonutrition compared with a control enteral diet significantly reduced both severity of infections and postoperative stay, while the reduction of postoperative infection rate was not significant (190,213).

Braga and coworkers reported that the provision of immunoenhancing substrates before surgery appears to play a key role in reducing postoperative infections by a substantial activation of the immune response (209). Their data suggest that perioperative immunonutrition is efficacious regardless of the baseline nutritional status of the patients. In fact, preoperative administration of immunoenhancing diets reduced postoperative infections also in well-nourished patients in whom a severe postoperative impairment of the host defense mechanisms has been reported (214).

Galban et al. reported that immunoenhancing enteral diet reduced mortality rate and episodes of bacteremia in septic intensive care unit patients (215). In a prospective study by Fan et al., it was reported that perioperative nutrition support in the form of a solution enriched with branched-chain amino acids, dextrose, and medium-chain triglycerides was beneficial in reducing postoperative morbidity in patients undergoing major hepatectomy for hepatocellular carcinoma, especially when the liver was cirrhotic (216). Braga et al. reported that perioperative administration of immunonutrition ameliorated the host defense mechanisms and controlled the inflammatory response in patients with gastric cancer (217).

Another trial conducted by Snydermen et al. was more difficult to interpret because of poor study design and insufficient data in the manuscript. Patients scheduled for resection of head and neck cancers were randomized into four groups: (a) preoperative and postoperative IED, (b) postoperative IED, (c) preoperative and postoperative SED, and (d) postoperative SED. Thirteen patients were withdrawn from the study very early; of the remaining 129 (which are called the “intent to treat” group), 82 were randomized to the IED group, but only 47 to the SED group. Thirty-three of these patients failed to receive the correct formula. This left 85 patients who “actually fed” the correct therapy. In the “actual fed” group analysis, patients who received the IED had significantly fewer complications. This was also true for the “intent to treat” group analysis (218,219).

Meta-analysis provides the best estimate of overall treatment effect. In two published meta-analyses of immunonutrition, different investigators came up with different estimates of the overall effect on mortality. Heys and colleagues combined 11 randomized trials of immunonutrition in critically ill and surgical patients (220). Working with the data set that these investigators used, the effect on mortality was consistent with more harm than good, although the meta-analyses did not include several key papers published in non-English journals, published subsequent to 1998. Subsequent to this publication, Beale and colleagues aggregated the results of 12 randomized trials of immunonutrition in surgical and critically ill patients. Although there was some overlap between the two meta-analyses, the study by Beale et al. included recently published studies but was limited to studies of Impact (Novartis Nutrition Corp., Bern, Switzerland) and Immun-Aid (McGaw Inc., Irvine, CA) (221). Both meta-analyses concluded that use of IEDs had no significant effect on mortality rate (222). Moreover, Impact and Immun-Aid, the two enteral feeding preparations enriched with these “immunonutrients” that have been developed commercially for critically ill patients (Table 68-9), are slightly different in composition (221).

	Impact	Immun-Aid
Calories (kcal)	1000	1000
Protein (g)	56	37
Arginine (g)	12.5	14
Glutamine	—	9.0
Branched-chain amino acids (g)	—	20
Nudeic acids (g)	1.23	1.0
Fat (g)	27.8	22.0
Omega-3 polyunsaturated fatty acids (%)	10.5	4.5
Osmolality (mOsm/kg)	300	460
Vitamin C (mg)	67	60
Iron (mg)	12	9
Zinc (mg)	15	26
Selenium (μg)	46	100
Copper (mg)	1.7	2

TABLE 68-9. COMPOSITION OF ENTERAL FEEDS IMPACT AND IMMUN-AID

It is unlikely that there are adverse effects of immunoenhancing nutrients given the modest amounts of the nutrients that are in the enteral formulas and the relatively short period (e.g., a period of weeks) patients are fed formulas with immunoenhancing nutrients. However, any nutrient that can alter immune function needs to be critically evaluated for potential adverse effects. Certain lines of breast cancer cells may also be stimulated to replicate when large doses of either L-arginine or L-glutamine are administered (223,224). It has been hypothesized that nitric oxide synthesized from L-arginine triggers vascular smooth muscle dilation and could potentially promote septic shock (225). A sheep model of sepsis has demonstrated administration of excessively high amounts (e.g., 200 mg/kg/h) of L-arginine parenterally has adverse outcome (226). However, this dose of arginine would be equivalent to over 300 g/day for a 70-kg man, which is not possible with the levels found in immunoenhancing formulas (227).

It is difficult to expect improvement in outcome with such a limited intake of immunonutrients. Better metabolic and clinical results were obtained with perioperative administration of immunonutrients (214). Immunoenhancing nutrients in the correct dose given early for 5 to 7 days appear to be safe and promote beneficial outcomes in select patient populations (227). In conclusion, specifically the perioperative administration of the supplemented diet improved the synthesis of constitutive visceral proteins and significantly reduced the rate of postoperative infections and the length of stay in patients undergoing surgery for cancer (214).

Home Parenteral and Enteral Nutrition

Oral or tube feedings in the home setting are both financially and physiologically preferred over parenteral nutrition. However, patients who cannot tolerate oral or tube feedings may benefit from home TPN. The technology and science of nutrition support has flourished in the last 20 years but not without a significant increase in costs. It has been estimated that nutrition support accounts for approximately 1% of all health care dollars (228,229). As expected, most of these dollars are spent on hospitalized patients, but approximately 20% are spent on patients living outside the hospital (228). Half of these patients are nursing home residents and half reside at home. Twenty percent of home patients receive parenteral nutrition support and 80% receive enteral nutrition support (228). The cost for enteral feeding is estimated at $15,000/year with home parenteral nutrition support being at least 10 times as costly (229).

Patients with a curable malignancy, who require aggressive primary treatment causing anorexia, nausea, and/or ileus, may benefit from home nutrition support. Other indications for home nutrition support are patients who are “cured” from their primary cancer but are left with bowel dysfunction from irradiation or resection.

A voluntary patient registry, the North American Home Parenteral and Enteral Patient Registry, was formed in 1984 to follow clinical outcomes of home patients receiving home parenteral or enteral nutrition. There are approximately 204 programs with more than 10,000 home nutrition patients registered. The Oley Foundation has published outcomes information on patients registered to date (230).

For the individual deemed a candidate for home nutrition support, techniques used at home and in the hospital are essentially similar. In the home setting, the patient and the patient's family may take responsibility for solutions administered (231). For parenteral nutrition, central catheter administration is the preferred route for hyperalimentation. This allows provision of adequate calories and protein without large fluid volumes. If possible, a Hickman catheter is preferred because it has two Dacron cuffs that help secure placement and reduce the risk of ascending bacterial infection. Strict sterile technique is essential to reduce the risk of catheter infection and sepsis. Even with precautionary measures, the incidence of catheter-related sepsis is 4.5–11.0% (232). In addition to the traditional subclavian or internal jugular central venous access, peripherally inserted central catheters (233,234) can be inserted into the basilic or cephalic vein in the antecubital fossa and threaded into the superior vena cava. Peripherally inserted central catheter lines are safe and reliable central venous access routes for patients receiving parenteral nutrition, long-term antibiotics, and chemotherapy without the complications of pneu-mothorax or hemopneumothorax. For all patients with intravenous lines, close follow-up with a nutrition support team is important to monitor fever, fluid status, and electrolyte abnormalities. To improve quality of life, patients can have enteral or parenteral feeding cycled at night to allow mobility during the day.

CONCLUSIONS

It is well known that patients with malignancy have a high incidence of malnutrition and cachexia resulting from decreased intake as well as metabolic alterations due to the influence of the tumor. The clinician must not only identify those patients at risk for malnutrition but must also identify those who will benefit from nutrition support.

Routine use of TPN in patients with cancer has not been substantiated in the literature (235). The clinician must carefully assess the severity of malnutrition, treatment options, and potential quality of life in the cancer patient before opting to use nutrition support as an adjunctive therapy. Decisions regarding methods and aggressiveness of the nutritional intervention should be based on these issues as well. The enteral route is always preferable to TPN in terms of physiological response, immune competence, quality of life, and cost (236).

ISSUES IN NUTRITION AND HYDRATION

ZHENG-BO HUANG
JUDITH C. AHRONHEIM

Modern living conditions and advanced health care have changed the way people die. In the United States, 78% of people live past the age of 65, and 75% of the elderly will be challenged by incurable, progressive, or disabling illnesses during the last year of life (1). In many cases, difficulty with eating and drinking will occur during these processes, making decisions about whether to provide artificial nutrition and hydration (ANH) common events in most hospitals and long-term care facilities (2,3,4,5,6,7,8 and 9).

For many people, when dying appears inevitable, the quality of remaining life and the quality of dying become more important than duration of life. The palliative care and hospice care movements have been strongly motivated by the perception of unnecessary suffering at the end of life from futile medical interventions and neglect of patient's and family's wishes or goals surrounding dying. For the past three decades, the courts have upheld the right to refuse life-sustaining treatment, and all states have enacted one or more statutes creating advance directives or other mechanisms to uphold these rights (10,11 and 12). Likewise, an ethical consensus regarding these rights has been well established. However, issues regarding ANH at the end of life have been less thoroughly resolved.

The medical community has been reexamining its practice regarding ANH at the end of life. Although there are still controversies and debates, health care providers should be able to make appropriate recommendations regarding ANH and provide effective patient-centered care. This chapter will discuss the major issues surrounding ANH at the end of life: legal and ethical consensus and controversies, complexity of ANH issues in a diverse patient population, current practice in different clinical settings, observational studies of ANH in terminally ill patients, and the importance of respecting the values of patient and family. Suggestions to improve management of ANH issues in terminally ill patients will be focused on good communication under an integrated end-of-life palliative care plan.

LEGAL AND ETHICAL CONSENSUS AND CONTROVERSIES

Despite long-standing ethical consensus regarding the right to refuse medical treatments, a persistent debate has surrounded forgoing ANH at the end of life. Ethical consensus holds that ANH is a medical treatment that can be refused like any other treatment (13,14,15 and 16). Most professional organizations concur with this consensus (17,18,19,20 and 21), although an alternative position holds that ANH constitutes basic care that must be provided, and does not distinguish this medical treatment from the provision of food and water (22,23 and 24). Although this position may be based in religious or other moral beliefs, it could also be influenced by misunderstanding of the medical aspects of ANH; specifically, it may be driven by the mistaken perception that forgoing ANH leads to a painful death (25,26 and 27). Likewise, there may be a failure to recognize the potential medical complications and resulting discomfort from ANH as delineated elsewhere in this chapter. In parallel with an increasing dialog within the literature in the past decade, some commentators for the alternative position, which favors the use of ANH in almost all circumstances of inability to eat and drink, allow for decisions to forgo this treatment when the burdens outweigh the benefits (28,29).

In addition to the general ethical consensus, a legal consensus has emerged that ANH may be refused like any other treatment. A series of appellate court cases in the 1980s (30) culminated in the *Cruzan* decision in 1990, which was the first “right-to-die” case that reached the U.S. Supreme Court (31). In this case, the family of a Missouri woman in persistent vegetative state (PVS) asked that her enteral feeding tube be removed and she be allowed to die, a choice denied by the Missouri Supreme Court. The U.S. Supreme Court ruled that ANH constitutes medical treatment that can be refused like other treatments, but held that the states can develop their own standards of decision making for the incompetent. In the case of Nancy Cruzan, lower courts had applied a strict evidentiary standard for. refusal of life-sustaining treatments and ruled that there was not “clear and convincing evidence” of the patient's wishes regarding withdrawal of her treatment, and the U.S. Supreme Court upheld Missouri's application of that standard. Since *Cruzan*, many states have developed additional methods of decision making for the incompetent, including laws with surrogate, decision-making provisions, which establish a hierarchy of decision makers who decide for incapacitated patients who lack advance directives (11). Although the “clear and convincing standard” was not applied specifically to ANH in the Supreme Court decision, many state statutes maintain separate and higher legal standards for ANH as compared with other life-sustaining treatments, or contain separate provisions regarding ANH that can be confusing or misleading (32). To date, there is no evidence that state-by-state variations in the use of tube feeding in patients who lack capacity correlate with specific legal standards (33). However, the persistence of separate standards raises concerns as to their constitutionality and could lead to misunderstanding on the part of patients and surrogates, as well as fear on the part of physicians that recommending the withdrawal or withholding of ANH might lead to legal repercussions.

It is noteworthy that none of the appellate tube-feeding cases involved people with cancer (30). Most involved people with PVS, perhaps reflecting the long duration of tube feeding in the persons whose cases were decided (average 3.5 years). In the experience of one patient advocacy organization, most disputes over tube feeding involve elderly patients with dementia (30). In that group of patients, disputes about life-sustaining treatments in patients with other serious illnesses, such as cancer and organ failure, generally involved life-sustaining treatments other than, or in addition to, ANH, even if ANH was currently being provided. Legal theory regarding ANH or tube feeding is generally based on a very specific type of patient—that is, one with a fixed or slowly progressive neurological deficit. This probably reflects the lower use of tube feeding (2) and shorter presumed prognosis or actual survival of patients with advanced cancer, and perhaps a greater acceptance by the health care team and family that death is inevitable in advanced cancer. It may also reflect a higher proportion of cancer patients who have decisional capacity and can be involved in the decision, and who would face fewer legal obstacles in the forgoing of ANH. In the patient with advanced dementia or PVS, medical and prognostic issues may lead to a perception that withholding or withdrawing ANH amounts to “killing the patient,” who might otherwise live for a prolonged period. In the case of the patient with advanced dementia, however, increasing evidence suggests that average life span is approximately 6 months (34,35,36 and 37) and ANH does not appear to affect the overall prognosis (34). It is likewise probable that ANH would not affect the overall prognosis in a patient with advanced cancer.

COMPLEXITY OF ARTIFICIAL NUTRITION AND HYDRATION ISSUES IN A HETEROGENEOUS PATIENT POPULATION

People die from different diseases, in different settings, with different levels of readiness, and different perceptions regarding good quality of dying, with different goals and wishes regarding their dying, and with different patterns, or “trajectories.” Confusion and controversy in the care of these patients, specifically with regard to ANH, can easily arise when patients are classified with a general term, such as “terminally ill” or “end of life,” without reference to a more specific stage, situation, or individual perception of quality of death.

Three Trajectories of Terminal Diseases

Most Americans will die from disabling, progressive, or chronic disease. Lynn has characterized three trajectories that patients generally follow before death (38). The first trajectory applies to the patient with “terminal cancer,” who usually can perform activities of daily living and preserve their decision-making capacity until quite late. Most of the studies examining the impact of dehydration and the role of artificial hydration in patients with terminal illness have been conducted in this group of patients (6,39,40,41,42 and 43). The second trajectory represents those dying mainly of chronic organ system failure such as heart, lung, renal, or liver disease. Such patients are usually very sick for months or years with recurrent exacerbations. The timing of death usually remains unpredictable until very late in the disease. Persons with

progressive disability, such as strokes, dementia, or general frailty accompanying very old age, follow the third trajectory; many of them are incompetent months or years before death. Most of the studies around tube feeding have been conducted in this group (25,34,44,45 and 46). The situation that the patient, family, and physician confront when they have to make decisions regarding artificial support of nutrition and hydration at the “end of life” can be quite different among these three groups of patients.

Defining Terminal Illness and the Dying Stage

The natural history of the common symptoms and signs present in terminally ill patients is not well characterized, and adequate staging systems are lacking (47,48). The concepts of “terminal illness” and “end of life” are vague, and there is no unanimity about their definition. Within the law, “terminal” may be defined loosely as death “imminent” or expected to occur in a “relatively short time,” or in a time-limited fashion (typically, 6–12 months) (49,50 and 51). In addition, “terminal illness” has been defined with respect to administration of life-sustaining treatments—for example, a condition that would result in death within 6 months *even with* administration of life-sustaining treatment (52), or one that would result in death within a relatively short time *without* the administration of life-sustaining treatment (53). Some of these definitions might be especially problematic when questions of ANH arise. For example, one could argue that ANH would postpone death beyond a specific time limit in certain circumstances, such as a severe neurological impairment, or that the person could not be considered “terminally ill” if this treatment were provided. Given the higher standards that often exist in the law regarding ANH, as noted earlier (see the section Legal and Ethical Consensus and Controversies), gaps exist between the body of law, on the one hand, and the diverse clinical scenarios that actually occur.

Prognostic uncertainties seen in patients with chronic organ system failure (the second trajectory) and patients with progressive disability (the third trajectory) have been recognized as the major barrier to enrolling these patients in hospice programs in a timely fashion (54,55), and could influence physician recommendations about lifesustaining treatments, especially ANH. Studies seeking to define or stage terminal illness have mostly used patients with cancer (the first trajectory). Vigano et al. conducted a systematic literature review on prognostic factors for survival in cancer patients considered to be terminal and found no standard criteria in the literature to define this phase (48). A predicted survival of 3–6 months is often the time when treatment goals change from curative to palliative (48,56,57), although the phase may actually last 12 months or so in some patients. However, physicians have a tendency to overestimate the final 3–6 months of survival (58,59,60,61 and 62). The uncertainty in estimating survival contributes to the difficulty in decision-making regarding ANH at the end of life. It also limits the rigor of studies on ANH, as patients are not uniform in terms of representing similar and specific (inception) points during the course of their disease.

Where the Patient Dies

In general, the majority of Americans die in a hospital (63,64,65 and 66). In 1994, 62% of all deaths in the United States occurred in hospitals, 16% in nursing homes, and 17% at home (66). Only 10% of dying patients were in hospice care (66), but in 1999, this rose to approximately 29% (67). Marked variations in the care of dying patients exist across geographical regions, depending very much on the local availability of hospital beds and the capacity of community heath care provider to meet the dying patient's needs (63). The majority of Canadians also die in hospitals (68). The setting can indirectly affect decisions about ANH because of the perceived lower urgency and importance of ANH compared to other treatments, the readiness of patient and family to accept the inevitability of death, and experience of the staff in handling these issues (4,5,64,69).

Attitudes, Values, and Culture of Patients, Families, and Health Care Providers

Attitudes about appropriateness of use or nonuse of ANH at the end of life are diverse, varying among patients, surrogate decision makers, and health care providers, and may be related to an individual's definition of quality of life, the individual's values and perceptions, and the ethnic or cultural background of dying patients and their families (57,70,71,72,73,74,75,76,77,78 and 79).

The cultural, religious, or ethnic background can influence the attitude of both patients and health professionals. For example, elderly Catholic patients at a Veteran's hospital appeared less willing to undergo tube feeding than other Christian patients in response to a hypothetical end-of-life scenario (74). Many studies have shown that black patients are more likely than white patients to desire life-sustaining intervention, including tube feeding (75,76,79,80,81 and 82). In a related study, black physicians were less likely than white physicians to consider tube feeding as “heroic” and more likely to request aggressive treatments, including artificial feeding for themselves if they were in PVS (78). In a survey of elderly Chinese attending a day care center in Singapore who were asked about life support measures at the end of life, 55.8% said they would want nasogastric feeding and 65.1% would want intravenous (i.v.) hydration (77). In an international study, none of the nurses in North America interviewed would “force-feed” a hypothetical elderly patient with incurable, advanced cancer who refused to eat, whereas all the Chinese nurses interviewed would feed such a patient (83).

Provision of accurate and thorough information can influence patients' attitudes and decisions. A recent study among a small group of family caregivers of patients in a palliative care program revealed diverse attitudes about hydration in terminal care (70). Without receiving information specific to hydration, some felt that hydration might enhance comfort in terminal dehydration, some thought that it might be a burdensome and useless procedure, and some were not able to identify advantages or disadvantages. One central factor was the individual's perception of benefits or burdens of artificial hydration for the dying. Other factors, such as their beliefs about life prolongation and the patient's previously stated preference, also influenced their attitudes. Nevertheless, most family caregivers thought that they would like to know from the physician the options, as well as the advantages and disadvantages of hydration, in the situation. Others would not be concerned with this information and would expect the medical professionals to make the decision (70). A 1994 survey of terminal care preferences in 108 gynecological cancer patients found 63% would consider continuing ANH in end-stage disease (71). Interestingly, 47% of those with active disease, compared with 28% of those with inactive disease, thought that they would withhold or withdraw ANH if this issue were to arise. However, in these hypothetical situations, it is not possible to know what the patient would want if death were a closer reality, if the scenario given were more specific, or if the physician's opinion about ANH at the end of life were given. In fact, a patient's attitude may sometimes be influenced by the information from the doctor. For example, in a recent survey of 379 randomly selected, decisionally capable residents from 49 nursing homes, 33% stated they would prefer tube feedings if no longer able to eat because of permanent brain damage; but 25% of the latter changed their preference on learning that physical restraints are sometimes applied during the tube feeding process (79). The impact on patient decision making of information about a treatment's potential burdens or lack of survival value has been demonstrated in other situations, such as do-not-resuscitate decisions (84). Thus, fundamental “attitudes” and “values” of patients and surrogates cannot be ascertained unless accurate information is provided.

CURRENT USE OF ARTIFICIAL NUTRITION AND HYDRATION IN PATIENTS WITH TERMINAL ILLNESS

Artificial Hydration in Acute Hospitals

Depending on the type of facility where the patient dies, the practice of ANH among patients in their last few weeks or days of life can be quite different. The emergence of palliative care has increased the awareness among physicians in the acute setting to identify those who are dying and to switch the treatment goal to comfort care as soon as possible (7). However, most patients dying in the hospital continue to receive i.v. fluids (4,5,68,72).

Alpert et al. reviewed 7400 inpatient records between 1987 and 1989 in a Boston teaching hospital and identified 181 patients with coma and a small chance of recovery, dementia with coexisting terminal illness, or PVS (72). Of these patients, 70% continued to receive artificial hydration. A multiinstitutional study of 229 patients dying from 1989 to 1992 in four Minnesota hospitals showed that 53% were given i.v. fluid at the end of life (5). These proportions do not include 16% who had i.v. fluid withheld (5). A Canadian study found that continuous i.v. fluid was used in 90%, 63%, and 28% of the patients dying from 1992 to 1993 in a large acute hospital, two small acute hospitals, and one continuing care facility, respectively (68).

Terminally ill patients admitted to a hospital usually have acute and potentially reversible illness, and these conditions may be aggressively treated until very late in the course of the underlying illness. A chart review of 200 consecutive adult deaths in a New York City teaching hospital found that physicians identified 72% of patients as dying during the hospitalization (7), but they were identified as dying an average of 8.7 (median, 4.5) days from admission and 9.6 (median, 3.5) days before death. Only 64% of those identified as dying had a comfort care plan, and this was put in place an average of 15 days after admission despite a 17-day overall mean length of stay. Very often, when the patient is identified as dying in an acute hospital, invasive, life-sustaining treatments, including ANH, may already be in place. In such a situation, the major decisions by physicians and families, not surprisingly, focus on cardiopulmonary resuscitation, ventilator, pressor use, pain control, transfusions, and dialysis, rather than ANH (4,72). In fact, withholding resuscitation is generally the first step in decisions to limit treatment, whereas i.v. fluids and tube feeding are forgone relatively rarely or late in acute hospital practice (4,72,85,86).

Artificial Hydration in the Palliative Care Setting

Most patients enrolled in palliative or hospice care have advanced cancer (87). For these patients, the overall goal of comfort care has already been established and decisions about cardiopulmonary resuscitation, ventilator, and dialysis usually have been settled. If such patients do not die quickly from superimposed acute illness, such as hemorrhage, infection, or a cardiovascular event, they may progressively reduce oral intake because of growing weakness, anorexia, multiple comorbidities, delirium, or disease progression, and will soon die regardless of whether parenteral fluid is given. Palliative care professionals with extensive clinical experience in end-of-life care generally believe that the symptoms of terminal dehydration per se are mild, can be managed by simple mouth care, and that artificial hydration is

usually unnecessary for symptom control in dying patients (88,89). This approach is supported by some empirical observational studies (39,40 and 41). However, others in palliative medicine maintain that dehydration may sometimes have undesirable consequences, such as confusion or potentiation of opioid toxicity, and they routinely use subcutaneous hydration or rectal hydration when dying patients are not able to take in the minimal daily requirement (90,91 and 92). These types of artificial hydration are different from traditional, continuous, larger-volume i.v. infusion that has been criticized by many authors in the past, and observational studies showed that patients tolerated the nontraditional approaches well (90,91 and 92). But there are no controlled studies that have evaluated the advantage of using any form of artificial hydration for patients dying of cancer or other illness (see below).

Enteral Tube Feeding in Elderly Patients with Advanced Disease

In the United States, the number of elderly receiving percutaneous endoscopic gastrostomy (PEG) increased from 15,000 to 123,000 between 1989 and 1995 (45). In nursing homes, 7–40% of residents with severe dementia have feeding tubes (33,93,94). Tube-fed elderly are mostly patients with advanced diseases associated with dysphagia, anorexia, aspiration pneumonia, or malnutrition (80,95). Many of these elderly patients died soon after feeding tubes were placed (45,80,95,96).

A large proportion of patients who die in hospitals have a feeding tube in place. In the Boston study previously cited (see the section Artificial Hydration in Acute Hospitals), 27% of the 181 patients in the terminal phase of life received artificial nutrition (72), and the above-cited Canadian study (68) (see the section Artificial Hydration in Acute Hospitals) found that tube feeding was used in 85%, 58%, and 40% of patients dying in a large acute hospital, two small acute hospitals, and one continuing care facility, respectively. A recent study in a New York City teaching hospital found 51% of dementia patients and 11% of cancer patients had a feeding tube in place at death (2).

There are geographical and international variations in the use of tube feeding. A recent nine-state survey of elderly who had very severe cognitive impairment and resided in nursing homes during 1994 found significant interstate differences in the prevalence of tube feeding, ranging from 7.5% in Maine to 40.1% in Mississippi (33). Among severely demented patients in Kansas, those in urban nursing homes were almost three times as likely to have a feeding tube than those in rural ones (46). An international study (97) found that tube-fed patients were more likely to have a diagnosis of dementia (60.4% versus 10.9%, p <.001) and less likely to have had a stroke (35.4% versus 71.7%, p <.001) in Boston than in Ottawa. Also, decisions to insert feeding tubes in nursing home patients were significantly more like to be made in Boston than in Ottawa (68.7% versus 6.5%, p <.001).

OUTCOME STUDIES OF ARTIFICIAL NUTRITION AND HYDRATION IN TERMINALLY ILL PATIENTS

Over the last two decades, controversies have continued over whether artificial hydration is necessary to enhance comfort in dying patients. Most of our knowledge in this regard has been derived from studies on terminally ill patients with advanced cancer in palliative care settings. In contrast, controversies regarding enteral feeding tubes have been mostly focused around patients with advanced neurological diseases, such as severe dementia, and have addressed the question of whether tube feeding would reduce the incidence of aspiration pneumonia or prolong life. However, with regard to all of these questions, prospective, randomized, controlled trials are lacking and would be extremely difficult to perform in terminally ill patients. All existing data to date come from retrospective or observational studies. In the absence of rigorous controlled studies, however, descriptive observational studies remain valuable and have revealed some useful information.

Do Symptoms Such As Thirst and Dry Mouth Correlate with Fluid Status or Fluid Therapy in Dying Patients?

Healthy subjects, especially the non-elderly, generally develop troublesome symptoms with dehydration. Symptoms vary from thirst, dry mouth, muscular fatigue, nausea, abdominal pain, loss of appetite, headache, irritability or drowsiness during mild dehydration (1–5% body water loss), to trembling, trouble sleeping, progressive obtundation or delirium with more severe dehydration (6% or more body water loss) (98).

Patients with terminal illness suffer many physical and psychological symptoms from various conditions, even without dehydration. Symptoms seen in dehydrated healthy persons, such as dry mouth/thirst, anorexia, vomiting, drowsiness, and confusion, each occur in one-third or more of terminally ill patients (98). In some studies, thirst or dry mouth occurred in 66–95% of dying patients who could respond to questions (40,63,99). However, these symptoms are very nonspecific, and in dying patients, it is difficult, if not impossible, to distinguish them from symptoms that may be due to their underlying disorders, medication, the oral condition, or unknown mechanisms of the dying process. Indeed, in terminally ill patients, a cause-effect relationship between dehydration and these symptoms has not been established.

There is no consistent relationship between thirst/dry mouth and fluid status or fluid therapy (40,51,99). In a carefully designed study of symptoms associated with dehydration in 52 terminal cancer patients in an inpatient palliative care setting, Burge found a high incidence of thirst, dry mouth, bad taste in the mouth, and fatigue (100). However, there was no correlation between these symptoms and quantified fluid intake, metabolic abnormalities, or use of drying medications. Mean and median serum sodium, osmolality, and urea were within normal limits. Half of the patients were excluded from the study because of drowsiness, confusion, or weakness. Ellershaw et al. observed 82 dying cancer patients in a hospice setting with median time of 2 days from entry into the study until death (range, 1–5 days) and showed no significant relationship between respiratory tract secretions and the level of hydration based on laboratory data (40). For those who were able to respond to questions (28%), no correlation between level of hydration and thirst/dry mouth was demonstrated. All subjects died without artificial hydration. Serum samples obtained at the entry point had a mean osmolality of 289 mOsm/kg, with more than 50% being less than 295 mOsm/kg. Musgrave et al. followed 30 patients in the last 24 hours of life in a hospital oncology unit who died while receiving i.v. fluids to assess the effects of these fluids on their level of thirst (99). Of the 19 patients who were able to verbally respond to questions, 18 had various degrees of thirst in spite of i.v. hydration, and 70% had clinical signs of fluid retention. No relationship was found between the degree of thirst and the amount of i.v. fluids received, serum sodium, or blood urea nitrogen.

Can patients with terminal cancer die comfortably without ANH? Experienced hospice physicians have long believed that dying patients do not require ANH for comfort (88,89). Lately, some empirical studies have reported the same conclusion, showing that thirst and dry mouth can be relieved by careful mouth care, sips of water or ice, and voluntary oral intake if the patient desires (39,41,42).

McCann and his colleagues followed 32 terminally ill patients in a comfort care unit in a long-term care facility (39). Most of the patients had cancer, and all were initially able to report symptoms. The goal of the study was to determine whether hunger, thirst, and dry mouth in terminally ill patients could be palliated without ANH. Comfort measures included offering oral nutrition and liquids at the patient's request, careful mouth care, and standard treatments for other symptoms (e.g., opioids for pain and dyspnea). Many of these patients were able to consume fluids or food initially. Twenty patients (63%) never experienced any hunger, while 11 patients (34%) had hunger only initially. Thirst or dry mouth was present in about one-third only initially and in another one-third until death. In all patients, symptoms of hunger, thirst, and dry mouth could be alleviated, usually with small amounts of food and fluid by mouth, or by the use of ice chips and lubrication to the lips. Twenty-seven (84%) of the patients were judged to be comfortable with regard to hunger, thirst, or dry mouth during the stay. The average length of stay until death was 40 days (range, 4–199 days). Thus, this observational study provided direct evidence that it may not be necessary to provide ANH for those terminally ill patients who gradually lose desire or capacity to eat or drink in order to assure their comfort.

Vullo-Navich et al. recently published a prospective study at an inpatient hospice unit of a Veteran's Hospital (41), observing the spontaneous, oral fluid–intake pattern of dying cancer patients who did not receive parenteral fluid. Only 31 (26%) of 116 patients admitted to the unit were studied, usually because the patient died before consent could be discussed. The length of stay from entry point to death ranged from 2 to 35 days with an average of 15 days (median of 13 days). Among the 31 cases, 19 (61%) met the clinical criteria of dehydration (drinking less than 500 ml of fluid per day for 2 consecutive days) before death. The most common symptom was dry mouth, which was easily relieved with local measures, similar to previous studies (39,42,89). The level of comfort was scored from 1 (uncomfortable) to 4 (comfortable). Scores from three nursing shifts were summed to create daily comfort scores ranging from 3 to 12. A perfect comfort score was realized in 85% of the 678 patient days and there was no significant difference between mean comfort scores for the period before and after the appearance of dehydration. This observation reinforces the belief that fluid depletion in dying cancer patients does not produce adverse symptoms, and that comfort can be maintained without artificial hydration in the last few days of life. This is important information to share with the patient and the family.

Does Artificial Hydration Improve Delirium in Dying Patients?

Terminal confusion or delirium is very common. According to prospective data on patients with advanced cancer, the occurrence rate of delirium ranges from 28% to 42% among patients newly admitted to a palliative care unit and is as high as 88% before death (101,102). Delirium in terminally ill patients may generate extreme distress for some patients, as well as their families and caregivers (102,103 and 104), and it is usually treated by increasing the dose of sedation (105,106,107 and 108). Although natural or sedation-induced coma in terminally dehydrated patients is believed to promote a “peaceful death” (109,110 and 111), some commentators have raised the concern that patients and families might wish to avoid deterioration in cognition if this would prevent meaningful interaction with family and friends (102,103,112,113). A national survey showed that being mentally aware at the end of life was rated as important by 92% of randomly selected veterans with advanced chronic illnesses who had been hospitalized for these diagnoses within the prior year, but was so rated by only 65% of the physicians in the survey (114).

The causes of “terminal confusion” or “terminal delirium” are multiple (102). There may be differences between typically described delirium—a transient and potentially reversible condition—and “terminal delirium” that is often seen in the last few days or hours of life (102). Some hospice specialists have questioned whether we fail to identify some cases of reversible delirium because we assume that death is imminent (102). Some have advocated vigorous screening for mental status changes and evaluation for possible reversible and treatable causes (91,103,115). Lawlor et al. recommended recently that when the care goals of dying patients include preference

to treat delirium by attempting to reverse it, the standard approach should involve searching for reversible causes and providing specific symptomatic treatment for delirium to avoid premature initiation of deeper sedation (102).

Dehydration can be one of the potentially reversible causes of delirium in some dying patients. However, whether hydration can improve mental status of a dehydrated cancer patient who is dying from the underlying disease is not clear. Waller et al. assessed 68 hospice patients during the last 48 hours of life to correlate various measures of hydration with their level of consciousness (42). Nearly all of the patients had dehydration based on laboratory data, and the level of consciousness correlated inversely with serum sodium and urine osmolality. However, those who were treated with i.v. fluids (13 cases) did not have improvement in their level of consciousness. It is possible that underlying conditions and not dehydration alone are largely responsible for the reduced mental status of these patients.

Pereira and colleagues (115) evaluated data on 321 patients with advanced cancer and severe symptoms who were admitted to a hospital palliative care unit where Mini Mental State Examination (MMSE) was routinely conducted in all the patients on admission and once or twice weekly thereafter. Because of visual or motor deficits preventing some patients from performing the entire MMSE, the results are expressed as percentage of 1. Scores of less than 0.8 were considered consistent with cognitive impairment and patients underwent further assessments, including delirium evaluation. When delirium was diagnosed, a standard protocol was followed to assess possible dehydration, opioid toxicity, infection, brain metastases, uremia, hypercalcemia, and hypoxia. Efforts were made to correct these underlying causes when possible and appropriate. The mean length of stay was 27 ± 22 days with a median of 20.5 days. Of 87 patients, 25 (29%) with abnormal MMSE on admission improved to a normal score on final testing before death (N = 13) or discharge (N = 12). Time between admission and the first normal MMSE score averaged 10.3 ± 9.4 days (range, 1–36 days; median, 7 days). However, there are no details about the causes of the delirium, and the contribution of hydration to the improvement of these patients' mental status is not clear from the study.

Some palliative care clinicians and researchers have argued that neurological symptoms in dehydrated terminally ill patients who receive high doses of opioids might be prevented by appropriate hydration and opioid rotation (6,91). The rationale behind this is that dehydration reduces intravascular volume and glomerular filtration and thus may slow renal elimination of active opioid metabolites (116,117 and 118), the accumulation of which can cause agitated delirium and myoclonus (116,117 and 118). Fainsinger and Bruera suggested gentle hydration by using subcutaneous hydration (hypodermoclysis) or rectal hydration (proctoclysis), in addition to opioid rotation, in terminally ill patients who are not able to take adequate fluid orally (6), noting that agitated delirium in their palliative care unit reduced from 26% to 10% after they changed the practice to more frequent use of hypodermoclysis (91). Other changes in their practice, however, such as switching opioids earlier if toxicity developed and the use of less toxic antipsychotic agents, may also have contributed to the reduction of agitated delirium. Randomized, controlled studies are needed to confirm whether clysis or other forms of artificial hydration would reduce agitated delirium and reduce the need for heavy sedation.

Does Enteral Tube Feeding Reduce the Risk of Aspiration Pneumonia or Prolong Life in Elderly Patients with Advanced Disease?

Like research on artificial hydration in terminally ill patients, there have been no randomized controlled studies examining the outcome of feeding tube placement. Studies in this regard are usually conducted in elderly patients who received gastrostomy tube placement, but not in those specifically defined as being terminally ill. Retrospective reviews or prospective observations, so far, have failed to demonstrate that tube feeding can reduce the risk of aspiration pneumonia (25,44,119,120,121,122 and 123), and jejunostomy does not do better than gastrostomy in this regard (124,125). Studies on the outcome of those receiving feeding tubes have consistently shown a high short-term mortality rate. A national study of 7369 veterans who received a PEG tube from 1990 through 1992 reported a mortality rate of 23.5% during the hospitalization in which the PEG tube was placed. The median survival of the whole cohort was 7.5 months (95). Another study of 81,105 older Medicare beneficiaries who received gastrostomy insertion following hospital discharge in 1991 revealed an overall mortality rate of 23.9% at 30 days, and 63.0% at 1 year (80). A prospective cohort study in an Indiana community of approximately 60,000 residents identified 150 patients age 60 and older receiving PEG from November 1997 to January 1999, and found a 30-day mortality of 22%, and a 1-year mortality of 50% (45).

More recently, commentators have questioned the benefit of tube feeding in older patients with severe dementia. In a recent study of acutely hospitalized patients with advanced dementia in a New York City teaching hospital, 50% received a new feeding tube during the index hospitalization (34). With or without a feeding tube, these patients had a 50% six-month median mortality (34). As noted above (see the section Enteral Tube Feeding in Elderly Patients with Advanced Disease), the prevalence of feeding tubes in nursing home patients with severe dementia is very high. In one study, the 1-year mortality rate for older nursing home residents who received PEG tubes was about 50% (96). Retrospective and observational studies in severely demented patients with chewing and swallowing problems also failed to show the benefit of survival in those receiving tube feeding (93,94).

The high mortality rate after gastrostomy tube placement shows that many of these patients were actually near death when feeding tubes were placed and suggests that the indications for its use should be reexamined (126,127). Since survival varies greatly among patients who receive feeding tubes, it would be inappropriate to apply population data to individual patients. The impact of baseline diseases and functional status on the prognosis of an individual patient, and the potential burdens and complications of tube feeding, should be strongly considered in the decision process (126,127).

Biomedical Approach Is Not Enough

Biomedical studies, such as those discussed above, are very important because they can help to provide information about pathophysiological changes in dying patients and their physical responses to our interventions, which is information we need to share with patients and families in end-of-life care planning. However, the suffering of dying patients and their loved ones is far more than physical (114,128,129). Unfortunately, physicians may tend to judge the outcome by biomedical parameters and pay less attention to the perspective of patient and family (114,128,129 and 130).

It has become more clear that the clinical usefulness of medical interventions cannot be justified fairly without consideration of the emotional and psychosocial concerns of patients and their families (47,65,131,132). For example, observational studies have reported that comfort could be achieved in dehydrated, terminal-cancer patients treated in facilities with policies of generally avoiding artificial hydration (39,40) or providing carefully monitored hypodermoclysis or proctoclysis to almost all dying patients (6,90,91). The patients and their families in these studies seemed to accept either approach quite well. This suggests that it may not be the avoidance or provision of artificial hydration that makes the patient and family comfortable and satisfied. The atmosphere of the care setting, the attitude of the staff, the quality of the interpersonal relationship and communication between staff and patient and family, and the overall care plan may all contribute to the success of these approaches.

IMPROVING COMMUNICATION AND MANAGING ARTIFICIAL NUTRITION AND HYDRATION-RELATED ISSUES UNDER A COMPREHENSIVE END-OF-LIFE CARE PLAN

Promotion of quality of life and quality of death as defined by the patient and family are finding their way into all aspects of health care, especially at the end of life (1,47,65,114,128,131,133). Even for a non-dying patient, a good technical or biomedical outcome doesn't always guarantee acceptable quality of life and patient satisfaction (134). Whether to use ANH in the terminally ill is neither strictly an ethical nor strictly a biomedical issue. For a specific patient, the issue should be managed as part of a good, comprehensive, patient-centered, and family-sensitive care plan, and, as with any end-of-life treatment, communication is critical in care planning. However, open doctor-patient communication about end-of-life treatment may be rare or late (135,136,137 and 138). Discussion about ANH in terminally ill patients may be even less common, or in haste and late in the course (9,70). The disparity of views in quality of death between physicians and patient or family (114,128,139,140), the various attitudes of patients (57,70,71 and 72,136) and physicians (6,141) about ANH, and lack of understanding on the part of patients regarding their options in end-of-life care (142) all highlight the need to improve communication about this particular treatment.

Physicians should initiate end-of-life discussions early and incorporate ANH issues into the discussion. Even patients who express their wishes and values very clearly still may need the physician to initiate the discussion (138,143). Listening and knowing the patient's and family's values, concerns, and level of understanding are critical (138). It is also important to make sure patient and family understand their legal rights and the ethical consensus surrounding the use or nonuse of ANH to ensure that their own values and preferences will be respected, and that efforts will be made to relieve suffering. However, the upholding of the patient's right to choose from among care options is insufficient if the patient or surrogate does not fully understand the benefits and risks of these options (1,138). In the experience of the authors, patients and loved ones may fail to ask whether ANH must be given and are often unaware that it can be avoided, or discontinued, and what the consequences are. Therefore, health care professionals should be mindful of this “unasked question” and should provide accurate information regarding what is known about the benefits and burdens of ANH and the likelihood that a particular patient can be kept comfortable without it. It is also important to enumerate the potential alternatives to ANH in the patient in question (10). For example, small amounts of desired food and fluids can be given at the patient's request. This is a potentially comforting alternative to ANH, and family and friends can take an active role, which may be comforting for loved ones as well. Dietary restrictions (such as salt avoidance for fluid retention, or sugar restriction for diabetes) should be avoided, if at all possible, and personal and ethnic food preferences should be addressed. If a decision is made to start artificial hydration or to institute tube feeding in a terminally ill patient, there should be a specific goal in mind, and the physician and patient or surrogate should be prepared to reevaluate periodically the appropriateness of continuing it.

Appropriate and timely discussion of ANH issues in the planning of end-of-life care may avert a stressful, decisionmaking dilemma when the patient reaches the final stage of dying. Early discussion and planning for care options may also leave more time and may enhance the ability of the patient and family to work on more important issues of life closure (137,138). Good communication, which can itself be emotionally and spiritually healing (138), along with a good patient-centered and

family-sensitive end-of-life care plan (65), will maximize the likelihood of achieving the patient's goals.

SUMMARY

Increasing longevity has been accompanied by a risk of dying from incurable, progressive, and disabling chronic diseases such as cancer or dementia. Decisions around use or nonuse of ANH at the end of life have become common events in medical practice. A broad, legal, and ethical consensus supports a patient's right to decide whether to accept or refuse ANH as part of his or her end-of-life care. Meanwhile, arguments around the palliative effect of ANH in terminal illness continue. The issues are complicated by the broad spectrum of terminal illness (“trajectories of dying”), the various settings in which dying occurs, and persisting statutory provisions regarding ANH that may create confusion among providers and patients. Issues are further confounded by individual attitudes, values, and cultural backgrounds. Attitudes can be dependent on the provision of accurate information about the benefits and burdens of this treatment. Despite the lack of randomized, controlled studies, findings in retrospective and observational studies still provide some useful information. Physicians should not shy away from sharing the information and making recommendations, while at the same time paying attention to the values of the patient and family. ANH discussions should be incorporated early in end-of-life care planning. Good communication and a patientcentered and family-sensitive end-of-life care plan is the key for successful management of the complex issues surrounding this treatment.

REHABILITATIVE MEDICINE

RICHARD S. TUNKEL
ELISABETH A. LACHMANN

Patients with progressive medical diseases often benefit from physical rehabilitation. Referring to the cancer population, Dietz described four levels of rehabilitation: palliative, supportive, restorative, and preventive (1). In palliative rehabilitation, efforts are made to decrease dependence on others in activities of daily living (ADLs) and to provide comfort and emotional support. This approach is most appropriate for patients with advanced disease and short life expectancies.Supportive rehabilitation is focused on long-term impairments. Efforts are directed at maximizing function at any given level of disability. When impairment is expected to be short-lived, restorative rehabilitation is appropriate. These techniques, which are intended to return the patient to a previous level of function, may be very useful when function is impaired because of a side effect of cancer treatment (e.g., myopathy caused by corticosteroids). Preventive rehabilitation may be valuable when impairments are anticipated and interventions may be able to prevent them. For example, a simple exercise program for the patient fatigued by radiation therapy may prevent deconditioning.

Three terms are commonly used to describe physical, functional, or psychological deficits: impairment, disability, and handicap. *Impairment* is defined as “any loss or abnormality of psychological, physiological or anatomical structure or function” (2). *Disability* is “any restriction or lack (resulting from an impairment) of ability to perform an activity in the manner or within the range considered normal for a human being” (2). *Handicap* is “a disadvantage for a given individual, resulting from an impairment or a disability, that limits or prevents the fulfillment of a role that is normal (depending on age, sex, and social and cultural factors) for that individual” (2). Thus, an impairment may result in a disability, which in turn may give rise to a handicap.

SPECTRUM OF FUNCTIONAL IMPAIRMENTS

Functional impairment in the patient with cancer may arise from many causes (Table 70-1). Cancer may directly produce physical impairments that require rehabilitative intervention. A tumor may destroy normal structures, such as long bones or vertebral bodies. Pain from bone metastasis may represent impending or actual pathological fracture, which can affect a patient's function and rehabilitation by decreasing or inhibiting weight bearing on a limb or functional mobility when affecting the spine. The mass produced by a tumor may cause pressure effects, such as compression of neural structures resulting in focal neurological deficit. The neurological consequences of these pressure effects may be even more serious when the damage occurs within the bony confines of the cranium or spinal column. Hemiparesis from unilateral supratentorial lesions, paraparesis or quadriparesis from spinal (usually epidural) lesions, and incoordination or ataxia from cerebellar or brainstem lesions can all pose difficult rehabilitation issues. Similarly, lesions of the peripheral or central nervous system can cause disorders of speech or swallowing, which may require specific attention (3,4). More globally, central nervous system lesions that culminate in specific impairments of higher cerebral function (e.g., aphasia) or that produce overall cognitive impairment may complicate rehabilitative efforts at every level. Local pressure may also compromise vascular structures, producing limb edema; and in the case of lung lesions, local mass effect may decrease pulmonary capacity.

Direct effects of cancer	Treatments for malignancy
Indirect effects of cancer	Surgery
Paraneoplastic syndromes	Radiation therapy
Pain	Chemotherapy
Deconditioning	

TABLE 70-1. CAUSES OF FUNCTIONAL IMPAIRMENTS

Indirect effects of the neoplasm can also cause impairment. Pain may be quite debilitating, and general debility may have additional deleterious effects on function. Pain provoked by movement may produce functional weakness. Keeping the limb in a position that decreases pain may result in joint contracture (5). In populations with medical illness, musculoskeletal pains may result from the same pathologies that afflict those who are otherwise healthy, including myofascial pain syndromes, bursitis, tendinitis, or arthritis. At times, successful rehabilitation may help to diminish pain, as in the appropriate application of spinal bracing and improvement through a conditioning program.

Various paraneoplastic syndromes, such as the cancerrelated subtype of polymyositis-dermatomyositis, can produce weakness and also produce or worsen impairment (6,7). Impairments and disabilities also may result from sensorimotor paraneoplastic polyneuropathy, which is only one of a diverse group of paraneoplastic syndromes that may affect the neuromuscular junctions, dorsal root ganglia, or anterior horn cells (7,8,9 and 10). Paraneoplastic cerebellar degeneration may present with ataxia and dysarthria as the first evidence of a malignancy (11). Cancer-associated arthritis, which can complicate carcinoma, multiple myeloma, or leukemia, may resemble rheumatoid arthritis but may have asymmetric involvement, sparing the wrists and small joints (12,13). Hypertrophic osteoarthropathy, another paraneoplastic syndrome, may also cause polyarthritis as well as digital clubbing and periostitis. This is most commonly seen with bronchogenic carcinoma (14).

Most often, formal rehabilitation is requested to address impairments resulting from cancer treatment. Surgical resection of a tumor can produce varied impairments, depending on the tissues resected. Resection of lung tissue decreases pulmonary capacity. Creation of ostomies after gastrointestinal or genitourinary surgery requires instruction in their care and use. *En bloc* resection of lymphatic structures may give rise to lymphedema and focal muscle weakness may result from sacrifice of muscle tissue, as may occur in limb salvage procedures (15). Excision of bone for treatment of sarcoma may require placement of an endoprosthesis or amputation.

Surgery that injures nervous tissue often produces an obvious neurological deficit, and postoperative edema in the central nervous system may produce temporary deficits (16). For example, spinal accessory nerve palsy may arise after neck dissection for head and neck cancer or cervical lymph node biopsy (17,18 and 19). The patient may develop a depressed, protracted shoulder because of lack of trapezius upward rotation and retraction of the scapula. This results in impaired arm elevation.

Shoulder pain may arise when the upper limb is unsupported (20).

Radiation therapy may produce relatively acute effects, depending on the area irradiated. Chronic postradiation changes may evolve months or years later. The persistent impairments related to these effects may be profound.

Some chemotherapeutic agents have specific toxicities that affect target organ systems, such as the lungs or peripheral nervous system. Numerous chemotherapeutic agents cause polyneuropathy, with patterns that range from a presentation resembling Guillain-Barré syndrome (suramin) to sensory (cisplatin or paclitaxel) or sensorimotor (vincristine sulfate) neuropathy (21,22,23 and 24). Myopathy may result from corticosteroid use, with the predominate feature of proximal limb weakness (25). Avascular necrosis may occur from radiation therapy or corticosteroid use. All these measures may produce impairments that require rehabilitative intervention. Significant thrombocytopenia from chemotherapy may limit rehabilitation; “safe” platelet counts have not been precisely identified (26).

DECONDITIONING

Prolonged bed rest and immobility may produce a multitude of negative effects on various body systems. Muscle weakness and atrophy can result directly from immobility. As much as 20% of strength may be lost with each week of bed rest; endurance declines at a similar rate (27). The antigravity muscles of the trunk and lower limbs are often the first muscles to atrophy (28). Reconditioning often takes much longer than deconditioning. Strength increases approximately 12% per week until the muscle has threefourths of its maximal strength (29). Above this level, the rate of strength increase diminishes.

Muscles held in a fixed position gradually shorten, especially those that cross two joints. Patients undergoing prolonged bed rest maintain a position of comfort, often with the hips and knees flexed. This can result in contracture of the psoas and hamstring muscles. The gastrocnemius muscle often shortens as a result of positioning.

Prolonged bed rest may also result in osteopenia, which occurs when bone resorption exceeds bone formation (30). In severe cases, hypercalcemia may result and may worsen the hypercalcemia caused by bone metastases or other processes (31).

Cardiopulmonary deconditioning usually occurs with prolonged immobility. The resting heart rate can increase more than 30 beats per minute after only 2 weeks of bed rest (32). This is a compensatory means of maintaining cardiac output with decreasing stroke volume (31). Stroke volume decreases as immobilization diuresis leads to significant plasma volume loss (32,33 and 34). Postural hypotension may be another consequence of plasma loss. Although prolonged bed rest has no direct effect on pulmonary function, recumbency impedes diaphragmatic excursion, impairing cough (32,35). This may reduce tidal volume and cause compensatory tachypnea to sustain minute ventilation (33,35).

A hypercoagulable state related to malignancy combined with venous stasis from immobility places the cancer patient at high risk of deep vein thrombosis (DVT) (36). Remobilization of the patient with DVT may increase the risk of pulmonary embolus (37).

Prolonged pressure over bony prominences predisposes to pressure sores. Shearing forces, which are created when the patient slides or is dragged across the bed, may also compromise local blood flow and further increase the risk of pressure sores (38). Moisture from bodily fluids contributes to the formation of pressure sores by skin maceration and chemical irritation.

Finally, prolonged bed rest can lead to decreased gastrointestinal motility, which may predispose to constipation. Bowel dysmotility produced by immobility can augment the constipating effects of other disorders such as hypercalcemia, or treatments, including opioids.

THERAPEUTIC INTERVENTIONS

Rehabilitation interventions are best provided by a multidisciplinary team because of the diversity of functional impairments (Table 70-2).

Physiatrist	Psychiatrist
Physical therapist	Psychologist
Occupational therapist	Social worker
Speech pathologist	Clergy
Palliative care/pain specialist	Recreational therapist
Nurse specialist	Nutritionist

TABLE 70-2. MULTIDISCIPLINARY REHABILITATION TEAM

Rehabilitative interventions for the patient with progressive medical disease must be tailored to address the specific deficits of that patient (Table 70-3). Factors such as life expectancy, living environment, and the availability and capabilities of caregivers must be considered. Before a specific intervention is begun, the potential benefits to the overall quality of life of the patient must be weighed against the real costs in time, discomfort, and money as well as the potential physical, psychological, and psychosocial risks.

Therapeutic exercise	Physical modalities for pain relief
Mobility and gait training	Lymphedema treatment
Training in activities of daily living	Chest physical therapy
	Bowel and bladder retraining
Cognitive/perceptual rehabilitation	Speech and swallowing therapies
Orthotics and prosthetics	

TABLE 70-3. SPECTRUM OF REHABILITATIVE INTERVENTIONS

Therapeutic Exercise

Therapeutic exercise can help increase strength, endurance, range of motion, and coordination. It may significantly improve the patient's physical and psychological sense of wellbeing in a variety of settings (39). Cancer-related fatigue can be positively impacted by exercise (40,41). There is evidence that immunologic response can also be beneficially affected (42). Muscle can be strengthened through isometric, isotonic, or isokinetic exercises (43). Isometric exercise entails muscle contraction without joint movement. This form of exercise can be useful when pain is provoked by joint movement, such as in acute joint inflammation. Isometric exercise primarily affects strength and has little impact on endurance. Isotonic contraction produces joint movement against a constant force. Walking requires a series of isotonic contractions. Concentric isotonic contraction shortens muscle against constant resistance, whereas eccentric isotonic contraction partially counters a lengthening force on the muscle. This type of exercise helps to increase both strength and endurance. Isokinetic exercise is muscle contraction at a constant velocity and requires the

use of sophisticated, expensive equipment (44).

A typical reconditioning program for debilitated patients with progressive diseases features active range-of-motion exercises aimed at strengthening weak muscle groups (45). Exercises are generally done on an astolerated basis. Modifications may be necessary if precautions must be followed because of underlying organic conditions, such as metastatic bone disease or a recent myocutaneous flap. With significant weakness (less than antigravity strength), assisted active range-of-motion exercises may be needed. The therapist in part assists in moving the limb through its full range of motion. For patients with nonfixed joint immobility secondary to weakness, passive range-of-motion exercises performed by another person may be required.

In general conditioning exercises, low-resistance, highrepetition exercise is used to increase endurance (46). An elastic band may be used to strengthen muscle by providing low to moderate resistance. Patients who are isolated for medical reasons and are unable to walk for endurance training may benefit from the use of bicycle pedals. If feasible, a progressive resistance exercise program is initiated to further strengthen muscle (47).

Range-of-motion and strengthening exercises and compensatory techniques to achieve movement using less affected muscle groups are used in therapy for spastic hemiparesis. Neuromuscular reeducation techniques may facilitate or inhibit spastic synergistic patterns, eventually promoting isolated muscle movement. Neuromuscular reeducation may be facilitated by the use of electromyographic biofeedback or functional electrical stimulation (FES) (48,49 and 50). For example, FES may improve movement and position of the hemiparetic shoulder (51). If needed, arm positioning is further assisted through the use of a sling during ambulation. In the seated or bedbound patient, the sling should be removed and replaced by other supportive devices, such as a lap board or arm trough (52). The paraparetic and quadriparetic patient may benefit from neuromuscular reeducation and sustained muscle stretching. There is evidence that acupuncture and electroacupuncture can result in improved neurological and functional outcomes in hemiparetic stroke patients (53). Spasticity also may be decreased by physical modalities such as transcutaneous electrical nerve stimulation, ice, electromyographic biofeedback, and FES (54,55,56 and 57). Baclofen, administered orally or intrathecally, is an effective antispasticity agent when physical modalities are not helpful (58). The negative effect of losing what was functional spasticity—for example, quadriceps spasticity maintaining knee extension— must be balanced against the positive effect of increased mobility. When spasticity of an isolated motor group interferes with function, chemical or surgical neurolysis, motor point block, or tenotomy may be considered (57).

When nerve injury or muscle sacrifice has occurred, the goal of physical intervention is to increase active, functional movement. Exercise and FES may be aimed at increasing the strength of the partially sacrificed or partially denervated muscle. Other muscles are strengthened to compensate for the acquired weakness, and instruction in postural and compensatory techniques is given.

In cerebellar disorders, patients lose the smooth coordination of agonist and antagonist motor groups (59). Such incoordination produces intention tremor, ataxia of the limbs, and disturbance of fine and rapid alternating movement. The use of weighted equipment may help decrease tremor amplitude and increase function.

In selected patients, cardiovascular reconditioning may be hastened by appropriate therapeutic exercise. The first aerobic exercises usually recommended are walking or wheelchair mobility. To achieve aerobic benefit, these exercises should be performed for at least 15 minutes, 3 days per week (60). The physical or occupational therapist may use heart and respiratory rate, blood pressure determination, and pulse oximetry to monitor the patient's cardiopulmonary status.

Joint contractures may arise from prolonged immobilization, muscular imbalance, voluntary immobility to maintain a position of comfort, malignant invasion of joint or adjacent soft tissues, or high-dose radiation therapy to the joint (5,61). Prevention of contractures is easier than treatment. Once contractures develop, aggressive intervention is required when it is feasible. Range-of-motion exercises with sustained terminal stretch may be effective, especially in mild myogenic contractures (62). When not contraindicated, deep heating of tissue may increase the distensibility of collagen and assist in reducing contracture (63). With severe contracture, dynamic splinting or serial casting may be beneficial (64).

In the lower-limb amputee, lying in bed or prolonged sitting can encourage hip and knee flexion contracture. These contractures may not be prevented by ambulation without full joint extension. Lying prone at regular intervals daily may help prevent hip contractures.

Mobility and Gait Training

Early mobilization may help improve recovery after certain interventions, such as laparoscopic colonic resection (65). Patients with severe debility may benefit from mobility instruction. This begins with bed mobility, such as scooting, rolling, and sitting up; these actions may prevent some of the deleterious effects of bed rest, such as pressure sores. Patients who cannot tolerate upright positions because of orthostatic changes may require progressive upright tolerance training. The hospital bed can be used initially for this training. The patient may next begin sitting with the legs dangling. At times, the seated position cannot be tolerated. A tilt table may be used to gradually incline the patient from a supine position toward a standing position (45). Along with sitting and standing postures, instruction in static and dynamic balance in these positions may be necessary.

A transfer is defined as movement from one surface to another. The most common transfer is a standing transfer, for example, going from a bed to a chair. If patients are unable to transfer, they may require the assistance of another person or the use of an assistive device, such as a walker or sliding board (66). Some patients may require instruction for transfers directly into a chair or wheelchair. Those requiring a wheelchair usually are trained in transfers from a wheelchair to another seating device, such as a commode or car seat (67).

Early progressive ambulation can help prevent the negative effects of deconditioning. A walker or another assistive device may be required. Ambulation training may be facilitated by parallel bars or with support from a rolling pole or wheelchair. These assistive devices widen the base of support and involve the upper limbs in weight bearing (68).

Cerebellar gait ataxia may be associated with limb or truncal incoordination (59). In an effort to decrease the amplitude of the tremor, a weighted walker or limb weights may be beneficial, and other adaptive equipment may also be weighted (69). In some patients, ataxia cannot be improved through rehabilitative interventions.

The pathophysiology of sensory gait ataxia is proprioceptive loss in the lower limbs. The use of an assistive device allows proprioceptive feedback to one or both arms. Impaired joint position sense also may be partially compensated by attention to visual cues. Environmental adaptations should include adequate lighting and unobstructed walkways (70).

The spastic hemiplegic gait often features an extensor synergy pattern in the affected lower limb. The foot and ankle assume an equinovarus posture, with the knee held in extension. The patient may circumduct the affected leg, raise the hip, or lean away from the affected leg to permit foot clearance during the swing phase of gait (71). The use of an ankle foot orthosis (AFO) can assist in foot clearance. A double metal upright AFO may be attached to an orthopedic shoe; a calf band with Velcro closure is attached to the superior portion of the metal uprights. More often, a custom-molded plastic AFO is prescribed. This AFO extends from the plantar surface of the foot up the posterior aspect of the calf and is secured to the leg by a Velcro closure. Compared with the metal AFO, the plastic AFO is lighter in weight, has a larger area of contact, and offers a better cosmetic appearance. Either AFO may improve speed and decrease energy expenditure, but neither has a significant advantage over the other (72).

Lower limb weakness without spasticity may benefit from different compensatory techniques. Hip extension may be able to compensate for weak knee extensors (73). The knee may also be forcibly extended by the hand pushing backward on the thigh. In either case, genu recurvatum may be the undesirable result. Knee bracing may be required if knee instability persists despite efforts to compensate for the weakness. For example, this may occur after some limb salvage procedures. Bracing cannot effectively compensate for profound hip flexor or extensor weakness (52). Conversely, weakness localized to all or part of the distribution of the common peroneal nerve may be compensated for with an AFO. This prevents plantar flexion during the swing phase of gait and lessens the risk of falls associated with foot drop. With the use of effective leg braces, other assistive devices may not be needed.

Activities of Daily Living

ADLs include dressing, eating, bathing, and writing (74). Coordination and strength training in combination with ADL instruction may be needed for bilateral upper limb weakness. If one or both upper limbs are weak, adaptive equipment may be required for ADLs (75). The use of a rocker knife may assist in one-handed food cutting. Widehandled utensils, along with fine motor retraining, may be helpful for patients with distal upper limb weakness. Patients with severe, long-term dominant limb weakness may require dominance retraining for many of their ADLs. Bimanual activities should be encouraged in these patients. However, some have advocated constraint-induced movement therapy, in which the unaffected arm is constrained within a sling most of the waking time of the patient, for hemiparesis after stroke and traumatic brain injury. The hemiparetic limb with some residual function may make significant functional gains with intensive training (76). However, this remains controversial. A long-handled shoe horn and a reacher may help in dressing the lower extremities. Other adaptive equipment may be necessary in the wheelchair-dependent patient, such as a raised toilet seat, a tub chair, and various other environmental adaptations. ADL assessment may be of some help even in estimation of length of survival in terminal patients (77).

Cognitive/Perceptual Rehabilitation

Cognitive/perceptual rehabilitation helps improve or maintain the patient's level of daily function, especially with ADLs and social interaction. Simple techniques, such as the use of a notebook, may be helpful memory aids. The adverse impact of unilateral visual field deficit or neglect may be reduced in part by various occupational therapy exercises, some facilitated by computers. Other specific problems may also be helped by tailored strategies, which then require repetitive application.

Braces and Splints

An orthosis is a device that provides support to a body part and may assist in the function of that part. Orthoses may be used to support fractured long bones or a limb that is paretic or plegic. Functional splinting may be used when some volitional movement remains in the afflicted limb.

Upper extremity bracing includes the resting hand splint used for the spastically flexed hand and the cock-up wrist splint. The cock-up splint places the wrist in mild extension, enhancing hand function by placing the finger flexors in a mechanically advantageous position. Lower limb orthoses include the different AFOs and knee braces.

Spinal orthoses are used to add support to sections of the spine. They are especially useful to decrease pain provoked by movement of the afflicted area. These orthoses help prevent movements, especially forward flexion in the thoracic and lumbar spine, that place additional stress on vertebral bodies compromised by bone disease. Both abdominal binders and lumbosacral corsets provide some support to the spine by increasing intraabdominal pressure. For greater restriction of movement, lumbosacral or thoracolumbosacral orthoses may be prefabricated or custom-made as body jackets (78,79). All spinal orthoses must be used in a manner that avoids direct pressure over ostomy sites, hopefully without compromising the support provided by the orthosis. Patients with pulmonary compromise must be carefully assessed to avoid respiratory compromise caused by lumbar orthoses that increase intraabdominal pressure. Skin lesions may need to be accommodated by relief of pressure directly over the lesion.

Bracing of the cervical spine can provide the greatest restriction of movement (80). A soft cervical collar serves as a reminder, only minimally restricting movement. A more rigid device, such as a Philadelphia or Miami collar, provides some restriction, especially of flexion and extension. More limitation of movement is provided by a four-poster appliance or a sterno-occipito-mandibular immobilizer. More complete immobilization is achieved by a halo vest.

Prostheses

Sacrifice of the distal portion of a limb may require the use of a functional prosthesis. In the lower limb, the goal is a return to independent ambulation. The more proximal the level of amputation, the greater the increase in energy expenditure for reciprocal gait. The exertion required may preclude the use of prostheses by patients with comorbid cardiopulmonary disorders. Lighter-weight components, improved socket designs, and energy-storing feet whose elasticity allows some energy to be released during toe-off have improved modernday prostheses (81,82 and 83). In all cases, proper care of the distal residual limb and appropriate prosthetic training are required for maximal benefit to be achieved.

Upper limb amputation is much less common. A typical upper limb prosthesis has a socket that serves as an interface between the prosthesis and the residual limb. The most important functional component is the terminal device, which is available in different shapes (including a functional hand). Control of the terminal device may be achieved mechanically by shoulder movement. After forequarter amputation, a shoulder prosthesis may allow more normal fit of clothing. All prostheses, especially the expensive myoelectric ones, may be impractical for use in populations with advanced disease.

Physical Approaches to Pain Relief

Physical therapeutic modalities may be helpful in the cancer patient with pain of muscular origin (84). Both cold and heat have direct effects on local muscle spasm and can provide analgesia. Heat can increase local blood flow and metabolic rate and therefore is contraindicated in the cancer patient whose pain is at the site of a tumor mass. This is especially true with deep heating devices, such as ultrasound diathermy (85). These and other modalities, such as vigorous electrical stimulation and massage, are avoided in areas of active tumor growth and over irradiated tissues.

Therapeutic cold causes an initial decrease in temperature through vasoconstriction. Like superficial heat, cold may also be a counterstimulant, tending to inhibit the projection of pain information in the central nervous system. It, too, should be avoided over irradiated tissues (86).

Electrical stimulation, which may also have a counterstimulating effect, is usually applied superficially for pain via transcutaneous electrical nerve stimulation. If pain is strictly of myogenic origin, electrical current also may be used to fatigue muscle spasm or relieve muscular tightness from myofascial trigger points (87). Ischemic compression (pressure maintained over a trigger point) or the spray and stretch technique (vapocoolant spray followed by muscle stretch) may also be effective in releasing trigger points. When these methods are insufficient, injection of trigger points with local anesthetic, or dry needling, may be helpful. Acupuncture has also been useful in a number of musculoskeletal pain complaints (88). Whatever method is used, reconditioning of the muscle containing the trigger point is required. Therapeutic exercise should be aimed at recovering full range of movement and strength of involved muscles, as well as fostering improved posture and body mechanics. Recreational therapy may also play a role in pain management, even in hospice care (89).

Evaluation of the effective uses of different modalities in treating pain relies heavily on ratings of pain intensity by the patient. Certainly, aspects of physical or occupational therapy requiring movement may exacerbate or bring on pain. Therapy should be modified as needed. When getting ratings from the patient, it must be remembered to differentiate pain intensity from pain affect, and that recall of both in the past is positively correlated with current levels of perceived pain (90).

Treatment of Limb Swelling

DVT is a common problem in the cancer patient, especially in those who are bedridden. In addition to pharmacological measures, several mechanical methods have been used for prophylaxis of DVT (91,92,93 and 94). These measures include intermittent pneumatic pressure pumping, gradient pressure stockings, and electrical stimulation of calf muscles.

Controversy exists concerning the timing of mobilization of the patient with DVT. Early mobilization may place the patient at risk of embolization, but prolonged bed rest may increase venous stasis and encourage clot formation. The decision when to mobilize the patient is based in part on the location of the lesion, the length of time the patient has undergone anticoagulant therapy, and whether an inferior vena cava filter has been placed (95,96).

Lymphedema is a frequent cause of limb swelling in the cancer patient. Even when mild, lymphedema can produce profound psychological effects in the patient, in addition to physical sequelae (97,98). When lymphedema is soft and pitting, limb elevation may be helpful. Physical treatment, which has its foundation in the use of static compression garments, may be helpful even when the condition is mild. Most frequently employed are gradient pressure elastic sleeves or stockings. Bandaging techniques, using materials with little compliance, are also used, and a legging orthosis made of noncompliant Velcro straps has been helpful in certain instances (99,100). Static compression facilitates the muscle pump action of muscle contraction. Thus, therapeutic exercise in the affected limb should be performed while the patient is wearing the compression garment.

For more significant lymphedema, a pneumatic compression pump may be used, although its use is increasingly controversial. Compression is usually applied in a distal-to-proximal direction via an overlying sleeve covering the entire limb (101,102). The intent is to pump fluids out of the limb, but the concern is the lack of a means of egress for the fluid when lymphatic drainage is insufficient.

A combination of physical therapies featuring manual lymphedema treatment (MLT) is another approach that attempts to facilitate flow through residual patent lymphatic channels (99). In principle, MLT helps to enhance lymph drainage from one area of the torso to another. For example, if lymphedema after axillary lymph node dissection is secondary to impaired lymph drainage from both the ipsilateral limb and the upper quadrant of the torso, MLT attempts to enhance lymph flow from the affected upper quadrant to other areas of the torso via the collateral lymph channels. Bandaging the limb between MLT sessions helps to maximize treatment results (103). One study, however, suggested that adding MLT to bandaging, exercise, and education may not significantly further improve edema reduction (104). Active disease is a relative contraindication to any of these dynamic treatments, as may be local infection, congestive heart failure, or acute DVT (99). With severe lymphedema, some have suggested lymphaticovenular anastomosis in addition to postoperative bandaging (105).

Chest Physical Therapy

Chest physical therapy assists in mobilizing secretions and enhancing gas exchange in the lungs. Patients who are immobilized in bed should be repositioned every 2

hours (106). This may prevent pooling of secretions in the dependent portions of the lungs. The therapist can administer postural drainage to help remove secretions from specific areas of the lungs (107). Chest vibration or percussion is often used in combination with postural drainage to enhance its effect. A nebulizer may be used before chest physical therapy to loosen secretions and deliver a bronchodilator. In selected cases, muscles of ventilation are subjected to specific reconditioning exercises (108). The use of an incentive spirometer between therapy sessions may strengthen the muscles of respiration and help prevent arteriovenous shunting (107). Weekly counseling with breath retraining and relaxation exercises may improve distress from breathlessness in patients with lung cancer (109).

Bladder and Bowel Retraining

Bladder incontinence in the cancer patient is usually managed initially with Foley catheterization, either urethral or suprapubic. If practical, intermittent catheterization is preferred because of the decreased risk of bacteriuria and formation of bladder stones (110). Elevated intravesicular pressures can occur in neurogenic bladders with detrusorsphincter dyssynergia; this may be avoided with appropriate timing of clean intermittent catheterization. Condom catheters are an alternative in the male patient when this increased intravesicular pressure is not a problem (111).

In the patient with spinal cord disease, especially above T6, autonomic dysreflexia may be provoked by noxious stimuli below the level of injury. For example, bladder distention caused by indwelling catheter obstruction may cause headache, flushing, and sweating above the level of injury, as well as hypertension accompanied by bradycardia (112,113). Interventions for autonomic dysreflexia include correction of noxious stimuli and symptomatic therapies, such as elevation of the head of the bed or the use of antihypertensive medications if necessary.

Bladder incontinence may also be treated with drugs. For example, decreased bladder wall contractility in the spastic, reflex bladder may be achieved with anticholinergic agents. Conversely, cholinergic agents, which may increase bladder contractility, should be used cautiously.

A patient with an uninhibited bladder may require a scheduled voiding regimen. Timed voiding combined with such measures as the Valsalva maneuver, suprapubic tapping, and suprapubic pressure (Credé) may be particularly useful when mild urinary retention is present.

Constipation due to bowel dysmotility is a common problem in the medically ill. Many patients find that bowel movements are facilitated by the upright seated position, and this may be an important goal of rehabilitation. Increased mobilization enhances bowel motility and may be a part of a multimodal strategy for constipation, which commonly includes increased fluid intake, fiber consumption, and laxatives (114). Patients with neurogenic bowel due to a lesion of the spinal cord, cauda equina, or pelvic nerves may benefit from other techniques, such as stimulation of anorectal mucosa and the use of either suppositories or digital stimulation (115,116). With fecal impaction, digital extraction may be necessary (117).

Management of ostomies includes dietary manipulation, control of fluid intake, drug therapies (laxatives or constipating drugs), and appropriate local stoma care. The goal of appropriate care is to produce a controlled effluent and to minimize odor and soiling. A pouch may be worn to prevent soiling of clothes and to collect feces and urine. These patients should avoid wearing constrictive clothing.

Swallowing and Speech Therapies

The stages of swallowing are the oral phase, the pharyngeal phase, and the esophageal phase, each of which is defined by where the bolus of food is located. A swallowing disorder can arise from neurological dysfunction or a structural lesion that causes problems with any or all of these stages. A variety of rehabilitative approaches can be used to cope with dysphagia (118,119 and 120). The risk of aspiration may be lessened by different textures of food or liquids and by head and body positioning (e.g., a chin tuck) that help protect the airway.

The manner of oral intake also may be modified to reduce the risk of aspiration. In the supraglottic swallow, the patient holds the breath before and during the swallow and coughs at its completion, decreasing risk of aspiration. The use of a smaller bolus of food or multiple swallows per bolus can help clear the pharyngeal area. Vocal cord adduction exercises may be performed to improve airway closure and protection. Prosthodontic appliances may be required for patients who have undergone resection of part of the oral swallowing mechanism. For example, a palatal augmentation prosthesis adds bulk to the hard palate, which may enhance tongue-to-hard-palate contact after partial glossectomy (121).

Rehabilitative techniques may be used to address disorders of language. Language abilities may be improved by melodic intonation therapy and alternative communication techniques. In melodic intonation therapy, the patient produces verbal communication within the framework of a familiar tune to facilitate word production (122). Alternative communication techniques comprise a variety of nonverbal methods, such as a communication board with pictures, letters, or words.

Dysarthria may arise from neurological insult or structural damage. Patients with hypernasal speech may benefit from a palatal lift, which decreases nasal air emission. A palatal obturator may be used to fill a surgical defect of the hard palate. Techniques of pausing or rate control may be used to maximize speech production (123). Vocal cord adduction exercises may improve dysphonia after unilateral vocal cord paralysis.

Patients who undergo laryngectomy or tracheostomy may be aphonic or dysphonic. Several methods of voice production are available. An electrolarynx creates vibrations, which can be transmitted to the oral cavity either via an oral tube or by transmission through soft tissue when placed on the neck (124). Tracheoesophageal puncture uses a small voice prosthesis inserted into a fistula between the trachea and esophagus (125,126). The patient may also be instructed in esophageal speech (127). In all cases, extensive speech therapy is required for proper training.

BENEFITS OF REHABILITATION

Traditional Settings and Palliative Care

Rehabilitation interventions can play an important role for the patient with cancer in a variety of settings. Functional impairments often result from prolonged bed rest and the resulting deconditioning. This is frequently seen in combination with neurological loss (128). Chronic impairments that undermine quality of life are often addressed by palliative care specialists. Although pain is most frequently the reason for referral, many other symptoms warrant intervention. Rehabilitation referral is certainly appropriate when motor, sensory, or cognitive function is impaired, as well as those related to persistent pain. Its role is at times overlooked or underused even when patients are receiving intensive palliative care. Interventions can be arranged for the patient admitted to the oncology service depending on the impairments and any contraindications to therapy (129). Therapies may be delivered at bedside or in the rehabilitation department.

When the patient will benefit from more intensive rehabilitation, transfer to an inpatient rehabilitation service is of potential benefit, if the patient is medically stable. The full spectrum of specialists are then available to the patient, and physical and occupational therapists work with the patient each day. The patient's ability to participate at this more intense level is usually a prerequisite to admission. Many cancer-related impairments are quite similar to those more traditionally thought of as rehabilitation candidates. For example, those with central nervous system malignancy may have clinical manifestations of spinal or brain pathology that mirror those seen in spinal cord injury, traumatic brain injury, or stroke. It should be recognized that inpatient rehabilitation can help improve both motor and cognitive function in some patients whose impairment is malignancy- or treatment-related (130). Huang et al. found that those with brain tumor achieve similar functional outcome with shorter lengths of stay in the inpatient rehabilitation service than those with brain injury (131).

If the patient is discharged home from the medical, surgical, or rehabilitation service, therapy can be continued at home through the appropriate home services agency. If the patient is able to be transported and would benefit from a formal rehabilitation clinical setting, outpatient therapy can be arranged. Rehabilitation services are also available in most nursing homes and skilled nursing facilities.

Hospice Settings

For those with advanced disease and a life expectancy generally of less than 6 months, hospice care may be the most appropriate option. Such programs provide inpatient or home-based comprehensive care for the dying patient. Comfort care is emphasized, forgoing any concentration on curative therapies (132). An interdisciplinary hospice team may include physical and occupational therapists, but a physiatrist is involved only as a consultant in most programs. The team should regard the patient along with his family and close friends as the unit requiring care, and professional friendship and “gentle openness” are required of the team (133) (Table 70-4).

Physician	Occupational therapist
Nurse	Counselor
Social worker	Chaplain
Physical therapist	Nutritionist

TABLE 70-4. MEMBERS OF THE HOSPICE INTERDISCIPLINARY TEAM

Patients admitted to an inpatient hospice setting are often highly dependent and have major functional impairments. In one survey, fewer than 17% of patients could walk unassisted and only slightly more than 20% were chairbound; the rest were bedbound (134). A retrospective study found that surviving family members of deceased hospice patients reported that almost 90% of patients wanted to walk or use a wheelchair, almost 80% were satisfied with rehabilitation efforts, and more than 60% felt rehabilitation procedures had been effective (135). In general, inpatients in a hospice spend more time with their families and are more satisfied with their care than those receiving more conventional care (136,137).

The role of the physical therapist in the hospice setting is somewhat modified. The physical therapist must attend to the physical function of the patient and help maintain function as long as possible. The therapist must also attend to nonphysical aspects of care to possibly foster social cohesion, define meaningful physical activities, and help support the patient's confrontation with the issue of mortality (138). It is important for the therapist to be an active listener and problem solver, and to help reduce the burden for the caregivers (139). Similarly, the occupational therapist should help the hospice patient identify and carry out meaningful activities, including socialization with others (140). They may also help the team identify impairments in communication, which may be more prevalent than suspected (141).

CONCLUSION

Rehabilitation interventions can have a tremendously positive impact on the patient's quality of life. Even in those with a short life expectancy, functional improvements and pain reduction may benefit the patient's family and other caregivers. Interestingly, families that participate in the patient's rehabilitation feel it is more effective and satisfactory to the patient than those families that do not participate at all (135). Rehabilitation can also help the patient be more capable of putting personal and social affairs in order at the end of life.

REHABILITATION OF SPEECH DISORDERS

STEVEN B. LEDER

Communication, especially verbal communication, receives very little attention in everyday life. Why should attention be directed at something everyone does with such ease? All human societies, in fact, have used speech and have found it to be the most convenient form of communication (1). Most people rarely think, however, about not being able to speak, or suddenly having a speech mechanism that does not function as efficiently as it used to, or not being able to hear as well as they did. This, unfortunately, is exactly what happens when a surgical resection involves the structures of the mouth or larynx, a tracheotomy is performed for airway maintenance, or chemotherapy or external beam radiation therapy (EBRT) affects auditory acuity.

Speech communication is far more than just the obvious movement of lips and tongue. It is a highly complex phenomenon that takes place between a speaker and listener. It encompasses linguistic encoding and decoding (the message), physiological commands (neural and muscle activity), and acoustic features (the sound wave). Overlaid on this system is individual speaker variability, i.e., different people do not produce the same sound waves when pronouncing the same word. In fact, the same speaker does not even produce identical sound waves when pronouncing the same word on different occasions.

How, then, is speech understood? The listener does not rely solely on information from the acoustic features in the sound wave. Knowledge of the rules specific to a particular language and speech system, cues provided by context, and the identity of the speaker are all used to decode the speech signal. Speech communication, therefore, relies on a great number of ambiguous and, most importantly, redundant cues, not on a precise knowledge of a limited number of specific cues (1). This is the only way millions of different speakers producing many millions of different sound waves can be understood by millions of different listeners.

Communication is the essence of a person's personality and social identity (2). The goal of all communication rehabilitation after cancer treatment is to reinstate verbal communication as well as possible so the person can be accepted and not stigmatized by society. Speaking, rather than nonverbal communication (lipreading, communication boards, writing or typing, or computerized augmentative communication systems) is the preferred mode for receptive and expressive communication. Speaking is accepted best by the individual and family, is the most efficient and easiest to use (when possible), and maintains a familiar link with the pretreatment life with which the individual was familiar.

Meaningful and understandable communication is greatly needed after a diagnosis of cancer. Communication is critical to a patient's medical care, psychological functioning, and social interactions (3,4). When communication breaks down between the patient and health care professionals, the patient's ability to participate meaningfully in the health care plan is greatly restricted (5,6), and recovery and rehabilitation may be adversely affected (2).

This chapter discusses the ways cancer and its treatment affect the individual's ability to maintain verbal communication skills. It also discusses extensive rehabilitation methods whose goal is to reinstate verbal communication skills for the individual. In addition, the chapter considers the importance of hearing, its potential loss after cancer therapy, and rehabilitation strategies with the goal of maintaining optimal verbal communication.

PRODUCTION AND PERCEPTION OF SPEECH

Speech, swallowing, and breathing are different types of behaviors that share the same anatomical structures. Swallowing and breathing are very old evolutionary behaviors and occur in all animals. Speech is a recent evolutionary behavior and occurs only in humans (7). The shared anatomical structures that move and are involved in speech production are called the articulators: the lips, tongue, teeth, mandible, velum, pharynx, and larynx. Other shared anatomical structures are the oral and nasal cavities, which provide resonance, and the lungs and diaphragm, which provide the air supply and driving force without which normal speech would be impossible. Although the exact neural. controls for speech production are not known, the neural controls for swallowing and speech also overlap, and the reader is referred to Chapter 12, Dysphagia, for a more detailed discussion of the neural innervation of shared structures.

Speaking is a highly complex motor skill that consists of coordinated movements of the articulators—the lips, tongue, and teeth—on the air generated from the lungs (cf. 7–14 for a more detailed discussion of speech production and perception). With reference to speech, the vocal tract is defined by the larynx inferiorly and includes the pharynx, oral cavity, and nasal cavity superiorly. Any mass change (as with a tumor) or insult (as with a surgical resection or denervation) to the vocal tract or articulators may affect voice production (the sound source, voice quality, and resonance) and speech production (consonant and vowel articulation). Depending on the cancer treatment required, the person's ability to communicate verbally is affected mildly to severely to totally.

The speech-language pathologist's role is to diagnose the communication disorder and provide optimal rehabilitation after treatment, with the goal of having the patient acquire verbal communication skills that are as nearly normal as possible. Realistic goals, sometimes requiring interim steps, are presented to the patient. Success at each step is stressed to help the patient stay motivated and to help prevent depression. All types of communication, such as writing or lipreading, are used initially so as to connect the patient to the environment and foster participation in the rehabilitation plan as quickly as possible.

CLINICAL APPLICATIONS

Head and Neck Cancer Resections and Reconstructions

The results of surgery and reconstruction vary as they affect and change speech production skills, verbal communication, and speech perception acceptability, but they affect all cases to some degree. A database has been designed to evaluate functional outcomes of speech, swallowing, and voice after head and neck cancer treatment, and longitudinal data is currently being collected (15).

It should be kept in mind that as long as the intended target phoneme (consonant or vowel) is articulated with enough acoustic and distinctive features to be considered

an allophone of the target phoneme, the meaning of the word is not changed, and the verbal message is considered to be encoded and decoded successfully. Ideally, the surgical resection and reconstruction (with or without postoperative chemoradiation) coupled with appropriate rehabilitation allows for intelligible verbal communication by maintaining at least the minimal redundant cues in the speech signal needed for successful verbal communication. For example, it was reported that pre-/postoperative speech function did not differ in small oral and base of tongue resections when primary closure versus flaps were compared (16) and in irradiated versus nonirradiated postsurgical oral cancer patients (17).

Unsuccessful verbal communication, however, results when the surgical resection has altered the vocal tract or articulators to such a degree that the inherent redundancy built into the speech code becomes degraded. As a result, the target phoneme is decoded not as an allophone but either as a different phoneme (thus changing the meaning of the intended message) or as an unintelligible sound not considered part of the phonology of the target language, in this case English.

Counseling

Nothing can fully prepare the patient for the consequences of head and neck cancer surgery. Combined with the emotion and fear inherent in the word “cancer” is the fear of major surgery and its consequences, the fear of losing the ability to communicate effectively, and the fear of becoming a social and psychological burden on the family. An indepth discussion of the need for counseling, both preoperatively and postoperatively in the long term, appears in reference 2.

The speech-language pathologist offers preoperative counseling to discuss the surgery and its consequences and, just as importantly, the rehabilitation strategies that are used to restore verbal communication skills to as nearly normal a state as possible. Illustrations and models are helpful in having the individual understand what impact the planned surgery may have on the speech-production mechanism.

Counseling does not begin and end preoperatively. The immediate postoperative period of 1–14 days presents problems that are not encountered later on. Postoperative edema impairs articulation, and the patient should be reassured that this is a temporary condition. Sutures are frequently present, and localized pain may also reduce the proficiency of articulation. If the facial (C-VII), vagus (C-X), or glossopharyngeal (C-XII) nerves were involved in the surgical resection, paresis or numbness may be present, further impairing articulatory precision. Also, the patient's decreased motivation and sadness may make speech production worse in the immediate postoperative period than it will be in a few weeks' time. Counseling should continue postoperatively for as long as the patient needs it (2).

After the 2-week postoperative period, the patient is usually discharged home. Before discharge, the speechlanguage pathologist determines whether ongoing speech rehabilitation is required. If it is, additional goals are implemented to increase overall speech production skills and the intelligibility of speech, based on the surgical resections and the functioning of the remaining structures in the vocal tract. The patient is assured that articulation and speech intelligibility will improve with therapy. If there is a structural defect that can be compensated for with, for example, a palatal prosthesis, an appropriate referral to a prosthodontist is done as well.

Speech Articulation Rehabilitation

The ultimate goal of rehabilitation is to return the patient to as nearly normal a life as possible, regardless of the amount of time that remains. Speech articulation rehabilitation after resection of the articulators and vocal tract focuses on compensatory articulation and stresses precise articulation. The goal of speech articulation therapy is to produce either the target phoneme or an allophone of the target phoneme so the word, and therefore the message, is decoded correctly by the listener.

Labial Resections

Labial resection can result in decreased lip rounding, affecting vowel production (e.g., /u/), and labial closure, affecting articulation of bilabial /b,p,m,w/ and labiodental /f,v/ consonants.

Anterior Tongue and Floor of Mouth Resections

Resection of the anterior tongue and floor of the mouth can result in decreased lingua-alveolar ridge contact, affecting the production of all consonants with the /t,d,s,z,n,l/ place of articulation, as well as the linguadental phoneme /th/. The manner of articulation of these phonemes can also be impaired because of poor lingua-alveolar ridge contact. For example, inadequate lingua-alveolar pressure for the stop plosive phoneme /d/ results in articulation of an /n/ or /l/ phoneme.

Lateral Tongue Resection

Because of the redundancy built into the speech production mechanism and the decoding ability of the human brain, lateral tongue resections do not usually result in significant articulation errors that impair speech intelligibility. The remaining hemitongue is able to articulate allophones of the target phoneme. Lateral emission of air may occur after more extensive resection, especially if teeth are missing as well.

Posterior Composite Resections

Posterior composite resections affecting more than one structure, such as the tongue and the mandible, can result in decreased lingual and mandibular range of motion and control, paresis, and decreased sensation, which in turn can affect vocal tract shape for vowels, and place and manner of articulation for consonants, especially the velar phonemes /k,g/.

Hard and Soft Palate Resections

Hard and soft palate resection affects velopharyngeal closure, resulting in velopharyngeal insufficiency or oronasal fistulas. These defects may cause excessive hypernasal resonance because of the inability to separate the oral from the nasal cavities. The larger the surgical defect, the greater the inappropriate hypernasal resonance. All phonemes are affected, with stop plosive, fricative, and affricate phonemes—the pressure consonants—affected the most because of the inability to build up adequate intraoral air pressure for their articulation. For example, without adequate intraoral air pressure for the release burst, the stop plosive phonemes /p,b/ are articulated and perceived as the phoneme /m/, significantly impairing speech intelligibility.

Partial Laryngectomy

There are several different types of partial laryngectomies (2). The following are done in the vertical plane: cordectomy via laryngofissure (18), hemilaryngectomy (19), vertical partial laryngectomy (20), anterofrontal and extended anterofrontal laryngectomy (18), and near-total laryngectomy (21,22). Voice production and voice quality after these operations is dependent on the extent of the laryngeal resection and the type of neoglottic reconstruction used (19). Therefore, this population demonstrates a range of vocal capabilities (23).

In general, partial laryngectomy results in hoarseness and possibly breathiness because of the resection, which usually includes one arytenoid cartilage and one true vocal fold, and reconstruction of the neoglottis with mucosa opposing the remaining true vocal fold. The resultant novel vibration of the remaining true vocal fold against mucosa results in a turbulent sound source, changing vocal tract resonance patterns and producing the voice disorder.

Supraglottic Laryngectomy

The surgical procedure for a supraglottic laryngectomy is done in the horizontal plane. Candidates for a supraglottic laryngectomy are those with cancer of the epiglottis or ventricular vocal fold(s) without cancer extension across or into the ventricle or anterior commissure (18).

Supraglottic laryngectomy does not affect articulation or true vocal fold vibration, but may affect vocal tract resonance and voice quality because it alters the physical characteristics of the vocal tract. Specifically, the removal of the epiglottis, aryepiglottic folds, and false vocal folds in the pharynx alters the length and volume of the vocal tract and may change the resonant characteristics of the vocal tract. Information in this area is scarce. In one of the few studies reporting objective data on the phonatory results after supracricoid partial laryngectomy (24), it was found that the average fundamental frequency for the partial laryngectomy subjects was not significantly different from that for normal speakers. Additional data indicated that partial laryngectomy speech and voice production was less efficient than normal speech and voice production as evidenced by increased jitter, shimmer, and harmonics to noise ratio, and decreased maximum phonation time, speech rate, and phrase grouping.

Metal and Plastic Tracheotomy Tubes

The most disruptive change for the posttracheotomized patient is the loss of verbal communication (25,26 and 27). There are two major types of tracheotomy tubes: metal (stainless steel) and plastic. A metal (Jackson) tracheotomy tube is always cuffless. Inspiration occurs through the tube. Expiration occurs out of the tube when it is open and via the upper airway and out of the mouth and nose when the tube is occluded (Fig. 71-1). Plastic tracheotomy tubes can be either cuffed or cuffless. The cuff is an inflatable diaphragm attached around the distal end of the tube. When the cuff is inflated, expiration occurs out of the tube, and when the cuff is deflated and the tracheotomy tube occluded, expiration must occur via the upper airway and out of the mouth and nose (Fig. 71-2). Both types of tracheotomy tubes have inner cannulas whose purpose is to facilitate maintaining hygiene and the patency of the tube itself (Fig. 71-1 and Fig. 71-2). In addition, both types of tubes can be fenestrated, i.e., by a hole or holes placed on the superior surface of the tracheotomy tube that resides in the trachea to allow for air to pass through into the upper airway.

FIGURE 71-1. Metal (Jackson) tracheotomy tube with inner cannula.

FIGURE 71-2. Plastic tracheotomy tube with and without inflated cuff, and with inner cannula in place.

A tracheotomy tube can be occluded with a finger, cork, or flapper valve. If there is an upper airway problem that prevents easy expiration out the mouth and nose, intermittent finger occlusion is used to allow for inspiration through the tube, but only for selected expiration via the upper airway during speech production. If there is no upper airway problem but a tracheotomy tube is required for airway maintenance, either short-term or long-term occlusion of the tube with a cork is appropriate. This eliminates the need for occlusion of the tracheotomy tube with a finger during speech. A special type of metal tracheotomy tube is a Tucker tube (Fig. 71-3). This is a sterling silver tube with an inner cannula that contains a one-way flapper valve. The flapper valve allows inspiration through the tube but then passively closes during expiration, diverting air around the tube via the upper airway to be used for voice production or simply exhaled. The Tucker tube is used when a tracheotomy tube is required for a longer time.

FIGURE 71-3. Tucker tracheotomy tube with inner cannula containing one-way flapper valve.

“Speaking” Tracheotomy Tube

The primary goal of a speaking tracheotomy tube is to allow cognitively intact ventilator-dependent patients to communicate verbally (25,28,29). The Portex “Talk” tracheotomy tube has been shown to be successful in allowing this population of patients to speak (29). It is a doublelumen, unfenestrated, single-cuffed tube designed with an external airflow line at the nine o'clock position. Gas travels through the airflow line, exits via a slit just superior to the cuff, and then continues up through the glottis and vocal tract to allow for speech production (Fig. 71-4). The user can occlude the airflow line for independent speech production or, if upper extremity paralysis or weakness prevents self-use, the listener can occlude the airflow line to allow for verbal communication.

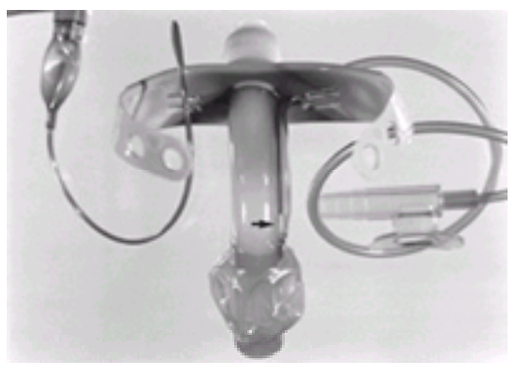

FIGURE 71-4. “Speaking” tracheotomy tube with external airflow line. Arrow shows slit where air exits.

One-Way Tracheotomy Speaking Valves

A one-way tracheotomy speaking valve attaches to the external hub of a tracheotomy tube, usually plastic, and permits inspiration through the tracheotomy tube, but on exhalation the tube is blocked and air must exit through the larynx and out the mouth or nose. Most one-way valves attach to plastic tracheotomy tubes (Fig. 71-5B, Fig. 71-5C, Fig. 71-5D), but a new one-way valve has been designed specifically to attach to a metal tracheotomy tube (Fig. 71-6). The one-way valves eliminate the need for finger occlusion. It circumvents the problem of a patient not tolerating permanent occlusion of the tracheotomy tube with a cork when he or she has an upper airway restriction such as tracheal stenosis, laryngeal web, laryngomalacia, or arytenoid edema (30).

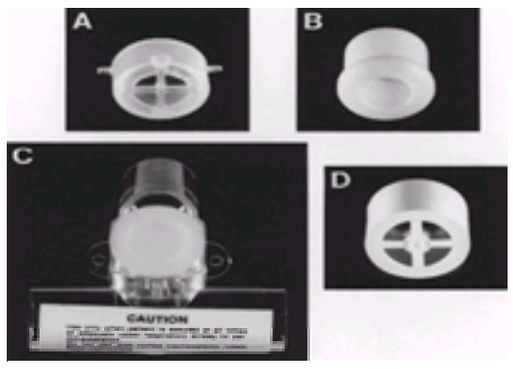

FIGURE 71-5. The four one-way tracheotomy speaking valves. **A:** Kistner, B: Montgomery, **C:** Olympic, **D:**Passy-Muir. (From Leder SB. Perceptual rankings of speech quality produced with one-way tracheostomy speaking valves. *J Speech Hear Res* 1994;37:1308, with permission.)

FIGURE 71-6. Passy-Muir one-way tracheotomy speaking valve for a metal tracheotomy tube.

Rehabilitation with a one-way tracheotomy speaking valve is straightforward. The tracheotomy tube cuff, if present, must always be deflated with valve use to allow for expiration around the tube and through the glottis and upper airway. Most patients require only a short acclimation period with the valve. During this trial period, the patient is told that breathing, especially expiration, may feel different because of the valve. If the patient experiences difficulty in breathing, continued trial periods of valve use, increasing in length, should be done to habituate the patient to the valve. A pulse oximeter can be used to monitor arterial oxygen percent saturation (30).

There are a number of different commercially available one-way speaking tracheotomy valves, for example, Kistner, Montgomery, Olympic, and Passy-Muir (Fig. 71-5). All have similar basic components, but they differ in their engineering and design. Each has a diaphragm that is either bias open (open at all times and closed only on expiration) or bias closed (closed at all times, inspiratory effort being needed for opening). All diaphragms close on expiration, and all valves attach to the hub of a tracheotomy tube. In addition, the Passy-Muir valve comes in two types, one for patients who are ventilator dependent and one for those who are not. The Passy-Muir valve has been identified with the best speech quality most often by both listeners and users, and it has also exhibited the fewest clinically relevant mechanical problems (30).

Total Laryngectomy: Alaryngeal Speech and Voice Restoration Rehabilitation

Unlike the consequences of surgery to the vocal tract, a total laryngectomy results in removal of the sound source itself: the true vocal folds. This obviously results in a significant problem for the resumption of verbal communication. The goal of voice restoration rehabilitation is to provide an alternative sound source to allow speech articulation, phoneme production, and meaningful verbal communication to occur. No one method for the alternative sound source is better than another. The goal is to match the method that is best for the patient at any particular time in the rehabilitation process.

The first 10–14 postoperative days can be divided into two distinct periods: immediate (1–4 days) and transition (5–14 days) (2). The immediate postoperative period is characterized by a reduced ability of the patient to interact with the environment; the recovery from the effects of general anesthesia; nonambulation; connection to monitoring equipment; and a greater level of discomfort from surgery than is evident in the transitional period. The transitional period usually includes ambulation; increased interaction with the environment as evidenced by writing, watching television, and resumption of oral feeding; and initiation of voice restoration rehabilitation with an electrolarynx.

Barring postoperative complications, the patient is usually discharged from the hospital after 10–14 days. Outpatient voice restoration rehabilitation continues the therapy begun during the transitional recovery period. Discussions with the speech-language pathologist regarding the use and timing of the various voice restoration techniques for verbal communication are carried out on a long-term basis so that an informed choice of optimal alaryngeal speech can be made.

Alaryngeal speech can be produced from four types of sources: (a) intrinsic (buccal, pharyngeal, and esophageal), (b) prosthetic (artificial or electrolarynx), (c) surgical (tracheoesophageal [TE] fistula or neoglottis), and (d) surgicalprosthetic (pharyngotomy with prosthesis or TE puncture with prosthesis) (31,32).

Intrinsic Voice Restoration

Intrinsic voice restoration does not rely on surgery or a prosthetic device. The sound source is produced by existing oral, pharyngeal, or esophageal structures. Buccal (“Donald Duck”) and pharyngeal (high-frequency and squeaky) speech are not desirable and should be discouraged.

Esophageal speech is a good goal but is not always obtainable. Esophageal speech is produced by injecting or inhaling air into the upper esophagus at the C-4 to C-6 level, thereby vibrating the walls of the pharyngoesophageal segment as the air is returned to the mouth (Fig. 71-7). Several methods can be used to produce successful esophageal speech using air injection and air inhalation techniques (cf. references 2 and 29 for detailed discussions). This new sound source has greater mass than the true vocal folds, and therefore the voice produced has a lower fundamental frequency. In addition, less air is available with esophageal speech than from the lungs, resulting in fewer words per air charge (33,34). It should be mentioned that not all total laryngectomees can achieve fluent and intelligible esophageal speech; some reports estimate that fewer than 10% of laryngectomees achieve acceptable fluency (31).

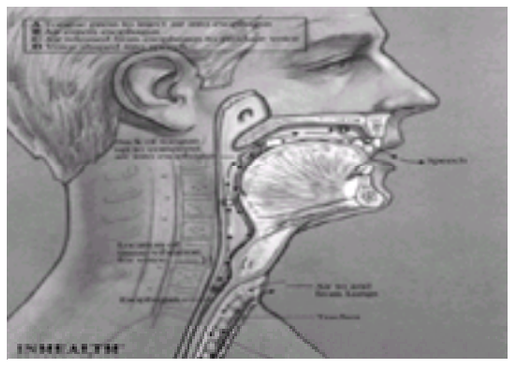

FIGURE 71-7. Esophageal speech (Inhealth Technologies, 1110 Mark Ave., Carpinteria, CA 93013-2918).

Prosthetic Voice Restoration with an Artificial Larynx and an Electrolarynx

An artificial larynx uses the laryngectomee's own lung air as the driving force for the new sound source. To do so, the artificial larynx connects the stoma with the oral cavity (Fig. 71-8). These devices are cumbersome to use, draw attention to the user, and are not generally used any more.

FIGURE 71-8. Artificial larynx.

An electrolarynx provides the new sound source by vibrating the air in the remaining vocal tract, either directly, as with an intraoral device, or transcervically, as with a neck placement device (Fig. 71-9). The devices have builtin sound generators that are battery driven, and they have on/ off, volume, and pitch controls that allow for some production of intonation and contrastive stress (35).

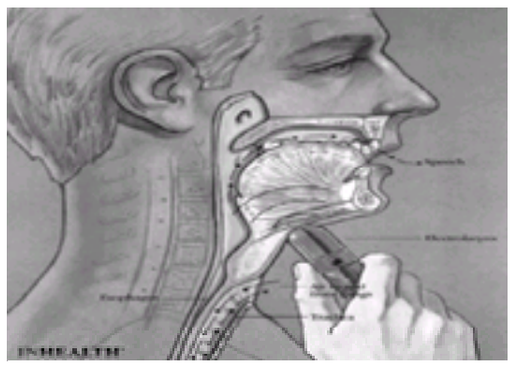

FIGURE 71-9. Electrolaryngeal speech (Inhealth Technologies, 1110 Mark Ave., Carpinteria, CA 93013-2918)

An electrolarynx should be provided to the new laryngectomee as soon as possible, usually 3–4 days postoperatively. Although optimal speech production and intelligibility are not obtained, the positive psychological benefits of voice restoration rehabilitation provided by early introduction of an electrolarynx far outweigh any frustration due to early use of the device for speech production. An electrolarynx can also be used during all voice restoration rehabilitation techniques.

There are three types of electrolarynxes: (a) those with an extraoral sound source and intraoral connector only, (b) those with an extraoral sound source with option of intraoral connector and transcervical (neck) placement, and (c) those with a totally intraoral sound source with extraoral control.

Figure 71-10 shows a typical device with an extraoral sound source and intraoral connector. Care must be taken so as not to block the end of the oral connector, and therefore the sound, with the tongue or with saliva. Optimal placement is usually 1.0–1.5 cm into the corner of the mouth between the buccal mucosa and tongue.

FIGURE 71-10. Electrolarynx with extraoral sound source and only intraoral connector [Luminaud, Inc. (Cooper-Rand Electrolarynx), 8688 Tyler Blvd., Mentor, OH 44060].

Figure 71-11 shows a typical device with an extraoral sound source but with two options for vibratory placement, intraoral and transcervical. The same technique as with the previous device (Fig. 71-10) is used with the optional intraoral tube. Approximately 1 month after laryngectomy, when the neck has healed and if neck induration is not a confounding factor, neck placement can be attempted.

FIGURE 71-11. Electrolarynx with extraoral sound source and both intraoral and transcervical vibratory placement options, with battery recharger (Siemens Hearing Instruments, Inc., 10 Constitution Ave., Piscataway, NJ 08855-1397).

When neck placement is used, the vibrator head should be pressed comfortably but firmly on the neck to allow the sound source to travel through the skin and vibrate the air in the vocal tract (Fig. 71-9). Experimentation with different neck placement positions and pressures is usually necessary before the best vocal quality and speech intelligibility are produced. Precise articulation, as well as correct use of the on/off button and correct placement of the intraoral connector or neck placement, is stressed. Variable pitch control can be achieved, if the device has two or more pitch controls, by neck tension or by placement of the device. It is important to remember that lung air is not needed for speech; therefore, stoma noise from exhaled air should be eliminated when an electrolarynx is used.

Figure 71-12 shows a device with a totally intraoral sound source with extraoral volume and pitch controls. The oral unit is custom-made to fit existing dentures or a new palatal retainer. The hand-held control unit houses the on/off, volume, and pitch controls and sends wireless radio commands to the oral unit, which houses the sound source and produces the desired pitch and loudness characteristics. The laryngectomee then uses the new vocal tract sound source for consonant and vowel articulation and phoneme production for intelligible verbal communication. The user holds the control unit out of sight in a pocket and does not have to use an intraoral or transcervical placement device.

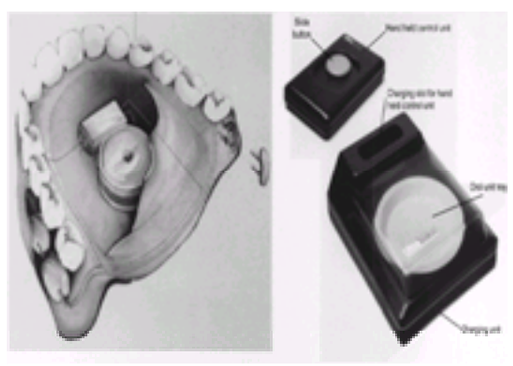

FIGURE 71-12. Electrolarynx with totally intraoral sound source and extraoral volume and pitch controls, with battery recharger [Health Concepts Inc. (Ultra-Voice), Inc., 279-B Great Valley Pkwy., Malvern, PA 19355].

Surgical Voice Restoration

Surgical voice restoration attempts to use lung air for speech by using various surgical techniques and the individual's own tissues, such as those of the esophageal mucosa, vein, skin tube, and tracheal tube (31). Unfortunately, unacceptable aspiration and tract stenosis leading to aphonia have occurred with most surgical procedure attempts. However, surgical voice restoration rehabilitation after total laryngectomy has not been abandoned completely (36), and innovative surgeons will surely continue to search for the optimal procedure.

Surgical-Prosthetic Voice Restoration Rehabilitation

Since the first reported successful total laryngectomy more than 100 years ago, many techniques, both surgical and mechanical, have been reported for speech restoration (37,38). Unfortunately, these early attempts were plagued by complications: aspiration, shunt stenosis, and fistula formation. Currently, the requisite essential for successful TE speech is a one-way prosthetic valve placed in the tracheostoma by a surgically created TE puncture, which permits expired air to be directed into the esophagus during tracheostoma occlusion but is closed at all other times to prevent saliva and food from entering the trachea (Fig. 71-13). The TE voice prosthesis is a hollow tube made of medical-grade silicone with a one-way valve at one end and retention collars on both ends (Fig. 71-14). Several different types are available, such as the Groningen button (39), the Provox (40), the Panje button (41), and the most widely used: the Blom-Singer TE prosthesis (42).

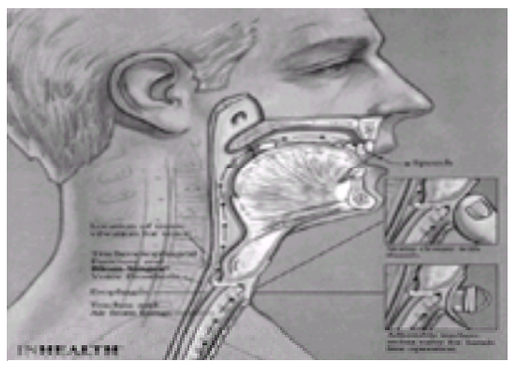

FIGURE 71-13. Tracheoesophageal speech (Inhealth Technologies, 1110 Mark Ave., Carpinteria, CA 93013-2918).

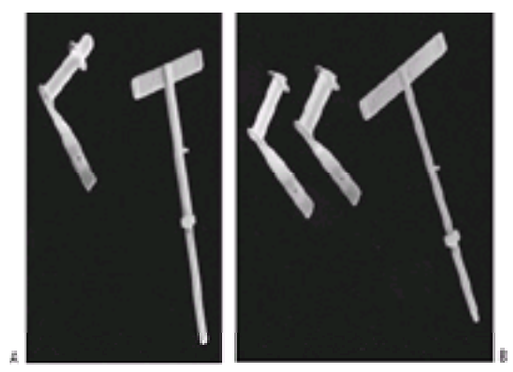

FIGURE 71-14. Blom-Singer tracheoesophageal voice prosthesis (Inhealth Technologies, 1110 Mark Ave., Carpinteria, CA 93013-2918). **A.** Duckbill voice prosthesis.

B. Low-pressure voice prosthesis.

The TE voice prosthesis resides in the puncture tract at all times to prevent stenosis of the tract and aspiration through the puncture tract. When the stoma is covered and exhalation occurs, air travels from the lungs, into the trachea, through the voice prosthesis, and into the esophagus. The esophagus vibrates, creating a new sound source, which sets the column of air in the vocal tract into vibration, allowing for speech articulation, resonance, and verbal communication to occur.

A common frustration experienced by TE prosthesis users is the need to change the prosthesis every 3–4 days. In fact, early (43,44 and 45) as well as later (46,47) studies reported as the greatest disadvantage of a TE prosthesis that it must be inserted and changed frequently by the user. Users found changing to be bothersome, difficult, or even impossible.

Recent product development advances, specifically the “gel cap” insertion method (48) and the extended-wear “indwelling” TE voice prosthesis (49), have eliminated this problem (Fig. 71-15). The gel cap provides a smooth, rounded configuration that transiently eliminates the retention collar. The gel cap then dissolves in 2–3 minutes in the esophagus, releasing the retention collar for internal anchoring. The indwelling TE prosthesis has larger retention collars on the tracheal and esophageal ends, is inserted and changed only by the speechlanguage pathologist or otolaryngologist, and can stay in place for as long as 6 months. Daily *in situ* cleaning with a flushing pipette is required of the user. Voice restoration rehabilitation is still required to achieve optimal speech intelligibility and pitch control by correct digital occlusion and pressure over the tracheostoma, and optimal use of a tracheostoma valve (48).

FIGURE 71-15. Blom-Singer tracheoesophageal voice prosthesis with gel cap insertion in place and extended-wear indwelling voice prosthesis (Inhealth Technologies, 1110 Mark Ave., Carpinteria, CA 93013-2918).

TE speech has been a viable and proven alternative to esophageal and electrolaryngeal speech for patients with total laryngectomy since the introduction of the Blom-Singer TE puncture technique and prosthesis in 1980 (42). Subsequent studies evaluating the TE puncture procedure and TE prosthesis speech rehabilitation by its developers (38,50,51), and, more importantly, by independent investigators (43,45,52,53,54 and 55), have shown both the procedure and the prosthesis to be reliable for TE speech production after total laryngectomy.

As stated in their original paper, “Although this [TE puncture] method appears uncomplicated, it is not always 'easy' and a number of factors must be considered” (42:532). Some factors are surgically or medically related, e.g., tracheostoma size and position, cricopharyngeus spasm, and irradiated tissue. Other factors are patient related, e.g., motivation, capability to care for the stoma and prosthesis, visual disturbances, and arthritis. Still other factors are speech-rehabilitation related, e.g., ability to follow directions, position and pressure for optimal digital stoma occlusion, TE valve use, and necessity of adequate follow-up (38,53,54). In all cases, the speech-language pathologist and otolaryngologist are a team that jointly selects, rehabilitates, and follows-up the patient with a total laryngectomy and TE prosthesis (42,52,56,57).

The TE puncture procedure can be done primarily at the time of total laryngectomy (54,58) or secondarily either after or in conjunction with esophageal and electrolarynx speech rehabilitation (42,55). A cricopharyngeal myotomy is done at the time of total laryngectomy during a primary puncture procedure. When a secondary puncture is recommended, transnasal insufflation testing is performed to assess pharyngeal muscle response to esophageal distention (59). The insufflation test assesses cricopharyngeous spasm, and a cricopharyngeal myotomy (60) or pharyngeal plexus neurectomy (61) may be necessary to allow for the fluent production of TE prosthesis speech.

The new sound source does not necessarily have to be the esophagus. In patients with extensive disease, a pharyngolaryngoesophagectomy with gastric pull-up may be necessary. Reconstruction may also include microvascular free tissue grafts, myocutaneous flaps, cervical flaps, and visceral transposition. The standard TE puncture procedure has been shown to be successful in voice restoration rehabilitation with this population, although the resulting voice is characterized by lower pitch, reduced intensity, slower rate, and an overall “wet” or “gurgly” quality in comparison with TE prosthesis speakers (62).

Tracheostoma Valve

The tracheostoma valve was developed to eliminate the need for manual occlusion of the stoma to divert air into the voice prosthesis for speech production (63). The valve system has several parts. The circular valve housing is glued to the skin around the stoma every day. The adjustable valve fits into the housing, and its diaphragm remains open during normal respiration but closes with increased expiratory airflow, thereby diverting air into the voice prosthesis and esophagus for hands-free speech production (Fig. 71-12 and Fig. 71-16). The diaphragm opens automatically when the user stops talking to allow for resumption of normal inspiration.

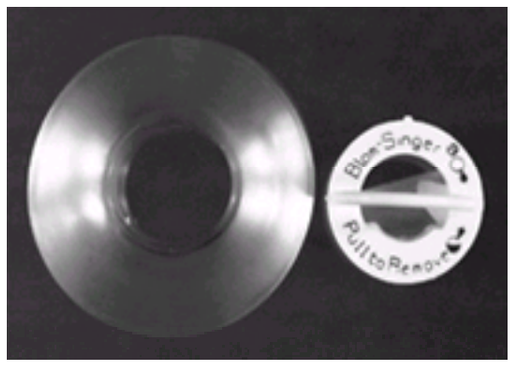

FIGURE 71-16. Blom-Singer tracheostoma valve (Inhealth Technologies, 1110 Mark Ave., Carpinteria, CA 93013-2918).

HEARING LOSS

Hearing loss goes hand-in-hand with speech production in the communication cycle (64). If hearing is impaired, the potential is great for the communication process to fail. For the individual with cancer, participation in the care plan, family discussions, conferences with caregivers, and informed consent for therapeutic decisions all rely on functional hearing. In addition, maintenance of orientation to the activities of daily living via the telephone, television, and radio are made much easier with the ability to hear at least as well as before treatment.

There are two types of hearing loss: conductive and sensorineural. Any impairment of the outer or middle ear with a normal inner ear results in a conductive hearing

loss. The difficulty is not with the perception of sound but with the conduction of sound to the analyzing system. The severity of the conductive hearing impairment ranges from slight to moderate: 15–60 dB hearing level (65). When the loss of hearing is due to a pathological condition of the inner ear or along the nerve pathway from the inner ear to the brainstem, the loss is called sensorineural. The severity of the sensorineural hearing impairment ranges from slight to profound, that is, 15–91 dB hearing level (65). There also can be a mixed hearing loss, involving components of conductive and sensorineural loss, affecting both sound conduction and sound perception.

Chemotherapy

Ototoxic chemotherapeutic drugs such as cisplatin have the potential to cause damage to the inner ear: the cochlea, vestibule, semicircular canals, and otoliths (66,67). The benefits of ototoxic therapy must be balanced with its potential for permanent damage to the inner ear and the resultant sensorineural hearing loss or balance disorders. Hearing and balance disturbances can have significant negative vocational, educational, and social ramifications. In an effort to minimize or even prevent ototoxic damage, audiologic testing before treatment and at regular intervals during and after treatment should be done. A comprehensive manual delineating guidelines for the audiologic management of individuals receiving ototoxic drug therapy is available (68).

External Beam Radiation Therapy

Osteoradionecrosis of the temporal bone after EBRT for malignant disease of the head and neck has been well described (69,70,71 and 72). Radiation can produce both early and late changes, ranging in time from 9 months to 20 years (73).

Hearing loss in 36% of irradiated ears has been reported to be caused by EBRT (74). Both types of hearing loss can occur. Osteoradionecrosis of the ossicular chain (75) and impaired eustachian tube functioning, which can lead to otitis media, can cause conductive hearing loss. Cochlea damage secondary to EBRT can lead to sensorineural hearing loss (74). Both conductive and sensorineural hearing loss can occur, depending on the extent of the radiated field.

Aural Rehabilitation

Aural rehabilitation for patients with hearing loss secondary to cancer or its treatment may be different from aural rehabilitation for other adults with hearing loss (76). Cancer patients may be depressed or weak from the disease and its treatment. The hearing loss, if conductive, may be transient and will improve spontaneously, for instance, when EBRT has been completed. The hearing loss, if sensorineural, may or may not be amenable to improvement with hearing aids. If cost is an issue, low-cost alternatives—assistive listening devices such as pocket amplifiers and telephone receiver amplifiers—may provide the extra volume needed for hearing and successful participation in the communication dyad instead of hearing aids.

Appropriate communication strategies with the person who is newly hearing impaired should be stressed. Strategies include proper positioning of the speaker and listener for unobstructed vision, placement of the hearing-impaired listener in close proximity to the speaker, elimination of interfering background noise, and good lighting to take advantage of visual cues. In other words, conversation should not take place in a poorly illuminated and noisy environment, as is the case in most hospital rooms, and with the caregiver or listener performing tasks in the room that make optimal visual and auditory input impossible (76).

CONCLUSION

The restoration of the best possible verbal communication is the goal of rehabilitation for people with impaired speech skills. Verbal communication, a uniquely human behavior, is critical to the patient's medical care, psychological functioning, and social interactions. Although cancer and its treatment may significantly alter the patient's ability to communicate verbally, many successful therapeutic interventions are available for the restoration of intelligible voice and speech production.

MUSIC THERAPY AND ART THERAPY*

LUCANNE BAILEY MAGILL
PAOLA M. LUZZATTO

Music and art are forms of human expression that have been used throughout time to heal, to establish communication, to gather communities, and to portray inner thoughts, feelings, experiences, and intentions. These creative mediums are universally accepted and called on during times of celebration, reflection, mourning, and transition. The multidimensional characteristics of music and art offer rich resources for aiding human dilemmas and conditions of adversity.

Music therapy and art therapy have become familiar approaches in working with patients contending with life-threatening and terminal illnesses. These therapies are identified as nonpharmacological treatment modalities offering a range of calming and expressive benefits to patients and families. Interventions are offered by trained music and art therapists to facilitate meaningful changes in physiological, psychological, social, and spiritual processes. In this chapter, the use of music therapy and art therapy in this context is reviewed. In addition, a theoretical model is presented that describes the therapeutic process that may occur with supportive interventions. Case examples are reviewed as ways to demonstrate the use of these therapies in supportive oncology and palliative care.

MUSIC THERAPY

Music therapy became a formalized profession in both the United States and in Europe in the mid-twentieth century. Originally, music therapy was used as a means for aiding ailing veterans returning from war. As degree programs in universities began to formalize the education and training of music therapists, the profession expanded to work in collaboration with health care providers in psychiatric and medical institutions. Today, music therapists, having completed degree and national certification requirements, are employed worldwide in a range of health settings.

Music therapy has been found to provide many benefits to patients, families, and significant others. The literature describes the effectiveness of music to break the cyclical nature of pain (1,2), to alter mood (3,4), to promote relaxation (5,6,7 and 8), and to improve communication (9,10,11,12 and 13). Music therapists have refined methods for treating anxiety in children (14) and adults (15). Music therapists and health care professionals have begun to research the impact that music has on the various components of the human experience in life-threatening and terminal illnesses, that is, physiological (improved cardiac, respiratory and adrenal functioning as well as decreased symptoms of nausea, insomnia, or fatigue), psychoemotional (alteration in mood and enhanced coping styles), and social (enhanced communication) (16,17,18,19 and 20).

During the past decade in particular, the use of music therapy in palliative care settings has increased substantially. Music therapists have begun to write extensively about clinical experiences and research in working with the seriously ill and dying and with their significant others. Theoretical models and methods of treatment have been developed and are being used by music therapists in the areas of pain management, music and neurological sciences, music psychotherapy, and integrative medicine.

Pain Management

Music therapy is one of the nonpharmacological treatments for pain and associated symptoms. Music therapists provide expressive methods to facilitate relief from suffering (1,21,22). In the management of pediatric pain, Loewy (23) has emphasized that the assessment of emotional and physical parameters determines the use of appropriate techniques. Other music therapists routinely use specific techniques such as entrainment—the use of sound stimuli to match and then alter responses (21,24). Other therapists use physioacoustic therapy, which is the use of pure sinusoidal sound waves (25) and nonrhythmic, slow tempos and low frequencies (26). More and more, music therapy is being used in the treatment of pain in cancer and advanced illnesses.

Music and Neurological Disease

Music can affect neurological mechanisms. Because hearing is the first sense to be developed and the last sense to deteriorate (27), music is a particularly effective stimulus to reach and make contact with patients who are otherwise not responding to words or touch. This attribute of music is relevant in work with advanced illness. Music can help restore relatedness, thereby reducing isolation or providing for moments of meaningful communication between patients and family members.

Research has clarified the impact of music on patients with neurological disease, such as brain tumors, central nervous system lymphoma, and metastatic illness. At the Instiute for Music and Neurologic Function in New York, Tomaino (working with Dr. Oliver Sacks) uses music as a “retrieval mechanism” to help patients with memory impairment recall significant events (28). For patients who have expressive aphasia, singing can facilitate renewed expression and articulation within the context of music (11). In studies by Rider (29), improvisational music therapy with entrainment is found to influence psychoneuroimmunological responses. This is explained in a theory of homeodynamism, that is, the neurological shifting and synchronization of electroencephalogram patterns.

Music can ameliorate pain and symptoms of fear, anxiety, depression, frustration, and loneliness. Thorough assessments guide the music therapist to offer interventions that best suit overall needs. Although there may be times when no music is used, such as with acutely distressed patients who may not be able to manage any surfacing of emotions, music has unique potential to operate multidimensionally, interacting simultaneously with physiological, psychological, emotional, social, and spiritual processes.

Music Psychotherapy

Music therapists are applying psychotherapeutic skills in the care and treatment of persons contending with advanced illness. Loewy (30), for example, uses music psychotherapy with children to facilitate expression and the processing of issues. Analytic music therapy has been found to benefit some adults through the uncovering of issues surrounding symptoms, some of which are psychosomatically based (31). Music therapists may base clinical work in various models of psychotherapy and attend to the multifaceted needs and issues presented by patients and significant others.

Integrative Medicine

Integrative medicine programs may offer music therapy as one of the complementary therapies in mainstream medical care (16). Music therapists work in conjunction with multidisciplinary team members as partners in the care of patients and families. The aims are to facilitate well-being and improve quality of life, providing music-therapeutic relationships within which persons can express, explore, improve communication, and process issues concerning living and dying (22,23,32,33,34 and 35). The term *medical music therapy* is used to describe the role that music therapists have in mainstream medicine today (36).

Clinicians have documented the use of melodic and improvisational music in populations with breast cancer (37) and human immunodeficiency virus/acquired immunodeficiency syndrome (38,39,40 and 41). Other techniques, which have been described by practitioners who are not boardcertified music therapists, include the use of specific melodic music during the active process of dying (42), Tibetan crystal bowls and vibrational tones, and tools such as tuning forks. Music therapists sometimes incorporate variations of these techniques into their clinical work as a means to improve physiological functioning, enhance relaxation, and diminish awareness of pain.

Music therapists elaborate on the essence of the musictherapeutic relationship that resides in the human contact and the supportive, caring presence of the therapist (34,43,44). Music therapists realize the significance of their roles in establishing a compassionate, attentive, and creative milieu, within which patients and families can explore and regain a sense of dignity and existential meaning.

ART THERAPY

Art therapy started in the United States and in Europe in the 1940s and became recognized as a discipline and as a profession, with postgraduate university training programs and national associations, in the 1960s and 1970s (45). Although most art therapists work with psychiatric populations, art therapy has slowly developed into other fields, such as education, social services, and medical care. Approximately 20% of the art therapists in the United States are currently working with medically ill populations.

The term *medical art therapy* is now being applied to the use of art therapy with individuals who are physically ill, experiencing trauma, and undergoing aggressive and longterm medical treatments (46). During the 1980s, cancer centers and hospices started to welcome art therapists into their multidisciplinary teams, and the trend has been increasing. In England, a “special interest” group of art therapists working in palliative care was formed in 1993. This group, known as “The Creative Response,” aims to work “with the whole person,” according to the definition of palliative care given by the UK National Council for Hospice and Specialist Palliative Care Service: “controlling pain, easing suffering and enhancing life . . . integrating psychological and spiritual aspects of care . . . and offering support to families during the patient's illness and their bereavement” (47).

The writing of art therapists who work with patients in pain is relevant to the field of palliative care. From work with burn patients, Russell (48) developed a useful model of art therapy to help the physically traumatized patient move through five different stages: (a) expressing anxiety, (b) providing relaxation, (c) offering search for meaning, (d) providing a reparative experience of creativity, and (e) dealing with loss and mourning. Landgarten (49) also describes work with a chronic pain patient as a series of steps, including overcoming the need of denial, ventilation of fears, release of rage, and mourning. Long (50) lists four ways of using art therapy in a pain management service: (a) focused work to evaluate pain levels, using drawings of pain in the body and collage work to connect the pain with psychosocial stressors; (b) free drawing to allow and deepen the expression of the pain experience and its transformations; (c) family art therapy, when there is a dysfunctional dynamics in the family system; and (d) drawings about pain before and after physiotherapy to reinforce positive changes.

Rosner-David and Illusorio (51) have provided art therapy to patients with tuberculosis and have focused their work on the special needs of patients in isolation. Others have used art therapy to help patients suffering from acquired immunodeficiency syndrome; the approaches have ranged from individual single sessions to ongoing groups (52,53,54 and 55). Some of the most significant contributions from art therapists working with medically ill patients, specifically in palliative care, are included in three volumes published in the late 1990s (56,57 and 58).

The use of art therapy with children has been developing over the years. Art therapy with medically ill children may start from the body and the visualization of pain (59) and move to the broad area of the child's thoughts and emotions (60,61,62,63 and 64). It also may include the challenging and often forgotten field of children's spiritual needs (65). Councill (66) shows that art therapy may offer important contributions to any pediatric unit, at all stages of the child's illness: diagnosis, maintenance, and advanced-stage. Favara-Scacco (67) describes the use of art therapy techniques to support children with leukemia during painful procedures: the “clinical dialogue” to explain the medical procedures; “visual imagination” to activate an alternative thought; “medical play” to increase in the children a feeling of control; and both “free” and “structured” drawings to help them externalize and contain feelings of confusion, loneliness, and fear.

Stimulating reports have appeared that describe the use of art therapy with laryngectomy patients (68) and with mastectomy patients (69). Camic (70) explored the combination of different expressive modalities for the relief of chronic pain and Hiltebrand (71) described the use of different techniques of visualization and image manipulation. Minar (72) reflected on symbolic imagery in an art therapy group with cancer patients and described the recurrent images of the “hurter” and the “healer.” The use of mental and visual imagery to help cancer patients deal with their illness has been explored by Archterberg (73). Riley (74) illustrated the role of art therapy to facilitate communication and decrease the stress within the family and Belfiore (75) described the use of supportive art therapy to decrease stress in health care providers.

A range of innovative art therapy interventions is being developed to treat cancer patients in hospitals, hospices, and private homes. Connell (76,77 and 78) pioneered the use of art therapy with cancer patients at the Royal Marsden Hospital and experimented with special open groups, poetry writing and readings, and group notebooks containing new images and reflections made by the patients. These notebooks were designed to be looked at and read by the other patients, as a form of ongoing communication.

Thomas (79) described how it is possible to “create a space for stillness” for patients in the hospice. A 10-week art therapy program called “The Creative Journey” has been devised by Luzzatto in the Department of Psychiatry at Memorial Sloan-Kettering Cancer Center (80) to address the needs of patients undergoing bone marrow transplantation and having to be in isolation for long periods of 6–8 weeks (81). McGraw (82) described how the studio-based model of art therapy may help patients with chronic illness and pain focus on their healthy side, and Bell (83) has developed an “adaptive theme-oriented approach” for terminally ill patients in their own homes, in which issues of ill health, pain, suffering, aging, and dying emerge and are visualized and shared in the friendly setting of the family's kitchen.

It has been pointed out that art therapists working with the terminally ill have to be aware of their own responses to the existential themes of illness and death (84). In her review of the literature in the field of art therapy in palliative care, Wood (85) concludes that art therapy seems to be able to touch on “all aspects of the person's being.” This may be the specific contribution of art therapy—that it can provide “an experience which can address physical pain, can facilitate a search for meaning, can provide an outlet for strong feelings and can enhance the person's quality of life” (85).

STAGES OF THE THERAPEUTIC PROCESS IN MUSIC AND ART THERAPY

Although research in the effectiveness of the arts-based therapies is still scarce, numerous reports suggest that cancer patients may benefit in a special way from the use of creative modalities such as music therapy and art therapy. These expressive mediums can soothe pain as well as stimulate imagery and association, promote release of buried emotions, and provide creative spaces for the discovery or rediscovery of the inner self.

The connections between music and art are natural and obvious, as music and art are together part of the creative arts world. Music and art therapies are different professions, however, and make use of inherently unique therapeutic modalities. These modalities are based on two different senses—*hearing* and *sight*— and emphasize two different communicative dimensions—*time* in music therapy and *space* in art therapy.

The goal in music and art therapies is to facilitate expression and elaboration of the patient's internal world. Music and art therapists offer special tools to fulfill the same aims. The following is a summary of therapeutic factors that are characteristic of both music and art therapies and are particularly relevant in the cancer population.

1. *The protected expression of the negative.* Any “negative” experience, from physical pain to disturbing memories and emotions, may be expressed in a protected way, through the indirect and symbolic route of colors, shapes, and sounds. The patient may create a rhythm or melody or make an image, without explaining to anybody what it refers to, and possibly without knowing what it may refer to. Even when the physical sensation is about pain and the mental state is about suffering, the personal translation into sounds and images may give the patient important feelings of control and autonomy.
2. *The strengthening of the positive experience.* The creative process involved in the expression through musical instruments and art materials seems to have the capacity of transforming moods. This may happen in two directions: from active to receptive and from receptive to active. A patient who feels anxious may use sound-making, songs, or image-making to feel more relaxed. Likewise, a patient who feels fatigued and depressed may use different forms of these techniques and may start to feel pleasure and energy.

3. *A step toward verbal communication.* At times, the created piece of music or art may be an unconscious communication towards a relative or member of the staff. Other times, the communication may be conscious and intentional, i.e., the patient may “want” a relative to listen to his/her piece of music, or may “want” to show a certain image. After the first step of nonverbal communication, very often the patient desires to add words to the sounds, such as in songwriting, or to the image. Quite often the door is open at this point to say more and to feel more connected to others.
4. *Musical and visual elaborations.* Music and art therapists try to establish contact and break barriers, fill emptiness, and facilitate a psychoemotional “flow” in their patients and their significant others. The patient may feel no energy, or no hope or interest in what is happening inside (or outside) of self. It may be that the patient is feeling frustration, fear, or sadness—these feelings are forms of barriers. The music therapist knows that a sound stimulates another sound; the art therapist knows that an image leads to another image. The “flow” of the music and visual creation is very important, as it becomes a stimulus for the flow of the patient's own energy.
5. *Self-narrative and self-awareness.* Although music and art therapists have their own techniques to stimulate the patient's self-awareness and narrative, they both essentially use two main tools: nonrational “free association” and the more rational effort of “making sense” of what has emerged through the free association. Series of sounds or lyrics in songs may become personal songs, and series of images may become personal stories. These forms of self-exploration and self-revelation are usually connected to an experience of discovery about the self.
6. *Dealing with existential and spiritual needs.* Patients in palliative care settings are faced with questions about pain and quality of life, loneliness and life meaning, life and death. They do not necessarily have the answers to these questions. Care for “the whole person,” however, implies attention to this aspect of their lives. Music and art therapists realize that music and art offer the creative, lyrical, or symbolic means to address existential and spiritual needs during the process of dying.

INTERVENTIONS

Music Therapy

In working with patients who have life-threatening illnesses and their families, music therapists employ methods to attend to multifaceted needs. Regular and thorough assessments are critical to facilitate comfort and provide for meaningful expression and elaboration. Through questioning, observation, and interdisciplinary collaboration, therapists gain a perspective on the patients' perception of pain as well as the functions that affective, cognitive, and sensory processes are attributing to the experience. Music therapists become acquainted with prior musical skills, i.e., “music listener” (one's primary experience is as a listener), “music performer” (one has had numerous experiences as a performer), or “music eventer” (one associates music primarily around events in life) (5), to reestablish a sense of identity and to support the integration of music into the therapeutic process. Music therapists strive to create a musical space into which persons can enter, a space that invites reflection, identification, and exploration of thoughts, attitudes, memories, and emotions. Music is used that reflects the mood and overall needs, and is chosen and created by the music therapist, patient, and significant others. It is within this therapeutic milieu that symptoms of suffering may be alleviated.

Music therapy sessions can take place in various locations. Work is generally done at the patient's bedside, although work can also be done in clinic rooms, music therapy rooms in offices and outpatient centers, or at home during home care visits. Music therapists generally use a selection of instruments in their work, such as guitar, keyboard, harp, autoharp, stringed or woodwind instruments, crystal bowls, and percussion instruments. Patients and family members are offered opportunities to spontaneously create the music or to play or listen to favorite selections, live or recorded, of instrumental or lyrical music. The therapeutic aims are to facilitate self-discovery and enhance personal well-being, whether it is through the use of precomposed songs, instrumental and lyrical improvisation, toning and chanting, the use of imagery in music, or listening techniques.

Five case examples illustrate the types of interventions used by the music therapist. These patients were treated through the Music Therapy Program of the Integrative Medicine Service at Memorial Sloan-Kettering Cancer Center.

Use of Precomposed Songs

Songs are unique forms of musical presentations in that they combine words with rhythms, melodies, and harmonic tones. Precomposed songs are dynamic tools for use in music therapy because they convey thoughts, speak of feelings, and tell stories about the tribulations of humankind; or they present themes—such as love, faith, hope, or loss. Patients may select songs that reflect messages that are foremost in their thoughts, such as those reflecting deep yearnings, insecurities, or sorrows, or they may choose songs reflecting personal beliefs concerning life and meaning (86,87). Songs can be used to facilitate expression of “negative” and “positive” experiences in safety and may be used to promote communication. Often the patient is not conscious of the lyrical connections to immediate circumstances. However, choosing, singing, and listening to songs provides less threatening vehicles of expression among patient, family, and therapist, often deepening awareness of unresolved issues. Songs are also beneficial with emotionally fragile patients who may need the structure of words to guide frightening images and thoughts.

Case Example

Carl, age 28, was diagnosed with lymphoma after a 12-year remission from childhood Hodgkin's disease. He was recently married and had been leading a normal life before this onset of disease. He was referred to music therapy by the Supportive Care Program due to his intense neck and shoulder pain and his high levels of anxiety and tension. His verbal communications were limited to “yes” and “no” statements.

The music therapist approached Carl and offered to sing a song of his choice. He refused to select, but stated that he would like to hear music. The music therapist chose songs that reflected home and country, such as “Take Me Home Country Roads.” Carl rested on the bed and gazed at the ceiling. During the next session, Carl asked the music therapist if she knew the song “Mr. Bojangles.” During the song, he faced the therapist and stared intently at the guitar. He asked her to sing it again, only “this time, sing it louder.” She did, and when she arrived at the verse that stated: “his dog up and died, and after 20 years he still grieves,” Carl shouted, “louder, louder!” He asked her to sing the song several times that day as well as in the ensuing sessions, during which he repeated his requests for loud singing during the verse that spoke of loss and grieving. After several weeks of music therapy sessions during which Carl repeatedly requested to listen to “Mr. Bojangles,” Carl began to speak to staff and family members about his sorrow and grief, his desires to return home and to live the life that he knew.

In this example, precomposed song material provided a safe vehicle through which the patient could begin to express and process feelings of loss and sorrow in ways that could not be verbalized at that time. The opportunities for expression in this way helped mobilize his feelings as he moved from “protected expression” to “self-awareness.” He was then able to reestablish meaningful communication with others.

Improvisation

Instrumental and vocal improvisation offers opportunities for spontaneous expression in music, release, communication, and discovery. Because creativity can take any direction during improvisation, sounds, melodies, and rhythms can be played to portray the self through music in any way the person chooses. Thus, the music becomes a landscape of sounds that may depict deep inner feelings or thoughts. Improvisation is often done with the therapist offering support on the same or another instrument, providing the quality of “being heard” that is invaluable in therapeutic relationships. The use of the voice in improvisation adds the unique attribute of intimacy, because the voice is the most intimate means of self-expression. The voice can accompany instruments or can be improvised solo, with or without the addition of chosen lyrics. Vocal improvisation can include spontaneous songwriting with lyrics that articulate personal messages. Improvisational techniques provide for unconscious or intentional disclosure of emotions and can lead to deepened awareness, self-identity, and relatedness with others. Common improvisation techniques include active playing of instruments to express self, listening to improvisations that may reflect moods or images, and songwriting.

Case Example

Alex, age 57, was an academic achiever, with numerous professional roles in the education and health care professions. He was referred to music therapy due his agitation, restlessness, and pain. At the time of referral, he was in the advanced stages of lymphoma and was receiving chemotherapy to diminish some of his distressing symptoms.

The music therapist visited Alex and explained the potential for music to help express (as well as to diminish) pain. After listening to quiet reflective music of his choice, Alex appeared calm and relaxed until another staff member entered and offered to help move his swollen legs. He then became agitated, only reluctantly agreeing to let her help him.

The music therapist then offered the keyboard to Alex. He situated it on his lap in bed and began to slowly play 8- to 10-note, free-flowing melodies. He played for nearly 20 minutes nonstop, and directed the music therapist to stand near him with the guitar to strum with him. She followed his music by combining notes with chords. He played with intensity and determination and then requested to play for his wife as she entered the room. He became energized and immersed in the sounds. His wife stood by his side and listened to the lengthy improvisation. When he finished, he said, “That was my concerto. When can I do this again?”

The music therapist offered to return the next day and following days. Alex continued to use improvisation and began to have a renewed sense of identity and feelings

of control. His agitation diminished as he found new ways to create and direct the outcome of certain events. He also began to compose songs with the music therapist articulating his feelings of love for his family, his feelings of satisfaction concerning his accomplishments in life, and his feelings of sorrow regarding his approaching death. One song in particular was his favorite, a song that he and the music therapist wrote about his success in rescuing a mother and baby dolphin, also seeming to speak poignantly of his deep love for his family:

> “eye to eye, heart to heart, in spirit we're never apart;
> I trust you, you trust me, Oh dolphins of the sea.”

In this example, improvisation offered the patient meaningful exploration and sensitive communication with his family during a time of pain and loss. This technique allowed the patient free space to express suppressed feelings and experience a renewed sense of self-worth in taking an active role to provide for his wife and family. As seen in this example, the spontaneity that is characteristic in improvisation enhances interrelatedness between patient and others and opens passageways of communication.

Chanting and Toning

Chanting and toning have been used for centuries in indigenous cultures as ways to commune in fellowship, achieve spiritual enlightenment, and gain physical comfort or strength. Toning has been used as a method in spiritual practices to improve spiritual and physical well-being. Likewise, chants are common to every culture as a means to focus intention and unite in purpose.

These techniques are useful in therapeutic arenas as methods to promote attentiveness and relaxation. Toning is the use of vocalized vowel sounds at various pitches (88). Toning is used in music therapy to stimulate energy flow and enhance sensory awareness. Music therapists work closely with patients in pain to engage cognitive processes—that is, to actively vocalize and “breathe” sound “to,” “in,” “around,” and “away from” the pain. Such vocalizations, when possible, can energize and bring the release of tension and the eventual refocusing of attention. The technique of toning also offers the patient a tool that he or she can use during pain episodes, such as vocalizing with exhalations to express the pain, release tension, and refocus attention.

Chanting is similar in that vocalizations are repetitive (89). Chanting, however, includes the dynamic of tempo and the use of words that are purposefully selected by the patient and family. Music therapists establish a rhythmic pattern that is suitable to the moment, often matching the patient's rate of respiration and then changing to a tempo that could potentially result in relaxation. This use of rhythm follows the familiar music therapy method of entrainment, wherein sound stimuli “lock in” and can influence the flow of physiological responses such as heart rate and breath rate (90). The repetitive nature of chanting is soothing and lulling. The words selected often reflect desire, hope, faith, or personal strengths. Chanting, then, can result in increased awareness, improved levels of comfort, and a restored sense of self-efficacy.

Toning and chanting are beneficial to those seeking tools to help themselves regain a sense of control, as well as those with difficult-to-manage pain who are hoping to find ways to call on their inner resources. However, toning may not be suitable for emotionally fragile patients, who may need the direction and guidance of structured music, such as songs or formal compositions, to help assuage hyper reactions or to placate frightening images and feelings of apprehension. Toning and chanting can, however, help mitigate symptoms for many patients and families.

Case Example

Bonnie, age 56, was admitted to the hospital for the first time shortly after her diagnosis of stage IV ovarian cancer at another medical center. She had just received the news of her advanced disease and was told that she could receive chemotherapy as an attempt to deter further progression of disease. She agreed and planned to stay for treatment. The nursing staff referred her to music therapy due to her pain, fear, and overwhelming anxiety.

As the music therapist went into the room, Bonnie spoke quickly and said “please come in and stay by me . . . I am so afraid.” She was alone, and, leaning back on her bed, appeared to be in discomfort due to abdominal distention. The music therapist sat near Bonnie and listened to her relate her story. Bonnie wept as she talked and shared how out of control she was feeling. After she finished talking, the music therapist offered music therapy and Bonnie was eager to try.

Because the initial goals in music therapy are to attend to immediate needs, the music therapist offered toning and chanting to help Bonnie regain focus and sense of control, while also providing her space within chanting to begin to further articulate her feelings and thoughts. She leaned back on her pillow while the music therapist sat near her and made soft tones, progressing from low to high. At the start, Bonnie made some sounds too and then fell asleep.

Bonnie requested toning sessions daily. She also began to chant images of favorite places and words describing her attributes. Often, her close friends joined in the sessions, surrounding her bedside. Bonnie exclaimed that the toning and chanting refreshed her in ways that “words can't describe” and that she had a regained sense of self-identity. She became less anxious and more relaxed. After discharge, she went home for 2 weeks before she died, during which her friends toned and chanted with and for her at her side.

In this example, these techniques became important tools for the patient to use to renew her fleeting sense of self. Through opportunities to “hear” her own voice and to “feel” the sound vibrations within her, Bonnie was able to “feel” in touch with her physical self once again, as well as be in touch with the “chanting” words that had special meaning to her.

Imagery in Music

The use of imagery within the context of music is a technique that can be used with active or receptive participation. The active use of imagery in music is beneficial for patients who are encumbered by long periods of anxiety or isolation. It can open pathways of communication regarding buried emotions or memories of significant events. This technique can offer opportunities for “protected expression,” to explore images and the related feelings that arise in the music within sessions. Thus, the active support of the music therapist is vital. The receptive use of imagery in music may be offered to patients who have episodic pain, nausea, insomnia, or other disease-related symptoms. Receptive use of imagery is also used with patients who may be too weak to articulate thoughts. Patients may benefit from focusing on images to guide thoughts, help calm anxiety, or focus on the “pleasing” sensations of the music. The therapist inquires about the images that are helpful to the patient and then spontaneously sings the images, encouraging the patient to relax breath flow and tension and to “drift” with the music.

Case Example

Ann, age 63, was referred to music therapy due to pain associated with advanced breast cancer. She was a nurse specializing in gerontology and had lived a very active life until this admission. She smiled broadly when the music therapist entered the room. She was alone sitting quietly in bed. She talked briefly about her “difficult-to-cope-with” pain, but then changed the subject, relaying her love for the sea and how she missed seeing it that summer. She closed her eyes and leaned back on her pillow. The music therapist began to play the guitar softly, encouraging Ann to look out over the water during the music. She then asked Ann to convey what she saw in her internal gaze. The therapist then sang a progression of images, moving over the sea and describing the colors, sounds, smells, and views clearly.

> “blue calm waters all 'round me”
> “wide blue sky now over me”
> “warm sea sand now covering my feet”

While listening, Ann appeared deeply relaxed. As the music continued, she suddenly raised her arms gently and moved them up and down. The therapist followed her movements with the music. She whispered, “I am flying and my shoulder isn't hurting.” The music continued until Ann rested once again and fell asleep.

During later sessions, Ann requested to receptively engage in imagery in music. She selected the places where she wished to travel with the therapist in the music. She routinely became relaxed and often smiled peacefully. She repeatedly claimed that the music helped her pain “drift away.”

The use of imagery in music helped this patient, as it does others, transport attention into places of interest. This process, while aiding in the reduction of awareness of pain, can instill a sense of peace. Images relating to memories can sometimes evoke emotions of sorrow and feelings of loss. Thus, the support of the therapist plays a significant role. It is beneficial for this technique to be improvised spontaneously to provide for supportive verbal interventions and for meaningful and manageable flow of images.

Music Listening Techniques

Patients sometimes request to listen to live or recorded music in music therapy to reminisce, reflect, introspect, or refocus attention. Listening to familiar music naturally

stimulates association and builds bridges to memories. This music can take a person immediately back to a certain time and place, the sights, sounds, and often smells of which are imprinted in the memory. Patients often request to hear significant musical selections as ways to reminisce and rebuild connections to transformative events in life, such as relationships with spouses, young children, friends, or parents in early childhood. In advanced stages of illness, there is a focused tendency to reflect on the past, a process that helps resolve unresolved issues and build self-esteem through reflection on accomplishments. This process also can help “make sense” of current predicaments through the introspection on existential meaning and the “purpose” of one's life. Familiar music can stir emotions and conjure feelings of loss and grief. During such reminiscences, the supportive presence of the music therapist can help facilitate. exploration, rebuild communication with significant others, and help patients, when ready, come back to the present with new awareness and insight.

Listening to unfamiliar music is also beneficial. Such music does not necessarily contain the inherent associative attributes that familiar music does. The sounds of new melodies, harmonies, and rhythms can offer opportunities to reflect on inner imagery and help the patient focus on immediate feelings and needs. Unfamiliar music is suggested for use in the management of acute pain due to this potential for engagement without the strong presence of past memories.

The music therapist may improvise melodies and lyrics to reflect mood and medical requirements, i.e., adapting the rhythm of the music to breathing rate and then altering tempo to facilitate improved relaxation or energy flow. The music therapist also can encourage “mindful music listening” (91) as a particular way to benefit from music. This technique combines music with some of the principles set forth by Jon Kabat-Zinn in his mindfulness-based stress reduction methods (92). Patients are encouraged to practice sensory awareness by listening carefully to the instrumentations, paying attention to breath and muscular tension release, and centering themselves in the moment in the music. Such focus can result in a diminution of apprehension and fear as well as a deepened state of relaxation.

Case Example

Michael, age 44, was diagnosed with acute myelogenic leukemia at another hospital in a faraway state. He was not responding to the lengthy chemotherapy treatments there and came to a new hospital for further evaluation and care approximately 2 months after diagnosis. His leukemia was aggressive, and he was fatigued and lethargic. He was referred to music therapy due to his anger, feelings of frustration, and controlling behaviors. He agreed that he would try music therapy due to his “life-long favorite past time of listening to music.”

As the music therapist approached him, he immediately directed her to sit in a chair and listen with him to his favorite compact discs. She did, and listened to him talk at length about the recordings and the memories associated with them. He also stated that he felt very alone and was “trying to keep strong to fight this leukemia.” He asked her to return daily, if possible.

The frequent music therapy sessions were centered on listening to Michael's favorite music. He continued to reminisce at length about his relationships, those that he regretted and those that he treasured. As he listened, he talked about his feelings of dissatisfaction with life's events and his general frustration. Together they listened to recordings of songs that began to reflect and support his verbalizations. The music therapist also sang new songs that articulated some of his thoughts. Michael gradually began to release some of his sorrow and anger as, with the help of the music therapist, he made a “musical journal,” containing titles of songs that depicted significant events in his life. The music therapist taught him “mindful music listening” to use during the nighttime episodes of tension that distressed him. Over time in music therapy, during a 6-month hospitalization before his death, Michael reported improved comfort, exhibited fewer controlling behaviors, and obtained an enhanced sense of self-esteem and self-appreciation.

Listening to music helped this patient achieve a closer view and deepened perspective on the events in his life. The process of reminiscence and the elaboration of feelings associated with memories can assist in the resolving of unfinished business and help patients renew a sense of selfappreciation for personal strengths and accomplishments. Listening to music for Michael, as it can for others, also provided for enhanced relaxation during times of discomfort, anxiety, and insomnia.

Art Therapy

Art therapy interventions in pain management and palliative care are focused on assisting patients in expressing, exploring, and transforming sensations, emotions, and thoughts connected with physical and psychological pain. The art therapist may meet the patient in different settings and offer a variety of therapeutic interventions.

Some patients are seen individually, in the privacy of their hospital room. The art therapist takes a minimum set of art materials, which may consist simply in a block of white paper, a set of colored markers, and a set of oil pastels. Although these bedside interventions are usually brief encounters with the art therapist due to the patient's short length of stay in hospital, they still may be very meaningful for the patient. When the patients are in isolation for bone marrow transplantation, the relationship may become ongoing for the whole time of isolation, and might even continue after discharge.

Other patients are invited to attend an art therapy open studio, in which a group of patients works on individual projects in a quiet, often silent setting, or with suitable music in the background. The open studio, which may be held by the art therapist in the patients' lounge or library, or even in a waiting room, allows patients to drop in and stay as long as they want, according to how they feel at that moment. In the open studio there may be more art material available to stimulate the patients' creativity, and silence is respected to convey a feeling of privacy and safety.

Yet other patients may wish to join an ongoing art therapy group, in which patients meet and interact with each other, often explaining the meaning of their pictures and responding to the images of the other members in the group. The group may be open to new patients every week, or it may be a closed group, with the same patients meeting regularly for a year or longer. A series of art therapy workshops may be offered on specific themes, such as stress management, dreams and fantasies, negative feelings and their transformations, and working towards inner peace. Other art therapy workshops may focus on the patients' free expression and creativity.

Finally, a patient also may be seen individually for shortterm or long-term “art-psychotherapy” to deal with some deeper personal issue or to modify dysfunctional ways of coping with the illness. In this context, the art therapist devotes more time to the verbal interaction with the patient, and to cognitive and psychodynamic interventions, in addition to the symbolic work with the patient's imagery. The therapist may help the patient relate to the imagery, understand it, and explore alternative images.

Five case examples of “brief” art therapy interventions illustrate the varied approaches. These patients were treated in the Department of Psychiatry and Behavioral Sciences at Memorial Sloan Kettering Cancer Center.

Case Example 1: Focusing on the Pain

This patient decided to paint her pain (Fig. 72-1, “The Wound”). This is usually a complex experience, involving concentration on the body, on one level, and on the white page that is outside the body on another level. The patient may experience both the physical pleasure of using colors and shapes, and the psychological positive experience of giving form to something unformed. This combination of factors may increase the capacity to tolerate the pain experience. This patient said that after painting her pain she could “look at it” and “distance herself” from it. Furthermore, in the act of choosing the title for her image, she selected a word that is rather ambiguous (“the wound”), as it may refer to a physical pain and also to a psychological pain, and she liked the ambiguity. The whole experience was relaxing and meaningful for her.

Case Example 2: Transforming the Pain

This patient wanted to modify the pain experience through the act of painting (Fig. 72-2, “Turning Pain from Bad to Good”). The kinetic quality of the art therapy experience is used here as a therapeutic factor. The art therapist offered a circular form (called *Mandala*), and the patient filled it with colors he selected, starting from the center and moving towards the outside (the Mandala may be used also with a movement from the outside toward the center, with a different therapeutic aim of feeling “centered”). This patient needed to experience an expansion away from the pain, toward other people and other aspects of his life. Some patients need to reaffirm positive feelings, whereas others need to express the negative ones. This patient experienced a transformation of his pain and entitled his work “from bad to good.”

Case Example 3: Integrating Negative and Positive

Figure 72-3, “The Mystery of Life and Death,” was made with the simple technique of placing some tempera with a brush in the center of the page, then folding the page, playing with the finger on the paper to spread the paint, then opening up the sheet and finding out what has happened (it is a very simple technique, often used with children in school). One of the main features of this technique is the element of unpredictability and surprise about the final outcome of the picture. The simplicity of the technique did not prevent this patient from developing an image that is quite deep in its meaning. She chose the black tempera, folded the paper, and played with her fingers on the folded paper for quite a while, which was a relaxing movement in itself. She had in mind the theme of “life and death,” and she wanted to end up with an image of some white spaces in between black spaces. The shape that emerged was partly the shape she wanted, but partly a surprise. She said it helped her to give form to her feeling, that death for her was not bad or frightening but was more like that picture: unpredictable, “a mystery.”

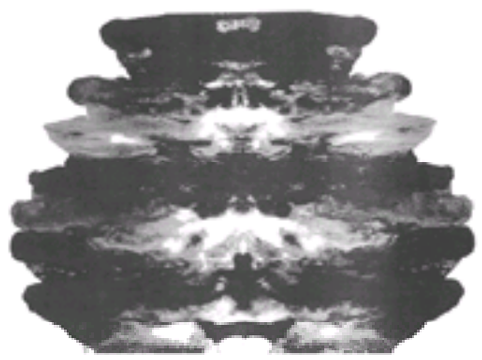

FIGURE 72-3. Integrating negative and positive: “The Mystery of Life and Death.” (Permission granted and copyright held by Paola Luzzatto, Ph.D.)

Case Example 4: Combining Visual and Emotional Processes

Figure 72-4, “Future,” is the result of a long session with a suicidal patient, who was referred by a social worker. The suicidal feeling was first expressed through the choice of the black paper. The patient had been talking and crying with the social worker for a long time, without finding any relief from her despair. Slowly, the patient moved into a different direction, toward a feeling of hope, mainly through the silent relationship with the art materials, within the supportive relationship with the art therapist. This session is an example of how the tool of free association may be important to help a patient to move from a negative to a more accepting state of mind. The patient started with the black paper, then decided to explore her free associations to the color “white”: She imagined “a white blanket” and “a baby under the blanket,” then she imagined “white milk . . . spilled on the kitchen's floor.” Very slowly she moved on to other memories, connections, and fantasies, and ended up with the image of a “white flower” with a yellow center and green leaves. She glued each piece on the black paper. At this point, the patient decided to call this collage “Future”; she told the art therapist that she felt OK, and added the following statement: “I was able to do this, because I was not talking, and therefore I was not crying. I could concentrate, and this happened almost by itself. There is no doubt that something happened, and I feel different about life.” She thanked the art therapist, and she left.

Case Example 5: Responding to Spiritual Needs

Many art therapists find that when the patients are in pain, or they are very weak and cannot sit up on the bed, or cannot hold art material in their hands, it is not possible to have an art therapy session. Nevertheless, apart from the possibility of working with visualization and mental images, the patient who has an image in mind at times may guide the art therapist to “make the image for him/her.” In Figure 72-5, “The Spirit Inside Me,” the patient was shown a preformed body outline, and she told the art therapist how to fill it. She described in detail that she wanted the inside of the body “white” and the outside of the body “blue,” with three flowers on both sides at her feet. Then she wanted some “yellow and orange” outside the circle, and the titles: “The Savior for All” on the top and “The Spirit Inside Me” at the bottom. She was very pleased with the result, and she wanted to hang it in her hospital room. She died a few days after she had made this image, and this picture became an

important legacy for her family.

CONCLUSION

The use of music therapy and art therapy as palliative care interventions requires flexibility and innovation from music therapists and art therapists. New concepts and new interventions are being developed in this field in many countries around the world. Exciting developments are occurring within each of these two disciplines, and cooperation is growing among all creative arts therapies, including movement, poetry, and drama therapies.

The role of the music therapist and of the art therapist within an interdisciplinary team still needs to be clarified, and the specific contributions that these new modalities can offer must be better understood and researched. There are some common misunderstandings: The role of music and art therapists must not be confused with the role of recreational therapists or “arts healers,” who also fulfill essential but different needs. They also must not be seen as providing a specialized activity for musically or artistically talented patients. But where, when, and how are music therapists and art therapists most needed and most helpful in the context of palliative care? Through analysis of the literature and through our own clinical experience in this field, we have come to the conclusion that music and art therapists seem to be particularly effective in three areas: (a) the enhancement of positive feelings of calmness, relaxation, and personal well-being, (b) offering safe cathartic expressions and transformations of sensations and emotions, and (c) facilitating the elaboration of existential and spiritual issues on symbolic and creative levels. On this basis, the inclusion of these two modalities among the interventions offered by a palliative care team could greatly increase its effectiveness.

ACKNOWLEDGMENTS

We wish to thank Dr. Jimmie Holland, Chairman of the Department of Psychiatry and Behavioral Sciences at MSKCC, for her pioneering support of this music therapist's work in the early 1970s and her visionary introduction of Art Therapy as part of the Psycho-Oncology Service in 1995. We also wish to thank Dr. Barrie Cassileth, Chief, Integrative Medicine Service at MSKCC, for her innovative introduction of the Music Therapy Program in the Integrative Medicine Service in 1999. We also thank Dr. Russell Portenoy for his ongoing interest in and support of the use of these therapies in supportive oncology and palliative medicine. We also wish to extend heartfelt gratitude to patients and families, and to the internship students, who, through their courage, reflections, and insights have helped us gain deeper understanding of the role of music and art therapies in supportive oncology and palliative medicine. We thank the patients who gave permission to use their pictures (Fig. 72-1, Fig. 72-2, Fig. 72-3, Fig. 72-4 and Fig. 72-5) and the intern, Roy Capps, for his work with the patient who created “The Spirit Inside Me” (Fig. 72-5).

COMPLEMENTARY AND ALTERNATIVE APPROACHES

BARRIE R. CASSILETH

A vast collection of disparate approaches, from unproved cancer cures to soothing, adjunctive regimens, is subsumed under the single umbrella term “complementary and alternative medicine,” known commonly by the acronym “CAM.” Although they are typically discussed in the aggregate, it is clinically and conceptually necessary to distinguish between the two categories because they comprise profoundly different modalities.

Alternative therapies generally may be perceived literally as such; they are promoted as cancer treatments and sometimes as cancer cures, and are often sold for use instead of mainstream therapy. By definition, alternative therapies are unproved. If they were backed by solid data, they would not be “alternative.” Rather, they would be found in every oncology program and used as viable cancer treatments.

Alternative regimens, which are typically invasive and biologically active, are usually very expensive and potentially harmful. They may harm directly through physiologic activity, or indirectly when patients postpone receipt of mainstream care. Late-stage patients are especially vulnerable to these therapies, as they often promise cure of even advanced disease.

Complementary therapies, in contrast, are used for symptom management and to enhance well-being. They serve as adjuncts to mainstream care; promoted not as cancer cures, but as means of enhancing patients' quality of life. Complementary therapies are supportive, palliative care in every respect. They address body, mind, and spirit, aiming to control pain and other symptoms and to optimize quality of life for patients and families. This definition is essentially identical to that proposed by the World Health Organization for palliative care (1).

In CAM, therefore, we must work with two poles of a continuum. Patients need the knowledge and support to forego the siren calls to seek metabolic therapies in Tijuana; to buy shark cartilage; to self-treat with high-dose vitamins and other products sold over the counter or delivered intravenously in alternative clinics; and to seek remission of disease through self-proclaimed healers, electromagnetic cures, and many other products and approaches.

At the same time, patients need access to the comfort of supportive complementary modalities. These therapies are becoming increasingly available not only directly to patients on a private basis, but also in hospitals, clinics, and homes as part of symptom control and the general effort to ease the physical, psychosocial, and spiritual distresses associated with cancer and especially with end-stage disease.

This chapter addresses the state of CAM in the larger health care system, and reviews the alternative therapies that are so widely and temptingly available to patients and families. Physicians and other caregivers need to know about these pervasive alternatives. Helpful complementary therapies are reviewed as the conclusion to this chapter.

IMPACT OF COMPLEMENTARY AND ALTERNATIVE MEDICINE ON THE HEALTH CARE SYSTEM

The acceptance of unconventional therapies, along with the advent of managed care, advances in biotechnology, and other significant medical and societal events, marked health care in the 1990s and was among the significant changes that occurred during that time. The popularity of CAM has affected every component of the health care system and all specialties of medicine, including palliative oncologic care. It has left its mark on the thinking and practice of physicians and other health professionals, and broadened patients' involvement and influence in their own care.

No longer a collection of covert practices (2), unconventional cancer medicine today is highly visible, and information about it is widely available to the general public. It is a multibillion dollar business in the United States, and of equivalent impact and importance throughout the developed world.

Internationally as well as in North America, the use of CAM for cancer is widespread. A systematic review (3) located 26 surveys of cancer patients from 13 countries, including five from the United States. The average prevalence of CAM use across all studies was 31%. Therapies most commonly adopted around the world included dietary treatments, herbs, homeopathy, hypnotherapy, imagery or visualization, meditation, megavitamins, relaxation, and spiritual healing. New investigations substantiate these results (4,5 and 6).

All but one of the United States surveys obtained information about specific therapies employed. Patients used Laetrile, metabolic therapies, diets, spiritual healing, megavitamins, imagery, and “immune system stimulants” (3). Across samples, the prevalence of CAM use in the United States ranged from 7% to 50%.

Additional surveys involving members of the U.S. general public (not cancer patients) uncovered prevalence rates of one-third in a representative sample of 1539 adults as reported in 1993 (7). Two surveys published in 1997 report prevalence rates of 50% of 113 family practice patients (8) and 42% of 1500 members of the general public (9). A 1998 publication reports that 42% of 2055 people surveyed used CAM (10). A large, 1999 survey of over 24,000 individuals found 8% use of CAM, with or without mainstream care (11).

Prevalence rates from all CAM studies, conducted in the United States and internationally, vary from less than 10% to more than 50%. This broad range, with its apparent discrepancies, may be attributed primarily to variable understandings and definitions of CAM. Surveys often do not define CAM, or more typically, define it extremely broadly, resulting in the inclusion of lifestyle activities such as weight loss efforts, exercise, church attendance, and support activities such as group counseling, thus resulting in bloated figures for CAM use. Moreover, few studies distinguish between use of alternative therapies (in lieu of mainstream cancer treatment) versus adjunctive use of complementary modalities.

Although research evidence is scanty (2), it appears that approximately 8–10% of tissue-biopsy diagnosed cancer patients eschew mainstream therapy and immediately seek alternative care. The vast majority of CAM users, however, seek complementary, not alternative, therapies for cancer.

The profound influence of 1994 legislation allowing herbal medicines and other “food supplements” to be sold over the counter without U.S. Food and Drug Administration (FDA) review is evident in the increased use of herbal remedies from 3% in 1991 to 17% in 1997 (11). It is estimated that sales of dietary supplements more than doubled in the 6 years since passage of the 1994 law. However, herbal supplements sales began to decline in 1998, growing just 12% that year, and sales grew only 1% in 2000 (12). The decline is presumed to be due to several factors, including unrealistically high public expectations, media reports about safety concerns

and questionable effectiveness, and public confusion about the vast array of products (12).

Virtually all studies conducted to date of cancer patients and of the general public internationally show that those who seek CAM therapies tend to be female, better educated, of higher socioeconomic status, and younger than those who do not. They tend to be more health conscious and to use more mainstream medical services than do people who do not use CAM. Despite the drop in sales of herbal remedies, there is indication of a growth in CAM use by cancer patients in recent years (3); a secondary analysis of close to 3000 cancer patients estimates a 64% increase after 1987 (13). It is likely that this reflects expanded use and variety of over-the-counter remedies and broader availability of complementary therapies in mainstream cancer programs and centers.

Complementary and Alternative Medicine Use among Pediatric Cancer Patients

The use of CAM methods among pediatric oncology patients represents a special and understudied issue. Surveys in Australia and Finland (3), in British Columbia (6), and in the Netherlands (14) indicate substantial interest in CAM, especially in more recent years, with 40–50% of pediatric oncology patients in those countries receiving alternative or complementary therapies.

Few studies of CAM use among U.S. pediatric oncology patients have been published in the past 10 years (15). A 1998 article reported that 65% of 81 U.S. cancer patients used CAM, whereas 51% of 80 control-group children receiving routine checkups did so. Of particular interest is the type of CAM received. Prayer, exercise, and spiritual healing accounted for more than 96% of CAM used. Excluded from this sample by definition, however, were the pediatric patients brought for alternative treatment to clinics in the United States, Mexico, or elsewhere. Patients who received only alternative cancer therapies did not appear in CAM surveys, because all but one such survey were conducted in mainstream clinics or hospitals.

Public Access to Information

CAM today is very much an open and public issue, discussed widely in the media and readily found on the Internet. Magazines and television specials provide the general public with details about new CAM therapies. The yellow pages of telephone books in most cities and towns typically list various types of CAM practitioners.

Information available to the public varies widely in accuracy. Many Web sites and publications that appear to be objective actually are sponsored by commercial enterprises that promote and sell the products they report. Misinformation about health issues is widespread. In 1999, the U.S. Federal Trade Commission (FTC) announced that it had identified hundreds of Web sites promoting and selling phony cures for cancer and other serious ailments among the estimated 15,000–17,000 health-related Web sites (16).

In 2001, the FTC told six companies to stop making false health claims, including the claim that mild electric currents kill parasites that “cause” cancer and Alzheimer's, and that herbs should be used to treat cancer instead of conventional treatments such as surgery and chemotherapy (17).

This is part of the FTC's “Operation Cure All,” an effort to stop bogus Internet health claims (18). The U.S. Department of Health and Human Services released a report expressing concern about the lack of information to enable consumers to properly evaluate the credibility of Internet health information (19).

Recognition by Mainstream Journals and Physicians

A survey of 295 family physicians in the Maryland-Virginia region (20) revealed that up to 90% view complementary therapies such as diet and exercise, behavioral medicine, and hypnotherapy as legitimate medical practices. A majority refers patients to nonphysicians for these therapies or provides the services themselves. Homeopathy, Native American medicine, and traditional Oriental medicine were not seen as legitimate practices.

Two hundred Canadian general practitioners held similar views, noting their patients' interest especially in chiropractic. These physicians perceive chiropractic care, hypnosis, and acupuncture for chronic pain as the most effective CAM therapies, and homeopathy and reflexology as less efficacious (21). A meta-analysis of 12 studies in Great Britain suggests that British physicians view complementary medicine as only moderately effective (22), a level of enthusiasm that contrasts with the fervent efforts of the British Royal Family to promote homeopathy and other complementary therapies, and to merge them with mainstream care.

In addition to increasing coverage of CAM services by health insurers, a final marker of mainstream interest noted here is the publication of CAM research articles in major mainstream medical journals. Articles about CAM in major journals shifted from commentaries through the 1970s expressing realistic concern about quackery (e.g., 23–25), to surveys of patients' knowledge and use of unproven methods in the 1980s (e.g., 26–28), to reports of actual research results starting primarily in the mid-1990s.

The *Journal of the American Medical Association*, the *New England Journal of Medicine*, the *Lancet*, the *British Medical Journal*, and specialty journals such as *Cancer* and the *Journal of Clinical Oncology* have published reports of CAM research in recent years. In 1996–1997, the National Library of Medicine added many new CAM search terms to its medical subject headings, and began to cover alternative medicine journals previously not reviewed for inclusion in Medline.

However, not all mainstream physicians are pleased with CAM, with current efforts to integrate CAM and mainstream medicine, or with a separate National Institutes of Health research entity for CAM (29,30 and 31).

COMPLEMENTARY AND ALTERNATIVE MEDICINE THERAPIES AND PRACTITIONERS

CAM therapies may be categorized in a variety of ways. The seven categories noted here were developed by the Office of Alternative Medicine (32), now the National Center for Complementary and Alternative Medicine: diet and nutrition; mind-body techniques; bioelectromagnetics; alternative medical systems; pharmacological and biological treatments; manual healing methods; and herbal medicine. Currently popular therapies are discussed within each of these categories. Most of these approaches are unproved methods promoted as alternatives to mainstream cancer treatment. Helpful complementary or adjunctive therapies are discussed separately at the end of this chapter.

Diet and Nutrition

Advocates of dietary cancer treatments typically extend mainstream assumptions about the protective effects of fruits, vegetables, fiber, and avoidance of excessive dietary fat in reducing cancer risk, to the idea that food or vitamins can cure cancer. Proponents of this belief make their claims in books with titles such as *The Food Pharmacy: Dramatic New Evidence that Food is your Best Medicine*, *Prescription for Nutritional Healing*, and *New Choices in Natural Healing*.

The macrobiotic diet is a persistently popular example of such dietary approaches. As currently constructed, it is similar to recent U.S. Department of Agriculture dietary pyramid recommendations for healthful eating, except that the macrobiotic diet omits dairy products and meat. This diet derives 50–60% of its calories from whole grains, 25–30% from vegetables, and the remainder from beans, seaweed, and soups. All animal meat and certain vegetables and processed foods are to be avoided, and soybean consumption is promoted. Despite claims in publications and Web sites, there is no evidence that the macrobiotic diet can cure or is beneficial for patients with cancer. Moreover, this diet may be nutritionally deficient and can cause problematic weight loss, especially in patients with advanced cancer.

Metabolic Therapies and Detoxification

Metabolic therapies continue to draw patients from North America to the many clinics in Tijuana, Mexico. These therapies involve practitioner-specific combinations of diet plus vitamins, minerals, enzymes, and “detoxification.” One of the best known sites for metabolic therapy is the Gerson clinic, where treatment is based on the belief that toxic products of cancer cells accumulate in the liver, leading to liver failure and death. The Gerson treatment aims to counteract liver damage with a low-salt, high-potassium diet, coffee enemas, and a gallon of fruit and vegetable juice daily (33). The clinic's use of liquefied raw calf liver injections was suspended in 1997, after sepsis in a number of patients.

Other Tijuana clinics and practitioners provide their own versions of metabolic therapy, each applying an individualized dietary and “detoxification” regimen. Additional components of treatment are included according to practitioners' preferences. Metabolic regimens are based on belief in the importance of “detoxification,” which is thought necessary for the body to heal itself. Practitioners view cancer and other illnesses as symptoms of the accumulation of toxins. This is a nonphysiologic but venerable concept that originated in ancient Egyptian, Ayurvedic, and other early efforts to understand illness and death, both of which were believed caused by the putrefaction of food in the colon. Decay and purging were major themes in early cultures' therapeutic regimens. Neither the existence of toxins nor the benefit of colonic cleansing has been documented.

Modern variations on the older approach to internal cleansing are drinkable cleansing formulas, said to detoxify and rejuvenate the body. Many variations are available

in health food stores, books, and on the Internet. A shake of liquid clay, psyllium seed husks, and fruit juice, for example, is said to remove harmful food chemicals and air pollutants (34). These products tend to function as major laxatives, potentially dangerous when taken over days or weeks or on a regular basis as recommended by promoters, and of special concern for cancer patients.

Megavitamin and Orthomolecular Therapy

Some patients and alternative practitioners believe that large dosages of vitamins—typically hundreds of pills a day—or intravenous infusions of high-dose vitamin C can cure disease. In 1968, Nobel Laureate Linus Pauling coined the term “orthomolecular” to describe the treatment of disease with large quantities of nutrients. His claims that massive doses of vitamin C could cure cancer were disproved in clinical trials (35,36), but megavitamin and orthomolecular therapy—the latter adds minerals and other nutrients— remain popular among cancer patients. There is no evidence that megavitamin or orthomolecular therapy is effective in treating any disorder.

Mind-Body Techniques

The potential to influence health with our minds is an extremely appealing concept in the United States. It affirms the power of the individual, a belief intrinsic to U.S. culture. Some mind-body interventions have moved from the category of alternative, unconventional therapies into mainstream complementary or supportive care. Good documentation exists, for example, for the effectiveness of meditation, biofeedback, and yoga in stress reduction and the control of some physiologic reactions (37,38).

The argument that patients can use mental attributes or mind-body work to cure cancer is not tenable (39,40). Attending to the psychological health of cancer patients is a fundamental component of good cancer care. Support groups, good doctor-patient relationships, and the emotional and instrumental help of family and friends are vital. However, the idea that patients can influence the course of their disease through mental or emotional work is not substantiated and can evoke feelings of guilt and inadequacy when disease continues to advance despite patients' best spiritual or mental efforts (41).

Bioelectromagnetics

Bioelectromagnetics is the study of interactions between living organisms and their electromagnetic fields. According to proponents, magnetic fields penetrate the body and heal damaged tissues, including cancers (42). No peerreviewed publications could be located for this work, or for any clinical cancer-related claims regarding bioelectromagnetics. Despite the lack of data and the patent absurdity of these claims, proponents continue to sell electromagnetic therapy as a cure for cancer and other major illnesses (17,43).

Electromagnetic therapy and the related group of energy therapies, discussed in the section Manual Healing Methods, illustrate a striking difference between previous and currently popular alternative practices. Whereas many earlier alternatives reflected concepts important to scientific study of the time, many of today's popular alternatives are mystical and explicitly contrary to contemporary scientific and medical thought. It is as though the new millennium encouraged deeper adoption of explanatory notions applied in millennia past.

Alternative Medical Systems

This category includes ancient systems of healing typically based on concepts of human physiology that differ from those accepted by modern Western science. Two of the most popular healing systems are traditional Chinese medicine and India's Ayurvedic medicine, popularized by bestselling author Deepak Chopra, MD (44).

“Ayurveda” comes from the Sanskrit words “ayur” (life) and “veda” (knowledge). Ayurveda's ancient healing techniques are based on the classification of people into one of three predominant body types. There are specific remedies for disease, and regimens to promote health, for each body type. This medical system has a strong mind-body component, stressing the need to keep consciousness in balance. It uses techniques such as yoga and meditation to do so. Ayurveda also emphasizes regular detoxification and cleansing through all bodily orifices.

Traditional Chinese medicine explains the body in terms of its relationship to the environment and the cosmos. Concepts of human physiology and disease are interwoven with geographic features of ancient China and with the forces of nature. Chi, the life force said to run through all of nature, flows in the human body through vertical energy channels known as meridians.

The 12 main meridians are believed to be dotted with acupoints. Each acupoint corresponds to a specific body organ or system, so that needling or pressing the acupoint can redress the life-force imbalance causing the problem in that particular organ. To determine the source of the blockage, the practitioner relies on pulse diagnosis, a technique applied by doctors of traditional Chinese medicine today as it was millennia ago. It involves concentration on several body pulses by the practitioner for approximately 45 minutes.

Although the very existence of chi or a “vital energy force” remains unproved, tai chi is a well-documented, effective, gentle exercise technique, particularly useful in preventing falls among the frail or elderly (45,46 and 47).

Traditional Chinese medicine also includes a full herbal pharmacopoeia with remedies for most ailments, including cancer (48). Chinese herbal teas and relaxation techniques are soothing and appealing to many patients with cancer, who use them as complementary therapies. The potential anticancer benefits of many Chinese herbal compounds and other botanicals are under investigation in the United States and elsewhere.

Pharmacological and Biological Treatments

Because pharmacological and biological alternative treatments are invasive and biologically active, they are highly controversial. Probably the best known and most popular pharmacological therapy today is antineoplastons, developed by Stanislaw Burzynski, MD, PhD, and available in his clinic in Houston, Texas (49). Laboratory analysis conducted by a respected scientist concluded that antineoplastons did not normalize tumor cells (50).

Promising anecdotal reports encouraged a clinical trial for pediatric patients with brain tumors, but a National Cancer Institute research effort failed to accrue patients. Further research at the Burzynski Institute was permitted under an investigational new drug (IND), but preliminary data were criticized as uninterpretable, and the therapy as useless and toxic, by respected mainstream scientists (51). Burzynski and his patients continue the antineoplaston therapy and remain vocal advocates of its efficacy.

Immunoaugmentive therapy (IAT) was developed by the late Lawrence Burton, PhD, and offered in his clinic in the Bahamas. Injected IAT is said to balance four protein components in the blood and to strengthen the patient's immune system. Burton claimed that IAT was particularly effective in treating mesothelioma. Documentation of IAT's efficacy remains anecdotal. The clinic has continued to operate after Burton's death, but its popularity seems to have waned (52).

Interest in shark cartilage as a cancer therapy was activated by a 1992 book by I. William Lane, PhD, *Sharks Don't Get Cancer*, and by a television special that displayed apparent remissions in patients treated with shark cartilage in Cuba. The televised outcome was strongly disputed by oncologists in the United States. Advocates base their therapy on its putative antiangiogenic properties, but the shark cartilage protein molecules are too large to be absorbed by the gut and would be destroyed even if absorbed. Shark cartilage actually decomposes into inert ingredients and is excreted. A recent phase I–II trial of shark cartilage found no clinical benefit (53).

Cancell is another biological remedy that appears to be especially popular in Florida and the Midwestern United States. Proponents claim that it returns cancer cells to a “primitive state” from which they can be digested and rendered inert. FDA laboratory studies, which showed Cancell to be composed of common chemicals, including nitric acid, sodium sulfite, potassium hydroxide, sulfuric acid, and catechol, found no basis for proponent claims of Cancell's effectiveness against cancer (54).

Laetrile, an illegal and documented useless product long thought banished (55), was only dormant. It returned in the year 2000, readily available on the Internet.

Manual Healing Methods

Osteopathic and chiropractic doctors were among the earliest groups to use manual methods. Today, there are numerous approaches involving touch and manipulation technique, including hands-on massage. The benefit of chiropractic treatment of low back pain was supported by a National Institutes of Health

consensus conference (56), but its value is widely disputed by mainstream physicians (57).

One of the most popular manual healing methods is therapeutic touch (TT), which, despite its name, involves no direct contact. In TT, healers move their hands a few inches above a patient's body and sweep away “blockages” to the patient's energy field. Although a study in the *Journal of the American Medical Association* showed that experienced TT practitioners were unable to detect the investigator's “energy field” (58), and despite mainstream scientists' unwillingness to accept its fundamental premises, TT is taught in North American nursing schools and widely practiced by nurses in the United States and other countries (59).

Related to TT are several therapies that involve manipulation of a putative human energy field, or use of an individual's special gift for energy healing. Healing of this type, which has remained popular over the centuries in less developed areas of the world (60,61), has gained increasing public interest and acceptance in the United States. Healers in many areas of the United States claim the ability to cure people of cancer. Although they may cause only minor difficulties when patients also receive mainstream care, many patients are firmly convinced of healers' abilities and decline even to have tumors removed surgically in favor of healers' ministrations.

A large advertisement in the *New York Times* (July, 1999) and its companion Web site claim the ability of a Dr. Yan Xin to emit healing qi (chi). The charge is $3.5 million to cure a fatal disease, and $5000 for stress release, weight reduction, or “other health improvements” (62).

Herbal Treatments for Cancer

Herbal remedies typically are part of traditional and folk healing methods with long histories of use. Herbal medicine is found is most areas of the world and across all cultures historically. Although many herbal remedies are claimed to have anticancer effects, only a few have gained substantial popularity as alternative cancer therapies.

For decades, Essiac has remained a popular herbal cancer alternative in North America. Developed initially by a Native healer from Southwestern Canada, it was popularized by a Canadian nurse, Rene Caisse (Essiac is Caisse spelled backwards). Essiac is comprised of four herbs: burdock, turkey rhubarb, sorrel, and slippery elm. Researchers at the National Cancer Institute and elsewhere found that it has no anticancer effect. Essiac is illegal in Canada (32), but it is widely available in the United States.

Iscador, a derivative of mistletoe, is a popular cancer remedy in Europe, where it is said to have been in continuous use as folk treatment since the Druids. It is used in many mainstream European cancer clinics, typically in conjunction with chemotherapy. Despite many studies, definitive data in support of the usefulness of Iscador have not emerged.

Herbal Remedies

Cancer patients use many over-the-counter herbal products in addition to or instead of those promoted specifically as cancer treatments. It is therefore important to recognize herbal remedies that are toxic or tend to interact with other medications as well as those that may help cancer patients. Because neither the FDA nor any other agency examines herbal remedies for safety and effectiveness, few products have been formally tested for side effects or quality control, but information is beginning to emerge on the basis of public experience with over-the-counter supplements.

Reports in the literature describe severe liver and kidney damage from some herbal remedies. These reports underscore the fact that “natural” products, contrary to apparent consumer belief, are not necessarily safe or harmless (63). Most members of the public apparently are not aware that herbs are essentially dilute natural drugs that contain scores of different chemicals, most of which have not been documented. Effects are not always predictable.

Moreover, the potential for herb-drug interaction is sufficiently problematic that patients on chemotherapy or other major medications should not use herbal remedies. Similar cautions are necessary for patients receiving radiation, as some herbs photosensitize the skin and cause severe reactions. Some herbs interfere with coagulation and produce dangerous blood pressure swings and other unwanted interactions with anesthetics (64). Herbs such as feverfew, garlic, ginger, and ginkgo have anticoagulant effects and should be avoided by patients on warfarin sodium (Coumadin), heparin sodium, aspirin, and related agents. The risk of herb-drug interactions appears to be greatest for patients with kidney or liver problems.

The California Department of Health found unsafe levels of mercury and other toxic metals in more than a third of Asian patent medicines studied. Several instances of heart problems resulting from digitalis-contaminated supplements have been reported (e.g., 65). Concerns have been raised even about dietary antioxidants, which may interact with chemotherapeutic agents (66).

Regulatory and Safety IssuesM

Dietary supplements, which include vitamins and minerals, homeopathic remedies, herbal treatments, antioxidants, and other over-the-counter products, are probably the most popular unconventional remedies used today by cancer patients, as well as by the public in general. According to *Nutrition Business Journa*l, 1998 sales of supplements sold over the Internet alone reached $40 million, an increase from $12 million in 1997. *Nutrition Business Journal* estimates sales of food supplements at $160 million for 1999 and $500 million in 2001.

No legal standards exist for the processing or packaging of herbs. Quality-control standards and reviews are needed. Because they are not mandatory, however, few food supplement companies voluntarily self-impose quality evaluation and control. Consumer protection and enforcement agencies cannot provide protection against contaminated or falsely advertised products. Current federal regulations do not permit such oversight, and regulatory capability would prohibit full analysis and ongoing oversight of the estimated 20,000 food supplement items now sold over the counter.

The magnitude and seriousness of the problem hopefully will result in the establishment of government oversight programs of some kind, despite anticipated efforts on the part of the food supplement industry to block efforts that could lead to regulation.

COMPLEMENTARY THERAPIES

Complementary therapies are safe, nontoxic, noninvasive, easy to use, and inexpensive. Many may be self-managed, meaning that practitioners often are unnecessary, which gives patients the rare and important opportunity to maintain a measure of control over their well-being. Supportive or complementary modalities also are soothing, comforting, and distracting, and are backed by good efficacy data.

Some complementary therapies, such as relaxing in a warm bath or painting soothing mental pictures, are intuitively comforting and helpful. Major supportive therapies have been singled out for more detailed review. These therapies—music therapy, therapeutic massage, acupuncture, and mind-body modalities—address some of the most pervasive and difficult problems faced by patients under palliative care. Although data do not always come from the patient population of concern to us here, research shows that these minimally invasive, side effect–free therapies effectively reduce anxiety, depression, pain, dyspnea, nausea, and fatigue.

Music Therapy

Music therapy is provided by professional musicians who are also trained music therapists. They often hold professional degrees in music therapy, and are adept in dealing with the psychosocial as well as clinical issues faced by patients and family members.

Music therapy is particularly effective in the palliative care setting. Formal music therapy programs in palliative medicine exist in several major institutions, including the Memorial Sloan-Kettering Cancer Center and the Cleveland Clinic (67). Although music therapy extends back to folklore and Greek mythology (Apollo was the god of both music and medicine), it has been studied scientifically only in recent years.

Controlled trials indicate that music therapy produces emotional and physiologic benefits, reducing anxiety, stress, depression, and pain. Music intervention significantly reduced heart rate, respiratory rate, and anxiety scores among inpatients after myocardial infarction (68), ventilatory assistance (69), and patients undergoing flexible sigmoidoscopy (70). Live versus recorded music more effectively reduced anxiety (71).

In the preoperative setting, randomized trials found that music reduced anxiety and its physiologic correlates such as blood pressure (72,73 and 74) and salivary cortisol, a biochemical marker of stress and anxiety (75). Music lowered blood pressure and anxiety scores during and after eye surgery (76) and among women undergoing hysterectomies in a randomized, controlled trial (77).

Music therapy was shown to be effective against laboratoryinduced pain (78), among cancer outpatients (79), and among cancer patients with chronic pain (80). Music reduced intraoperative analgesic requirements compared to controls (81), and patients randomized to a music intervention reported significantly less pain and required less pain medication (82,83). In what was possibly the largest trial of its type, 500 surgical patients were randomized to control, recorded music, jaw relaxation, or a music/jaw relaxation combination. Music led to significant decreases in both pain intensity and related distress associated with pain (83,84 and 85). Music also can help reduce depression (86,87,88 and 89).

Massage Therapy

The benefits of massage therapy are documented for end-of-life populations (90,91 and 92), and the pain-reducing effects of this intervention are well documented for cancer patients at various stages of illness (93,94 and 95). In the largest study to date, 87 hospitalized cancer patients were randomized to foot massage (also called reflexology) or to control on a crossover basis. Pain and anxiety scores fell with massage, with differences between groups achieving substantial significance *(p* = .001) (95).

Pain scores fell by two-thirds immediately after the first massage of patients with postburn itching and pain, and improvements appeared to be cumulative. No similar changes were seen in controls (96). Other studies found similar results for burn patients (97) and patients with postoperative pain (98).

Acupuncture

Several randomized, controlled trials have examined acupuncture for dyspnea. A laboratory-based model of methacholine-induced bronchospasm, which was a blinded, placebo-controlled, randomized investigation, allowed good experimental control. Significant differences in lung function emerged between needling true versus inactive (“sham”) points for airway conductance, forced expiratory volume, and forced expiratory flow (99).

A similarly controlled study in a laboratory setting involved asthmatic children. Exercise-induced reductions in forced expiratory volume, peak expiratory flow rate, and forced vital capacity were significantly lower in real compared to sham acupuncture (100). A trial of acupressure for chronic obstructive pulmonary disorder also found significant differences between groups for subjective breathlessness (101). Only one trial has been reported in cancer. Although uncontrolled, the results are provocative. Twenty patients in palliative care received a single session of acupuncture. A 43% reduction in breathlessness after 10 minutes of needle insertion was found, and it was maintained at 6-hour follow-up (102).

Cancer-related fatigue is a highly distressing and common symptom for which there is no known effective treatment. Published case reports include fatigue associated with multiple sclerosis (103) and chronic fatigue syndrome (104,105). One randomized trial of acupuncture in which fatigue was an end point has been published (106). Although this trial was very small (13 patients) and the acupuncture prescription used was for the treatment of pain and nausea rather than fatigue, patients receiving acupuncture experienced approximately a 15% reduction in fatigue scores; the mean change among controls was zero. Anecdotal information has been obtained from the acupuncturists and patients in the Memorial Sloan-Kettering Cancer Center Integrative Medicine Service. Several cancer patients scoring 5 or higher on a 10-point scale experienced clinically important reductions in fatigue after acupuncture treatment.

Meta-analyses and systematic reviews of acupuncture for pain support its usefulness for dental and back pain (107,108). An uncontrolled report of acupuncture for pain in hospice patients indicates that 62% had a good or excellent response (109). A systematic review (110), as well as a pilot study (111), indicates that acupuncture effectively reduces nausea. In a study of 183 cancer patients, almost half experienced decreased pain after acupuncture (112).

Mind-Body Therapies

The varied group of mind-body therapies is geared to decrease stress and promote relaxation in different ways. Hypnotherapy has been shown to reduce chemotherapyrelated nausea and vomiting in children (113), and possibly to control anxiety and nausea (114). Hypnosis for pain is well supported (115,37). Other techniques, including visualization and progressive relaxation, also decrease pain and promote well-being (116,117).

Other complementary therapies, such as spiritual care, counseling, and group support, have been part of supportive and palliative care in cancer for decades. The complementary therapies discussed here represent an extension of those efforts to decrease symptoms and enhance patients' quality of life. Our challenge is to help patients avoid the pitfalls of useless unproved therapies, while ensuring their access to the safe, noninvasive, beneficial complementary modalities reviewed here (118).

LONG-TERM SURVIVORSHIP: LATE EFFECTS

NOREEN M. AZIZ

Owing, in part, to tremendous strides in disease treatment, cancer survivors are living for extended periods beyond their initial diagnoses, often with various physical and psychosocial sequelae. Conceptually, cancer is increasingly being considered a chronic disease for the individuals diagnosed with it, and for their families. Questions of particular importance to cancer survivors include surveillance for the adverse sequelae, or late effects, of treatment, and the development of new cancers. These questions not only occupy a central core of importance in and of themselves, but also have the potential to impact on infrastructure systems such as databases, follow-up requirements for clinical trials, new therapeutic approaches, dosages of chemotherapeutic drugs, surveillance recommendations, and the cancer research agenda itself.

Statistical trends show that, in the absence of other competing causes of death, 59% of adults diagnosed with cancer today can expect to be alive in 5 years. Estimated 5-year survival rates for those diagnosed during childhood (< age 19) are even higher, with almost 75% of childhood cancer survivors estimated to be alive at 5 years and 70% at 10 years. Prevalence proportions estimated from cancer incidence and follow-up data in the Surveillance, Epidemiology, and End Results registry indicate that there are currently 8.9 million cancer survivors in the United States, representing approximately 3.3% of the entire U.S. population (1).

These dramatic strides in survival over the past three decades are the result of advances in early detection, adjuvant and other aggressive therapeutic strategies, and the widespread use of combined modality therapy (surgery, chemotherapy, and radiotherapy). Cancers such as testicular cancer, acute lymphoblastic leukemia (ALL), and Hodgkin's disease are now considered amenable to cure. Patients with many common cancers, such as breast and colorectal, can look forward to a vastly improved disease-free and overall survival, and patients with potentially incurable disease can look forward to living for extended periods as a result of better disease control (2,3 and 4).

These benefits of antineoplastic therapy are balanced by a spectrum of late complications, which range from minor and treatable to serious and, occasionally, potentially lethal (5). One-fourth of late deaths occurring among pediatric cancer survivors during the extended survivorship period, when the chances of primary disease recurrence are negligible, can be attributed to a treatment-related effect such as a second cancer or cardiac dysfunction. The most frequently observed sequelae include endocrine complications, growth hormone deficiency, primary hypothyroidism, and primary ovarian failure (6). Also included within the rubric of late effects are second malignant neoplasms arising as a result of genetic predisposition (e.g., familial cancer syndromes) or the mutagenic effects of therapy. These factors may act independently or synergistically. Synergistic effects of mutagenic agents such as cigarette smoke, or toxins such as alcohol, are largely unknown.

This chapter discusses both late and long-term effects. The discussion includes (a) relevant definitional issues, (b) generalizations about long-term and late effects, (c) issues unique to certain cancer sites, (d) special considerations when primary diagnosis and treatment occurs during childhood or various stages of adulthood, (e) a review of late and long-term sequelae by organ system or tissue affected, (f) second malignant neoplasms, (g) ancillary sequelae, and (h) follow-up care for late and long-term effects.

DEFINITIONAL ISSUES

“Cancer survivorship” was first described by Fitzhugh Mullan, a physician who had been diagnosed with cancer himself (7). His earlier definition coincides with the widely accepted one today: “everyone diagnosed as having cancer, beginning from the point of diagnosis to the end of life, is a cancer survivor.” Mullan described the survivorship experience by equating it with the climatic seasons of the year. He recognized three “seasons” or phases of survival: (a) *acute* (extending from diagnosis to the completion of initial treatment; issues dominated by treatment and its side effects); (b) *extended* (beginning with the completion of initial treatment for the primary disease or remission of disease; dominated by watchful waiting, regular follow-up examinations, and intermittent therapy); and, (c) *permanent* survival (not a single moment in time—evolves from extended diseasefree survival when the likelihood of recurrence is sufficiently low). An understanding of these phases of survival is important vis-à-vis the recognition and optimal management of late effects of treatment.

The physiological sequelae of cancer and its treatment incorporate two related areas: (a) *long-term physiological effects* (chronic physiological sequelae persisting beyond the acute cancer treatment phase), and (b) *late effects* (delayed physiological sequelae occurring months to years after treatment). Physiological sequelae can further be classified as (a) *system-specific* (e.g., organ damage, failure, or premature aging; immunosuppression or compromised immune systems; and endocrine damage); (b) *second malignant neoplasms* (e.g., an increased risk of recurrent malignancy, increased risk of a certain cancer associated with the primary malignancy, or increased risk of secondary malignancies associated with cytotoxic or radiologic cancer therapies); and (c) *functional changes* (e.g., lymphedema, incontinence, pain syndromes, neuropathies, fatigue), *cosmetic* changes (e.g., amputations, ostomies, and skin/hair alterations), and *comorbidities* (e.g., osteoporosis, arthritis, and hypertension).

Late effects of cancer treatment occur because effects of therapy on organs or tissues may become manifest only with time or because there is unmasking of hitherto unseen injury to immature organs by developmental processes (3). Any side effect for which a cancer patient must compensate during life is a long-term, or persistent, effect. Because tissue damage noted during or at the end of therapy may remain stable or become progressive, late effects refer specifically to unrecognized toxicities that are absent or subclinical at the end of therapy but manifest later as a result of growth, development, increased demand, or aging. Compensatory mechanisms that initially maintain the function of injured organs may fail over time or with organ senescence. Persistent symptoms differ from late effects of treatment as they begin during treatment and continue after treatment, rather than appearing months to years after the completion of treatment (8). Some researchers classify cognitive problems, fatigue, lymphedema, and peripheral neuropathy as persistent symptoms. Patients demonstrating signs or symptoms of late or long-term effects may have to undergo major lifestyle adjustments for which they are unprepared (9,10,11 and 12).

GENERALIZATIONS ABOUT LATE EFFECTS

It is now possible to anticipate certain types of late effects on the basis of specific therapies the survivor was exposed to, the age of the survivor at the time of treatment, combinations of treatment modalities used, and the dosage administered. There are differences in susceptibility between pediatric and adult patients. Generally, chemotherapy results in acute toxicities that can persist, whereas radiation leads to sequelae that are not apparent immediately and surface after a latent

period. Combinations of chemotherapy and radiation therapy are more often associated with late effects in the survivorship period.

Toxicities related to chemotherapy, especially those of an acute but possibly persistent nature, may be related to proliferation kinetics of individual cell populations, as these drugs are usually cell cycle dependent. Thus, organs or tissues most susceptible are those with high cell proliferation (turnover) rates such as the skin (epidermis), bone marrow, gastrointestinal mucosa, liver, and testes. Theoretically, the least susceptible organs and tissues are those that replicate very slowly or not at all, including muscle cells, neurons, and cells of the connective tissue (13).

There are important exceptions to the above statement. Neural damage may be caused by commonly used chemotherapeutic drugs, such as methotrexate, vinca alkaloids, and cytosine. Bone injury may be caused by methotrexate, and cardiac sequelae may occur after treatment with doxorubicin (Adriamycin). Importantly, injuries occurring in tissues or organs that have low repair potential because they replicate very slowly or not at all may be of a permanent or long-lasting nature (13). Also important is the finding that risk of late death due to causes other than recurrence is greatest among survivors treated with a combination of chemotherapy and radiotherapy (6).

ISSUES UNIQUE TO CERTAIN CANCER SITES

Late effects have been studied in greater depth for certain cancer sites. The examination of late effects for childhood cancers such as ALL, Hodgkin's disease, and brain tumors have provided the foundation for this area of research. A body of knowledge on late effects of radiation or chemotherapy is subsequently being developed for adult sites, such as breast cancer. For example, studies have evaluated and reported on the development of neurocognitive deficits after chemotherapy for breast cancer, a late effect that was initially observed among survivors of childhood cancer receiving cranial irradiation or chemotherapy. Late effects of bone marrow transplant have been studied for both adult and childhood cancer survivors, as have sequelae associated with particular chemotherapeutic regimens such as Adriamycin, Bleomycin, Vinblastine, Dacarbazine (ABVD) and Mechlorethamine, Oncovin, Procarbazine, and Prednisone (MOPP) for Hodgkin's disease, and Cytoxan, Methotrexate, and Fluorouracil (CMF) and Fluorouracil, Adriamycin, and Cytoxan (FAC) for breast cancer. Chemotherapeutic drugs for which late effects have been reported most frequently include doxorubicin (Adriamycin), bleomycin sulfate, vincristine sulfate, methotrexate, cyclophosphamide, and many others (Table 74-1).

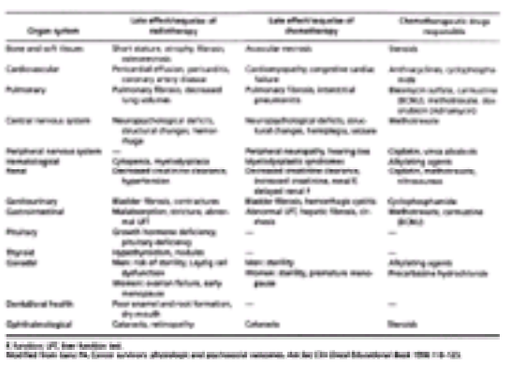

TABLE 74-1. POSSIBLE LATE EFFECTS OF RADIOTHERAPY AND CHEMOTHERAPY

The side effects of radiotherapy, both alone and in conjunction with chemotherapy, have been reported fairly comprehensively for most childhood cancer sites associated with good survival rates. It is important to bear in mind that most cancer treatment regimens consist of chemotherapy in conjunction with surgery or radiation, and multidrug chemotherapeutic regimens are the rule rather than the exception. As such, the risk of late effects must always be considered in light of all other treatment modalities to which the patient has been exposed.

SPECIAL CONSIDERATIONS IN CHILDHOOD CANCERS

Cancer therapy may interfere with development in terms of physical and musculoskeletal growth, neurocognitive/intellectual growth, and pubertal development. These effects may be most notable during the adolescent growth spurt.

Alterations in Physical Growth

Linear Growth Effects

Decreased linear growth is a common problem among children treated for cancer. Catch-up growth leading to resumption of normal growth may occur after treatment so that premorbid growth status is resumed. However, in some survivors, such as those with childhood brain tumors or leukemia, short stature may be permanent or progressive. Whole brain radiation, especially in high doses administered to children younger than 5 years of age, is the principal cause of short stature. This results from injury to the hypothalamo-pituitary axis, which leads to severe growth hormone deficiency. Dosages of 24 Gy may lead to normal baseline levels of growth hormone but an abnormal response to stimulation (14) or atypical patterns of release, especially around the time of puberty (14). If doses of radiotherapy are low, growth velocity may proceed normally until puberty, but the pubertal growth spurt itself may be minimal.

Early onset of puberty is also common after cranial radiation, especially when radiation is administered at younger ages. This leads to a small window of time for the pubertal growth spurt and consequently a reduced ultimate height (15,16). Chemotherapy, especially in combination with radiotherapy, may contribute to decreased linear growth. Chemotherapy alone may cause temporary growth retardation, with resumption of normal growth velocity once treatment ends.

Higher body mass index and obesity, progressive or stable once treatment ends, also has been reported in survivors of childhood leukemia treated with cranial radiation or chemotherapy (17,18 and 19). Vertebral stature loss, seen in brain tumor patients receiving radiation to the whole spine or to the T10-L5 level in dosages greater than 3500 Gy, is impacted by the overall dose and age at radiation (20). These patients may have a reduced sitting (crown to rump) height even in the presence of overall normal height. Treatment of other cancers, such as Wilms' tumor, Hodgkin's disease, medulloblastoma, and sarcoma, may also diminish vertebral growth.

Hypoplasia

Localized radiotherapy can exert a direct, negative effect on musculoskeletal or integumentary growth, leading to a form of growth impairment known as hypoplasia. This occurs especially among children treated with radiation. It usually results from asymmetric radiation fields that may lead to differential growth of the radiated versus nonirradiated tissue. Functional effects reported include radiationinduced scoliosis, which in turn can cause back or muscle pain. Hypoplasia is usually not apparent at the end of therapy and manifests itself with growth, especially the pubertal growth spurt.

Another form of hypoplasia may occur in patients whose adipose tissue is particularly sensitive to radiation, leading to asymmetric fat distribution or weight gain. Breast asymmetry, arrested development, or hypoplasia also may occur after unilateral chest radiotherapy with radiation dosages between 10–20 Gy in the prepubertal period (21).

Alterations in Intellectual Development

The impact of therapy on intellectual outcome is one of the most important sequelae of cancer treatment during childhood. The severity is affected by both the dose of therapy and the age of the child at the time of diagnosis and treatment. In children with leukemia, a variety of neuropsychological abnormalities have been associated with regimens for central nervous system prophylaxis that include whole brain irradiation (22). Specific risk factors for such abnormalities include radiation in doses greater than 24 Gy or the onset of treatment during preschool years (23). Children with these risk factors are more than three times more likely to need special education or to be classified as learning disabled. Attention and visual motor skill deficits may lead to difficulties in reading, language, and arithmetic (24). Preschool children who receive cranial radiotherapy or intrathecal chemotherapy often require special educational resources to learn basic skills after 18–24 Gy of cranial radiotherapy. The same dosages may lead to difficulties with mastering complex information such as a new language or high-level mathematics in older children. Cognitive sequelae may become apparent over time as intellectual growth starts to lag behind the expected course.

Significant cognitive deficits are most likely at doses >36 Gy, administration of radiation therapy for brain tumors before 2 years of age, or after intense intrathecal and infusion chemotherapy for the treatment of childhood leukemia (25). Cognitive sequelae are postulated to occur as a result of cellular neuronal changes that have not yet been well delineated.

Altered Pubertal Development

It is important to monitor pubertal development throughout the pubertal time period since it is difficult to evaluate the extent of treatment-induced gonadal damage during childhood, and because initial pubertal developmental manifestations, such as the appearance of pubic hair, may occur in the presence of severe gonadal damage. Sertoli cells are more sensitive to radiation and alkylating agents than Leydig cells (26). Consequently, boys without Leydig cell damage can experience normal masculinization, potency, and libido even in the presence of azoospermia. Ovaries are less sensitive to gonadotoxic agents than the testes, but secondary gonadal insufficiency due to impaired production of luteinizing hormone or follicle stimulating hormone can occur as a result of cranial radiation, especially in high doses. The effects are more profound in female brain tumor patients receiving hypothalamic-pituitary axis radiation in combination with alkylating agents. In these cases, both direct gonadal effects and secondary gonadal insufficiency may be observed.

SPECIAL CONSIDERATIONS IN ADULT CANCERS

Some late effects of chemotherapy may assume special importance depending on the adult patient's age at the time of diagnosis and treatment. Diagnosis and treatment during the young adult or reproductive years may call for a special cognizance of the importance of maintaining reproductive function and the prevention of second cancers. These are also key issues for children whose cancers are diagnosed during childhood.

Cancer patients diagnosed and treated during middle age may need specific attention to sequelae such as premature menopause; issues relating to sexuality and intimacy; pros and cons of using estrogen replacement therapy; prevention of neurocognitive, cardiac, and other sequelae of chemotherapy; and the prevention of coronary artery disease and osteoporosis. It has been reported that sexual dysfunction persists after breast cancer treatment, despite recovery in other domains, and includes vaginal discomfort, hot flashes, and alterations in bioavailable testosterone, luteinizing hormone, and sex hormone binding globulin (27). Menopausal symptoms such as hot flashes, vaginal dryness, and stress incontinence are very common in breast cancer survivors and cannot be managed with standard estrogen replacement therapy (28). The normal life expectancy of survivors of early-stage cancers diagnosed during these years of life underscores the need to address their long-term health and quality-of-life issues.

Although older patients (older than 65 years) bear a disproportionate burden of cancer, advancing age is associated with increased vulnerability to other age-related health problems and concurrent ailments such as diabetes, chronic obstructive pulmonary disease, heart disease, arthritis, and hypertension. Any of these could potentially affect treatment choice, prognosis, and survival. Hence, cancer treatment decisions may need to be made in the context of the older individual's preexisting health problems (comorbidities). Measures that can help evaluate the existence, nature, and severity of comorbidities among older cancer patients in a reliable manner are needed. Currently, there is little information on how comorbid age-related conditions influence treatment decisions, the subsequent course of the disease, the tolerance of compromised older cancer patients to the stress of cancer and its treatment, and the management of concomitant comorbid conditions (29).

Late and Long-Term Effects By Organ System or Tissues Affected

System-Specific Physiological Sequelae

System-specific sequelae include organ damage or failure, and premature aging due to chemotherapy, hormone therapy, radiation, surgery, or any combination modality therapy.

Cardiac Sequelae

Cardiac damage is most pronounced after treatment with the anthracycline drugs doxorubicin and daunorubicin. These drugs are used widely in the treatment of most childhood cancers and adjuvant chemotherapy for breast cancer. An additive effect has also been reported when anthracyclines are used in conjunction with cyclophosphamide and radiation therapy. Cyclophosphamide alone has been associated with the development of congestive cardiomyopathy, especially when administered at the high doses used in transplant regimens. Anthracyclines cause myocardial cell death, leading to a diminished number of myocytes and compensatory hypertrophy of residual myocytes (30). Major clinical manifestations include reduced cardiac function, arrhythmia, and heart failure (2,3).

Cardiac injury that becomes clinically manifest during or shortly after completion of chemotherapy may progress, stabilize, or improve after the first year of treatment. This improvement may either be of a transient nature or last for a considerable time. There is also evidence of a continuum of injury that manifests itself throughout the lives of patients (31). From a risk factor perspective, patients who exhibit reduced cardiac function within 6 months of completing chemotherapy are at increased risk for the development of late cardiac failure (32). However, a significant incidence of late cardiac decompensation manifested by cardiac failure or lethal arrhythmia occurring 10–20 years after the administration of these drugs has also been reported (33).

Congestive cardiomyopathy is directly related to the total dose of the agent administered. Subclinical abnormalities have also been noted at lower doses. Cardiac toxicity may occur at lower doses when mediastinal radiation is combined with the chemotherapeutic drugs mentioned earlier in this section.

Late onset of congestive heart failure has been reported during pregnancy, rapid growth, or after the initiation of vigorous exercise programs in adults previously treated for cancer during childhood or young adulthood. Decompensation results from increased afterload and the impact of the additional stress of such events on marginal cardiac reserves. Initial improvement in cardiac function after completion of therapy appears to result, at least in part, from compensatory changes. Compensation may diminish in the presence of these stressors or myocardial depressants such as alcohol (2,5).

Effects of radiation on the heart may be profound, and include valvular damage, pericardial thickening, and ischemic heart disease. Adult patients have a markedly increased relative risk (RR) of both angina and myocardial infarction (RR = 2.56) years after mediastinal radiation for Hodgkin's disease, and the RR of cardiac death is 3.1 (34). This risk is greatest among patients receiving >30 Gy of mantle irradiation and those treated before 20–21 years of age. Protecting the heart reduces the risk of cardiac death due to causes other than myocardial infarction (2,3,5,35).

Neurocognitive Sequelae

Progressive dementia has been reported in some long-term cancer survivors as a result of whole brain radiation, with or without chemotherapy, and occurs most often in brain tumor patients and patients with small cell lung cancer who have received prophylactic therapy (2,3). Neuropsychological abnormalities have also been reported after central nervous system prophylaxis using whole brain radiation for leukemia in childhood survivors. Cognitive changes in children received initial recognition as treatments for childhood cancer, especially acute lymphoblastic leukemia (ALL), became increasingly effective. These observations have resulted in changes in treatment protocols for childhood ALL (35,36).

Several studies have reported cognitive dysfunction in women treated with adjuvant therapy for breast cancer (37,38). Additionally, although cranial irradiation is the most frequently identified causal factor in both adults and children, current work in adults indicates that cognitive problems may also occur with surgery, chemotherapy, and biological response modifiers (39,40 and 41). These findings need to be validated in prospective studies along with the interaction between treatment with chemotherapeutic agents, menopausal status, and hormonal treatments. Emotional distress also has been related to cognitive changes in studies of patients beginning cancer treatment.

Patients have attributed problems in cognition to fatigue, and others have reported problems with concentration, short-term memory, problem solving, and concerns about “chemobrain” or “mental pause” (42). Comparisons across studies are difficult because different batteries of neuropsychological tests have been used, and patient samples have varied by diagnosis, age, gender, and type of treatment. There also has been inconsistency in the timing of measures in relation to treatment landmarks. Despite these methodological issues, studies have shown impairments in verbal information processing, complex information processing, concentration, and visual memory (43,44,45 and 46).

Gonadal Toxicity

Treatment-related gonadal failure or dysfunction, expressed as amenorrhea or azoospermia, can lead to infertility in both male and female cancer survivors, and may have its onset during therapy (47). Infertility can be transient, especially in men. The testis is more sensitive to cytotoxic therapies than the ovary, but late recovery has been reported, even though the mechanism of this slow repair is unclear. Reversibility is dependent on the dose of gonadal radiation or alkylating agents. Ovarian

function is unlikely to recover long after the immediate treatment period, and long-term amenorrhea is commonly due to loss of ova. Psychological counseling should be provided to facilitate adjustment to this long-term consequence of therapy. Cryopreservation of sperm before treatment is an option for men, but limited means are available to preserve ova or protect against treatment-related ovarian failure for women (5,48,49).

The risk of premature onset of menopause in women treated with chemotherapeutic agents, such as alkylating agents and procarbazine hydrochloride, or abdominal radiation therapy, is age-related. Women older than age 30 at the time of treatment have the greatest risk of treatment-induced amenorrhea and menopause. There is a sharply increased rate when chemotherapy is administered around the age of 40 years. Tamoxifen citrate has not been associated with the development of amenorrhea (50), but cyclophosphamide at doses of 5 g/m^2 is likely to cause amenorrhea in women older than 40; many adolescents continue to menstruate even after cyclophosphamide doses of >20 g/m^2 (51). Although young women may not become amenorrheic after cytotoxic therapy, the risk of early menopause is significant. Female disease-free survivors of cancer diagnosed at ages 1–19, who were menstruating at age 21, had a four times higher risk of early menopause compared to controls (52).

Direct radiotherapy to the ovaries has also been reported to cause infertility among survivors of Hodgkin's disease and Wilms' tumor (when ovaries were in the radiation field). This outcome reflects a direct effect on the ovaries or an effect on the uterine vasculature leading to an impaired ability of the uterine muscle to grow with pregnancy (53). Cranial radiation may also impair fertility because of deficient gonadotropin from the hypothalamic-pituitary axis. Hyperprolactinemia, another potential effect of hypothalamic-pituitary irradiation, also can affect growth, libido, and fertility (54). The risk is dose dependent at 55 Gy or more of radiation.

The testes are much more sensitive to both radiation and chemotherapy, and sterility has occurred frequently after 10 g/m^2 of cyclophosphamide. Being in a prepubertal state at treatment does not offer much protection to the testes vis-à-vis the effects of cyclophosphamide. In fact, 10% of males have been reported to become sterile after one or two cycles of chemotherapy with the MOPP regimen for Hodgkin's disease, and 80–100% become sterile after six cycles (55). Even low doses of radiotherapy can cause azoospermia in males as spermatozoa are much more sensitive to cytotoxic therapies than the testosterone-producing Leydig cells.

Pulmonary

The acute effects of chemotherapy on the lungs may be lethal, subside over time, progress insidiously to a level of clinical pulmonary dysfunction, or be manifested solely by abnormal pulmonary function tests (2,5). Classically, high doses of bleomycin sulfate have been associated with pulmonary toxicity. However, drugs such as alkylating agents, methotrexate, and the nitrosoureas also may lead to pulmonary fibrosis, especially when combined with radiation therapy. Radiation is thus an important contributor to pulmonary sequelae of chemotherapy (56). Alkylating agents can injure the lung parenchyma, cause restrictive lung disease by inhibiting chest wall growth, and lead to thin anteroposterior chest diameters even 7 years after completion of therapy. Bleomycin sulfate may cause pulmonary insufficiency and interstitial pneumonitis (57).

Pulmonary fibrosis can cause late death in the survivorship period. Among children treated for brain tumors with high doses of nitrosourea and radiotherapy, 35% died of pulmonary fibrosis—12% within 3 years and 24% after a symptom-free period of 7–12 years (58). The risk for overt decompensation continues for at least 1 year after cessation of therapy, and can be precipitated by infection or exposure. to intraoperative oxygen. In terms of long-term outcomes, a recent study noted that 22% of Hodgkin's disease patients with normal pulmonary function tests at the end of therapy (three cycles each of MOPP and ABVD or two cycles of each plus 2550 cGy of involved field radiotherapy) developed abnormalities with follow-up of 1–7 years.

The long-term outcome of pulmonary toxicity is determined by factors such as the severity of the acute injury, the degree of tissue repair, and the level of compensation possible. Pulmonary dysfunction is usually subclinical and may be manifested by subconscious avoidance of exercise owing to symptoms. Premature respiratory insufficiency, especially with exertion, may also become evident with aging. Recent aggressive lung cancer treatment regimens consisting of surgery, radiation, and chemotherapy may well put patients at high risk for decreased pulmonary function and respiratory symptoms.

Genitourinary Tract

Several drugs, such as cisplatin, methotrexate, and the nitrosoureas, have been associated with both acute and chronic toxicities to the genitourinary tract, including glomerular and tubular injury (59). Glomerular injury may recover over time, whereas tubular injury generally persists. Hemodialysis to counteract the effects of chronic renal toxicity may be warranted for some patients. Ifosfamide may cause Fanconi's syndrome, with glycosuria, phosphaturia, and aminoaciduria, and also may affect glomerular filtration. Hypophosphatemia may result in slow growth with possible bone deformity if untreated. Radiation therapy may cause tubular damage and hypertension due to renal artery stenosis, especially when doses are greater than 20 Gy or treatment is given to children (60). Radiation and chemotherapy may act synergistically, the dysfunction occurring with only 10–15 Gy.

The bladder is particularly susceptible to certain cytotoxic agents. Acrolein, a metabolic by-product of cyclophosphamide and ifosfamide, may cause hemorrhagic cystitis, fibrosis, and occasionally, diminished bladder volume. An increased risk of developing bladder cancer also exists. Radiation may lead to bladder fibrosis, diminished capacity, and decreased contractility, with severity proportional to dose and area irradiated. The resultant scarring may diminish urethral and ureteric function (2,5).

Thyroid Gland

Patients receiving radiation therapy to the head and neck may develop subclinical or clinical hypothyroidism. This risk is significant in patients receiving mantle radiation therapy for Hodgkin's disease (61). Compensatory hypothyroidism is manifested initially by elevated thyroid stimulating hormone (TSH) but normal T_3 and T_4 and a clinically euthyroid state. Deterioration of thyroid function leads to clinical symptomatology. Animal studies show that chronically elevated TSH levels in the presence of irradiated thyroid tissue can enhance tumor development. Thyroid disorders observed after thyroid irradiation also include benign nodules (3.3%), Graves' disease (3.1%), thyroid cancer (1.7%), and Hashimoto's thyroiditis (0.7%) (2,5).

Gastrointestinal/Hepatic

There are few studies describing long-term effects to the gastrointestinal system, either due to underdetection or a longer latency period than for other organs. Fibrosis and adhesions are known to occur after radiotherapy to the bowel. Hepatic effects may result from the deleterious effects of many chemotherapeutic agents and radiotherapy. Transfusions may increase the risk of viral hepatitis. Hepatitis C has been identified in increasing numbers of survivors, 119 of 2620 tested (2). Of the latter patients, 24 of 56 who agreed to participate in a longitudinal study underwent liver biopsy. Chronic hepatitis was noted in 83%, fibrosis in 67%, and cirrhosis in 13%.

Compromised Immune System

Hematological and immunological impairments can occur after either chemotherapy or radiation, and are usually acute in nature. They are temporally related to the cancer treatment. Occasionally, persistent cytopenias may persist after pelvic radiation or in patients who have received extensive therapy with alkylating agents. Alkylating agents may cause myelodysplastic syndrome or leukemia as a late sequela. Immunological impairment is particularly seen as a long-term problem in Hodgkin's disease, relating to both the underlying disease and the treatments used. Hodgkin's disease patients are also at risk for serious bacterial infections if they have undergone splenectomy (2,5).

Peripheral Nerve

Peripheral neuropathy is common after treatment with paclitaxel, vincristine sulfate, and cisplatin. However, despite the frequent use of such chemotherapeutic agents, few studies have characterized the nature and course of neuropathies associated with these drug regimens or dose levels (62,63). Peripheral neuropathy may or may not resolve over time, and potential residual deficits are possible. Clinical manifestations may include pain, paresthesias or sensory loss, or weakness and clumsiness in the hands and feet years after completion of cancer treatment.

SECOND MALIGNANT NEOPLASMS AND RECURRENCE

After cancer therapy, there may be an increased risk of second primary cancers or recurrence of the primary disease. This risk may be related to the neoplasm itself or the antineoplastic therapy. Examples include the development of breast cancer after Hodgkin's disease, ovarian cancer after primary breast cancer, and cancers associated with the HNPCC gene.

Survivors of childhood cancer have an 8–10% risk of developing a second malignant neoplasm within 20 years of the primary diagnosis (64,65). This is attributable to the mutagenic risk of both radiotherapy and chemotherapy. This increased risk may be further potentiated in patients with genetic predispositions to malignancy. The

risk of secondary malignancy induced by cytotoxic agents is related to the cumulative dose of drug or radiotherapy (dose-dependence) (3).

The risk of malignancy with normal aging results from the risk of cumulative cellular mutations. Compounding the normal aging process by exposure to mutagenic cytotoxic therapies results in an increased risk of secondary malignancy, particularly after radiotherapy, alkylating agents, and podophyllotoxins. Commonly cited secondary malignancies include (a) leukemia after alkylating agents and podophyllotoxins (66); (b) solid tumors such as breast, bone, and thyroid cancer in the radiation fields in patients treated with radiotherapy (68); (c) bladder cancer after cyclophosphamide; (d) a higher risk of contralateral breast cancer after primary breast cancer; and (e) ovarian cancer after breast cancer (2,5).

The leukemias tend to arise earlier, 2–3 years after podophyllotoxins and 5–10 years after alkylating agents. In contrast, the latent period for many of the solid tumors is 10–20 years or longer (3). Breast cancer in women treated with conventional dose radiotherapy during the peripubertal period is of particular concern, with studies showing that more than half of these individuals may develop breast cancer by the age of 40 years (67). Older adolescents should be taught breast self-examination, whereas survivors in their twenties may benefit from mammograms, ultrasound, and annual clinical breast examinations. Relevant screening tests for diverse cancer sites should also be considered in other populations at high risk (3).

The genetic risk of a second cancer is very prominent in patients with an abnormal retinoblastoma gene (68). Children with hereditary retinoblastoma may have a 60% risk of secondary malignancy by the age of 30–40 years (69). The lag time between the first and second malignancy is shortened in this group with exposure to radiotherapy. Patients with the Li-Fraumeni syndrome, characterized by the presence of an abnormal p53 gene, are also at increased risk for second malignant neoplasms. The p53 gene limits a cell's ability to stop proliferating after chromosomal damage has occurred. Women with BRCA I and II are at a higher risk of a second primary in the breast, and ovarian cancer. Finally, the HNPCC families are at high risk of developing several associated cancers (2,3,5).

Ancillary Sequelae

Lymphedema

Lymphedema can occur as a persistent or late effect of surgery or radiation treatment. It has been reported most commonly after breast cancer treatment, which yields incidence rates ranging between 6% and 30% (70). Lymphedema can occur in anyone with lymph node damage or obstruction to lymphatic drainage. Women undergoing axillary lymph node dissection and high-dose radiotherapy to the axilla for breast cancer are regarded as the highest risk group. Clinically, lymphedema symptoms may range from a feeling of fullness or heaviness in the affected limb to massive swelling and major functional impairment. Recommendations from the American Cancer Society's conference on lymphedema in 1998 emphasize the need for additional research on prevention, monitoring, early intervention, and long-term treatment. Treatments suggested encompass multiple modalities, including skin care, massage, bandaging for compression, and exercise. Intermittent compression pumps were recommended only when used as an adjunct to manual approaches within a multidisciplinary treatment program, and routine use of medications such as diuretics, prophylactic antibiotics, bioflavinoids, and benzopyrones was discouraged in the absence of additional research. The impact of sentinel node biopsy in lieu of extensive axillary node dissection procedures for breast cancer on the incidence of lymphedema is not known at this time.

Fatigue

Fatigue has been reported as a persistent side effect of treatment in many studies (71,72,73 and 74). This is especially true among patients who have undergone bone marrow transplant (75). Treatment-related fatigue may be associated with various factors, such as anemia, infection, changes in hormonal levels, lack of physical activity, cytokine release, and sleep disorders (76). The impact of exercise interventions on fatigue is a promising area of research. Fatigue is an important influence on quality of life for both the patient and the family and needs to be managed effectively.

Sexuality and Intimacy

Sexuality encompasses a spectrum of issues ranging from how one feels about one's body to the actual ability to function as a sexual being, and has been reported as a persistent effect of treatment. In a recent study on breast, colon, lung, and prostate cancer survivors, issues related to sexual functioning were among the most persistent and severe problems reported (77,78). Preexisting sexual dysfunction may also be exacerbated by cancer and its treatment.

Other Issues

There are numerous functional and cosmetic changes, and comorbidities, that may occur as late effects. These are addressed in other chapters of this volume.

FOLLOW-UP CARE FOR LATE AND LONG-TERM EFFECTS

Optimal follow-up of survivors includes both ongoing monitoring and assessment of persistent and late effects of cancer treatment, and the successful introduction of appropriate interventions to ameliorate these sequelae. This is challenging, and must recognize both the importance of preventing premature mortality from the disease or its treatment, and the prevention or early detection of the physiological and psychological sources of morbidity. The prevention of late effects, second cancers, and recurrences of the primary disease requires watchful follow-up and optimal use of early detection screening techniques. Physical symptom management is as important in survivorship as it is during treatment. Effective symptom management during treatment may prevent or lessen lasting effects.

There has been no consensus on overall recommendations for routine follow-up after cancer therapy. Regular monitoring of health status post–cancer treatment is recommended because it should (a) permit the timely diagnosis and treatment of long-term complications of cancer treatment; (b) provide the opportunity to institute preventive strategies such as diet modification, tobacco cessation, and other lifestyle changes; (c) facilitate screening for, and early detection of, a second cancer; (d) allow timely diagnosis and treatment of recurrent cancer; and (e) improve the detection of functional, physical, or psychological disability.

Follow-up care and monitoring for late effects is usually done more systematically and rigorously for survivors of childhood cancer while they continue to be part of the program or clinic. The monitoring of adult cancer patients for the development of late effects, particularly outside oncology practices, is neither thorough nor systematic. It is important that survivors of both adult and childhood cancers be monitored at regular intervals for the late and longterm effects of treatment.

The patient's age at diagnosis, side effects of treatment reported or observed during treatment, calculated cumulative doses of drugs or radiation, and an overview of late effects most likely for a given patient given the treatment history should be summarized and kept on file. A copy of this summary should be provided to the patient, or to the parent of a child who has undergone treatment for cancer. The importance of conveying this detailed treatment history to primary care providers should be clearly communicated, especially if follow-up will occur in the primary/family care setting. Finally, screening tests that may help detect subclinical effects that could become clinically relevant in the future should be listed.

Recommendations for follow-up of certain documented late effects, based on the literature reviewed earlier (Table 74-2), appear in the following sections. The relevance of each recommendation differs by site of disease, extent of treatment, and age at diagnosis.

TABLE 74-2. FOLLOW-UP CARE AND SURVEILLANCE FOR LATE EFFECTS

Women who are contemplating a pregnancy, and those who are pregnant, should be evaluated by a cardiologist. Obstetricians should be made aware that women who have a history of anthracycline treatment for cancer or chest wall radiation may have limited ability to compensate for the increased blood volume and requisite increased cardiac output of pregnancy. Careful monitoring during pregnancy, particularly the postpartum period, is essential. Pregnancy may carry an unacceptable risk for women with significantly limited cardiac reserves in the setting of treatments as described above.

Screening tests, such as dobutamine stress echocardiography, can detect myocardial injury in the majority of anthracycline-treated patients, even at cumulative doses of 45 mg/m^2 (79). If myocardial injury has occurred, clinical response to diuretics and digoxin is only temporary, and the patients may ultimately die of cardiac causes. Improvement in cardiac function can be significant with afterload reduction. It remains to be determined whether such an intervention can delay or even prevent late decompensation in patients at risk.

Neurocognitive Sequelae

Patients reporting severe persistent cognitive problems or those who are extremely concerned about cognitive changes may be referred to a neuropsychologist for a specific diagnosis and compensatory or remediation techniques. Cognitive problems of recent onset and a history of worsening over time should be evaluated. Written appointment cards, appointment reminder calls or letters, simple printed information about medications, and printed instructions about laboratory work or tests that need to be done before a follow-up appointment are examples of provider-initiated actions that can be helpful to patients experiencing deficits in short-term memory.

Gonadal Toxicity

Early hormone replacement therapy should be considered in women who develop premature menopause, unless contraindicated, to reduce the risk of accelerated osteoporosis and premature heart disease related to estrogen deficiency. Prediction of fertility in an adult female survivor can usually be determined by evaluation of the menstrual cycle and age at treatment because the same dose of chemotherapeutic drug or radiation is more likely to affect an older person than a younger one. Emerging reproductive technologies, artificial insemination, and sperm banking are being shown to be beneficial in terms of pregnancy outcomes for infertile or sterile survivors. Appropriate endocrinological interventions with bromocriptine mesylate and similar dopamine agonists may be helpful. For boys receiving higher doses of therapy, testosterone levels as well as pubertal development should be assessed. During early adolescence, testosterone levels in the lower ranges of normal for an adult male are to be expected. By late puberty, testosterone deficiency should be treated in order to normalize libido and masculinization (78). Female cancer survivors experiencing pubertal delay and amenorrhea may need hormone therapy to initiate and maintain feminization, and to prevent osteoporosis and early coronary artery disease.

Pulmonary Sequelae

Patients treated with pulmonary radiation and cytotoxic agents such as carmustine (BCNU), lomustine (CCNU), and bleomycin sulfate should undergo pulmonary function tests every 5–8 years. This is important because symptomatic decompensation of pulmonary function may occur even a decade after treatment with nitrosourea or other agents. Patients who have been exposed to these therapies should be counseled to avoid exposure to pulmonary toxins and cigarettes.

Urinary Tract

The kidney and bladder are the most susceptible sites vis-à-vis late effects. Patients who have received cyclophosphamide or ifosfamide should have an annual urinalysis. Detailed urological workup should occur if hematuria is reported.

Thyroid Gland

Annual assessment of TSH should be performed in patients with a history of mantle radiation therapy for Hodgkin's disease. Treatment with thyroid hormone may be instituted if there is persistent evidence of compensated hypothyroidism.

Peripheral Neuropathy

Patients at high risk or those who report persistent neuropathy should be identified and monitored. Changes in sensation in the hands and feet, paresthesias, constipation, bladder problems, vision, hearing, muscle strength, sexual dysfunction, and changes in gait should be assessed, and physical examination performed, at each visit. The location and extent of neuropathy should be documented. A referral to a specialist for consultation and examination may be beneficial. Routine inspection of the feet for injuries, special care in fitting shoes, avoiding high-risk situations like walking barefoot, and using care in toenail trimming are logical self-care recommendations for sensory manifestations. For peripheral neuropathy manifested as pain or burning, referral to a pain management specialist is appropriate.

Lymphedema

Patients should be asked about the presence or development of swelling, or sensations of aching or fullness, in areas distal to treated lymph nodes or the arm on side of the axillary dissection. General cautions to avoid injuries to the skin on the affected limb, including venipunctures, and cleaning cuts and scratches when they occur, should be observed.

Fatigue

Specific causes of fatigue such as decreased thyroid function, persistent anemia, infection, compromised pulmonary function, sleep problems, cardiac problems, and physical deconditioning should be investigated. Underlying physiological problems should be treated. Physical activity such as regular walking may be helpful.

Surgical Toxicity

Pneumococcal vaccine before splenectomy and then every 5–7 years is recommended. A penicillin or alternative antibiotic should be used for prophylaxis or illness. Medical care should be sought (and antibiotic coverage administered) at the first sign of fever.

Screening

There are no evidence-based guidelines for cancer screening or surveillance in individuals with a past history of cancer. It is logical that cancer survivors follow general guidelines for cancer screening recommended for adult men and women, such as regular examination of the skin, colorectal cancer screening with either stool occult blood testing or sigmoidoscopy, regular Pap smear, and annual mammograms after age 40 (age 30 for female survivors of Hodgkin's disease treated with mantle radiation), depending on the site of primary cancer. It may also be a good idea to screen for associated cancers in patients who were diagnosed at ages younger than commonly reported for a given cancer, those with a positive family history of cancer, or those with a rare hereditary susceptibility gene such as BRCA I and II or HNPCC.

For the prevention of second malignant neoplasms occurring as a late effect of treatment, such as breast cancer after Hodgkin's disease, hematological malignancies, bladder cancer, and sarcomas within a radiation port, a detailed history and physical examination, complete blood counts, routine urinalysis, and screening modalities such as those already mentioned should be part of the follow-up plan.

Physicians, caregivers, and the family must be able to hear and observe what the patient is trying to communicate, reduce fear and anxiety, counter feelings of isolation, correct misconceptions, and obtain appropriate symptom relief. Practitioners inheriting care for child or adult survivors need to understand the effects of cytotoxic therapies on the growing child or the adult at varying stages/ages of life, and be knowledgeable about interventions that might mitigate the effects of these treatments.

Patient education should guide lifestyle and choices for follow-up care, promote adaptation to the disease or relevant sequelae, and help the patient reach an optimal level of wellness and functioning, both physical and psychological, within the context of the disease and treatment effects.

GRADING OF LATE EFFECTS

Grading of late effects can provide valuable information for systematically monitoring the development or progression of late effects. There is, to date, no universally accepted grading system. Garre et al. developed a set of criteria to grade late effects by degree of toxicity as follows: grade 0 (no late effect); grade 1 (asymptomatic changes not requiring any corrective measures, and not influencing general physical activity); grade 2 (moderate symptomatic changes interfering with activity); grade 3 (severe symptomatic changes that require major corrective measures and strict and prolonged surveillance); and grade 4 (life-threatening sequelae) (80). The Swiss Pediatric Oncology Group grading system has not been validated so far (81). It also ranges from 0–4, as follows: grade 0 (no late effect); grade 1 (asymptomatic patient requiring no therapy); grade 2 (asymptomatic patient, requires continuous therapy, continuous medical follow-up, or symptomatic late effects resulting in reduced school, job, or psychosocial adjustment while remaining fully independent); grade 3 (physical or mental sequelae not likely to be improved by therapy but able to work partially); and grade 4 (severely handicapped, unable to work independently). It is important to be aware that these tools are available, to validate them in larger populations, and to examine their usefulness in survivors of adult cancers.

CONCLUSIONS

A large and growing community of cancer survivors is one of the major achievements of cancer research over the past three decades. Both length and quality of survival are important end points. Many cancer survivors are at risk for, and develop, physiological late effects of cancer treatment that may lead to premature mortality and morbidity. As in the past, when treatments were modified to decrease the chance of developing toxicities among survivors of childhood cancer, the goal of future research and treatment should also be to evaluate late effects systematically and further modify toxicities without diminishing cures. Interventions and treatments that can ameliorate or effectively manage both persistent and late physical effects of treatment should be developed and promoted for use in this population. Oncologists, primary care physicians, and ancillary providers should be educated and trained to effectively monitor, evaluate, and optimize the health and wellbeing of a patient who has been treated for cancer.

Additional research is needed to provide adequate knowledge about symptoms that persist after cancer treatment or those that arise as late effects. Prospective studies that collect data on late effects are needed, as most of the literature on late effects is derived from cross-sectional studies. It may not be clear from these studies whether a symptom began during treatment or immediately posttreatment. Continued, systematic follow-up of survivors will result in information about the full spectrum of damage caused by cytotoxic or radiation therapy, and possible interventions that may mitigate the effects. Interventions, therapeutic or lifestyle, that can ameliorate these late effects need to be developed. Practice guidelines for follow-up care of cancer survivors and evaluation and management of late effects must be developed so that effects can be mitigated when possible.

Our knowledge about the late effects of cancer treatment, in large part, comes from studies conducted among survivors of pediatric cancer. We need to explore further the impact of cancer treatment on late effects in survivors diagnosed as adults. We also need to examine the role of comorbidities on the risk for, and development of, late effects of cancer treatment among these adult cancer survivors.

Each person with cancer has unique needs based on the extent of the disease, effects of treatment, prior health, functional level, coping skills, support systems, and many other influences. This complexity requires an interdisciplinary approach by health professionals that is organized, systematic, and geared towards the provision of high-quality care. This may facilitate the adaptation of cancer survivors to temporary or permanent sequelae of the disease and its treatment.

PSYCHOSOCIAL ASPECTS OF CANCER SURVIVORSHIP

SUSAN A. LEIGH
ELIZABETH J. CLARK

> What happens when my body breaks down happens not just to that body but also to my life, which is lived in that body. When the body breaks down, so does the life. Even when medicine can fix the body, that doesn't always put the life back together again (1).
>
> —Arthur Frank

Survivorship is not just about long-term survival but about quality of life from the moment of diagnosis onward. To better understand this issue from the consumer's perspective, it is helpful to understand the difference between curing and healing. The concept of cure has become a medical reality for many types of cancer; yet, the concept of healing after cancer and its treatment is a completely different story. Although curing resides within a disease-repair system and is defined biomedically, healing focuses on health and wellness and can be explained both physically and psychosocially. *Disease* is what is seen, treated, and measured and is the tangible focus for cure. *Illness* is what is felt and experienced and is a more intangible focus for healing. Lerner notes that, “Although the capacity to heal physically is necessary to any successful cure, healing can also take place on deeper levels whether or not physical recovery occurs” (2). By understanding the difference between the treatment of an external disease and the personal, lived experience of illness, physicians can more readily acknowledge and appreciate the psychosocial sequelae, which may include spiritual or existential influences, that often accompany or follow a diagnosis of cancer. This chapter will attempt to redefine the cancer experience, especially from the consumer's perspective, review psychosocial aspects of survival along an expanded continuum, and offer strategies to enhance survivorship.

CANCER MYTHS

At the beginning of fall semester, 1995, the question, “What does cancer mean to you?” was posed to a class of second-year medical students at the University of Arizona. Their responses reflect current feelings within Western society as a whole and include descriptives such as *death, terminal, sadness, fear, chemotherapy, mutilation, pain, financial loss*, and, last but not least, *cure*. Their attitudes about cancer echo the generally negative sentiments that would have been expected decades ago. The only positive word was *cure*, and it was at the bottom of the list.

Cancer continues to instill dread and to masquerade as a ruthless, secretive assailant. Early in this century, it was believed that, “If it was not fatal, it was not cancer” (3). In *Illness as Metaphor*, Sontag (3) writes that a diagnosis of cancer will remain an automatic death sentence until its causes are known and effective treatments are discovered. Even though recent advances in science and medical technology have increased the chances for survival, the often paralyzing fear of eventual death from the disease still lingers today. This fear will obviously continue to invade our lives as long as certain types of cancer are untreatable or incurable.

Along with the myth of imminent death, cancer evokes other misunderstandings, especially concerning causation. Decades ago, many people theorized that cancer was caused by emotional resignation and hopelessness (3). Although attempts to identify “cancer personalities” became a popular trend in the 1970s, there were suggestions that patients unfortunate enough to be diagnosed with cancer must have done, thought, or repressed something to allow this disease to happen. Current pop psychology that often oversimplifies causation and blames the sick individual for having done something wrong may be rooted in this myth. Although the paranoia surrounding cancer is gradually diminishing, the disease continues to harbor elements of fear, stigma, shunning, discrimination, and withdrawal of support (4).

When the biology of a disease is not understood, mythological speculation and oversimplification are apt to define the sickness. Of major importance in defining cancer is that it continues to be identified as a homogeneous disease. Cancer is less often seen as many diseases with multiple causes and treatments and more frequently seen as a single entity with simple causation. The prevalent idea that stress causes cancer often overrules other causative factors, such as genetic predisposition, decreased or damaged immune competence, dangerous health habits, and environmental carcinogens. But not all myths are rooted in the individual. The health care system itself is also full of myths and misunderstandings.

HEALTH CARE MYTHS

As medical researchers and clinicians focus on extending and saving lives, patients become acutely aware of issues affecting the quality of their lives. Two current myths involved with quality of life concerns are (a) the allpowerful role of the physician, and (b) the healing environment within our hospitals (4).

The power and control in the management of patients was historically held by doctors. In this current age of increased bureaucracy, expensive delivery of care, and cost containment, decision-making powers are now shifting to financing and regulatory agencies (5). Physicians are required to spend increasing amounts of time on administrative matters, which decreases the amount of time available for patient care. Patients have longer waits for appointments, and the choice of doctors is more limited. Meanwhile, out of necessity a new prototype of health care consumer is emerging. Consumers who are more assertive in asking questions and requesting information are more inclined toward partnership *with* rather than paternalism *from* their providers of care. As the decision-making powers shift, this attitude can either enhance or strain the already challenged physician-patient relationship.

The second area of misunderstanding is the type of environment in which healing is fostered. The delivery of care is now complicated by diagnosis-related groups, gatekeepers, cost containment, utilization reviews, managed care, and mountains of paperwork. While the old system allowed unlimited stays in the hospital and actually encouraged passivity and invalidism, the new system has gone to the other extreme. Because discharging patients from the hospital as soon as possible has become fiscally prudent, patients return home sooner and sicker. The healing environment, then, becomes the home rather than the hospital, and greater responsibility is placed on the patient and family members or other caregivers. These changing social trends are actually forcing a shift from passive patienthood to a more proactive survivorship.

SEMANTICS OF SURVIVORSHIP

The concept of survivorship was initially introduced to the field of oncology in 1986 with the founding of the National Coalition for Cancer Survivorship. The events preceding this organizational meeting included medical advances and social trends that provoked exploration of new issues related to cancer. As new therapies became available to treat cancer, the hopes and expectations of surviving this disease were elevated. Access to information about scientific breakthroughs became readily available to the general public; awareness about cancer prevention, early detection, second opinions, and treatment options increased; many types of cancers shifted from acute to chronic diseases; and some patients were actually cured. Oncologists were finally able to rejoice, along with their patients, because not everyone

would die of this feared disease. Yet, as patients and family members savored the sweetness of survival, they also realized that life would never be the same and that it would always be full of uncertainty. In *Of Dragons and Garden Peas*, wherein a patient talks to doctors, Trillin sums up this dilemma: “So, once we have recognized the limitations of the magic of doctors and medicine, where are we? We have to turn to our own magic, to our ability to 'control' our bodies” (6).

Control comes in many forms. Before this decade, the cancer patient's agenda was more often than not set by health care providers, especially physicians. Eventually, patients decided to take more control, either directly or indirectly, over all aspects of cancer care that affected their lives. Thus, support groups, hotlines, resource materials, and patient networks proliferated. As the shift to recognize the consumer voice began, the concept of *survivorship* emerged.

Mullan describes survivorship as “the act of living on . . . a dynamic concept with no artificial boundaries” (7). Carter further describes this theme as a process of *going through*, suggesting movement through phases (8). From these models, the concept of survivorship is viewed as a continual, ongoing process rather than a specific time frame, stage, or outcome of survival (9). Survivorship is not just about long-term survival, which is how the medical profession generally defines it. Rather, it is the experience of living with, through, or beyond cancer (10,11). From this point of view, survivorship begins at the moment of diagnosis and continues for the remainder of life (7).

Other discrepancies in semantics revolve around who is or is not a cancer survivor. When cancer was considered incurable, the term *survivor* applied to the family members whose loved one had died of the disease. This terminology was used for years by the medical profession and insurance companies. But when potentially curative therapy became a reality, physicians selected a 5-year parameter to measure survival. Freedom from disease and biomedical longevity became the standards of success where the outcome was measurable and quantifiable.

As treatment successes improved over the years, this limited definition failed to consider patients who are not cured of their disease, require maintenance therapy, or periodically change treatment modalities, yet remain alive for more than 5 years. Others experience late recurrences, are diagnosed with second malignancies, or develop delayed effects of treatment. Even as the 5-year landmark has been modified as a parameter for describing survival, medical professionals seem inclined to categorize anyone receiving therapy or not completely free of disease as a “patient” and everyone who is not under treatment or with no evidence of disease as a “survivor.”

Many people who have histories of cancer feel that survivorship extends far beyond the restrictions of time and treatment. As the empowered consumer encourages the shift from paternalism to partnership, survivors began describing themselves as victors, graduates, triumphers, veterans, and thrivers. Later came a greater sense of power as survivors became activists, advocates, and warriors. More recently, an African-American group considered survivorship a spiritual journey and asked to be called “the blessed.” While all these labels can confuse providers and consumers alike, Gray (12) notes in *Persons With Cancer Speak Out* that, “The act of defining is an act of power.” This is all about the people—the survivors—identifying their own issues and defining themselves rather than relying on the agendas and descriptives of the health care community (9). Any or all of these labels can be considered correct, both quantitatively and qualitatively; they simply need to be defined within the context in which they are used. Thus, the term *survivor* in this chapter reflects the National Coalition for Cancer Survivorship definition: “from the time of its discovery and for the balance of life, an individual diagnosed with cancer is a survivor” (7).

STAGES OF SURVIVAL

Obviously, cancer survivors have different issues, depending on their circumstances along the survival continuum. In the classic article, “Seasons of Survival: Reflections of a Physician with Cancer,” Mullan (13) was the first to propose a model of survival that includes acute, extended, and permanent stages.

Acute Stage

The acute (or immediate) stage begins at the time of the diagnostic workup and continues through the initial courses of medical treatment. The survivor is commonly called a *patient* during this stage, and the primary focus is on treating the disease and physical survival. Usually, without any prior training, persons diagnosed with cancer are required to make sophisticated medical decisions at a time of intense vulnerability, fear, and pressure. Inexperienced in navigating the complicated culture of medicine, many survivors continue to rely solely on their physicians to make treatment-related decisions. Others, though, ask for information, explanations, and more effective communication in an attempt to understand their choices.

Although supportive care services are most available at this time in many oncology arenas, their availability is at risk due to current cost constraints. Yet, access to the health care team, counselors, patient support networks, resource libraries, hotlines, advocacy organizations, and family support systems helps survivors navigate this stage. But the picture changes, sometimes dramatically, once treatment ends.

Extended Stage

If the disease responds during the initial course of therapy, the survivor moves into the extended (or intermediate) stage of survival. This stage is often described as one of watchful waiting, limbo, or remission, as survivors monitor their bodies for symptoms of disease recurrence. Uncertainty about the future prevails, as medical-based support systems are no longer readily available. Recovery entails dealing with the physical and emotional effects of treatment, and reentry into social roles is often challenged by ignorance and discrimination.

Although no longer a patient, the person may not feel entirely healthy and may have difficulty feeling like a survivor. Ambiguity defines this stage, as survivors find themselves afloat in a mixture of joy and fear, happy to be alive and finished with treatments, yet afraid of what the future may hold.

The need for continued supportive care during this transitional stage has recently received attention (7,8,9,10 and 11). Community and peer networks often replace institutional support, and recovery entails regaining both physical and psychological stamina.

Permanent Stage

A certain level of trust and comfort gradually returns, and survivors enter the permanent (or long-term) stage of survival. This is roughly equivalent to cure or sustained remission. Although most survivors experience a gradual evolution from a state of “surviving to thriving,” as described by Hassey-Dow (14), others must deal with the chronic, debilitating, or delayed effects of therapy. Although many of these long-term survivors have no physical evidence of disease and appear to have fully recovered, the life-threatening experience of having survived cancer is never forgotten. The metaphor of the Damocles syndrome illustrates the apprehension or fear of living under the sword, never knowing whether or when it might drop (15,16).

For many cancer survivors, long-term follow-up tends to be as unpredictable as today's health care system. Generally, there are scant, if any, guidelines for specific follow-up, nor are there wellness-focused programs tailored to the altered health care needs of this population. One exception is pediatric oncology, which is far beyond adult oncology in the systematic follow-up of long-term survivors. Standardized assessments in specialized clinics help identify problems, such as disease recurrence, second malignancies, or late effects of treatment, and interventions can be initiated as soon as possible.

Adults, on the other hand, often feel burdened by a “glorification of recovery” (17), whereby they are praised for overcoming adversity and encouraged to minimize their complaints. The appearance of health can actually hamper the identification of real problems, as no one wants to believe that something might still be wrong (17,18). But symptoms of distress, both biomedical and psychosocial, must be taken seriously. And, in this age of cost containment and managed care, survivors need continued access to appropriate specialists who understand the consequences of survival and can treat accordingly.

As the population of cancer survivors increases, attention to survival issues needs to be encouraged. Even if the disease is eradicated, the psychosocial sequelae of surviving a life-threatening experience must be recognized as barriers to a full recovery.

PSYCHOSOCIAL ASPECTS

How well an individual adapts psychologically and socially to living with cancer depends on a wide variety of factors. First are the physical factors, including the age and sex of the individual, the type and stage of disease, the kinds and duration of recommended treatments, the outcomes of treatment, disease progression, and residual side effects. Added to these are permanent disabilities, physical limitations, and possible disfigurement and altered body image. Next are the psychological variables. Where is the individual in life-stage development? What previous experiences has the person had with illness in general and with cancer in particular? What individual psychological strengths and weaknesses are brought to the cancer experience? What kinds of coping mechanisms usually are employed by the individual in crisis situations? Does the individual have a history of emotional problems such as depression, anxiety, or other mental health concerns? Self-esteem, independence and motivation, as well as interactional skills, also play a part.

When aspects of social functioning are added to the equation, many other variables need to be considered. These include the sociodemographic factors such as marital status, race, ethnicity, religious orientation, educational level, employment history, and financial stability. Next are the social roles ascribed to the individual such as spouse, parent, employee, and friend. In addition to the sociodemographic variables, other social factors include the type of social support available to the individual. What kinds of changes will a history of cancer bring for the individual and the family? Will the individual be able to fulfill existing job requirements, or will joblessness or employment discrimination become a factor? Despite this wide range of individual variability, there are numerous shared experiences that occur along the continuum of cancer survivorship. Also shared are the most common problems and needs faced by persons with cancer.

Needs of Cancer Survivors

Houts and his colleagues (19) conducted one of the most comprehensive studies to date on the needs of cancer survivors. They interviewed a random sample of 629 persons who had been diagnosed with cancer within the past 2 years and also interviewed 397 persons involved in their care. Four major categories of unmet needs were identified: (a) emotional/social needs (including family issues), (b) economic needs (financial, insurance, and employment issues), (c) medical staff needs (the need for information and increased availability), and (d) community needs (including home care and transportation) (19).

In 1988, the Canadian Cancer Society conducted a needs assessment with over 2000 persons who had been diagnosed with cancer or had had a cancer recurrence between 1982 and 1989 (20). Subjects were selected to represent a cross section of types and stages of cancer and various geographical locations. The greatest needs identified were for prompt medical attention, emotional support, pain management, practical assistance, attention to employment and financial problems, and information.

Loescher and her colleagues (21) evaluated the needs of long-term survivors of adult cancer using the Cancer Survivor Questionnaire. They interviewed a small sample of individuals more than 2 years after cancer therapy. Deduction content analysis revealed several themes. The needs identified were for reassurance, control, information, insurance coverage, and money as well as the need to talk about the cancer experience.

In one of the most recent quality-of-life studies in longterm cancer survivors, Ferrell and colleagues (22) used a mailed survey approach to assess the quality of life of 687 cancer survivors. Of the four domains of well-being (physical, social, psychological, and spiritual) that were evaluated using a Quality of Life–Cancer Survivors Tool, the psychological wellbeing subscale had the lowest score. The authors conclude that while distress related to the cancer experience abates over time, the psychological impact of the distress lingers.

Addressing the wide variety of psychosocial needs and concerns of cancer patients mentioned above is beyond the scope of this chapter. However, several salient themes have been selected to receive expanded coverage and to indicate some psychosocial sequelae that perhaps are specific to the cancer experience.

Normlessness (Lack of Societal Norms) of the Cancer Experience

Many of the psychological problems associated with cancer are related to a lack of knowledge and requisite skills needed for negotiating the cancer experience. Cancer survivors experience a sequence of crises for which habitual problem-solving activities are not adequate and that do not lead to the previously achieved balanced state (23). Therefore, cancer may be a normless or anomic situation for a significant number of persons.

Anomia can be defined as “a temporary state of mind occasioned by a sudden alteration in one's life situation, and characterized by confusion and anxiety, uncertainty, loss of purpose, and a sense of separateness from one's usual social support system” (24). Persons newly diagnosed with cancer may not know how to think or talk about their situation. They need information, but because of the shock and unfamiliarity of the situation, they may be unable to understand the broad significance or assimilate what information they do receive.

Added to this is the stigma that accompanies a cancer diagnosis. Despite treatment advances and extended survival rates for various cancers, cancer remains a stigmatized disease, and persons with cancer must contend with the consequent societal attitudes, prejudices, and discrimination (1,3).

Eventually, most persons with cancer become expert about their own illness and treatment. They know more or less what to expect medically, and they learn how best to navigate the health care system. They develop the requisite language and needed coping skills to manage the crisis periods. They often interact with other cancer patients, and perhaps by attending support groups or with the help of their medical team and counselors, they find that while the disease of cancer is a personal experience, there are numerous commonalities among individuals regarding the illness process and its consequences. In short, they learn how to live with cancer. There may be recurrent crisis situations, both physical and psychosocial, but gradually the normlessness first experienced after the cancer diagnosis subsides, and life takes on a somewhat normal, albeit a “new normal,” cadence that incorporates the physical, emotional, and spiritual changes catalyzed by the cancer experience (25).

Problems with Reentry

For many patients, active cancer therapy eventually ends, but the successful end of cancer treatment does not necessarily signal an end to the difficulties and stresses faced by persons with cancer and their family members. The period of waiting to see whether the treatment abated the disease process, and worry about not receiving any active intervention, may create new anxiety and fear (26). The survivor enters what Hurt and her colleagues (27) refer to as “neutral time”: a period of remission characterized by uncertainty and lacking in “safety signals” indicating that the disease will not return. At this time, some individuals face an illness-related identity crisis. They may no longer be perceived as cancer “patients” because they are not in active treatment, yet they may have difficulty thinking about themselves as cancer “survivors” or achieving reentry into a “well-role” (11). Another anomic situation, what Maher (24) refers to as “the anomia of good fortune,” may occur.

When the concept of anomia is applied to cancer recovery, the positive experience of doing well, perhaps even of being cured, may be mixed with negative elements. These elements might include: (a) the withdrawal of the intensified social support that accompanied diagnosis and treatment, (b) ambivalence about the discontinuation of treatment, (c) anxiety about recurrence of disease, (d) adjustment to permanent disabilities resulting from the disease or its treatment, (e) the need to resume life-oriented modes of thought after a successful adjustment to the idea of death, (f) anger at perceived inadequacies, or (g) confusion about feelings of depression when the objective situation has improved (24).

Reentry also entails problems with assuming previous roles and responsibilities, and with readjustment and readaptation to daily life (28). The stress of a diagnosis of cancer and its subsequent treatment disrupts the patterns of a lifetime and requires adaptation to personal and interpersonal changes. While active treatment is ongoing, family members frequently assume some of the instrumental, and even emotional, duties of the person with cancer. This redistribution of tasks can have a marked impact on the family unit. When cancer treatment ends, interpersonal relationships may be further strained because the new patterns of interaction and functionality need to be negotiated once again. Another area of reentry that may be of concern for some cancer survivors is rejoining the workforce. The majority of persons with cancer remain actively employed during the treatment phase, but some experience brief or extended absences from work. Returning to work can entail various psychological stresses. There may be a difference in the way the employee is treated by others. Some co-workers may still believe that cancer carries an automatic death sentence and may stigmatize and isolate the returning employee. There may be changes in physical appearance, such as permanent disfigurement from cancer surgery, or temporary changes in appearance, such as hair loss, that initially make the cancer survivor feel insecure and awkward. An added concern may be reduced physical stamina, which makes it difficult to meet the previous work demands and can have an impact on relationships with co-workers.

Employment Discrimination

Of paramount importance to most survivors is financial stability and the opportunity to retain their jobs during or after therapy. Yet, many who are able and willing to work encounter discrimination by being dismissed or demoted, by having benefits reduced or eliminated, or by experiencing conflict with co-workers because of a lack of understanding, ignorance, or fear about cancer (11,29,30). Hoffman (30) estimates that approximately 25% of individuals with a history of cancer experience some form of employment discrimination solely on the basis of their medical histories. Health care professionals, as well as cancer survivors, must take action on three levels to combat cancer-based discrimination: individual and group advocacy, public and professional education, and appropriate use of legal remedies (31).

Advocates hoped for legal protection against employment discrimination for qualified survivors with the passage of the Americans With Disabilities Act, but this has recently been challenged in court. Also, the Federal Rehabilitation Act of 1973 affords limited protection to those survivors whose employers receive federal funds. Most states have laws against discrimination in general, while a few states protect cancer survivors specifically. A major challenge is to test the system and file suit when discrimination is suspected.

Living with Uncertainty

Reentry may require some compromises on both the personal and the interpersonal levels. The cancer survivor may have to learn to live with physical compromises

related to the disease or to the effects of the cancer therapy. Adverse late effects of treatment may not appear for years after the completion of therapy, and the person with a history of cancer has to live with an awareness of the vulnerability associated with delayed treatment effects, recurrence of disease, or susceptibility to a second cancer. Family members also must live with these fears, and overprotectiveness by family members may be an issue after the completion of treatment. Schmale and his colleagues (32) found that 1 year after diagnosis, both survivors and family members were careful about the survivors' activity level, even when there were no obvious physical limitations.

Maintaining a Positive Future Orientation

For a while after a cancer diagnosis, the future is foreshortened, reduced to the span of time between treatments or between episodes of active disease (24), and frustration and disappointment may occur as a result of the nonlinear quality of healing (7). Cancer in the family can have a profound negative impact, and yet hopefulness and a positive future orientation are important components for quality of life in cancer survivorship. Hope is a complex concept and often is misunderstood by health care professionals. Much of the reason for this confusion is that health care professionals generally think only in terms of therapeutic hope—that is, hope that refers to a cure or remission of disease (33). Many other kinds of hope, generalized and particular, are described in the literature.

Farran et al. (34) maintain that hope is a critical clinical construct and provide the following working definition of hope (34):

> Hope constitutes an essential experience of the human condition. It functions as a way of feeling, a way of thinking, a way of behaving, and a way of relating to oneself and one's world. Hope has the ability to be fluid in its expectations, and in the event that the desired object or outcome does not occur, hope can still be present (34).

Staats and Stassen (35) define hope as a cognitive-affective resource that is a psychological asset. The purpose of hope is to guard against despair, and, as a coping strategy, it can reduce ongoing stress and discomfort quickly and for prolonged periods.

Hope is individualistic, and persons have various capacities for hoping and different approaches for maintaining hope. Individual hope is generally influenced by the patterns of hoping within the family (36).

There is a temporal aspect to hope that involves a consideration of the future, and hope changes as situations and circumstances change. Even when hope for survival is dim, individuals will find other things to hope for: pain control, mending strained relationships, or even a dignified death. Disconfirmation of one's hope usually leads to a reformulation of hope, not to its destruction (37).

Cancer survivors need and desire accurate and honest information about their disease, its treatment, and the potential side effects. They need to be aware of problems that they may have to face in the future. If these issues and concerns are presented with compassion and with assurance for continuing support, they can accept even bad news, and new, more realistic goals can be assimilated into the hoping process.

Cancer survivors are challenged to find ways to cope with uncertainty and with maintaining a positive future orientation. The fear of recurrence of cancer and heightened vulnerability may diminish over time, but the consensus is that it never completely goes away (38).

Survivor Guilt

One additional, related aspect of long-term cancer survival deserves special mention. Numerous long-term survivors express guilt over the fact that they have survived when many others have not (39). This may be a particularly salient issue for persons who have been well integrated into a support group and who have watched other members of that group succumb to their disease.

Arthur Frank, in his book *At the Will of the Body*, gives an excellent example of the concept of survivor guilt: “At the same time I was diagnosed as having cancer, a good friend my age also was diagnosed, and my mother-in-law came out of remission again. They both have died. I can make no sense of their deaths and my survival” (1).

Many survivors search for meaning and purpose in their survival and make a renewed commitment to life (40). They also may decide to try to “give something back” in practical and tangible ways. This often includes advocacy efforts on behalf of other survivors.

Living with Loss

Nothing ever prepares us for the really bad things in life, and loss is an encompassing life theme. Losses are a part of life— we lose loved ones, we lose jobs, we lose chances, and we lose dreams. There are many necessary losses when one has cancer. Some of these losses, like hair loss and loss of fertility, are physical, but emotional losses are associated with cancer as well. For example, cancer survivors may have to learn to live with some limitations, and they may have to alter goals, expectations, and hopes to fit the current, after-cancer reality.

Every loss requires a concomitant grief response or some type of mourning, but American society is uncomfortable with grief. Therefore, persons tend to hide their feelings and emotions. A secondary factor is that the person who appears to be coping well relieves others of the burden of support, so hidden grief is reinforced.

Grief, however, cannot be postponed indefinitely. It must reach expression in some way, and hidden grief may be transformed into a variety of emotional responses such as anger, guilt, anxiety, helplessness, or sadness.

The literature on the tasks of mourning is well developed (41,42). These tasks can be summarized as (a) accepting the reality of the loss, (b) experiencing the pain of the grief, (c) adjusting to a changed environment, and (d) emotionally relocating the loss in one's life and moving on.

Perhaps the most important way of helping persons experiencing loss is to “enfranchise” their grief (43). This includes recognizing their right to express emotions and encouraging them to verbalize their feelings and sadness (44). A basic step in helping people live with loss is educating them about the grief process and encouraging them to openly discuss loss issues. Through expression can come emotional healing.

REDEFINING THE CANCER EXPERIENCE

With an increasing sense of empowerment, survivors are redefining the cancer experience for themselves. For example, in 1988 the Cancer Survivors' Bill of Rights (see Appendix 75-1) was written by a survivor for the American Cancer Society. It addresses quality of life issues and identifies individual, interpersonal, and social rights to greater care and satisfaction throughout the cancer experience. Also, survivors are requesting—and sometimes demanding—that nonmedical supportive services be an integral part of cancer care and recovery. Many are working on their own to provide support, resources, and education for fellow survivors, while others are working in conjunction with health care institutions to provide these services. Survivors are joining support groups, producing publications, staffing telephone hotlines, and sharing information through online services. Others are developing community-based, mutual aid networks, are testifying before Congress, and are forming national organizations and coalitions. Advocacy—on personal, community, national, and political levels—has become a major component of the cancer care equation and is increasingly important to assure access to quality cancer care.

FINDING MEANING

Weil (45) suggests that there is no meaning to cancer—it is simply cancer. The meaning attached to the experience is different for everyone and reflects individual interpretations of the disease, treatments, and circumstances. Formulas or recipes are not enough in the assessment and care of people who are distressed and suffering. Ferrell fears that the concept of quality of life is an endangered species in today's medical and political climate and “may be lost during healthcare reform and amidst what [she has] termed the 'dehumanization' of cancer” (46). In response to this growing concern, the Texas Cancer Council outlined 10 Ethical Principles for Cancer Care (see Appendix 75-2) as the moral basis for delivering comprehensive care to people with cancer. Guidelines for action are also delineated in the complete work so that these principles can be put into practice.

The increasing needs, both biomedical and psychosocial, of this expanding population of survivors call for cooperative efforts among the recipients and providers of care, the payors who finance care, the scientists who develop better methods of care, and the politicians who set public policy as to what kind of care will be available and to whom. To ensure the integrity of our health care system, the mythology of cancer must be dispelled, caring must expand into long-term survival, and attention

must be paid to the psychosocial aspects of living with, through, and beyond cancer.

APPENDIX 75-1

CANCER SURVIVORS' BILL OF RIGHTS

The American Cancer Society presents this Survivors' Bill of Rights to call public attention to survivor needs, to enhance cancer care, and to bring greater satisfaction to cancer survivors, as well as to their physicians, employers, families and friends:

1. Survivors have the right to assurance of lifelong medical care, as needed. The physicians and other professionals involved in their care should continue their constant efforts to be:
   - sensitive to the cancer survivors' lifestyle choices and their need for self-esteem and dignity;
   - careful, no matter how long they have survived, to have symptoms taken seriously, and not have aches and pains dismissed, for fear of recurrence is a normal part of survivorship;
   - informative and open, providing survivors with as much or as little candid medical information as they wish, and encouraging their informed participation in their own care;
   - knowledgeable about counseling resources, and willing to refer survivors and their families as appropriate for emotional support and therapy which will improve the quality of individual lives.
2. In their personal lives, survivors, like other Americans, have the right to the pursuit of happiness. This means they have the right:
   - to talk with their families and friends about their cancer experience if they wish, but to refuse to discuss it, if that is their choice and not to be expected to be more upbeat or less blue than anyone else;
   - to be free of the stigma of cancer as a “dread disease” in all social relations;
   - to be free of blame for having gotten the disease and of guilt for having survived it.
3. In the workplace, survivors have the right to equal job opportunities. This means they have the right:
   - to aspire to jobs worthy of their skills, and for which they are trained and experienced, and, thus, not to have to accept jobs they would not have considered before the cancer experience;
   - to be hired, promoted, and accepted on return to work, according to their individual abilities and qualifications, and not according to “cancer” or “disability” stereotypes;
   - to privacy about their medical histories.
4. Since health insurance coverage is an overriding survivorship concern, every effort should be made to assure all survivors adequate health insurance, whether public or private. This means:
   - for employers, that survivors have the right to be included in group health coverage, which is usually less expensive, provides better benefits, and covers the employee regardless of health history;
   - for physicians, counselors, and other professionals concerned, that they keep themselves and their survivorclients informed and up-to-date on available group or individual health policy options, noting, for example, what major expenses like hospital costs and medical tests outside the hospital are covered and what amount must be paid before coverage (deductibles);
   - for social policy makers, both in government and in the private sector, that they seek to broaden insurance programs like Medicare to include diagnostic procedures and treatment which help prevent recurrence and ease survivor anxiety and pain.

APPENDIX 75-2

ETHICAL PRINCIPLES FOR CANCER CARE

I. Since cancer affects a person's entire sense of well-being, cancer care cannot be equated with or limited to prevention, early detection, and treatment of bodily disease. To deal with the effects of cancer, this care should address humans as whole persons with biological, emotional, social, economic, informational, moral, and spiritual needs.
II. Benefiting persons with cancer is the highest priority of health care professionals. Individuals fully benefit when they receive personalized, comprehensive, coordinated, and culturally sensitive care.
III. Patients are to be respected as autonomous, self-governing persons with the right to express their needs and emotions and make informed decisions in their own best interests.
IV. To make informed decisions, patients must be provided with information that is understandable, sufficient, and applicable to their circumstances.
V. Effective communication is essential in order to benefit persons with cancer and respect their autonomy. This communication rests on trust, concern, mutual respect, honesty, and self-awareness.
VI. Terminally ill patients are to receive continued health care, support, respect, and assurance.
VII. Collegial teamwork is essential for attending to the total human dimensions of cancer care.
VIII. Teamwork is sustained by caregiver collegiality, which is based on a mutual understanding of and respect for the individual and professional contributions of colleagues.
IX. The ability of health care professionals to care for patients and those close to the patient depends on caregivers attending to their own personal, psychological, social, moral, and spiritual needs.
X. Basic, clinical, and psychosocial research is integral to improving cancer prevention, early detection, diagnosis, treatment, long-term followup, and the personal dimensions of cancer care. All research should contribute to, not detract from, beneficial and respectful care of individuals with cancer.

PALLIATIVE CARE IN PEDIATRICS

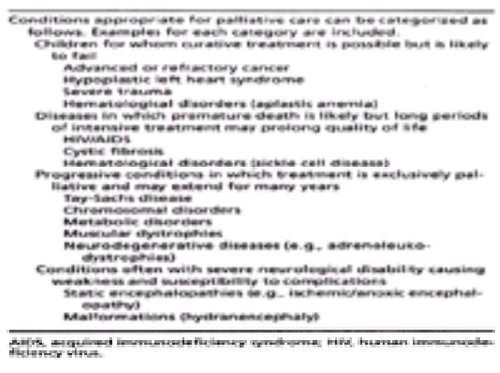
JAVIER R. KANE
BRUCE P. HIMELSTEIN

PEDIATRIC PALLIATIVE CARE

As defined by the World Health Organization, palliative care is compassionate and all-inclusive care when curative treatment is no longer possible. This care addresses physical, spiritual, emotional, and psychological needs of the dying (1). More broadly, palliative medicine for children is the art and science of family-centered care aimed at enhancing quality of life and minimizing suffering. Cassel eloquently defined *suffering* as “the state of severe distress associated with events that threaten the intactness of the person” (2). Inherent in this definition is the possibility of delivering palliative care in partnership with curative care for children with life-limiting illness or for children who may not die. Many principles already reviewed in other sections of this book are universally applicable across the age spectrum of the dying, so this chapter provides an overview of issues specific to the care of the life-threatened child.

The overall improvement in the health of Americans over the 20th century is best exemplified by a dramatic decline in age-adjusted death rates and an increased life expectancy (3). The impact of scientific and technological advances in modern medicine is evident in the notorious drop in childhood mortality rates from all causes and a shift from infectious illnesses to chronic disease and trauma as the primary causes of death in children. This shift in the morbidity and mortality of pediatric diseases calls for an ever-increasing attention to palliative care issues for seriously ill children and their families. In 1998, over 20,000 infants and 26,000 children ages 1 to 19 years died in the United States (4), many of them experiencing long, protracted illnesses associated with substantial pain, and emotional and spiritual challenges.

Although cancer is the most common cause of nontraumatic death in children in the United States, and approximately one-third of children with malignancy still die in economically advantaged areas of the world, there are many other diseases for which palliative care is appropriate. Using a broad definition of advanced illness, the diseases of childhood which might be appropriate for palliative care might include those outlined in Table 76-1; it should be noted that this definition falls well outside of the scope of traditional hospice care, as defined in the United States Medicare Hospice Benefit.



Conditions appropriate for palliative care can be categorized as follows. Examples for each category are included.
- Children for whom curative treatment is possible but is likely to fail
  - Advanced or refractory cancer
  - Hypoplastic left heart syndrome
  - Severe trauma
  - Hematological disorders (aplastic anemia)
- Diseases in which premature death is likely but long periods of intensive treatment may prolong quality of life
  - HIV/AIDS
  - Cystic fibrosis
  - Hematological disorders (sickle cell disease)
- Progressive conditions in which treatment is exclusively palliative and may extend for many years
  - Tay-Sachs disease
  - Chromosomal disorders
  - Metabolic disorders
  - Muscular dystrophies
  - Neurodegenerative diseases (e.g., adrenoleuco-dystrophies)
- Conditions often with severe neurological disability causing weakness and susceptibility to complications
  - Static encephalopathies (e.g., ischemic/anoxic encephalopathy)
  - Malformations (hydranencephaly)

AIDS, acquired immunodeficiency syndrome; HIV, human immunodeficiency virus.

TABLE 76-1. CRITERIA FOR PALLIATIVE CARE

There is little substantive data to assist in determining the potential scope of practice for children with palliative care needs worldwide. In England, Goldman estimated that 50,000 to 100,000 children are living with life-threatening illness. In parts of the world where medical care may not be as readily accessible as in highly developed countries, the scope of practice might be significantly larger (5).

Epidemiology of Suffering

Despite best efforts, children living with chronic, life-threatening, and terminal illnesses experience substantial suffering. This experience of serious disease is multidimensional. It has broad-ranging implications in the child's life as a whole and in the family as a functional unit. Suffering results from a threat to one's physical and psychological self, from a threat to one's relationships with others, and from a threat to one's relationship with a transcendent source of meaning (6). Suffering is a profoundly personal experience and is endurable, and at times even fulfilling, when it becomes meaningful (7).

Within the physical realm, the published experience speaks best to those with malignant diseases. Recent studies by Wolfe (8) and Collins et al. (9) point to the wide variety and high prevalence of symptoms from which children suffer with life-threatening illness, including fatigue, nausea, pain, dyspnea, anorexia, constipation, and diarrhea, just to name a few. Furthermore, currently available treatments may not be successful in easing suffering associated with these symptoms that can cause significant distress. The work of Wolfe also demonstrates significant discrepancies between the reports of parents and physicians regarding the children's symptoms in the last month of life, with parents reporting each symptom more than the physicians.

For children with nonmalignant diseases, some of the more troublesome symptoms might include gastroesophageal reflux, neuroirritability, immobility, incontinence, seizures, muscle spasms, pressure ulcers, contractures, recurrent infections, increased secretions, restlessness, sleep disturbance, and edema. There are few valid and reliable tools available to assess these symptoms and little data to substantiate the use of many of the interventions currently prescribed. Equally important is the need to recognize the role that health care providers have in contributing to the overall experience of suffering for patients and families, particularly when the emphasis is placed on life prolongation and the use of aggressive medical procedures and other painful interventions in realistically futile situations.

Serious illness threatens children's sense of personal integrity and shatters all aspects of their lives. Physical pain and other symptoms cause fear, depression, and isolation. Illness affects their daily activities, sense of well-being, physical strength and agility, and the motives and quality of their relationships. Disease crushes their

sense of security, and brings fears of the unknown, rejection, and punishment. Children also become confused by the experience of a mixed variety of emotions of anger, anxiety, sadness, loneliness, and isolation in the presence of a threatening situation (10). Children are highly vulnerable to the stress inherent to the experience of severe illness. They have an egocentric view of the world and lack a fully developed repertoire of coping mechanisms, such as problem solving or decision making, which are influenced by age-dependent behavior and cognitive abilities.

Suffering, for the parents of a child with a life-threatening illness, can be a multidimensional experience of pain, fear, failure, despair, powerlessness, hopelessness, purposelessness, and vulnerability. These experiences are both personal and interpersonal. Parental anxiety is due in part to the changing parent-child structure, the need to understand the illness experience, become familiar with the hospital environment, adapt to the changing relationships with their child and other family members, and negotiate with professionals about their care (11,12). Parents must also deal not only with the immediate threat of disease on their child's life, but also with important additional family stressors during treatment such as lifestyle changes, marital tension, financial strain, loss of self-esteem, and even loss of sleep (13,14 and 15). Furthermore, when confronted with the suffering and possible death of their child, parents frequently recognize their own limitations and mortality. Their perception of life, death, and the world around them is changed dramatically by the reality of the loss of their child, a loss that involves not only a loved family member, but also the future embodied in the hopes and dreams that were invested in the child (16). In addition, parents must also satisfy the emotional needs of other children in the family which many times parallel those of the seriously ill child (17). Finally, children and their families may also suffer spiritually. This may be manifested as a sense of isolation and abandonment, a sense of hopelessness and uncertainty about the meaning and ultimate purpose of life.

Barriers to Pediatric Palliative Care

Poor symptom control is only one of many barriers to access to good palliative care. Most important in pediatrics, hopes for peaceful dying, comfort, lack of suffering, and escalating engagement with caregivers are often lost in the wish to maintain life at any cost, as death in childhood defies the natural order. Moreover, the gradual transition from curative therapy to comfort as the primary goal of care is marked by uncertainty, the decision points are ambiguous, and the process is painful and difficult for all involved. Additional barriers to access for palliative care that enhance suffering and degrade quality of life for lifethreatened children are outlined in Table 76-2.

Rarity of death in childhood
Inexperience of personnel providing pediatric palliative care
Differences between children and adults and their diseases
Defiance of the natural order when children die
Provider sense of failure when a child dies
Immeasurable parental distress at loss of child
Inability to predict time of death
Requirement for "do not resuscitate" orders
Inadequate education for providers and families about palliative care
Association of palliative care with "giving up" and "hopelessness"
Fragmentation of medical and psychosocial/spiritual services for children
Poor reimbursement for time and labor-intensive, bio-behavioral palliative care
Difficulty of death communication across chronological and developmental ages
Lack of symptom assessment tools
Lack of pharmacokinetic data for children taking symptom relief medications

TABLE 76-2. BARRIERS TO ACCESS FOR PEDIATRIC PALLIATIVE CARE

Models of Care Delivery

The American Academy of Pediatrics supports an integrated model of palliative care in which the components of palliative care are offered at diagnosis and continued throughout the course of illness, whether the outcome ends in cure or death (18). The basic principles necessary to provide compassionate pediatric palliative care are outlined in Table 76-3. In different socioeconomic arenas, reviewed in the Compendium of Pediatric Palliative Care (19), many different approaches to palliative care service delivery might be successful. These essentials do not mandate a particular structure for care delivery other than to suggest the function of an interdisciplinary team of health care and allied health care professionals to provide care coordination and to facilitate the delivery of services with the goal to minimize suffering and improve quality of life. As shown in Figure 76-1, care coordination can bridge the gaps between traditionally defined supportive care (part of active disease treatment), active palliative care, traditionally defined hospice (end-of-life) care, and bereavement.

Care is child-focused, family-oriented, and relationship-centered.
Care focuses on relief of suffering and enhancing quality of life for the child and family.
All children suffering from chronic, life-threatening, and terminal illnesses are eligible.
Care is provided for the child as a unique individual and the family as a functional unit.
Palliative care is incoporated into the mainstream of medical care regardless of the curative intent of therapy.
Care is not directed at shortening life.
Care is coordinated across all sites of care delivery.
Care is goal directed and is consistent with the beliefs and values of the child and his or her caregivers.
An interdisciplinary team that is always available to families to provide continuity delivers care.
Advocacy for participation of the child and caregivers in decision making is paramount.
Facilitation and documentation of communication are critical tasks of the team.
Respite care and support are essential for families and caregivers.
Bereavement care should be provided for as long as needed.
"Do not resuscitate" orders should not be required.
Prognosis for short-term survival is not required.

TABLE 76-3. BASIC PRINCIPLES OF PEDIATRIC PALLIATIVE CARE

FIGURE 76-1. Advanced illness care coordination.

Advanced Care Coordination

Much of the fragmentation of services that occurs in modern health care systems results from the lack of a coordinating entity. The loss of continuity may be addressed by providing a medical home for these children along with the services of an advanced-illness care coordinator. This may be a registered nurse whose primary responsibilities are to enhance communication across settings, facilitate the participation of the patient and family in the decision-making process, ensure that health care providers adhere to the goals and principles of palliative care, and honor the patient and family's wishes. The coordinator may also be responsible for ensuring access to proper management of pain, and psychosocial and spiritual support. The advanced-illness care coordinator may advocate for change in the nature of the palliative care interventions according to the stage of disease and the patient and family's expectations, values, and beliefs. In our experience, provision of a trained, advanced-illness care coordinator to facilitate end-of-life communication also increases utilization of and length of stay in end-of-life services and completion of advance directives. The roles provided by a physician advocate and the integration of services facilitated by the advanced care coordinator are essential for

maintaining a patient-focused, relationship-centered approach and promotion of palliative care goals.

Goals of Care

In the provision of palliative care, assessment of the goals of care is paramount to avoid unnecessary physical and emotional suffering (20). Painful procedures and other medical interventions should be recommended in the palliative care of seriously ill children only after all alternatives have been considered and the goals of care are defined in a way that is consistent with the beliefs and values of each family. Palliative care should be offered for all children suffering from serious illness. However, the relative priority of the goals of medical care is influenced by many factors, including past experiences, the child and family's perceptions of the severity of the illness, prognosis, and whether or not the illness progresses and the patient is approaching death. Physicians have been trained to cure, and many times losing a patient to progression of disease is perceived as a failure. Consequently, it is frequently difficult for physicians, particularly for those caring for children, to let go of the need to “succeed” in the cure of disease when treatment appears to be futile. When a child is diagnosed with a serious illness, the focus is mostly on the illness and its treatment, guided by what science dictates as the most effective therapy to restore bodily function. The goal to restore function is progressively less important as the disease progresses and death appears closer. The experience of living with a terminal illness grows to be more personal and subjective, and the need to have a sense of integrity and wholeness becomes essential. The process involves a gradual and seamless transition from the time of diagnosis to the time of death. Supportive care services must be offered at the time of diagnosis, when treatment with aggressive curative intent is given. When cure is no longer a realistic goal, palliative care interventions may be offered to prolong a life of good quality. When the illness becomes terminal, palliative care can be provided through programs that focus on end-of-life care at home if consonant with the family's wishes. Finally, grief and bereavement counseling should be offered to family members before and after the child dies.

Of note, the use of complementary and alternative medicine to treat chronic illness or disability in children is increasing. Although some alternative medicine practices may be justified, particularly for illnesses that impose a heavy burden of suffering for which mainstream therapies are insufficient, there are no published guidelines for the use of these practices in children (21). In the case of vulnerable children suffering from serious illness, parents may be willing to try a variety of approaches hoping for benefit in a desperate situation, some of which may be potentially harmful (22). To best serve the interests of children, physicians must maintain a scientific perspective, provide balanced advice about therapeutic options, and establish or maintain a trusting relationship with families (23). The management and maintenance of hope in these circumstances is of utmost importance.

Ethical Issues

Shared decision making in pediatrics, driven by communication between child, parent, and physician, defines the standard in medical ethics. Judgments that relate to withholding and/or withdrawing certain therapies, as well as judgments concerning futile medical interventions, are essentially subjective but realistically indispensable (24). There is marked variability among physicians regarding the use of artificial life support, but in general, decisions must be goal directed and in consonance with the child's and family's beliefs and values (25). Maintaining open and honest communication and continuity of care is essential. The decision to discontinue life-support measures should be carried out in the most compassionate and practical way. In conversations with the parents, one must consider the prognosis for recovery, the goal that is being pursued, the quality of the life that is being prolonged, and whether or not the child is experiencing suffering or is permanently unaware of self and his or her surroundings. Advanced care planning for the child with life-limiting illness must include discussions regarding withholding and/or withdrawing of artificial lifesustaining therapies, such as cardiopulmonary resuscitation, mechanical ventilation, and medically provided artificial hydration and nutrition, or other interventions that may potentially prolong life such as chemotherapy, antibiotics, and transfusion of blood products. Discussions regarding establishment of “do not resuscitate” orders should occur in the context of a general approach to minimize suffering and improve quality of life rather than as an isolated plan to discontinue an intervention unrelated to the child's overall experience. Each drug, intervention, or treatment should be assessed in terms of beneficence (to do good) and nonmaleficence (to do no harm) (26).

Withholding and withdrawing artificial, life-sustaining interventions in children, particularly medically provided artificial hydration and nutrition, is often controversial. However, if there is insufficient justification for continued treatment when it is determined with a high degree of certainty that the patient has no hope of regaining some potentiality for function and human relationships, withdrawal of treatment is appropriate (27). As with adults, there is no ethical obligation to continue life-sustaining therapy for children when there is no therapeutic benefit other than to prolong life or if no goals of medicine are obtained such as improving health and quality of life, restoring function, or relieving pain and suffering (28). Discontinuation of nonbeneficial interventions is squarely within the scope of parental, decision-making authority for their child and is not inconsistent with the child's best interests. Although children are allowed to assent rather than to consent to plans regarding their care, parents and health care providers must recognize the subjective personal nature of suffering and respect the child's autonomy and capacity to make decisions, particularly for emancipated and mature minors (29). Whenever possible, caregivers must make an effort to invite children to participate in medical decision making and honor their end-of-life care wishes. This is particularly important for any child, regardless of age, who can understand his or her medical condition, who can communicate his or her preferences, and who is able to reach a reasonable decision and can understand its consequences. In addition, the principles that guide the rule of double effect and sedation of highly symptomatic patients with pain or dyspnea in adults also apply in the care of children (30,31). In difficult cases, institutional ethics committees can help resolve conflicts about treatment decisions, provide a forum for discussion of hospital policies, and educate the health care community about ethical concepts (32).

SYMPTOM CONTROL

This section briefly addresses management of the most common symptoms. Several outstanding and more comprehensive resources are available for pain management in children (33,34,35 and 36).

Pain Assessment and Management

Pain is “an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage” (37). It is subjective in nature.The experience of pain can be modulated by environmental, developmental, behavioral, psychological, familial, and cultural factors. Unrelieved pain for the child can produce fear, mistrust, irritability, impaired coping, and posttraumatic stress symptoms. Parents feel guilt and anger when pain is undertreated. Many children have pain at some time during their course with lifethreatening illness; it can be disease related, treatment related, and/or related to psychological distress (38). Incidental, or traumatic pain, can still occur in a life-threatened child as well.

Pain assessment must be age-appropriate and requires a careful history and physical examination, determination of the primary cause(s) of pain, and evaluation of secondary causes and modulating features. Pain complaints should always be taken seriously; severe pain for a child is a medical emergency.

Elements of the pain assessment should include the quality of the pain, region and radiation, severity, temporal factors, and provocative and palliative factors. Additional historical elements include disease stage and context, fear of pain, ability to take medication, prior analgesic use, potential role of disease-specific treatment, reactions of parents and family context, and other nonpain symptoms, including depression and/or anxiety, sleep disturbance, and most important, interference with activities of daily life, including play.

Methods of pain assessment must be appropriate to the child's age, situation, emotional resources, developmental level and context, and wishes of the child and family. Ideally, pain assessment, being subjective, should be by self-report. For children >7 years of age, visual analogue or verbal response scales are appropriate. For children ages 3–7, several validated, self-report tools are available, including Faces Scale (39), Oucher (40), poker chip tool (41), body maps, and pain thermometers (42,43). For infants, toddlers, and preverbal children, several behavioral assessment scales exist, including CRIES (44), the Neonatal Infant Pain Scale (45), and CHEOPS (46). Collins et al. (9) have recently published a tool that can be used to measure a variety of symptoms in children with cancer 10 to 18 years of age without cognitive impairment. A tool to measure symptoms among children ages 8 to 13 years is in preparation by the same group. The International Association for the Study of Pain has published an excellent review of pain assessment in children (47).

In general, pain management for children should follow the World Health Organization analgesic ladder (48). Table 76-4 lists some of the more commonly used and available medications for mild, moderate, and severe pain. Particularly for children who cannot swallow pills, the long half-life, low cost, and availability in concentrated liquid formulation make methadone a good choice for long-term analgesia (49). A short initial and long terminal half-life requires judicious titration to prevent oversedation. Given toxic metabolite accumulation and the availability of several alternatives, meperidine cannot be recommended and is excluded from the table.

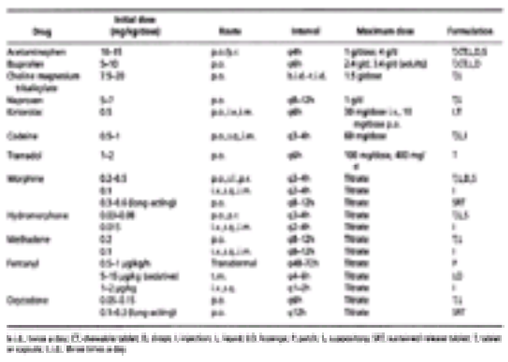


TABLE 76-4. OPIOID AND NONOPIOID ANALGESICS

Medications for pain should be administered according to a regular schedule; “p.r.n.,” “as needed,” and “reverse p.r.n.” dosing requires that children first experience pain before they can receive medication. Rescue doses should be provided for intermittent or more severe breakthrough pain. Expert anticipation, prevention, and treatment of medication side effects are critical.

Depending on the etiology of pain being treated, there are many nonopiate adjunct therapies available. Table 76-5 lists some of the more commonly used medications and their indications.

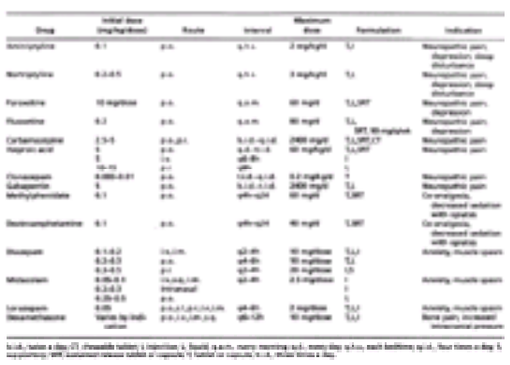

TABLE 76-5. ADJUVANT DRUGS USEFUL IN PEDIATRIC PAIN MANAGEMENT

For children in particular, choose the simplest, most effective, least painful route which for most children will be oral or sublingual, or for those with central venous access, parenteral. Intramuscular injections should be avoided if possible. Rectal administration is possible, and many medications, including nonopiates and opiates as well as medication for nonpain symptoms, can be absorbed rectally. Subcutaneous infusion, popular in adult hospice and palliative medicine, is possible in children but may be inadvisable for needle-phobic children. Transdermal and inhalational routes may also be used in children, but little pharmacokinetic data is available regarding their use; anecdotally, absorption and/or metabolism of transdermal fentanyl may be faster in children, requiring patch changes every 2 days if breakthrough pain occurs.

Promotion of good psychosocial and spiritual care must be partnered with appropriate pharmacology. Children should be given choices as often as possible. Behavioral methods, such as deep breathing (blowing bubbles), progressive relaxation, and biofeedback, have a role in pain management for children. Physical methods, such as touch therapies, including massage, transcutaneous electrical nerve stimulation, physical therapy, heat/cold, and acupuncture and/or acupressure, for example, are helpful adjuncts. Cognitive modalities, including distraction, music, art, play, imagery, and hypnosis, are also effective in children. Studies have demonstrated efficacy of many of these modalities alone or in combination with pharmacological therapies (50). These therapies should be approached from a familycentered perspective; parents can easily be taught many of these techniques. Providing effective tools for parental involvement in symptom management should increase feelings of control in an often uncontrollable situation.

Respiratory Symptoms

Shortness of breath, “air hunger,” and dyspnea, the subjective sensation of not being able to catch one's breath, are potentially distressing and frightening to children and parents alike. In children, there are many potential causes, but the major contributors are space-occupying lesions, such as metastatic tumor or tumor-associated effusions, infectious processes, such as aspiration or acquired pneumonia, and finally, severe skeletal or neuromuscular abnormalities which impede normal respiratory excursion.

The assessment of these symptoms relies heavily on objective measures, such as respiratory rate or transcutaneous oxygen saturation, but, except for maximal inspiratory pressure, these measures, as well as more complex pulmonary function measures, do not necessarily correlate well with the subjective sensation of dyspnea (51). There are some validated visual and numeric dyspnea scales for the assessment of breathlessness in adults (52,53). Pianosi et al. (54) have begun to validate a pictorial tool to assess breathlessness in children that should assist investigators attempting to conduct clinical trials of interventions for dyspnea.

Treatment modalities for dyspnea depend on the disease stage and progression, proximity to death, and patient/family context. Dyspnea, given its association with severe distress, should be treated promptly and aggressively. Specific measures aimed at the underlying pathology should always be considered, for example, drainage of effusions, treatment of pneumonia, or chemoradiotherapy or surgical extirpation for pulmonary metastases. For symptomatic relief, combination therapy with oxygen, oral or parenteral opiates and/or benzodiazepines should be considered without concern regarding potential for respiratory suppression (55). Although many hospice and palliative care specialists advocate the use of inhaled or nebulized opiates, there are no randomized clinical trials to clearly prove their benefit (56).

Gastrointestinal Symptoms

Children with chronic and serious diseases often have gastrointestinal complaints. Nausea and vomiting are among the most common gastrointestinal symptoms seen in children and cause significant distress and diminish function and quality of life. Assessment of nausea is difficult in the young child who may lack the cognitive abilities to distinguish the symptom and express his or her experience verbally. Nausea in these children may manifest as inactivity, weakness, irritability, and poor appetite. In older children, self-report is the preferred method of assessment. Nausea and vomiting may be secondary to gastrointestinal illness such as gastroenteritis, constipation, gastric stasis, ileus, peritoneal irritation, pancreatitis, obstruction, appendicitis, food poisoning, or overfeeding. Neurological causes of nausea and vomiting include increased intracranial pressure secondary to brain tumor, subdural hemorrhage, or obstructive hydrocephalus. Middle ear disease or some brain tumors may cause nausea and vomiting from stimulation of the vestibular pathway. Certain medications, including chemotherapy, narcotics, antibiotics, nonsteroidal anti-inflammatory agents, and anticholinergics can cause severe nausea and vomiting. Systemic infections as well as other illnesses, such as congenital adrenal hyperplasia, inborn errors of metabolism, and Reye's syndrome, among others, can also present with emesis. Anticipatory nausea and vomiting may reflect the presence of anxiety and stress. Postoperative nausea and vomiting is also a common occurrence in children.

The presence of nausea and vomiting calls for immediate action on the part of the caregivers. Identification of the source of these symptoms is important to select appropriate therapy. Management of nausea and vomiting in children is the subject of a recent review (57). Table 76-6 lists some of the antiemetics used in the treatment of children. Prokinetic agents, such as metoclopramide and cisapride, are useful in the treatment of ileus and intestinal hypomotility. Cisapride can cause arrhythmias, particularly in children receiving antifungal therapy. Antihistamines (e.g., diphenylhydramine, dimenhydrinate, meclizine), phenothiazines (e.g., promethazine, chlorpromazine), and butyrophenones (e.g., haloperidol) are useful in the treatment of centrally mediated nausea and vomiting as in increased intracranial tumors or vestibular stimulation but are also good antiemetics for patients with gastrointestinal disease. Ondansetron and granisetron are 5-HT3 antagonists and the treatment of choice in chemotherapy and radiation therapy–induced and postoperative nausea and vomiting. In patients receiving highly emetogenic chemotherapy, these medications must be used as part of an aggressive antiemetic regimen (58). Corticosteroids have intrinsic antiemetic properties and potentiate effect of other antiemetics. Cannabinoids have antiemetic properties, as well, but its use in pediatrics is limited. Synthetic cannabinoid preparations are also

available and may be helpful in severe cases. Benzodiazepines may reduce anxiety and the likelihood of anticipatory nausea. Nondrug measures for palliation of nausea and vomiting that may enhance the effect of antiemetic drugs include acupuncture, psychological techniques, and transcutaneous electrical nerve stimulation (59).

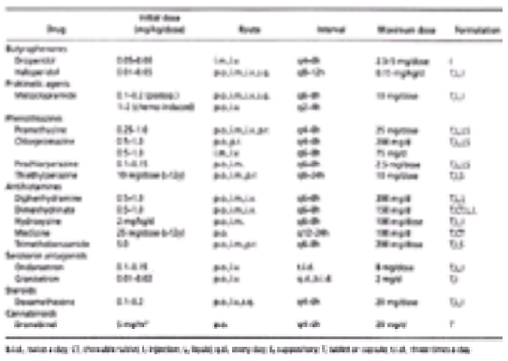

TABLE 76-6. ANTIEMETICS

Constipation, defined as the passage of small hard feces infrequently and with difficulty, is a common complaint among pediatric patients (60). Constipation is a self-perpetuating problem in children. Hard stools are difficult and painful to evacuate, and that may lead to a vicious cycle of constipation. In the child with severe constipation, encopresis may be mistaken by diarrhea. On physical examination, clay-like masses may be palpated in a partially distended abdomen and hard stools may be palpated on rectal examination. Opioids, vincristine, and drugs with anticholinergic effects, such as phenothiazines and tricyclic antidepressants, may cause constipation. Other causes include malignant intestinal obstruction and metabolic conditions such as dehydration, cystic fibrosis, hypothyroidism, and hypercalcemia. Spinal cord injuries or other neuromuscular illnesses may be associated with constipation as well.

As in adults, prophylactic measures are the first line of intervention (61). Children, particularly older school-age patients and adolescents, should be encouraged to remain as mobile as possible. Adequate fluid intake and increased fiber in the diet are helpful. Drugs that cause constipation may be discontinued or a laxative may be added to the regimen. Also, children must be encouraged to attempt defecation after meals to take advantage of the gastrocolic reflex. Hospital staff must allow children privacy for defecation and, whenever possible, the use of a commode or lavatory rather than a bedpan should be encouraged. Treatment of constipation in children includes a variety of oral laxatives and/or enemas. The selection of laxatives can be made by considering modes of action of available agents. Patients with hard stools can receive laxatives with predominately softening action such as mineral oil, lactulose, or docusate sodium. If on physical examination the rectum is full of soft feces, a predominantly peristalsis-stimulating agent such as senna or bisacodyl may be indicated. Osmotic laxatives, such as polyethylene glycol or magnesium citrate, and rectal laxatives, such as glycerin suppositories, sodium docusate, or sodium phosphate enemas, can also be used in symptomatic children with severe constipation. Maintenance therapy may be necessary for patients with chronic constipation. The use of laxatives in these patients does not lead to dependence. Mineral oil does not cause malabsorption of fat-soluble vitamins and may be used in children as part of a maintenance regimen but should be avoided in neurologically impaired children at risk of bronchoaspiration. More recently, glucomannan, a soluble fiber, has been recommended for the treatment of constipation in the neurologically impaired child (62). Among the nonpharmacologic interventions, biofeedback may be potentially useful in children (63).

Diarrhea, one of the most common problems encountered by pediatricians, is defined as the passage of frequent, loose stools. Viral, bacterial, and parasitic infections are among the most common causes of acute diarrhea. Most patients with acute diarrhea have viral gastroenteritis, especially if stools are watery and do not contain either blood or mucus. Patients with fever, abdominal cramps, and/or bloody stools most likely have dysentery syndrome and should be treated empirically with trimethoprim/sulfamethoxazole while awaiting results of culture and bacterial susceptibility (64). Diarrhea persisting for longer than 3 weeks is said to be chronic and may be linked to serious organic noninfectious diseases such as anatomical defects, malabsorption syndromes, endocrinopathies, and neoplasms.

Dehydration is particularly common in young children with diarrhea and vomiting. Aggressive, prophylactic treatment with hydration solutions (e.g., Pedialyte) and careful follow-up are paramount to prevent serious complications. Kaolin and pectin may be useful adjuncts in the treatment of diarrheal illness in children. Products containing salicylates (e.g., bismuth subsalicylate) should be avoided in children. Probiotics (e.g., lactobacillus species) have been used in the treatment and prevention of antibiotic-associated diarrhea, preventing relapse of *Clostridium difficile* infections, and as an adjunct to rehydration therapy, but their use in children remains controversial (65,66).

Gastroesophageal reflux is particularly common in children with neurological impairment, some of whom may require surgical fundoplication to reduce symptoms and decrease the risk of aspiration pneumonia. Useful medications include aluminum hydroxide with or without magnesium hydroxide, calcium carbonate, and H_2-receptor blockers such as ranitidine. Prescription proton pump inhibitors (e.g., omeprazole or lansoprazole) for children with gastroesophageal reflux and peptic ulcer disease continue to increase as clinicians become more aware of their range of action and safety profile (67).

For patients experiencing cachexia as a result of prolonged, chronic childhood diseases, megestrol acetate, a synthetic progesterone derivative, appears promising as an agent to reverse the growth failure observed in these patients (68). Cyproheptadine can be used as an appetite stimulant in children. Corticosteroids and cannabinoids may also have a therapeutic role. However, anorexia and cachexia are often a normal part of the dying process; appropriate patient and family counseling about this fact may reduce distress and obviate the need for therapeutic intervention with medication or with artificial hydration and nutrition.

Pruritus

Pruritus, defined as any stimulus that promotes scratching, may be multifactorial in children but is most commonly related to dry skin or to medication side effects, in particular opiates. As for many other childhood symptoms, there are no standardized assessment tools for pruritus other than the telltale physical signs, including excoriation, lichenification, and/or erythema, as well as behavioral clues such as rubbing of eyes, nose, and/or other skin surfaces. Treatment depends upon the cause; topical therapy with moisturizers and emollients may ameliorate itching associated with dry skin. Systemic corticosteroids may be effective for the often severe pruritus associated with progressive lymphomas. For drug-induced pruritus, modification of the drug regimen is the best therapy. If children must be maintained on a medication associated with pruritus, appropriate pharmacotherapy should be instituted, including antihistamines or partial opiate antagonists such as nalbuphine. Doxepin may also be used enterally or topically. Although attractive options for other indications, nonsedating antihistamines, such as loratadine, may be less effective for pruritus.

Bone Marrow Failure

Bone marrow failure can result in significant suffering and diminution of quality of life for children. It is most often the result of primary malignancy, such as leukemia or neuroblastoma in the bone marrow, or due to the toxic effects of medications. Progressive anemia and resultant fatigue, leukopenia, and its associated risk of infection, and thrombocytopenia and its associated risk of bleeding, may significantly impact upon the ability of the child to participate in play and school, the critical activities of the child.

Treatment decisions should primarily be made in consideration of the child's quality of life. Some children with progressive leukemias, for example, can be maintained with excellent quality of life with a combination of palliative chemotherapy with blood product support and expectant treatment of infectious complications. Oral chemotherapeutics, such as etoposide, Cytoxan, hydroxyurea, or antimetabolites, as well as phase agents, may have a role in such a care plan. Conversely, such support may not be appropriate for a child with protracted bleeding, severe infection, or other complications of end-stage bone marrow failure that significantly impair quality of life. Comfort and prevention of suffering should be optimized regardless of the level of overall support and intent to prolong meaningful life.

For anemia, red cell transfusions to keep the hemoglobin above 7 g/dl may be beneficial. One must weigh the relative increase in risk of thrombocytopenic bleeding, however, at very high hemoglobins. For thrombocytopenia, prophylactic platelet infusions to keep the platelet count above 10,000/mm^3 may be appropriate; clinical titration with scheduled infusions may be easier on the child and family. Gentle oral hygiene with soft toothettes is necessary. Agents to treat mucosal bleeding should be available in the home. Aminocaproic acid, tranexamic acid, desmopressin, and topical thrombin may all have a role. Families should be prepared for the possibility of severe bleeding with appropriate opiates, sedatives, and darkly colored towels to absorb blood.

For neutropenic patients or other patients at risk of infections, such as aspiration pneumonia, decisions need to be made proactively regarding use or nonuse of antimicrobial therapy. For immunocompromised patients with central catheters, and depending upon the availability of home services, blood culture bottles and antibiotics tailored for ease of use and broad coverage such as ceftriaxone or ciprofloxacin can be stored in the home to be used as needed. For children at risk for aspiration, the authors often keep a supply of unreconstituted powder or tablet form of antibiotics, such as amoxicillin/clavulanic acid or azithromycin, for empiric

treatment at onset of fever and/or respiratory distress. Again, parents must be well aware of the risks of treatment failure, including death, in these clinical scenarios.

Genitourinary Symptoms

Retention of urine in children is most often a side effect of anticholinergic medications, in particular opiates, antihistamines, direct anticholinergics, such as hyoscyamine or scopolamine, or tricyclic antidepressants. Urinary infection can also mimic drug-induced retention. Particularly in a nonverbal child or in a child with fever, assessment of urinalysis and culture may be appropriate to rule out infection unless a more obvious source can be found. In children with malignancy, changes in urination may be a sign of incipient spinal cord compression; careful history and neurological assessment should be performed if there is suspicion. Dehydration may also mimic urinary retention, but there are typically other obvious physical signs and symptoms to suggest this diagnosis. Finally, chemotherapy and radiation therapy may be associated with both immediate and long-term sequelae on the bladder and urinary system. For example, hemorrhagic cystitis from alkylating agents can recur months or years from treatment, sometimes in the setting of intercurrent viral illness.

Therapeutically, conservative measures, such as warm compresses or gentle pressure to the bladder and ambulation, if possible, may be effective. Reversal of drug-induced urinary retention may be accomplished most often by changes in medications; occasionally cholinergics, such as bethanechol or opiate antagonists, may be helpful adjuncts. When these maneuvers fail, clean catheterization may be required. Depending upon proximity to death, mobility, and patient/family preference, indwelling catheterization may be preferable to clean intermittent catheterization when outlet obstruction is anticipated to be prolonged.

Fatigue

Fatigue is among one of the most prevalent symptoms in children dying with cancer (8,9). It is a nonspecific symptom that is difficult to measure and describe due to its subjective nature and the lack of confirmed physiological and laboratory indicators (69). Symptoms of fatigue may include physical weakness, mental exhaustion, disruption of sleep, reduced energy, emotional withdrawal, decreased play, or participation in usual activities. Prolonged, persistent, or chronic fatigue may be observed in a wide variety of childhood illnesses, including infectious, inflammatory, and malignant processes. In addition, severe stress, anxiety, depression, and dysfunctional family dynamics may be among some of the psychiatric conditions that may produce chronic fatigue. Some medications, including chemotherapy regimens used for the treatment of cancer, can cause fatigue and generalized weakness. Fatigue is also a common complaint among patients with chronic, progressive disease, particularly when dyspnea, pain, or other significant symptoms are present and unrelieved for a period of time.

Except for a symptom assessment tool described by Collins (9), there are no other reliable tools to measure fatigue in children and, as in other age groups, verbal report should constitute the basis for intervention. It is important to exclude common causes of prolonged fatigue such as anemia, hypothyroidism, sleep disturbances, anxiety, and depression, among others. A good history and physical examination may point to other potential causes that may respond to therapy. If available, treatment should be directed at the medical or psychiatric condition most likely associated with fatigue. In addition, a graded and gradual increase in exercise and rehabilitation may be helpful. Cognitive-behavioral approaches may also be an effective counseling technique to assist the child in switching to a more adaptive coping strategy. Whenever possible, graded reintegration with peer and school activities is recommended. The use of drugs has not been explored well in children. Steroids, transfusion of blood products, thyroxine, recombinant erythropoietin, and methylphenidate have been used in the treatment of fatigue with varying results.

Neurological Symptoms

Some of the more common and distressing neurological symptoms in children with malignant disease may include seizures, headaches, and sleep disturbances. Children with neurodegenerative disorders or static encephalopathies may suffer from muscle weakness, muscle spasms, contractures, progressive immobility, and loss or nongain of developmental milestones and communication difficulties. An interdisciplinary approach to these complex symptoms often requires not only the palliative care team but also rehabilitation specialists, neurologists, speech therapists, occupational and physical therapists, and equipment specialists, for example. A proactive, preventive approach, coupled with patient-family education, is paramount.

Seizures in children with malignancy are often due to primary or metastatic brain lesions, metabolic disturbances, or as a side effect of chemoradiotherapy or medications. For children with known seizures, maintenance medications are appropriate; for children at risk for seizures, availability of at least one anticonvulsant in the home should be planned. For children unable to take medications orally, as most would be during a generalized seizure, administration of several agents by alternative routes is possible, including valproic acid, phenytoin, pentobarbital, lorazepam, and diazepam rectally, lorazepam sublingually, midazolam and phenobarbital subcutaneously, and fosphenytoin, phenobarbital, and lorazepam intramuscularly. Rectal diazepam gel provides premeasured medication in a convenient dose delivery device; its efficacy and safety in childhood have been demonstrated in randomized clinical trials (70).

Headache, like seizures, is often multifactorial. A careful history and examination of the child will often suggest the cause. Increased intracranial pressure may result in symptoms associated with headache, such as nausea, vomiting, photophobia, lethargy, transient neurological deficits, or severe irritability, in the preverbal child. Depending on the cause, increased intracranial pressure may be treated with surgery, chemotherapy, radiotherapy, steroids, or expectant management only. Immediate and aggressive use of analgesics, antiemetics, and, often, benzodiazepines, is critical for management of rapidly escalating headache.

For children oversedated from opiates, the addition of adjuvant medications may permit dose reductions. The use of long-acting oral preparations or continuous parenteral infusions may reduce periods of increased sedation due to large bolus doses. The consideration of locally directed therapies for local and regional pain syndromes, and/or addition of psychostimulants such as methylphenidate or dexamphetamine in the morning and at lunchtime (starting at 0.1 mg/kg/dose, maximum 0.5 mg/kg/dose), can significantly improve quality of life.

Sleep disturbance and insomnia in children often are undetected unless specifically elicited in the history. Problem sleeplessness in children may result from behavioral, circadian, biological, or medical abnormalities (71). Sleep problems of varied nature and intensity are more common among young, school-age children but decrease significantly over the primary school years (72). In chronically ill children, the presence of other symptoms, such as pain, dyspnea, or wheezing, and emotional symptoms, such as anxiety, may be contributing factors and should be treated aggressively. Hypnotics are the mainstay for therapy for inadequate sleep; low-dose tricyclic antidepressants, such as amitriptyline, may also be appropriate, particularly for children also presenting with neuropathic pain.

PSYCHOSOCIAL SUPPORT

The death of a child is the most catastrophic loss a human being can face, and is inherently difficult to prepare for. Life-threatening pediatric illness is a major stressor that precipitates the development of emotional and spiritual distress in children, caregivers, and the broader community to which the child belongs. Psychosocial support in palliative care calls for attention to effective communication and informed decision making to assure optimum quality of life and to decrease suffering in all of its dimensions. Good psychosocial care encompasses listening empathically and asking questions, providing honest information, talking about feelings and fears, and identifying hopes and realistic goals of care. Hopes for peaceful death, comfort, lack of suffering, and nonabandonment and escalating engagement with the health care team and community should be stressed.

Children are part of an integrated system formed by many components, including parents, siblings, relatives, caregivers, and the broader community, including religious, educational, and recreational connections. Psychosocial support of the child and family includes addressing the needs of all communities involved in the life of the sick child. Palliative care teams must include services to provide care and support for the siblings of seriously ill children, and extend their educational activities to school classmates and religious programs involved in the life of the sick child (73).

There are consistent themes that prevail across most families. Sick children and their parents need to feel in control of some aspects of their lives. Maintaining a sense of normalcy in the child's life is equally important. Many of the challenges that patients and families must deal with become overwhelming in the face of uncertainty. Children and their parents generally want to understand their illness, know what to expect, and discuss strategies for treatment and comfort. Central to the existence of the dying person, adult and child alike, are the needs to have meaningful relationships, a sense of completion in one's life, a sense of meaning, and a sense of unconditional love. In addition, surviving family members experience significant emotional and spiritual morbidity after the death of the child and the need to provide support during the bereavement process can never be overemphasized (74).

The beliefs, attitudes, and functional dynamics of individual family members, the family unit, as well as of the extended community, have a significant influence on the child's experience of severe disease and death (75). Families with low cohesion, high conflict, and poor conflict resolution report higher intensity of grief and psychosocial morbidity (76). In parents of children diagnosed with cancer, high levels of emotional distress correlate with marital tension, feelings of isolation, and the need for more counseling for themselves (77). Palliative care teams and psychosocial providers must assess patients and families and identify whether these and other needs are being fulfilled.

Table 76-7 describes the illness experience according to the child's stage of cognitive development. The psychological adaptation of the primary caregivers to the challenges of serious illness is important for the mental health of the children (78,79 and 80). Interventions to assist children and their caregivers in developing adequate coping skills to avoid inappropriate and destructive behaviors, and provide individual, couple, family, child, and adolescent counseling are important and

should be recommended. One must keep in mind, however, that the impending death of a child may not necessarily alter a family's coping style—the team must first seek to understand the family. Members of the interdisciplinary team help patients and families to recognize the factors that contribute to their experience of suffering, and support them in their quest to fulfill the universal needs of meaning, purpose, value, self-worth, and a sense of competence in the care of their child (81). The team must also help patients and families with the “letting go” process of anticipatory grieving, and assist them in developing and maintaining adequate coping mechanisms which correlate with bereavement outcomes after the death of the child (82). In a series of intensive care patients, for example, mothers who receive support designed to increased their coping skills provided more support to their children and reported less negative mood state and parental stress (83). Psychosocial interventions in palliative care can also be directed to encourage honest communication between children, their families, and health care professionals, and strengthen interpersonal relationships so that they may feel connected and part of each other. The palliative care team can gently encourage the patient and the family to act on the opportunities for reconciliation, to express their love for each other, their forgiveness of past transgressions, and their gratitude. Interventions also aim to help patients understand their condition, to participate in the decisionmaking process, and to restore their sense of personal integrity, dignity, autonomy, self-mastery, and self-control.

TABLE 76-7. ILLNESS EXPERIENCE

Family support and family therapy are important means of intervention for seriously ill children and their families to improve family function, particularly cohesiveness, conflict resolution, and expression of thoughts and feelings (84). A group experience with other chronically ill children provides an opportunity to observe others with similar problems and attenuates feelings of being singled out. This support group creates opportunities for social interaction, constructive peer relationships, and serves as an outlet for active verbal and social expressions. Group treatment methods with the chronically ill child can mobilize the development potential of group relationships to master special adversity and foster growth (85). Patients and individual family members identified as having high levels of anxiety or clinical depression can be referred for individual counseling or psychiatric evaluation and possible pharmacotherapy by a child psychiatrist and member of the palliative care team.

Children's Understanding of Death

Most children suffering from a life-limiting illness understand death better than other children their age. Their learning is primarily determined by their personal experiences with disease, the death of their peers and important adults in their lives, and their stage of emotional and cognitive development. From birth to 3 years, children grasp events at the level of feeling and action which corresponds to Piaget's sensorimotor stage of cognitive development. Children at this age may interpret death as a temporary separation or abandonment. During Piaget's preoperational stage of cognitive development, children ages 3–6 years view death as a state of immobility which may be temporary and reversible. Between 6 and 12 years of age, during Piaget's stage of concrete operations, children begin to realize that people who die are not able to function. By the age of 7, most children recognize the four major concepts regarding death: irreversibility, finality, inevitability, and causality (86). As children enter Piaget's stage of formal operations, which usually spans from 12 years of age onward, they develop the ability for abstract reasoning, and their thoughts about death are similar to those of a mature adult. It is again important to note that chronically ill and dying children, given the appropriate explanations, may come to understand concepts of death and dying well beyond that expected for their chronological age.

It is also important to talk to children about their illness with openness and honesty. Keeping information from a child is not only futile but also harmful. One must be careful, however, not to strip away the child's resources used to cope with severe illness, at times manifested as avoidant behavior (87). Children cannot envision their own death easily. They think only old people die and cannot understand why. It is not until the later stages of cognitive development when children are able to foresee death as an ever-present possibility in their own lives. It is often helpful to let children guide the conversations about difficult issues. Caregivers can guide those conversations by creating the opportunities for the child to express his or her emotions, which are often varied and complex. Stories, games, play, art, or music are among many tools that caregivers have to stimulate communication by helping children to freely express their thoughts and emotions.

Adjustment Disorder

Chronically ill children who have difficulty coping with the challenges imposed on their lives are often diagnosed as having an adjustment disorder. The essential feature of an adjustment disorder is the development of clinically significant emotional or behavioral symptoms in response to identifiable psychosocial stressors. This must be distinguished from the nonpathological reactions to stress. The definition of adjustment disorder implies that caregivers must make a determination of whether the patient is experiencing distress in excess of what would be expected given the nature of the illness and whether there is significant impairment in the child's age-appropriate social and cognitive functioning. This assessment may be particularly difficult in the severely ill child who often experiences multiple medical problems and who may be at the end of his or her life. Children with serious and chronic illness are at increased risk for adjustment disorders (88). When present, these may occur with depressed mood, anxiety, disturbance of conduct, or a combination of these. Identification of children who may have difficulty adjusting is important as most of these children may benefit from appropriate behavioral and cognitive-behavioral therapies.

Anxiety

Anxiety disorders are one of the most prevalent categories of childhood and adolescent psychopathology (89). The assessment and treatment of anxiety disorders in childhood and adolescents is well studied, and excellent reviews of the subject are available (90). One of the dilemmas in clinical practice is to define what constitutes an anxiety disorder in comparison with normal anxiety in the presence of stressful life circumstances. Separation anxiety, generalized anxiety disorder, and social phobia are among the most prevalent anxiety disorders in children. Adolescents also begin to develop vulnerability to other anxiety disorders, including panic disorder and agoraphobia. Anxiety disorders in children often do not appear in isolation but as part of a broad array of other symptoms and maladaptive traits such as timidity, social withdrawal from novel or unfamiliar situations, lack of selfconfidence, dysphoria, and hypersensitivity among others.

Seriously ill children are under considerable personal and family strain and may experience symptoms of anxiety as a manifestation of psychological distress without meeting the criteria for diagnosis of an anxiety disorder. Children who experience difficulty functioning as a result of their anxiety symptoms may have an adaptive disorder. Some of the most common subclinical anxiety symptoms in children include overconcern about competence, excessive need for reassurance, fear of the dark, fear of harm to self or an attachment figure, and somatic complaints. In addition to the stress inherent to serious disease, other sources of anxiety for adolescents include consolidation of identity, sexuality, social acceptance, and independence conflicts. Teenagers may also manifest unrealistic fears, excessive worry about past behavior, and self-consciousness as signs of increased anxiety.

The presence of traumatic events in the child's life and limited access to support systems may account for the development of anxiety in children. About half of all mothers and fathers of children with cancer report high levels of distress (91). At least one-third of the children with anxiety disorders have other comorbid anxiety disorders, major depression, or attention-deficit hyperactivity disorder. Anxiety also affects school performance in children. Family history is essential as the rate of anxiety disorders is higher in children of adults with anxiety disorders.

Anxious children generally benefit from mastering themes of separation, autonomy, self-esteem, and ageappropriate behavior. Parents should be involved in the treatment so they learn to understand the patient's need for reassurance and to encourage the child to be more independent. Parents may need to resolve their own issues about separation and other sources of anxiety because they may exacerbate fears or communicate ambivalence about their child's safety, security, and autonomy (92). Working with the family system is the key way to decrease the anxiety symptoms experienced by the child. The aim of the therapy is to disrupt the dysfunctional patterns of interaction that promote family insecurity and to support areas of family competence. Attention to the child-parent relationship is vital for preventing and treating anxiety symptoms. Behavioral therapy, cognitive-behavioral therapy, and psychodynamic psychotherapy are useful therapeutic techniques to help the child and family in the process of coping with the challenges of a life-limiting illness.

Pharmacological treatment should not be used as the sole intervention but as an adjunct to behavioral and psychotherapeutic interventions. Commonly selected

medications for treating anxiety symptoms include tricyclic antidepressants and selective serotonin reuptake inhibitors. Selection of the medication depends on the presence of comorbidity. Tricyclic antidepressants may be used in the treatment of anxiety if enuresis is also present. Selective serotonin reuptake inhibitors may be used if there is an associated obsessive-compulsive disorder or depression. Either of these therapeutic avenues may also be appropriate for children with neuropathic pain or disturbed sleep. Benzodiazepines may be used on a short-term basis for anxiety symptoms.

Depression

Major depression and dysthymia are common disorders occurring in children and adolescents. Guidelines for the assessment and treatment of children and adolescents with depressive disorders are available (93,94 and 95). Fortunately, while children with medical problems appear to be at slightly elevated risk for depression and have higher rates of maladjustment, the majority of children with chronic disease are not depressed. In a series of children with cancer, for example, patients had unexpectedly low levels of depression, which can be attributed to a defensive bias as a mechanism to minimize the experience of distress (96). Whether clinical depression is more prevalent in terminally ill children as compared with other chronically ill children or healthy controls is not known.

Depressive disorders affect a child's development of social, emotional, cognitive, and interpersonal skills and the attachment between parent and child. The clinical picture of depression in children and adolescents varies considerably across different developmental stages. Younger children may show more somatic complaints, auditory hallucinations, temper tantrums, and other behavioral problems. Older children may report low self-esteem, guilt, and hopelessness. The family relationships of youth with depressive symptomatology frequently are characterized by conflict, maltreatment, rejection, and problems with communication, with little expression of positive affect and support. Parents of these children may themselves be depressed or have other illnesses that may interfere with their effectiveness in parenting. Every child can be sad occasionally. For children at the end of life, depressive symptoms may occur as a normal reaction to grief and could suggest the need to explore their fears and concerns, and find support in their search for meaning and understanding of their disease, suffering, and imminent death.

The most important tool in diagnosis of depression in children is the comprehensive psychiatric evaluation that should be conducted by a trained clinician. Standardized interviews are too long for use in clinical settings. In addition, some of these tests may not be appropriate for children with chronic illness in whom “depressive” symptoms, such as sleep, fatigue, or decreased performance, may be related to the illness without representing depression. Psychiatric symptom checklists derived from these standardized interviews have been developed and can be useful screening tools. Examining the role of factors associated with depression of children without a chronic illness, such as life stress, family functioning, and attributional style, as well as stressors unique to their medical condition and end-of-life situation, may assist clinicians in planning interventions (97).

The treatment of depressive youth should be provided in the least restrictive treatment setting that is safe and effective for a given patient. Given the developmental and psychosocial context in which depression unfolds, pharmacotherapy alone usually is not sufficient. Treatment may include a combination of cognitive-behavioral therapy, interpersonal therapy, psychodynamic psychotherapy, and other psychotherapies. For patients requiring pharmacotherapy, selective serotonin reuptake inhibitors are the initial treatment of choice.

SPIRITUAL SUPPORT

Patients and their families are especially concerned with spirituality in the contexts of suffering, debilitation, and dying (98). Spirituality is that part of our human nature that enables us to find a sense of meaning in our experiences. Many agree that the key to emotional coping with serious illness and disability is frequently found within the matrix of spirituality (99). Spirituality gives us meaning and direction, and brings a sense of order into our lives. This is equally true for children. Children, as well as adults, ask questions, search for a deeper understanding of their experiences, and express their emotions in response to their own interpretation of reality (100).

Seriously ill patients live deeply spiritual lives. Children, however, are likely to base their spirituality on the relationship with their parents or other primary caregivers. Children's spirituality matures and evolves out of these important relationships, which suggests that spiritual care should be offered to the patient as well as his or her family. In addition, children often take religious teachings literally and require explanations beyond these literal meanings to assist them in the process of understanding and interpreting their life experiences. Moreover, children may experience existential suffering, which can be intense during this process and manifested as a lack of order and meaning in their lives and a sense of abandonment.

Tools that can assist in the assessment of spiritual needs in children and their families can be found in the Compendium of Pediatric Palliative Care (19) published by the National Hospice and Palliative Care Organization. Assessment of the family dynamics is important. Some families have informal rules that interfere with the child's ability to express emotions and ask questions about the illness and possible death. The lack of guidance may lead children to experience guilt and self-blame. The developmental stages may assist in the determination of appropriate interventions for spiritual care for the seriously ill child. Typically, these interventions emphasize continued engagement with the child and caregivers, including thoughtful, age-appropriate questioning. Spiritual interventions introduced into the mainstream of medical therapy are directed to help children articulate their questions, express their emotions, and search for creative answers. These activities may allow patients and their families to discover meaning and purpose in their experiences, a sense of oneness with life, of belonging to something beyond themselves, of being part of something greater. This spiritual experience of transcendence beyond the self may facilitate coping by providing a sense of order despite the experience of serious illness and death. Many times at this stage, patients and families manifest a deep yearning for life but also a willingness to accept death, and to live their lives in harmony, giving and receiving love. Suggested spiritual interventions are included in Table 76-7.

GERIATRIC PALLIATIVE CARE

JESSICA L. ISRAEL
R. SEAN MORRISON

In our society, the overwhelming majority of people who die are elderly. They typically die slowly of chronic diseases, over long periods of time, with multiple coexisting problems, progressive dependency on others, and heavy care needs met mostly by family members. They spend the majority of their final months and years at home but, in most parts of the country, actually die surrounded by strangers in the hospital or nursing home. Abundant evidence suggests that the quality of life during the dying process is often poor, characterized by inadequately treated physical distress, fragmented care systems, poor to absent communication between doctors and patients and families, and enormous strains on family caregiver and support systems. In this chapter, we focus on the palliative care needs of older adults.

BIOLOGY OF AGING

Body Composition

Aging is a process that converts healthy adults into frail ones with diminished reserves in most physiologic systems and with an exponentially increasing vulnerability to most diseases and death (1). Aging is the most significant and common risk factor for disease in general. The process itself is a mystery, still poorly understood even in this age of advanced biotechnologic capability. Normal aging appears to be a fairly benign process. The body's organ system reserves and homeostatic control mechanisms steadily decline. Commonly, this slow erosion only becomes obvious in times of maximum body stress or serious illness. However, as the process continues, it takes less and less insult for the underlying physiologic weakness to become apparent. It is difficult to differentiate the effects of aging alone from those of concurrent disease or environmental factors. Eventually, a critical point is reached, when the body's systems are overwhelmed, and death ultimately results. Morbidity is often compressed into the last period of life (2).

Substantial changes occur in body composition with aging. These changes become important when related to nutritional needs, pharmacokinetics, and metabolic activity. As adults age, the proportion of bodily lipid doubles and lean body mass decreases. Bones and viscera shrink and the basal metabolic rate declines. Although specific age-associated changes occur in each organ system, changes in body composition and metabolism are highly variable from individual to individual.

Renal Function

The aging kidney loses functioning nephrons. Cross-sectional and longitudinal studies have also demonstrated a decline in creatinine clearance. There is also evidence to show decreased renal plasma flow, decreased tubular secretion and reabsorption, decreased hydrogen secretion and decreased water absorption and excretion (3). When kidney disease complicates this aging process, the outcome can be highly deleterious.

Underlying renal function is an important issue in geriatric pharmacology. Many medications rely on the kidneys' mechanisms for excretion and their metabolites may accumulate and lead to side effects or toxic injury in an impaired system. For example, the renally cleared metabolite meperidine, normeperidine, can accumulate in the elderly and predispose to delirium, central nervous system excitement, and seizure activity. Commonly used medications are more likely to damage older kidneys, including nonsteroidal anti-inflammatory drugs (NSAIDs), aminoglycosides, and intravenous contrast dye (4).

Gastrointestinal and Hepatic Function

The gastrointestinal tract changes less with aging than normal systems, but there are still some deficiencies that may affect medication delivery and breakdown, as well as nutritional status and metabolism. The esophagus may show delayed transit time. The stomach may atrophy and produce less acid. Colonic transit is greatly slowed, while small intestinal transit appears unaffected. Pancreatic function is usually well maintained, although trypsin secretion may be decreased.

The liver usually retains adequate function, although there are variable changes seen in its metabolic pathways. The cytochrome P-450 system may decline in efficiency and liver enzymes may be less inducible. The most significant change is the sharp decline in demethylization, the process that metabolizes medications such as benzodiazepines in the liver. This change may necessitate dosage adjustments. In addition, drugs that undergo hepatic first pass metabolism by extraction from the blood may have altered clearance with increasing age due to decreased hepatic blood flow.

Brain and Central Nervous System Changes

The brain and central nervous system slowly atrophy with age. Neurons stop proliferating and are not replaced when they die, resulting in neuronal loss as well as loss of dendritic arborization. These are also some degree of neurotransmitter and receptor loss. The extent of this loss is not well understood.

Age-related changes in pain perception may exist, but their clinical importance is uncertain. Although degenerative changes occur in areas of the central and autonomic nervous system that mediate pain, the relevance of these changes has yet to be determined (5). Clinical observations from elderly patients who report minimal pain and discomfort despite the presence of cardiac ischemia or intraabdominal catastrophe suggest that pain perception may be altered in the elderly. However, experimental data suggest that significant, age-related changes in pain perception probably do not occur (6). Until further studies conclusively demonstrate that the perception of pain decreases with age, stereotyping of most elderly patients as experiencing less pain may lead to inaccurate clinical assessments and needless suffering (5).

DEMOGRAPHY OF DYING AND DEATH IN THE UNITED STATES

The median age at death in the United States is now 77 years and has been associated with a steady and linear decline in age-adjusted death rates since 1940. In 1900, life expectancy at birth was less than 50 years; a girl born today may expect to live to age 79 and a boy to age 73. Those reaching 65 years can expect to live another 18 years on average and those reaching age 80 can expect to live an additional 8 years. These unprecedented increases in life expectancy (equivalent to that occurring between the Stone Age and 1900) are due primarily to decreases in maternal and infant mortality, resulting from improved sanitation, nutrition, and effective control of infectious diseases. As a result, there has been an enormous growth in the number and health of the elderly. By the year 2030, 20% of the United States' population will be over age 65, as compared to fewer than 5% at the turn of the twentieth century (7).

Although death at the turn of the twentieth century was largely attributable to acute infectious diseases or accidents, the leading causes of death today are chronic illness such as heart disease, cancer, stroke, and dementia. With advances in the treatment of atherosclerotic vascular disease and cancer, many patients with these diseases now survive for years. Many diseases that were rapidly fatal in the past have now become chronic illnesses.

In parallel, deaths that occurred at home in the early part of the twentieth century now occur primarily in institutions (57% in hospitals and 17% in nursing homes) (8). The reasons for this shift in location of death are complex, but appear to be related to health system and reimbursement structures that promote hospital-based care and provide relatively little support for home care and custodial care services despite the significant care burdens and functional dependency that accompany life-threatening chronic disease in the elderly. The older the patient, the higher the likelihood of death in a nursing home or hospital, with an estimated 58% of persons

over 85 spending at least some time in a nursing home during the last year of their life (8). These statistics, however, hide the fact that the majority of an older person's last months and years is still spent at home in the care of family members, with hospitalization and/or nursing home placement occurring only near the very end of life. National statistics also obscure the variability in the experience of dying. For example, the need for institutionalization or paid formal caregivers in the last months of life is much higher among the poor and women. Similarly, persons suffering from cognitive impairment and dementia are much more likely to spend their last days in a nursing home compared with cognitively intact, elderly persons dying from nondementing illnesses.

CARE SYSTEMS FOR OLDER ADULTS WITH SERIOUS AND LIFE-THREATENING ILLNESS

The incentives promoting an institutional—as opposed to home—death persist despite evidence that patients prefer to die at home. These incentives persist in the United States despite the existence of the Medicare Hospice Benefit (9), which was designed to provide substantial professional and material support (medications, equipment, skilled nursing visits) to families caring for the dying at home for their last 6 months of life. Reasons for the low rate of utilization of the Medicare Hospice Benefit vary by community but include the inhibiting requirements that patients acknowledge that they are dying in order to access the services, that physicians certify a prognosis of 6 months or less, and that very few hours (usually 4 or less) of personal care home attendants are covered under the benefit. In addition, the fiscal structure of the Medicare Hospice Benefit lends itself well to the predictable trajectory of late-stage cancers or AIDS, but not so well to the unpredictable chronic course of other common causes of death in the elderly such as congestive heart failure, chronic lung disease, stroke, and dementing illnesses.

Traditional Medicare coverage in the United States also fails to meet the needs of the seriously ill, older adult. Neither paid personal care services at home nor nursing home costs for the functionally dependent elderly are covered by Medicare, but instead are paid for approximately equally from out-of-pocket and Medicaid budgetary sources that were originally developed to provide care for the indigent.

In nursing homes, standards of care focus on improvement of function, and maintenance of weight and nutritional status. Evidence of the decline that accompanies the dying process is typically regarded as a measure of substandard care (10). Thus, a death in a nursing home is often viewed as evidence, particularly by state regulators, of poor care rather than an expected outcome for a frail, chronically ill, older person. The financial and regulatory incentives and quality measures that currently exist in long-term care promote tube feeding over spoon feeding and transfer to hospital or emergency department in the setting of acute illness or impending death. They fail to either assess or reward appropriate attention to palliative measures, including relief of symptoms, spiritual care, and promotion of continuity with concomitant avoidance of brink-of-death emergency room and hospital transfers (11).

PALLIATIVE CARE NEEDS OF OLDER ADULTS

Although death occurs far more commonly in older adults than in any other age group, remarkably little is known about how death occurs in the oldest old, those over age 75. Most research on the experience of dying has been done in younger populations, and most studies examining pain and symptom management have focused on younger populations with cancer or AIDS. Studies in older adults have focused primarily on patients' preferences for care rather than the actual care received. Indeed, the largest study to date of the dying experience in the United States (SUPPORT) studied the hospital experience of patients with a median age of 66 years (9). The median age of death in the United States is 77 years, and many of the oldest old die in nursing homes or at home rather than in hospital. Data from Medicare and state Medicaid registries suggest that expensive and high technology interventions are less frequently applied to the oldest patients, independent of functional status and projected life expectancy. Whereas these discrepancies may reflect patient preferences and indicate appropriate utilization of resources and patient preferences, it is more likely that they represent a form of implicit rationing of resources based on age. The implication is disturbing, considering that half of the highest-cost, Medicare enrollees survive at least 1 year (12).

Aside from pain and other sources of physical distress (discussed below [see the section Symptom Management: The Challenge of Pain]), the key characteristic that distinguishes the dying process in the elderly from that experienced by younger groups is the nearly universal occurrence of long periods of functional dependency and need for family caregivers in the last months to years of life. In SUPPORT, the median age of participants was 66 years and 55% of patients had persistent and serious family caregiving needs during the course of their terminal illness (13), and in another study of 988 terminally ill patients, 35% of families had substantial care needs (14). This percentage rises exponentially with increasing age. Although paid care supplements or provides the sole source of care in 15–20% of patients (transportation, homemaker services, personal care, and more skilled nursing care), the remaining 80–85% of patients receive the majority of their care from unpaid family members (14). Furthermore, most family caregiving is provided by women (spouses and adult daughters and daughters-in-law), placing significant strains on the physical, emotional, and socioeconomic status of the caregivers. Those ill and dependent patients without family caregivers, or those whose caregivers can no longer provide nor afford needed services, are placed in nursing homes. In the United States, this typically occurs after patients exhaust all of their financial savings in order to become eligible for Medicaid. At present, 20% of the over age 85 population reside in a skilled nursing facility, and this number is expected to increase dramatically in the next 50 years (15). Present estimates suggest the current number of skilled nursing facility beds in the United States will be woefully inadequate for the needs of our aging population.

SYMPTOM MANAGEMENT: THE CHALLENGE OF PAIN

The constellation of symptoms seen in dying, older, adult patients is different from that of young adults. Delirium, sensory impairment, incontinence, dizziness, cough, and constipation are more prevalent in older adults (16). The elderly, on average, have 1.5 more symptoms than younger persons in the year prior to death, and 69% of the symptoms reported for people aged 85 or more lasted more than a year as compared with 39% of those for younger adults (less than 55 years) (16).

Studies focusing specifically on the prevalence of pain have shown consistently high levels of untreated or undertreated pain in older adults. In one study of elderly cancer patients in nursing homes, 26% of patients with daily pain received no analgesic at all and 16% received only acetaminophen, a percentage that rose with increasing age and minority status (17). A subsequent study revealed that 41% of patients who were assessed to have pain on their first assessment continued to have moderate or excruciating daily pain on their second assessment 60–180 days later (18). Studies comparing pain management in cognitively intact versus demented elderly with acute hip fracture also found a high rate of undertreatment of pain in both groups, a phenomenon that worsened with increasing age and cognitive impairment (19,20). Similarly, a study of outpatients with cancer found that age and female sex were predictors of undertreatment, a disturbing observation given the dramatic rise in cancer prevalence with increasing age (21,22). Chronic pain due to arthritis, other bone and joint disorders, and low back pain syndrome is probably the most common cause of distress and disability in the elderly, affecting 25–50% of community-dwelling, older adults. It is likely that these symptoms also are consistently undertreated (23). These data suggest that the time before death among elderly persons is often characterized by significant physical distress that is neither identified nor properly treated.

Despite the high prevalence of pain and other symptoms in the elderly, most studies focusing on the assessment and treatment of pain and other symptoms have enrolled young cancer patients. It is unclear whether these results are generalizable to a geriatric population. Pain assessment in the elderly is often complicated by the coexistence of cognitive impairment. The assessment and management of pain in the cognitively impaired patient present special challenges to the health care professional. The cognitively impaired patient is often unable to express pain adequately, request analgesics, or operate patient-controlled, analgesia devices. This increases the risk of undertreatment. The fear of precipitating or exacerbating a delirious episode by employing opioids in the management of pain may also lead to inadequate pain management.

As with the cognitively intact patient, the initial step in the assessment of pain in the demented individual is to ask the patient. Although patients with severe dementia may be incapable of communicating, many patients with moderate degrees of impairment can accurately localize and grade the severity of their pain (24,25). In the noncommunicative patient, alternative means of assessment must be identified. The need for careful pain assessment in this population of patients is underscored by evidence that suggests that medical professionals undertreat pain in the presence of cognitive impairment (19,20,26) and that pain may be aggravated in the presence of cognitive deficits (24). Untreated pain can result in agitation, disruptive behavior, and may worsen or precipitate a delirious episode (27,28 and 29).

Pain assessment in the noncommunicative patient should begin with observation of both nonverbal cues, such as facial expressions (grimacing, frowning) and motor behavior (bracing, restlessness, agitation), and verbal cues, such as groaning, screaming, or moaning. Data from cognitively intact individuals suggest that nonverbal behaviors correlate with self-reported pain in nondemented patients recovering from surgery (30,31). Pharmacological therapy should be titrated upwards in small, incremental doses until the nonverbal/verbal behavior disappears or side effects become apparent. This approach is particularly useful in the agitated patient whose behavior may well stem from untreated or undertreated pain. The risk of undertreating severe pain is generally more concerning, both medically and ethically, than the risk of worsening delirium with medications.

Pharmacological therapy for pain must be modified in older adults. The World Health Organization's analgesic ladder approach may not be appropriate for the elderly. For example, the increased risk of side effects, including renal failure and gastrointestinal bleeding, mandates great caution in the use of NSAIDs. This caution extends to currently available parenteral NSAIDs because of the significantly increased risk of gastrointestinal bleeding, particularly with higher doses and with duration of use greater than 5 days (32,33 and 34). Selective COX-2 antagonists have been associated with a decreased incidence of gastrointestinal events and are probably preferred for use in older adults over traditional NSAIDs (35,36 and 37). A recent systematic review, however, suggest that there may be an increase in adverse cardiovascular events associated with the use of COX-2 inhibitors although the magnitude of this risk has yet to be determined (38). The American Geriatrics Society has recently recommended that opioids be considered as a first step treatment rather than NSAIDs (23). If NSAIDs are used, careful monitoring of renal function and

close observation for the development of gastrointestinal bleeding must be undertaken.

Opioid therapy remains the cornerstone of pain management in palliative care and this is also true for older adults. Some aspects of opioid therapy require special consideration in the elderly. Older adults will have a more pronounced pharmacological effect after any weight-adjusted opioid dose than younger patients. The analgesia is more intense, and cognitive and respiratory effects, and perhaps constipation, are more severe. This enhanced effect is likely due to a lesser volume of distribution (approximately half that of younger patients), a decreased clearance, and diminished target organ reserve (central nervous system, pulmonary function, and bowel function). Age is the single most important predictor of initial opioid dose requirements for postoperative pain (39). The following formula, based on a review of records of more than 1000 adults between age 20 and 70 years undergoing major surgery, provides a rough estimate of the appropriate starting dose in parenteral morphine sulfate equivalents for adult opioid naive patients (with the exception of the old-old): average first 24-hour morphine (mg) requirement for patients over 20 years of age = 100 – age (39). Other factors that will influence opioid effects, but to a lesser degree than that of age, are body weight, severity of pain, abnormal renal function, nausea/vomiting, and cardiopulmonary insufficiency. After the initial dose determination, drugs should be titrated based on analgesic effect.

Several opioids are best avoided in older adults. Meperidine is particularly hazardous as a result of the accumulation of its toxic metabolite, normeperidine, in patients with impaired renal function. Indeed, toxic levels can accumulate in older adults with “normal kidneys” due to age-related changes in creatinine clearance. There are almost no circumstances in which meperidine should be used on older adults. Similarly, pentazocine should also be avoided in older adults because of the increased incidence of delirium and agitation associated with its use. Finally, opioids with long half-lives (e.g., methadone, levorphanol) or opioids with sustained release preparations (e.g., sustained release morphine and oxycodone, and transdermal fentanyl) should be used with caution, rarely used in opioid naïve geriatric patients, and should probably only be used following steady state accumulation of shorter acting opioids.

With respect to adjuvant agents, amitriptyline and the other tricyclic antidepressants, although efficacious in some neuropathic pain syndromes, are poorly tolerated in older adults due to their anticholinergic properties. Bowel and bladder dysfunction, orthostatic hypotension resulting in falls, delirium, movement disorders, and dry mouth are very common with these medications. If tricyclics are to be used, then nortriptyline or desipramine are the agents of choice and initial dosages should be very low and dose titration should be undertaken very slowly.

ALZHEIMER'S DISEASE AND RELATED DEMENTIAS

Irreversible dementia is a frightening and difficult diagnosis for geriatric patients and their families. A diagnosis of dementia means a certain and progressive decline in cognitive abilities over time and an eventual loss of independence. The prevalence of dementia increases with each decade of life over age 65. By the age of 80, about 19% of the older adult population will suffer with dementia. Over 80, the prevalence increases to almost 50% and continues to rise with age. Sixty percent of adults older than 100 years carry a diagnosis of dementia (40). Alzheimer's disease is the most common dementia, accounting for 50% of all cases (40). Alzheimer's disease affects over 4 million Americans, and 22 million people worldwide. Vascular dementia is the second most diagnosed type in the United States and accounts for 20–40% of cases. Lewy body disease, Pick's disease, and Creutzfeldt-Jakob disease are less common. Many patients present with a “mixed” picture and may be difficult to categorize clinically (40).

Dementia is a progressive, incurable illness, and all treatments are palliative. The average survival after a diagnosis of Alzheimer's disease ranges from 7–10 years. During this time, persons with dementia pass through different and predictable stages of disease. In the early stages, they may experience mild deficits in memory, judgment, and spatial relationships. They may face difficulties with word finding, driving, or learning new skills. As patients move into the moderate stages of the disease, they lose the ability to perform the instrumental activities of daily living. They may no longer be able to balance their own checkbook or shop for food. Family members or hired home attendants begin to play a larger role in the patient's care. Patients may develop behavioral disturbances, such as agitation, paranoia, or wandering. Advanced dementia patients depend entirely on their caregivers for even the simplest activities of daily living, like dressing, bathing, toileting, and ambulation. They develop a decreased ability to chew and swallow. They may not be able to recognize and remember their caregivers and loved ones. They are unable to describe pain or discomfort and may be nonverbal. Often, they are bedbound. A large proportion eventually require nursing home care.

Patients with dementia require medical care that focuses on preserving dignity and quality of life. Physicians should seek to manage aggressively the symptoms that endanger these goals. This must be done in early stages of the disease, the more moderate stages, and finally the advanced stages. The needs of patients in each stage are different, but the focus is always to preserve dignity and quality of life.

In early dementia, perhaps the most important job for the physician is to recognize and diagnose the disease and then to educate patients and their families about what they can expect. At this stage, patients can still make decisions for themselves. Physicians should ask patients about their preferences for medical treatments in the later stages of their disease and facilitate these important conversations between their patients and caregivers. Specific discussions about life-prolonging treatments, like artificial nutrition and hydration, should take place. Physicians should ask patients to designate one or more primary decision makers to speak for them in preparation for later stages of disease when they are no longer able to make decisions for themselves. Patients should be encouraged to talk with their designated caregivers and loved ones about their views about advanced medical therapies like feeding tubes, mechanical ventilation, and cardiopulmonary resuscitation (CPR). Although it is important to explore patients' specific preferences with regard to medical technology, it is equally important to explore the patients' values and goals of medical care: What is most important in their lives? What makes their lives worth living? What religious or spiritual values may be important? There is evidence that early conversations about advance directives help to prepare families for future decision making and may reduce the difficulty that comes with later surrogate decision making (41).

The early stages of Alzheimer's disease may be amenable to pharmacological therapy with cholinesterase inhibitors. Treatment with these medications may improve performance in activities of daily living, modestly improve cognitive function, or slow the progression of the disease process. Aggressive control of vascular risk factors and the use of aspirin and cholesterol-lowering agents may slow the progress of vascular dementia. The goals of both types of therapies are to preserve independence for as long as possible.

Many patients with early-stage disease have concurrent psychiatric issues. Depression is especially common, affecting approximately 50% of the early Alzheimer's disease population (42). The symptoms of depression in early disease may be atypical and include indifference, difficulties with emotional engagement, and decreased motivation. Antidepressant therapies are often indicated, and cholinesterase inhibitors may be beneficial. Support groups may also be helpful at this stage of disease, both for patients and their caregivers.

Moderate-stage dementia is the longest stage of the disease. The physician's focus should be keeping the patient's environment safe, treating psychiatric symptoms, and supporting the patient's caregivers. As patients move to this more middle stage of disease, their need for supervision at home and help with performing activities of daily living become greater. Behavioral disturbances, agitation, and paranoia often occur in concert with increased dependence. These changes may become significant sources of caregiver stress. Palliative measures in moderate-level dementia include recognition and attention to caregiver stress, treatment of behavioral and psychiatric disturbance, and instituting environmental safety modifications. Additionally, patients with a moderate degree of cognitive impairment often exhibit impaired eating behaviors, and physicians must work with patients and their caregivers to meet nutritional demands, as well as modifying food products for easier mealtimes.

Caregiver stress is common as relatives take on a more active and demanding role in the everyday routines of patients with progressive dementia. Many have never been in the role of primary caregiver for anyone other than their own children. Some primary caregivers may be geriatric patients themselves. Most families will face a high level of financial stress. Unless a patient has access to social services (Medicaid in the United States), out-of-pocket costs for additional help at home, pharmaceutical products, and durable medical equipment are high. Adult day programs may be hard to find, and respite programs are typically expensive. Patients with this degree of cognitive compromise may be difficult to place in nursing homes because often they do not carry other comorbid diagnoses, and the reimbursement rate for pure custodial care is low. Many caregivers leave their jobs or families behind to care for their loved ones. Some need to take on a second job to keep up with the financial burdens.

Caregivers may feel underappreciated because their loved ones fail to acknowledge how hard they are working or the sacrifices they are making. Eventually, patients fail to be able to even recognize who their caregivers are. These very real stresses need to be recognized, acknowledged, and supported. Physicians should question caregivers about fatigue, social isolation, depression, and physical symptoms. They should remind caregivers to take breaks and encourage other family members to help out. Caregiver support groups may also be helpful.

Behavioral disturbances become more frequent as dementia progresses. Although they may occur at any stage of disease, they are associated with increasing cognitive and functional decline. Symptoms include anxiety, depression, paranoia, delusions, hallucinations, sleep disorders, agitation, and combativeness. The presence of behavioral disturbance, especially paranoia and aggression, can increase the likelihood of nursing home placement. Treatment should be aimed at improving the quality of life of the patient and caregiver and should include both pharmacological and nonpharmacological considerations. Careful attention should be given to alternative causes of behavioral disturbance, like uncontrolled pain, untreated infection, or suboptimal management of concurrent disease. Treatment of underlying medical illness may lead to sustained improvement in both cognitive status and behavior. In addition, the etiology of agitation may be based on basic human needs—hunger, thirst, or the need to change wet or soiled clothing. Identifying the root of the problem may be difficult, as patients with moderate degrees of dementia can't tell their caregivers what exactly is bothering them. Nevertheless, the presence of a new behavioral disturbance should precipitate a medical evaluation and

should not simply be considered a consequence of the underlying dementing illness.

Treating obvious etiologies as well as addressing possible modifications in the patient's care environment can be useful ways to address behavioral disturbances. For example, a careful history may demonstrate that agitated and paranoid behavior occurs at bath time. In this case, perhaps changing the water temperature or moving from a tub to a sponge bath may be less threatening for patients and lead to decreased agitation (43). Evidence suggests that involving patients actively in grooming routines may also decrease agitation. Calm environments, the use of usual routines, favorite pieces of music, and visits from children or pets may all be soothing. Attention to a patient's sleeping patterns is also important. Increasing daytime activities and decreasing daytime napping may help patients sleep better at night.

In addition to these behavioral interventions, low-dose standing or as-needed major tranquilizers, such as haloperidol, risperidone, or olanzapine, may be required to successfully manage behavioral disturbances and prevent hospital admissions. Bedtime dosing with major tranquilizers or with trazodone may help with sleep disturbances. Benzodiazepines may be associated with paradoxical agitation, excessive somnolence, and falls, and should be avoided in most patients.

Eating behaviors also change in patients with moderate dementia. Diminished acuity of taste and smell receptors as well as decreased sensitivity in thirst receptors predispose dementia patients to malnutrition and dehydration. Patients may have difficulty using utensils properly. Extra sweeteners and spices may be helpful, as well as supplying frequent nutritious snacks and beverages. Finger foods are a good option. Specially designed utensils or dishes may make feeding easier. Careful attention to concurrent medications that may decrease appetite is warranted. These may include diuretics, beta-blockers, digoxin, and statins and should be discontinued, if possible.

Advanced dementia is the final stage of this terminal disease. Patients with end-stage dementia are dying. Research has demonstrated a median 6-month survival rate for patients with end-stage dementia, with or without tube feeding, although the range of survival times is wide (44,45,46 and 47). Most patients in this stage of disease are bedbound and nonverbal. Many patients in this stage of disease are placed in a nursing home because of their increasing care demands. Although comfort care and palliation of suffering should be the paramount focus of care, patients with advanced dementia often receive nonpalliative interventions at the end of life, such as tube feedings, CPR, mechanical ventilation, and systemic antibiotics in their final days of life (20,45,48,49).

Surrogate decision making in end-stage disease is inevitable. The process is made easier for all involved if, in the early stages of disease, the aforementioned critical discussions of treatment goals and end-of-life preferences have occurred. Caregivers may face multiple, difficult decisions, including emergency surgery, intubation, feeding tubes, and CPR. Even if the advance wishes were well communicated, it may still be difficult for family members to carry them out. Nonetheless, decisions should always be based on previously expressed wishes (if known) and the best interest of the patient with respect to the potential benefits or burdens of the proposed treatment. Physicians should offer caregivers continued support and offer them regular and repeated reviews of the goals of treatment and the expectations that follow interventions.

Comfort measures and the relief of suffering should be the primary palliative goals. Careful attention to potential sources of discomfort, such as pain and concurrent illness, is important. Pain is very commonly overlooked and undertreated in this population. Analgesic therapy should be empiric and preventive if an underlying source exists or the patient faces potentially uncomfortable procedures such as dressing changes or position changes. Physicians also should recognize that patients with advanced dementia may experience more discomfort from routine procedures, such as vital signs monitoring, phlebotomy, finger sticks, and bladder catheterizations, because they cannot understand what is being done to them and why. Unnecessary procedures should be discontinued. Topical anesthetic preparations may make the necessary procedures more bearable.

CONCLUSION

As a result of the unprecedented improvements in maternal and infant mortality and successes in the control, if not cure, of common chronic diseases, most people who die in the United States are old and frail. Conservative projections suggest that in the next 30 years, we will see a dramatic shift in demographics, with over 20% of the United States population being over age 65 in the year 2030. The elderly die of chronic, progressive illnesses (such as end-stage heart and lung disease, cancer, stroke, and dementia). These diseases have unpredictable clinical courses and prognoses, and current care systems are not well adapted to the trajectory of illness or the clinical needs of this group of patients. In contrast to younger adults, older adults often have unrecognized and untreated symptoms, cognitive impairment, and an extremely high prevalence of functional dependency and associated family caregiver burden. It is clear that our current systems of reimbursement are illequipped to provide primary care with continuity, support for family caregivers, and home care and nursing home services. Because care for a frail, older adult typically includes preventive, life-prolonging rehabilitation and palliative measures in varying proportions and intensity based on the individual patient's needs and preferences, any new models of care will have to be responsive to this range of service requirements. Several “mixed management” models of care have recently been proposed to address the needs of the frail elderly. They include the PACE Demonstration Program (50), a capitated Medicare and Medicaid waiver program, and the *MediCaring* model (51,52), a program targeted at patients with advanced heart and lung disease. But these programs have to date targeted only a small percentage of the growing number of older adults. Future research needs to be targeted at understanding the palliative care needs of older adults, developing medical interventions that address these needs, and developing models and systems of care that will meet the global needs of these patients and their families.

PALLIATIVE CARE IN HUMAN IMMUNODEFICIENCY VIRUS/ACQUIRED IMMUNODEFICIENCY SYNDROME

STEVEN OPPENHEIM
JACQUELYN B. HAY
MICHAEL E. FREDERICH
CHARLES F. VON GUNTEN

PALLIATIVE CARE AND HUMAN IMMUNODEFICIENCY VIRUS

Palliative care is multiprofessional, interdisciplinary care to relieve suffering and improve quality of life. Palliative care for the patient with human immunodeficiency virus (HIV) infection seeks to meet the individual's physical, social, psychological, and spiritual expectations and needs with sensitivity to personal values, and cultural and religious beliefs and practices (1). This requires the integration of medical, nursing, psychological, social work, spiritual, physical therapy, and pharmacological expertise (2). Care planning includes the individual, family (as defined by the individual), and caregivers. HIV palliative care is not reserved to a single type of health care setting or agency (1,3).

The challenge in caring for patients with HIV is balancing medical treatments aimed at controlling the disease with palliative care designed to relieve suffering and improve quality of life. Contemporary HIV therapy has led the expectation for continued improvements in the ability to provide life-prolonging care (4). At the same time, contemporary therapy does not benefit all patients. “Successful” antiviral therapy can lead to prolonged suffering due to the adverse effects of the medications. Some patients still die of HIV infection and its complications, either in spite of contemporary therapy or because they do not have access to such therapy.

Although the dimensions of suffering for patients with HIV are not unique, some of the sources of suffering within those dimensions deserve emphasis: multiple symptoms, polypharmacy, multiple losses, personal experiences with illness or death related to HIV disease, social stigma and isolation, unpredictable disease course, and the complex and rapidly changing nature of HIV treatment approaches (5,6). Treatment changes have been so rapid and the results (and anticipated results) so broadly marketed, that many individuals with HIV disease do not see disability or death as an option because they expect dramatic new therapeutic advances. Consequently, it is common for these patients to seek health-restoring and life-prolonging therapy until death is near.

The tenacity and will to live is remarkable in many patients with HIV disease. Even the most vulnerable patients who have experienced multiple HIV and HIV-related losses, including the loss of loved ones and support systems, may want “everything done.” As a result, these patients change physicians to seek more aggressive therapy even when told there are no more treatment options. The key skill in managing these situations is to assess patient goals and expectations throughout the course of the disease trajectory. Suffering and quality of life are subjective and can only be determined by the individual, not by the clinician. Consequently, palliative care should be incorporated into the care plan as early in the disease trajectory as it is needed (7,8).

HUMAN IMMUNODEFICIENCY VIRUS AS A CHRONIC ILLNESS

For the majority of patients with access to contemporary therapy, HIV is a chronic illness (Fig. 78-1) (4). Challenges to quality of life occur throughout the course of the illness. These challenges start with the stress associated with the testing process to screen for HIV infection, continue with the various events that emerge during treatment, and culminate with the terminal phases of the disease. For some. patients, this period may be decades in length. Eight landmark events in HIV disease that may cause severe stress and uncertainty (Table 78-1) should be carefully considered when breaking the bad news of a new diagnosis (9). Clinical vigilance for the various manifestations of suffering during the entire continuum of this process is required to offer remedies to improve the quality of life when needed. These remedies include, but are not limited to, state-of-the-art HIV therapies.

Dying and death

TABLE 78-1. THE EIGHT MAJOR POSSIBLE LANDMARK EVENTS IN HUMAN IMMUNODEFICIENCY VIRUS (HIV) DISEASE

The increased survival many patients with HIV experience has led to many sequelae that were not seen earlier in the epidemic. Long-term metabolic, morphologic, and neurological consequences are associated with successful virologic control of the infection. For example, it is unclear whether the hyperlipidemias related to HIV infection will lead to accelerated atherosclerosis and its complications. Without proven medical therapy for the morphologic changes that accompany HIV therapy, these complications may increase the stigmatization of patients (10). These longterm consequences have caused patients and clinicians to question the appropriate time to initiate anti-HIV therapy.

There are other conditions that affect the patient with HIV infection (11). Depression can complicate the course of the disease and adversely impact successful treatment. The risk of financial loss can be overwhelming. The ravages of concomitant substance abuse may add to this suffering.

Chronicity of illness may produce medical, social, and psychological burdens for those living with HIV disease. The need to attend multiple medical appointments for treatment, often at various locations, can be exhausting, particularly for patients experiencing side effects of therapy or if transportation is a problem. Collaboration of health care providers is needed to minimize chaos and to prevent duplication of services. It is not unusual for patients with HIV to be linked to multiple community services; if not well coordinated, however, this can add stress and frustration to the patient, family, and providers. Patients with HIV should be asked whom their best advocate is when multiple “case managers” are involved.

Efforts aimed at managing HIV infection and its consequences must be combined with efforts to relieve suffering and enhance quality of life. This can be complex and requires skills and competencies that may be beyond the usual training of most HIV clinicians. The perspective of palliative care and the expertise and resources of hospice and palliative care programs may provide an opportunity to more comprehensively care for persons living with HIV infection.

A manifestation of this perspective is the development of San Diego Palliative Home Healthcare (SDPHH) in 1998, with the intent of providing “advanced care for advanced disease.” This HIV program is the first, disease-specific, palliative care program of its kind in the San Diego county service area. Critical care nurses are selected and trained as HIV palliative care case managers. Their role is to coordinate all aspects of the patient's care as well as provide direct intermittent care to the patient. Intensive clinical training includes management of anti-HIV treatment, assessment of symptoms and their relationship with adverse effects of drugs, and management of complex pain and symptom syndromes. Interdisciplinary case conferences involve clinical direction from two physicians. One physician is an expert in HIV clinical care and works in a large group practice for HIV disease management, as well as serving as the SDPHH HIV Team Medical Director. Another physician, who is an expert in palliative care, acts as a consultant for patients with complex pain or other symptoms. Both physicians make joint home visits with SDPHH HIV Team members as needed. Ongoing staff support has been essential to maintain the integrity of the team. Every case conference includes time to acknowledge the patients who have been discharged to self-care or who have died, which allows closure for the multiple patient loss issues experienced by the professional caregivers. Strong partnerships have been developed with various community HIV providers. SDPHH has earned a reputation for having a palliative care team with strong clinical skills in HIV disease management. The program has increased access to expert end-of-life care, especially for those who have been unwilling to utilize hospice services. Most important, SDPHH has made it possible for more HIV patients in San Diego County with advanced disease to experience relief of suffering and improved quality of life.

The purpose of this chapter is to provide specific information on the palliative care of patients with HIV not otherwise presented in this textbook. The content is directed to the general clinician, not the specialist in HIV palliative care. The goal is to increase awareness of the need to provide palliative care throughout the course of HIV disease and to discuss approaches to managing common problems.

HUMAN IMMUNODEFICIENCY VIRUS DISEASE—AN OVERVIEW

Human immunodeficiency virus infection is a dynamic process. It has become clear over the last several years that, starting from the time of primary infection, the concentration of virus particles in the blood (the plasma viral load) represents a balance between rapid viral replication and clearance. The viral load is used to help clinicians determine the appropriate time to initiate antiviral therapy, the virologic success of ongoing therapy, and the overall risk of disease progression. This information is combined with the T-helper CD4 count (a measure of the level of virally induced immune compromise) in order to make therapeutic decisions for antiviral therapy and opportunistic infection prophylaxis (12,13).

Even with the most successful suppression of the virus by antiviral therapy, it is now apparent that viral eradication is impossible. All patients have detectable HIV when the most sensitive assays are used. Consequently, HIV is now considered a chronic condition. Three-drug antiviral therapy is cost effective (14). In the best of circumstances, maximally suppressive HIV therapy may delay or prevent progression of the disease. Although the viral load and CD4 count are useful for staging the disease, they do not reliably reflect the degree of symptoms experienced and should not be used to predict the level of distress experienced by a particular patient.

The presence of the virus, despite suppression of virologic replication, initiates cytokine activation and contributes in part to the constitutional symptoms of HIV disease. The other factors that contribute to constitutional symptoms, such as fatigue and sweats, are poorly understood and need to be approached clinically with a consideration of multiple possible causes, including the virus, opportunistic infections, metabolic issues, hematological conditions, and antiviral therapy.

At the beginning of the epidemic, the average survival for someone with acquired immunodeficiency syndrome (AIDS) was 18 months. Now, with proper treatment, a normal life expectancy may be possible for many (4). Our successes in treating HIV have resulted in an increasing prevalence of people living with HIV and a need for more attention to non-HIV routine health maintenance.

Populations at Risk

Because of the nature of HIV transmission, the disease has adversely affected numerous populations. These populations include men who have sex with men (MSM), women, sex workers, substance users, the poor, and minority populations. The development of sensitivity and increased awareness of cultural differences is required if they are to be most effectively assisted (15).

MSMs comprise a decreasing proportion of those with HIV in the United Sates They may or may not identify themselves as homosexual, gay, or bisexual. They frequently have various less traditional family associations. In addition, their family may either be estranged or unaware of their lifestyle or HIV status. An increased awareness for the usual sexually transmitted diseases among MSMs is critical, particularly because of the recent rise of syphilis and rectal gonorrhea in this population (16,17). In addition, an awareness of the increased incidence of human papilloma virus and the development of anal cancer is important in this group (18).

Women comprise 24% of those reported with AIDS. A disproportionate number of these women are African-American and Hispanic. Intravenous drug use and heterosexual transmission, including sex for money, are the leading risk factors for acquisition of HIV by women. There are numerous psychosocial stresses these women with HIV experience. These include the need for help with child care, less access to health care, and issues with their significant other because of their HIV status.

Although the exact proportion of men and women with HIV who are commercial sex workers is not known, this population deserves special mention. This group, as a whole, tends to abuse substances more often and has less stable living situations. Although complete adherence to the recommendations for safer sex and substance use is rare, a harm reduction approach might result in fewer consequences resulting from these practices. This is a special. population for whom increased psychosocial support and utilization of community resources designed to assist this group will enhance the therapeutic success.

Substance abuse, as a whole, is not only a risk factor for the acquisition of HIV infection but serves as a harmful coping strategy for those experiencing distress because of their HIV status. The consequences of this strategy include the toxic and infectious complications of drug use as well as the deleterious effects on medical adherence and follow-up. Although abstinence may be preferred, a harm reduction approach to minimize the complications of substance abuse might be more successful for many. The attitude of the clinician with regards to these issues can seriously affect the level of trust and disclosure that the patient offers.

The poor and minority populations who are underinsured but overrepresented among those with HIV have a higher risk of receiving no or less care for their disease (19). This places them at a higher risk for disease progression and incomplete treatment of their symptoms. Although federal entitlement programs such as the Ryan White Care Act and the AIDS Drug Assistance Program make treatment available to the underinsured, there are still many who are eligible but do not access care. Further, the regional differences in program content leave certain aspects of care unavailable. An increased cultural awareness for these groups by the clinician can be a great asset to those served.

Contemporary Anti–Human Immunodeficiency Virus Therapy

The advent of highly active antiretroviral therapy with multiple drugs used in combination has dramatically changed the natural history of HIV since 1995. A detailed discussion of antiretroviral therapy is beyond the scope of this chapter, but a few comments can place the field into a contemporary perspective. Except for the approximately 5% of patients who are nonprogressors, it would appear that the remainder will ultimately experience increasing viremia and immune compromise (20).

Because of the problems associated with antiviral treatment, there has been a change in recommended therapy from “hit early, hit hard” to a more conservative postponement of therapy (11). This change has come from the recognition that many factors influence therapeutic success such as the effects of pill burden, the need for >95% adherence for maximal success, the long-term metabolic effects of therapy, and the challenges of treating patients with antiviral resistant virus (21). Despite the development of viral resistance assays to help guide the choice of drugs, the long-term benefit from using them is, as yet, unclear. Coupled with the limited armamentarium of antiviral agents, these observations support the advice to wait longer to initiate therapy.

At the time of this writing, there are 16 licensed drugs to treat HIV. Unfortunately, intraclass cross-resistance limits treatment options. Clinically significant adverse effects of the medications include nausea, bloating, diarrhea, rash, hepatic and renal dysfunction, neuropathy, cytopenias, and sleep disturbance. Careful attention to food and water requirements and the varied drug interactions is required. It is for these reasons and others that detailed knowledge about the medications or consultation with an HIV specialist is strongly recommended when a generalist cares for one of these patients.

Although progression of the disease can be prevented with the newer medications, this success is not without cost. There are a number of HIV-associated conditions that appear to be the consequence of metabolic disturbances resulting from the virus and/or the therapy used. These conditions include neuropathy, lipodystrophy, hyperlipidemia, and hyperglycemia. These conditions may be due to mitochondrial dysfunction and may be responsible for a large part of the morbidity associated with HIV (22).

It should be no surprise that structured treatment interruptions are being investigated to see if intermittent treatment may reduce toxicity without compromising control of the disease. Although this approach is purely experimental, it has been embraced by the HIV-infected community as a response to the significant adverse effects of therapy. This area of HIV medicine requires careful consideration of quality of life issues balanced with those of virologic control.

The ultimate goal of therapy needs to be customized by the health care professional and the patient. Many times, palliative antiretroviral treatment, as opposed to maximal viral suppression, may be more appropriate for patients with viral resistance precluding such control, and in those unable to tolerate a “complete” regimen.

Comorbidity

Among many possible comorbidities (cancer among them), it is important to mention the contribution of chronic hepatitis B and C virus infection to the overall morbidity of many patients with HIV infection (23). Not only can these conditions increase the chance of hepatotoxicity from multiple medications, but they may also be major causes of the constitutional symptoms that patients with HIV experience. With the new methods of treating these coinfections, selected patients may now benefit from cotreatment of their viral hepatitis. It is important to point out that all the symptoms a patient experiences may not be directly or indirectly related to HIV infection. Patients must be carefully evaluated for comorbid conditions.

HUMAN IMMUNODEFICIENCY VIRUS PALLIATIVE CARE

Setting Goals

Understanding the goals of the individual infected with HIV disease is the essential first step in palliative care. There are a range of possible goals. Cure, prolonging life, relief of symptoms, avoiding hospitalization, and putting affairs in order before anticipated death are but a few. There may be multiple goals. They may be contradictory. The process of setting goals, including a discussion of patient values, also serves to enhance the clinician-patient relationship through improved understanding of the patient by the clinician (7).

Goals are likely to change over the course of a lifetime or an illness. It is important that a conversation about goals occurs early following the diagnosis of HIV infection so that appropriate palliative care techniques may be applied throughout the course of illness. None of the palliative interventions discussed in this chapter will decrease longevity or hasten death.

Palliating Physical Symptoms

General principles of management guide the palliation of physical symptoms. Three of those principles deserve particular mention.

Communication

One of the most critically important tools is good communication. Without it, physical symptom assessment will be, at best, inaccurate and, at worst, impossible. In addition to assessment, communication serves a teaching and reassuring role. Given the myriad possible implications of a new or worsened physical symptom, one of the most important roles for clinicians caring for patients with HIV infection lies in telling them what they do not have. For example, good communication can reassure anxious patients that their common cold is not *Pneumocystis pneumonia* and that the bruise on their leg is not Kaposi's sarcoma (24).

Think Critically

A common pitfall in managing persons with HIV infection is to attribute all symptoms to the underlying HIV disease. Persons with HIV may, like cancer patients, have other etiologies for their symptoms that may be readily treated and resolved. Many clinicians abandon the problem-solving diagnostic approach used in other areas of medical practice when caring for someone with advanced-HIV infection. This is unfortunate because retaining this approach is essential for effective symptom management.

Prevent Problems

Good palliative care seeks to both anticipate and prevent likely events. Prescribing medication to prevent common symptoms is critical. Regular dosing of medication in order to prevent symptom recurrence should follow initial treatment of presenting symptoms (25).

Hematological Manifestations

Hematological abnormalities are extremely common in HIV disease and can pose a significant threat to the quality of life of the person affected. These abnormalities generally manifest as anemia, leukopenia, and thrombocytopenia resulting from direct or indirect effects of HIV, opportunistic infections, or medications used in management of HIV. A detailed description of the differential diagnoses and management of these conditions has been reviewed elsewhere (26,27). What follows is a general discussion of the hematological effects seen with HIV.

Anemia

Anemia is the most frequently observed hematological abnormality in HIV infection. It may cause fatigue, dyspnea, altered mentation, headaches, and cold intolerance (28). Anemia has been correlated with decreased survival and its resolution with an improved prognosis in HIV disease. Usually, the anemia of chronic inflammatory block is responsible. However, other hypoproliferative states may be responsible: medications (Table 78-2), marrow infiltration by tumor (e.g., lymphoma) or opportunistic infection, gastrointestinal bleeding, and vitamin B_{12} or folate deficiency. Rarely, anemia may result from autoimmune hemolytic anemia, drug-induced hemolysis from glucose-6-phosphate deficiency, or disseminated intravascular coagulation.

Drug	Anemia	Neutropenia	Thrombocytopenia
Amphotericin	X	X	X
Anti-neoplastic chemotherapy	X	X	X
Anti-RhD	X	X	X
Cidofovir	–	–	X
Flucytosine	X	X	X
Foscarnet	–	–	X

Trimetrexate	X	X	–
Zidovudine	X	X	–

TABLE 78-2. HEMATOLOGICAL EFFECTS OF MEDICATIONS USED IN HUMAN IMMUNODEFICIENCY VIRUS DISEASE

The approach to treating anemia requires evaluation for its cause and treatment of the underlying condition. If causative medications are identified, they should be eliminated, if possible. Transfusion requirements may be reduced or eliminated with the use of recombinant human erythropoietin. If the endogenous erythropoietin level is <500 units/ml, recombinant human erythropoietin may be dosed at 50–100 U/kg subcutaneously three times a week. Recent studies have shown that once weekly injection of the total dose is as effective. Generally, maintaining the hemoglobin concentration above 10 g/dl reduces symptoms related to anemia. However, it is important to mention that the symptoms may be multifactorial and may not resolve with treatment of anemia. Further, the baseline functional status of patients, their underlying conditions, and their goals are important to consider before treatment is applied to a low hemoglobin level.

Neutropenia

A lower than normal leukocyte count is quite common in HIV infection. This is most frequently due to a combination of lymphopenia due to CD4 reduction and neutropenia. The frequency and degree of neutropenia increase as HIV disease progresses. The causes of neutropenia may result from HIV infection itself, medications (Table 78-2), and concomitant infections. The neutropenia related to HIV alone is associated with myeloid precursor dysregulation, lower levels of granulocyte colony-stimulating factor and anti-granulocyte antibodies. The risk of infection increases when the absolute neutrophil count (ANC) is <500, and most providers consider some intervention when the ANC is <1000 (29).

Treatment of an identified condition contributing to the lowered ANC is always the first approach. The availability of recombinant granulocyte colony-stimulating factor has made it possible to continue some myelosuppressive therapies without the risk of complications from neutropenia. However, when multiple medications that cause neutropenia are being used, some adjustment of the medical regimen is usually required. This situation most frequently arises during the treatment of cytomegalovirus (CMV), toxoplasmosis, *Pneumocystis carinii*, and lymphoma.

Utilization of nonmyelosuppressive medications is preferred when possible, but granulocyte colony-stimulating factor 1–5 mg/kg/d usually elevates the ANC to eliminate any risk. After the ANC is >1000, the dose and frequency may be adjusted as indicated by the neutrophil response.

Thrombocytopenia

Thrombocytopenia is quite common in HIV infection, but hemorrhage from reduced platelets is not. Bleeding is rare because the counts are usually only modestly reduced. When the etiology of the thrombocytopenia is due to increased destruction, the remaining platelets tend to be younger and more functional.

The most common causes of thrombocytopenia associated with HIV result from decreased production related to the virus, marrow invasion by tumor or opportunistic infection, and medication effects on the megakaryocytes (Table 78-2). Increased destruction can also cause reduced platelets in the setting of infection, immune-mediated destruction, thrombotic thrombocytopenic purpura, or disseminated intravascular coagulation. After reviewing and eliminating medications and ruling out increased destruction by clinical evaluation and examination of the blood smear, the question is usually whether the thrombocytopenia is immune-based or due to marrow infiltration. If the clinical picture or marrow examination excludes the latter, immune thrombocytopenia caused by HIV is generally the cause.

Treatment of HIV-associated immune thrombocytopenia is initially approached by antiretroviral therapy. Older studies had positive responses using zidovudine, but it is unclear whether this was because this drug has a unique effect on platelet production or whether the limited choices of agents at the time led to this conclusion (30). Adjunctive therapies with danazol, intravenous immune globulin, anti-RhD, and prednisone can also help. The plasma-based treatments are effective but can be expensive and must be continued in order to maintain the remission. However, the long-term use of corticosteroids in these patients has to be balanced with the higher risk of opportunistic infection and progression of Kaposi's sarcoma. Splenectomy is rarely needed and places the patient at high risk of the usual infectious complications accompanied by asplenia. Platelet transfusions should be reserved for cases where life-threatening hemorrhage is likely and other more long-term treatments are planned as long as the patient's wishes and clinical situation warrant such therapy.

Constitutional Symptoms (Anorexia/Cachexia, Fatigue)

Anorexia (decreased appetite) and cachexia (weight loss) occur in as many as 70–90% of patients with AIDS (31). Cachexia is an independent risk factor for mortality. Advanced HIV infection is associated with weight loss in excess of 5% of the usual body weight. Although this may ultimately affect a majority of patients with AIDS, it may also be an early finding (i.e., early in the epidemic, 17% of patients had wasting as their AIDS-defining illness, and 24% will have it as a component of their presentation). The catabolic state of these patients also potentiates their already present immune deficiencies, thus increasing the risk of opportunistic infection (32,33 and 34).

The patient's anxiety about the meaning of weight loss and fatigue, as well as the loss of pleasures associated with eating and activity, may have a profound impact on quality of life.

Hellerstein and colleagues have implicated inflammatory cytokines, such as interleukin-1 and tumor necrosis factor, as causal mediators of anorexia-cachexia in AIDS (32). Opportunistic infections, particularly disseminated *Mycobacterium avium intracellulare*, have been implicated in causing fever and weight loss (35). Other common causes or contributors to anorexia/cachexia and fatigue include medications, such as the antivirals, sulfonamide antibiotics, and metronidazole, and endocrine disorders (including hypogonadism and rarely hypothyroidism), anemia, and depression.

Diminished food intake in patients with HIV infections may be due to lesions of the mouth, pharynx, or esophagus related to specific medications or associated with nutrient malabsorption or systemic infections. Several intestinal parasites, such as cryptosporidium, Isospora, and microspora, are major pathogens in AIDS and are clearly associated with intestinal dysfunction (34).

As in managing any symptom, before discussing specific therapy, patients should be asked whether or not they perceive their anorexia, cachexia, and fatigue to be problematic. It is not infrequent that this symptom complex is concerning to family or friends rather than the patient. If not, interventions may be foregone in accord with the wishes of the patient.

General measures are pursued first. These usually include a dietary consultation to identify foods that are likely to be attractive and appetizing as well as high in calories. Specific seasoning of food may be helpful. Dietary restrictions of calories, sweets, or sodium make no logical sense. A physical therapy consult for an evaluation and regimen to build endurance should be considered for patients with fatigue.

The patient's medication list should be evaluated for medications that may be contributing to anorexia and appropriate changes made where indicated. Specific conditions that are correctable should be searched for diagnostically, including opportunistic infections.

Anemia may be treated with erythropoietin injections or transfusion. Depression may be treated with psychostimulants or antidepressants. Hormonal replacement may be indicated. Hypogonadism should be treated with testosterone.

Growth hormone and anabolic steroids for patients with weight loss may also be effective. These modalities have been associated with increased appetite, energy, and lean body mass, which has been correlated with increased survival. Testosterone (200 mg i.m./wk or 5 mg topical gel/day) with or without oxandrolone 10 mg twice a day has been very helpful for lean body mass increases and an increase in functional status in men. Human growth hormone also can have these effects at a higher cost. It is given as a daily injection of 3–6 mg and is associated with a high incidence of reversible myalgia, arthralgia, carpal tunnel syndrome, and edema. Both approaches work best in the setting of optimal nutrition and a moderate exercise program.

Appetite stimulants, including corticosteroids, progestational drugs, and dronabinol, may or may not be helpful. They have been associated with only fat mass accumulation that has no effect on the overall prognosis but may have a palliating effect on the patient. Stimulants, such as alcoholic beverages or caffeine-containing beverages, may be helpful if given 30 minutes before meals.

Corticosteroids (e.g., dexamethasone, prednisone) are associated with a short-term increase in appetite (approximately 4 weeks) without significant weight gain. Some clinicians fear the use of these drugs in patients with HIV in view of the underlying immune deficiency. However, in patients with advanced HIV infection in whom a generalized improvement in well-being and stamina is desired, and for whom long-term therapy is not contemplated, corticosteroid therapy may be useful. Dexamethasone in a single morning dose of 2–6 mg may be effective, although a higher dose may be required.

Progestational agents like megestrol acetate (Megace) have been proven effective in improving appetite, with maximal weight gain usually demonstrated within 8 weeks of starting the medication in patients with AIDS (33,36). As a dose response with respect to weight gain has been demonstrated, it is best to begin therapy with 800 mg/day. If there is a response, the dose can be titrated to the smallest dose that maintains the desired effect. The drug is expensive and has been associated with hyperglycemia due to its glucocorticoid effect, and impotence in men from its inhibition of testosterone secretion. The latter effect can be prevented with concomitant testosterone therapy. Sudden withdrawal of megestrol acetate can precipitate adrenal crisis due its suppression of the adrenals.

Dronabinol (Marinol) and tetrahydrocannabinol (THC) have been shown to increase appetite and weight in AIDS patients (37,38 and 39). The therapeutic effect may not be seen for up to 4 weeks. The starting dose is 2.5 mg twice a day before meals, which is gradually increased until the desired effect is achieved. Clinically effective doses of dronabinol are associated with euphoria or dysphoria in some patients, particularly the elderly. Patients with a history of smoking marijuana are more likely to tolerate the drug well. Smoking marijuana may be more effective because absorption of oral. THC has been found to be erratic. Smoking, however, may place the HIV patient at risk for possible injury to the lung and immune system, with increased episodes of *Pneumocystis carinii*, bacterial, and fungal *(Aspergillus*) pneumonias (37).

Prokinetic medications, such as metoclopramide (Reglan), may help with symptoms of anorexia related to early satiety. Enteral nutrition supplements beyond optimal dietary management improve nutritional status only marginally, and are not well tolerated in patients with advanced HIV disease. If chosen, oral supplements should be lactose-free to minimize diarrhea and abdominal cramping.

Total parenteral nutrition is only recommended for HIV patients who have one of four conditions and are otherwise well: (a) severe refractory diarrhea associated with progressive weight loss and malnutrition, (b) persistent intolerance to enteral feeding in the absence of any acute, remediable, AIDS-related condition, (c) persistent severe gastrointestinal malabsorption, or (d) intraabdominal pathological condition resulting in indefinite continuous mechanical bowel obstruction. In advanced HIV disease, however, in the absence of one of the four conditions just named, total parenteral nutrition rarely helps the symptoms of fatigue and anorexia for which it is offered (8).

A care plan with short and long-term goals should be formulated and useful interventions continued, while those that are not effective are discontinued in a timely manner. For patients with advanced HIV disease, or those who fail interventions to correct anorexia and cachexia, clinicians can educate patients and families about what to expect and about the emotional meaning of weight loss and feeding. At this time, it is usually best to stop weighing the patient, thus removing another focus on a numerical value.

Fatigue is usually not easily overcome by rest. Symptomatic treatment includes planning and pacing activity and promoting adequate sleep, nutrition, and rest. An occupational therapy consultation may be helpful. Rest periods, however, should be differentiated from naps. Napping throughout the day may, in fact, increase fatigue.

Environmental manipulation is helpful. Thoughtful placement of phone, medications, drinking water, and other essentials decreases energy expenditure. Because immobility promotes fatigue, at least some exercise is helpful, whether it is passive or active (40,41 and 42).

Psychostimulants such as methylphenidate (Ritalin) 2.5–5.0 mg morning and noon, and dextroamphetamine (Dexedrine) 10 mg daily may be given to reduce fatigue (43). Medication should be given in the morning to prevent interference with normal sleep.

Pain

Pain may be as prevalent in patients with HIV as it is in patients with cancer (44,45). The approach to pain in the patient with HIV is not fundamentally different from that in the patient with cancer (46). Many different pains are found in patients with advanced AIDS, and studies show that these pains are consistently underdiagnosed and undertreated. A majority of AIDS patients have more than one type of pain, and the prevalence of pain increases as the disease progresses (44,45,47,48).

Good pain management relies on good pain assessment, including an adequate pain history and an ongoing evaluation of the response to analgesics.

Neuropathic pain occurs in 30–40% of HIV patients (46). Although some of the medications used in the management of HIV disease may cause peripheral neuropathy, this condition can also develop from the effects of HIV on the nervous system itself.

Patients frequently describe the pain of peripheral neuropathy as burning, shooting, numbness, or like pins and needles. Findings on physical examination that support the diagnosis of neuropathy pain are allodynia (a usually nonpainful stimulus like light touch provokes the pain), hyperesthesia, numbness, absent reflexes, or color changes in the affected area. Diagnostic tests, such as electromyography, are not generally necessary to confirm the diagnosis of painful peripheral neuropathy. Pain management may begin after an adequate history and physical examination have been completed.

The relief of pain in patients with AIDS is largely approached by pharmacological methods. Treatment should optimize the use of nonopioid, opioid, and adjunct analgesics. However, this does not minimize the adjunctive roles that explanation, empathy, understanding, and nonpharmacological analgesic therapies play (50). Psychological factors, such as low mood, fear, and anxiety, should be actively addressed.

In contrast with nociceptive pain, the control of neuropathic pain frequently requires adjuvant medications, such as antidepressants, anticonvulsants, and others, in addition to opioids. No one class of medication, or specific medication, is effective in every patient. Adverse effects and drug interactions often influence the choice of agents. If there is a strong clinical suspicion that the neuropathic pain is due to medications, these should be stopped so that the syndrome does not progress further. It should be noted that the neuropathy might progress for a month or two after discontinuation of the offending agent(s) before improvement is seen from drug discontinuation.

The tricyclic antidepressant, amitriptyline, is the most studied adjuvant for neuropathic pain. However, all of the tricyclics are analgesic. Although these analgesic effects, like the antidepressant effects, are presumably mediated through monoaminergic mechanisms, depression is not prerequisite for analgesic efficacy. Analgesia is frequently observed at dosages considered to be subtherapeutic for the treatment of depression. Desipramine and nortriptyline are more commonly prescribed because of fewer adverse effects (49,50).

Serotonin selective reuptake inhibitors may be less effective than the tricyclic antidepressants for neuropathic pain. They may have a role in the treatment of concurrent depression that can worsen pain. Venlafaxine (Effexor) has both serotonergic and adrenergic effects. This may explain some reports of its effectiveness as adjunctive analgesic therapy for neuropathic pain.

Anticonvulsants are also analgesic for neuropathic pain. Gabapentin (Neurontin) is widely used and has been proven effective in diabetic peripheral neuropathy and in postherpetic neuropathy. Carbamazepine (Tegretol), valproic acid (Depakote), and phenytoin (Dilantin) have all been described to have analgesic effects in

neuropathic pain.

Methadone is an opioid with unique characteristics that could theoretically enhance analgesic effects in neuropathic pain (51). Some have observed that patients with severe pain respond better to methadone than other opioids at equianalgesic doses. This has been attributed to the N-methyl-D-aspartate antagonist activity of the D-isomer of methadone. Commercially available preparations of this medication consist of a racemic mixture of levo and dextro isomers. The levo isomer has analgesic activity at opioid receptors.

Historically, the use of methadone has been eclipsed by long-acting preparations of opioids with more predictable pharmacokinetics. As an analgesic, methadone was considered a difficult medication to titrate due to its long half-life and concern that it is lipophilic and likely to be fat deposited. Now, however, clinicians are expressing renewed interest in methadone, particularly for HIV patients with mixed pain syndromes (both neuropathic and nociceptive). Their lower body fat stores make fat deposition less of a problem.

Most current conversion tables list 20 mg of methadone as dose equivalent to 30 mg of morphine. However, new data suggests that methadone is at least ten times as potent as morphine when converted at high doses (51). Conversion from the previously prescribed opioid may be done safely in 3 days by decreasing the dose of the previous opioid, one-third each day, and increasing the dosage of methadone by one-third of the target final dose each day (E. Bruera, personal communication).

In the recent experience of the authors, methadone is frequently effective for neuropathic pain in HIV patients, particularly those who have mixed pain syndromes. The stigma associated with methadone, related to its use in addiction medicine, takes work to overcome with some patients, but this is usually worth the effort in improved pain management (52).

A past or present history of recreational drug use raises an additional concern in the treatment of pain in patients with AIDS. Although this is treated as a general topic elsewhere in this text (see Chapter 41, Substance Abuse Issues in Palliative Care), a few remarks are in order. Most important, nonopioids should not be substituted for opioids in the management of pain merely because of a history of substance abuse (46). When treating patients with HIV infection and a history of opioid abuse, the clinician should anticipate using larger doses of the opioid analgesics than usual because of the incipient tolerance that may be present. Concerns regarding drug diversion or abuse need to be openly discussed with the patient. Contracts may be needed to clarify issues and expectations.

Nausea and Vomiting

Nausea is an unpleasant sensation that may be activated by any or all of four primary mechanisms involving stimulation of the chemoreceptor trigger zone (CTZ), vestibular apparatus, gastrointestinal tract, and cortical areas. In many HIV patients, the cause of nausea is multifactorial and will require combination antiemetics to manage.

One of the most common mechanisms is stimulation of the CTZ in the fourth ventricle. Because of the polypharmacy that almost always accompanies the treatment of a patient with advanced HIV infection, drug-induced nausea mediated through this mechanism is exceedingly common. Medications that commonly stimulate this mechanism include antiretrovirals, opioids, and antibiotics. Although discontinuing or changing these medications may prove difficult, treating this mechanism with inexpensive dopamine antagonists (promethazine, haloperidol, droperidol, metoclopramide) or more expensive serotonin antagonists (ondansetron, granisetron) may be effective in relieving nausea (53).

The vestibular apparatus is stimulated in motion sickness and as an initial effect of opioids. Treating this mechanism with an antihistamine (diphenhydramine) or anticholinergic (scopolamine) is usually effective. Histamine and acetylcholine receptors are also implicated in the CTZ.

Patients who describe early satiety, or who report persistent nausea and vomiting only after eating, may be suffering from an HIV-associated diffuse gastroenteropathy caused by dysmotility, mucosal CMV infection or infiltrative tumor (Kaposi's sarcoma or lymphoma). Nausea and dysmotility may also be a result of constipation. In addition to usual management of constipation, prokinetic agents like metoclopramide may be helpful (54).

Nausea caused by central cortical mechanisms may respond to multiple interventions. Benzodiazepines (lorazepam, diazepam) are probably effective through their anxiolytic and amnestic effects. Corticosteroids have broad antiemetic properties that are poorly understood. These effects are not explained by the treatment of nausea due to increased intracranial pressure from tumor or infection. Tetrahydrocannabinol, dronabinol (Marinol), or marijuana have antiemetic effects that relate to diffuse cortical effects that are poorly understood.

For many cases of nausea in patients with HIV disease, the precise etiology is either unclear or multifactorial. In these cases, empirical therapy with combination antiemetics is appropriate. Choices are best directed by a rational combination of antiemetics with different mechanisms of action. For example, a combination of diphenhydramine (Benadryl), which is effective at the sites of the vestibular apparatus and vomiting center, metoclopramide (Reglan), which is prokinetic, and a dopamine antagonist, effective at the CTZ, and dexamethasone, which is effective on central cortical factors, has been widely advocated as an empirical approach. This combination may be administered in an oral liquid preparation, a suppository, or as a parenterally administered infusion either intravenously or subcutaneously.

In cases of nausea and vomiting due to bowel obstruction, octreotide (Sandostatin) decreases gastrointestinal secretion, promotes intestinal water absorption, and prolongs gut transit time. This medication is given subcutaneously either in a continuous infusion or intermittently three times per day. A starting dose of 0.3 mg in 24 hours may be titrated daily to effect (usually no more than 0.8 mg per day) (54,55).

Diarrhea

Up to 90% of patients with HIV disease will experience diarrhea at some time during their illness. Common causes of diarrhea include infections, medications (antivirals, magnesium compounds in antacids, antibiotics, nonsteroidal antiinflammatory drugs, iron preparations, metoclopramide, and theophylline), tumor invasion (lymphoma and Kaposi's sarcoma), and lactose intolerance (8).

Although it is important to investigate causes, attempts to control the symptom can be instituted while the workup is proceeding. In the absence of bloody diarrhea and/or fever, prudent evaluation begins with stool studies and administration of antidiarrheal medication. If the diarrhea is unresponsive to modest symptomatic therapy (loperamide) and the stool studies nondiagnostic, the workup should then proceed to esophagogastroduodenoscopy with biopsy and colonoscopy with biopsy.

Definitive treatment should be based on stool study results, when available and helpful, but sometimes empiric antibiotic treatment may be initiated. Consideration of a combination of ciprofloxacin (Cipro) and metronidazole (Flagyl) may be indicated.

Nonpharmacological interventions include oral rehydration with balanced electrolyte concentrations and glucose. Avoiding milk products is advisable because a secondary lactase deficiency may exacerbate diarrhea. Supplemental digestive enzymes and calcium-containing antacids may also be helpful. Consideration should always be given to protecting the skin in incontinent patients and multiple barrier ointments are available.

Absorbent medications (pectin), adsorbent medications (kaolin), and attapulgite (Kaopectate) and psyllium do not affect diarrhea *per se*. However, turning frequent watery stools into less frequent semiformed stools may enhance comfort. Bismuth subsalicylate (Pepto-Bismol) contains aspirin and is useful for mild diarrhea, especially if there are abdominal cramps.

Loperamide (Imodium) is an opioid used for its constipating effect. Because of minimal systemic absorption, its effects are local. It is 50 times more potent than codeine. Morphine as an antidiarrheal has the additional benefit of increasing tone in the anal sphincter. Diphenoxylate with atropine (Lomotil) is a combination antidiarrheal that includes an opioid to decrease motility and an anticholinergic to decrease intestinal transit and secretion.

Refractory large volume diarrhea responds to octreotide (Sandostatin). A panel of U.S. physicians has recommended that patients who do not respond to 0.5 mg subcutaneously three times a day after 1 week have their therapy stopped. Those who respond to this regimen are tapered downward after 2 weeks by 0.1 mg per injection for 1 week, and then by 0.05 mg per injection in subsequent weeks, to the minimally effective octreotide dose (54).

Neurocognitive Symptoms (Dementia, Delirium, Depression)

Late-stage HIV is associated with a progressive dementia characterized by a loss of short-term memory, mental slowing, decreased concentration, and poor judgment not unlike the dementias seen in geriatric populations. For this reason (among many), it is suggested that advance directives be identified early in the course of HIV illness (56). The dementia is related to HIV infection and can be reversed or slowed with anti-HIV therapy.

By contrast, delirium is an acute change in global cognitive abilities. For appropriate patients, reversible causes of delirium should be sought. The resolution of an acute delirium leads to vastly improved quality of life as well as length of life. A contrast-enhanced magnetic resonance imaging of the head is an important first step. Enhancing lesions are most often toxoplasmosis (90%), although primary central nervous system lymphoma and other causes are possible. If the magnetic resonance imaging scan is not diagnostic, a lumbar puncture should be performed. Cryptococcal meningitis, CMV encephalitis, neurosyphilis, and tuberculous meningitis may present with no more than subtle changes in personality, mood, or progressive fatigue.

Medications that may cause or contribute to acute delirium include opioids, beta-blockers, anticholinergics, corticosteroids, anticholinergic medications, efavirenz (Sustiva), and metoclopramide. Dehydration may also be responsible. Delirium in a patient with diarrhea and resulting electrolyte abnormalities may resolve with rehydration.

Pharmacologic management of the symptoms of delirium relies on neuroleptics. Haloperidol (Haldol) 0.5–5.0 mg every hour until symptoms are settled, then every 6 hours for maintenance is indicated for the symptomatic management of patients presenting with agitated, hyperactive forms of delirium, including psychomotor agitation, delusions, and/or hallucinations. If sedation is a primary goal, then a more sedating neuroleptic may be used [e.g., chlorpromazine (Thorazine)]. The neuroleptics should be considered a temporary measure while other strategies to reverse the delirium are instituted, such as opioid rotation, rehydration, or the management of metabolic or infectious complications. If the overall goal is sedation and no efforts to reverse the delirium are to be attempted, such as in terminal delirium, then benzodiazepines may be used for their sedating, amnestic, antiepileptic, and muscle-relaxing properties.

A frequently encountered challenge is the patient who was previously independent and is now demented and unable to care for himself or herself. Social work intervention is invariably required. The patient's safety must be ensured. Often this means that 24-hour monitoring is required. A change in domestic arrangements or even a move to a nursing facility may be required.

Depression is prevalent in patients with HIV infection (56,57). It is often difficult to diagnose in advanced HIV disease because the somatic criteria for the diagnosis may be a result of the HIV disease progression. Therefore, in order to diagnose depression, clinicians must have a high index of suspicion and rely on psychological features.

Unfortunately, many patients and clinicians feel that depression is a normal or expected response in patients who know they have a life-threatening disease. For this reason, depression is underreported, underdiagnosed, and undertreated in HIV patients. This is a prominent risk factor for suicide (57,58). Depression, unlike sadness, is not a normal response to illness.

Once suspected or diagnosed, a therapeutic trial of treatment is indicated. Combining supportive psychotherapy and medication is frequently effective. The serotonin selective uptake inhibitor group of antidepressants is effective and has fewer side effects than older tricyclic agents. Citalopram has the fewest drug interactions and adverse effects in the chronically ill. However, a lag phase of several weeks occurs before onset of relief should be expected (59).

For patients in whom a faster response is desired, a psychostimulant (methylphenidate, dextroamphetamine) may be helpful to relieve symptoms of hopelessness, helplessness, and despair in a matter of days (60). Psychostimulants can be combined with other antidepressants. In this case, they are continued until the end of the lag phase, and then the patient is tapered off the psychostimulant. Psychostimulants should only be taken in the morning to prevent insomnia. Use of these drugs should be carefully considered in those patients with a history of stimulant abuse.

Dyspnea

Dyspnea is the sensation of shortness of breath. In patients with HIV disease, dyspnea and cough usually occur because of infections: bacterial, viral, protozoal, or fungal. Infiltrative processes, such as Kaposi's sarcoma or lymphoma, may also be responsible. Other common conditions, such as congestive heart failure, bronchospasm, pulmonary embolism, pleural effusions, and drug reactions, should be considered. Anemia is an often present but overlooked factor. Anxiety nearly always coexists with dyspnea and should be considered an exacerbating factor.

Symptomatic management and therapy directed at the cause can be instituted simultaneously. Several nonpharmacological interventions are helpful. Instructing the patient in pursed-lip breathing and elevating the patient's head are useful. The environmental air should be cool and humidity should be low. A slight cool breeze from a fan blowing on the patient's face is helpful. Activity should be limited to what is necessary and rest periods should be planned. Regular and frequent oral care helps decrease discomfort related to dry mouth (61).

Many patients describe relief of dyspnea when oxygen is administered. Patients may describe relief even when their hemoglobin oxygen saturation is normal in the absence of additional oxygen. This may be due to psychologic factors and the placebo effect because oxygen is a potent symbol of medical care.

Bronchoconstriction may be present in HIV patients without a previous history of asthma. A clinical trial of a bronchodilator, such as albuterol, may bring significant relief.

Opioids act both centrally and peripherally to diminish the sensation of dyspnea. They may also be administered by inhalation. Clinicians may be reticent to prescribe opioids at the same time they are attempting to treat a lung infection, owing to exaggerated fears of respiratory depression. Doses of opioids that relieve dyspnea do not cause central respiratory depression. This highlights a critical aspect of dyspnea management: the patient's self-report is used as the primary clinical indicator of relief. It is incorrect, and may lead to therapeutic misadventure, if opioids are titrated to respiratory rate rather than self-report of relief.

Dyspnea is one of the most frightening sensations that a patient can experience. In many, anxiety plays an important role in the symptom complex. For intermittent anxiety, an intermediate-acting benzodiazepine (lorazepam, 0.5–1.0 mg orally every 4 hours) may help. When anxiety is constant, a longer acting benzodiazepine (diazepam, 2–5 mg orally three times daily) may be indicated.

Oral Problems

Dry or sore mouth is common in HIV patients. Oral hairy leukoplakia is commonly seen on the lateral border of the tongue and correlates with advanced HIV disease, but is usually not symptomatic. Kaposi's sarcoma, which is commonly found on the palate but can involve any mucosal site, may respond to regional radiation therapy or systemic chemotherapy (62).

Painful oral lesions include those caused by thrush (candidiasis), herpes simplex virus, aphthous ulcers, and CMV. Oral candidiasis may present as a reddened mucosa without demonstrating the more familiar white plaques. Herpes may be present without the characteristic gray pustules on an erythematous base. Swabs and/or biopsies may be the only way to confirm the diagnosis. Treatment may be general with 2% viscous lidocaine topically for pain, or specific with nystatin oral solution, ketoconazole, or fluconazole for oral candidiasis, or acyclovir for herpetic infection. Oral aphthous ulcers respond to topical corticosteroid such as triamcinolone in Orabase or dexamethasone elixir. Difficult aphthous ulcers will usually resolve with systemic prednisone or thalidomide.

Dry mouth is common and impairs swallowing, causes halitosis, reduces taste and food enjoyment, induces infection and caries, and may interfere with talking. Providing oral hygiene at least twice per day is helpful and rinsing frequently, chewing gum, using citrus candies, and consuming ice chips are all beneficial interventions. Artificial saliva may also relieve dry mouth, and pilocarpine, 5 mg three times daily, will stimulate salivation.

Sore mouth may be due to oral mucositis, infections, poor dentition, or ill-fitting dentures. Mucositis may be the result of medication or radiation therapy. Conditions like mucositis that involve large surface areas of the oral cavity are often treated with a combination of medications. An example includes acetaminophen, diphenhydramine, tetracycline, dexamethasone, and nystatin that is swished and swallowed or spit every 4 hours.

Dermatological Problems

For reasons that are not entirely clear, HIV patients are commonly afflicted with dermatological disease. Seborrheic dermatitis occurs in up to 80% of patients. Seborrhea will often respond to 1% hydrocortisone and/or topical ketoconazole. Dry skin may be of such severity that it approaches that of ichthyosis and may be accompanied by disabling pruritus. Liberal amounts of skin moisturizers, both water and oilbased, are indicated, in addition to antihistamines like diphenhydramine and hydroxyzine for itching (63,64).

Rashes are common and may be related to drug sensitivity. Any new maculopapular rash that appears up to 7–10 days after the addition of a new medication should

be considered a drug eruption.

Skin infections include boils and carbuncles that may develop into abscesses. Cellulitis is relatively common and usually responds to systemic antibiotics. Fungal dermatoses usually respond to topical antifungals such as clotrimazole (Lotrimin). Disseminated herpes simplex or herpes zoster may be seen and treated with acyclovir, usually by the parenteral route. Molluscum contagiosum, which is due to papillomavirus infection, is common on the face and may be extensive. Regular treatment with cryotherapy, hyfrecation, or topical imiquimod may keep this problematic lesion at bay.

Infestations such as scabies should be suspected when a patient presents with any persistent, atypical rash. In an immunocompromised patient, scabies may develop into what is known as Norwegian or exaggerated, nodular or crusted scabies. It is very contagious because of the increased number of mites carried by each patient. Treatment is more difficult because repeated applications of a scabicide may be necessary to eradicate the infection. Ninety percent of live mites are usually eradicated in ordinary scabies by one application of permethrin or gamma-benzene hexachloride. However, in Norwegian scabies, it may be necessary to continue with repeated applications for up to 6 months.

Wounds may also occur in HIV patients, particularly in advanced disease when pressure ulcers may develop. Management of these conditions includes topical antibiotics and care to improve hygiene and odor. Strong astringents or solutions containing iodine or peroxide are contraindicated because they usually cause damage to normal tissue. Often, when wounds are poorly responsive to conservative measures, they are best managed by covering with protective barrier dressings. For any skin conditions that persist despite treatment, the help of a dermatologist or an ostomy or wound specialist nurse may be required. When appropriate, careful nutritional assessment and treatment may be required for complete healing of these wounds.

Drug Interactions

Some clinically significant drug interactions with medications used for symptom control and HIV antivirals deserve mention. This has been recently reviewed (65). Methadone's metabolism is increased by the following nonnucleoside and protease antivirals: efavirenz, nevirapine, amprenavir, lopinavir/ritonavir, ritonavir, and nelfinavir. Their effects may require an increase in the methadone dose from 35% to 50%. This becomes most important if the above medications are added to a stable methadone regimen, resulting in a loss of analgesia.

The anticonvulsants phenobarbital, phenytoin, and carbamazepine may result in decreased levels of the nonnucleoside and protease inhibitor antivirals that could impair their antiviral effectiveness. Alternative drugs, such as valproic acid and gabapentin, are preferred when antiviral therapy with these agents is ongoing. Midazolam, triazolam, and fentanyl are best avoided due to their impaired metabolism when the same antivirals are being used. Consultation with a knowledgeable pharmacist is recommended when potential interactions exist (64,66).

PSYCHOSOCIAL ISSUES

Fear of abandonment and social isolation are common for individuals living with HIV disease, based on past experience with being judged (67,68). Suboptimal or no provision of health care exists for many of the special populations that are disproportionately affected by HIV because health care providers lack knowledge, or are unaware of specific health care issues in populations or have discomfort in dealing with these groups. Also, some patients feel that many health care providers are discriminatory or hostile and prefer to avoid care because of this. Fear of stigmatization also prevents some individuals from identifying themselves as part of one of these populations (69).

As one example, health care issues in the lesbian, gay, bisexual, and transgender populations are overlooked when health care providers assume the patient is heterosexual. As many as two-thirds of physicians do not ask the sexual orientation of their patients. This is of concern because these patients are at increased risk for suicide, eating disorders, substance misuse, and breast and anal cancer (71). Similar issues arise in the group of patients who have acquired their HIV infection through substance abuse.

Depression, anxiety disorders, psychosis, and substance abuse are major morbidities that these patients suffer (71,72 and 73). A multidisciplinary approach utilizing social workers, psychotherapists and psychiatrists, and community support agencies and groups, can help bring comfort and stability to the lives of those affected. These conditions can lead to homelessness, and nonadherence with appointments and medications, which can all lead to HIV disease progression. Bringing all the help available to those who are willing to receive it can result in improvements in the quality of life, if not overall prognosis.

SPIRITUAL ISSUES

A new diagnosis of any complication of the disease can precipitate a spiritual crisis in an HIV-infected individual. Spiritual crisis or distress occurs when a person is unable to find sources of meaning, hope, love, or peace. Other symptoms of spiritual suffering are disconnection from community, diminished inner capacity to cope, and guilt and shame related to past, negative religious experiences. All clinicians need to understand and identify spiritual suffering (74,75). Religious support and spiritual support are not synonymous. “Spiritual support occurs in the context of an equal human relationship which allows a person to work through his feelings of anger and hopelessness, and achieve a sense of integration and a sense of responsibility. In a secure environment, free of physical suffering, where a patient feels accepted and not alone, it is possible to come to terms with death and view it not simply as giving up out of weakness, but as letting go out of strength” (76).

When a person finds comfort in religious faith, it is important to ensure support is offered in that religion. If a person in spiritual crisis wants religious support by clergy, no one else will do, but it should not be assumed that all community clergy are open and affirming. Many can be judgmental, adding to the patient's guilt and shame; others are not comfortable with death and dying. Palliative care trained clergy understand the complexities of the individual's relationships with religions, and the meaning of self, suffering, and death. Such clergy are important members of the care team and should be asked to see patients in need of help or further assessment for spiritual crisis. Their input can be most helpful for the overall management of the patient.

ACKNOWLEDGMENTS

PALLIATIVE CARE IN THE INTENSIVE CARE UNIT

THOMAS J. PRENDERGAST

Intensive care units (ICUs) combine in one physical location the most desperately ill patients with the most intensive physician and nursing staffing who are trained to use the latest in medical technology. The result is an approach to patient care that has been characterized as “rescue medicine” (1). This term correctly suggests that a primary goal of critical care medicine is to save the lives of patients who would die without its aggressive interventions. The term also carries a negative connotation: In their zeal to save lives, critical care practitioners (intensivists) may undervalue the wishes of the patient, the needs of the family, pain and suffering caused by treatment, and the potential for functional recovery as opposed to mere survival. Since these concerns form the very core of palliative medicine, there is a widespread assumption that critical care medicine is at best indifferent and at worst antithetical to palliative care. For example, one of the major (negative) outcome measures of the SUPPORT study was the presence of a patient in an ICU before death (2).

Accusations of a rescue mentality are anecdotal and difficult to assess (3). We might infer a mindset of rescue medicine when all dying patients receive all therapies, including ineffective cardiopulmonary resuscitation. This was the approach to patients dying in ICUs from their inception in the 1960s through the 1980s. From the late 1980s to the present, however, there has been an astonishing evolution in critical care practice (Table 79-1). In 2001, most ICU deaths follow a considered decision to withhold or to withdraw life-sustaining therapy (4). In the past decade, intensivists have acquired a new responsibility to manage the deaths of patients who do not survive. This is not yet palliative care, but it opens the door to palliative care because it raises the question: How is this newly appreciated responsibility to the dying patient handled, and how well (5)?

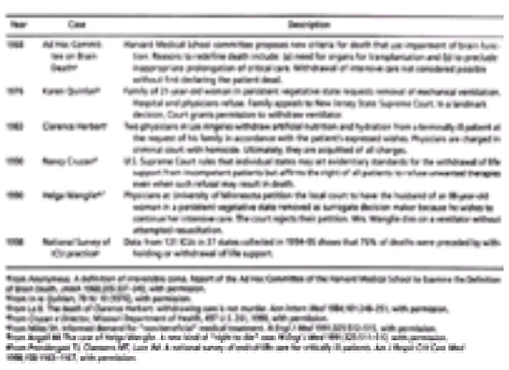

TABLE 79-1. CHANGING MANAGEMENT OF DEATH WITHIN AMERICAN INTENSIVE CARE UNITS (ICUs)

APPROACHES TO PALLIATIVE CARE IN THE INTENSIVE CARE UNIT

Some patients are referred to the ICU for symptom control that cannot easily be provided elsewhere in the hospital. Palliation of symptoms may require intensity of nursing care that is not available on the ward. It may require interventions more comfortably managed in the ICU [e.g., treatment of intractable distress with barbiturate or propofol coma (6)]. The therapeutic goal may be to initiate ICU specific interventions (e.g., vasopressor support or assisted ventilation) to allow time for family to arrive to say goodbye. Instances of specific, circumscribed palliative care are a legitimate, though uncommon, use of critical care resources. For such patients, the ICU is not only an appropriate location but quite likely the best place to die.

Patients admitted for symptom control represent a small minority of ICU admissions. Most patients are admitted to the ICU emergently, under the presumption to treat until more information is available, or because the clinician and patient/surrogate have made a decision to pursue a trial of curative therapy. There is an expectation of recovery or, at least, uncertainty about prognosis. Most patients improve and are discharged. Mortality rates vary from <5% of admissions to some surgical ICUs, to 15% of admissions to general medical ICUs, to 40% or more of admissions to ICUs that treat primarily oncology patients (4,7,8). Age alone does not appear to be an independent predictor of mortality (9). Certain diagnoses place patients at higher risk for death (10,11). Critically ill cancer patients have a particularly poor prognosis, with multiple studies documenting in-hospital mortality rates from 50% to more than 90% in patients who develop critical illness following bone marrow transplant (12). A recent attempt to develop a mortality prediction model specifically for cancer patients identified three variables associated with higher mortality: allogeneic bone marrow transplantation, progression of underlying disease, and poor performance status (7).

Patients admitted to the ICU for curative therapy also may benefit from palliative care. It is uncertain, however, which patients will benefit and when palliation should be emphasized in their course of intensive care. One approach emphasizes symptom control in patients known to be dying. Thus, intensivists may arrive at palliative care through a natural extension of the ICU's core mission to rescue the grievously ill: Treat aggressively for cure until death appears inevitable, then redirect the goals of care to control the patient's symptoms. This model and the accompanying language of transitioning from curative to comfort care have become commonplace in critical care medicine (13,14). The transition approach demonstrates a willingness to acknowledge dying and to attend to the details of patients' deaths. In this sense, it is a significant advance beyond the relentless drive to treat that sometimes has characterized critical care medicine. There are drawbacks to a transition approach, however. To state the obvious, there is more to palliative care than symptom control of the imminently dying. Another problem, one that remains underappreciated outside critical care medicine, is that it is surprisingly difficult to predict who is going to die (15,16).

A transition model of palliative care in the ICU depends on the intensivist's ability to identify a clinical change in individual patients that redirects the goals of care away from curative therapy toward symptom control. Experienced intensivists can accurately predict the short-term mortality of groups of patients; many computer-based mortality prediction models do the same (17). Neither computer-aided decision systems nor expert clinical opinion allows specific identification of the individual patient who will die (16). Data from the SUPPORT study (15) demonstrate that, in most patients, there is no identifiable point when death becomes imminent that allows for a change in direction of care (Table 79-2). These data challenge the assumption that we have advance notice of death. The uncomfortable reality is that a high percentage of ICU patients die but individual ICU patients are difficult to identify as dying. Therefore, if the criterion for palliative care in ICU patients is that providers first recognize that the patient is imminently dying, ICU practice will be deficient in two ways. Many patients will die without the benefit of palliative medicine because they will die unexpectedly. Those who do receive palliative care will receive it very late in their disease course.

Patient population	One day before death (%)	One week before death (%)
All deaths	17	51
Coma	5	27
Congestive heart failure	42	62
Chronic obstructive pulmonary disease	21	41

SUPPORT, Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments.

TABLE 79-2. MEDIAN PREDICTED 2-MONTH MORTALITY IN SUPPORT

Despite an emerging consensus that palliative care can coexist in parallel to aggressive critical care, many clinicians in and out of ICUs strongly support the concept of a transition to palliative care. There are many reasons for the persistence of this approach. A few patients do have an abrupt change in their clinical course that significantly changes their prognosis (e.g., the elderly patient with lung cancer who has a myocardial infarction that precipitates cardiogenic shock). Predicted survival may drop precipitously with additional organ dysfunction, and appreciation of this change may facilitate a decision to limit therapy. In other patients, the decision to change the direction of therapy is based on nonprognostic factors, such as suffering, quality of life, or comorbid illnesses, that suggest a high likelihood of recurrent hospitalization or death despite the possibility of short-term recovery (18). That same patient, now hemodynamically stable but with severe, permanent left ventricular dysfunction, may face a degree of debilitation that he and his family find unacceptable. Sometimes, clinicians and families frame the facts to suit their need for explanations in a way that creates transitions (19). Perhaps this patient's quality of life will be no different after his myocardial infarction but the event reshaped the patient and family's thinking toward acceptance of his mortality.

Finally, the transition model permits separation of the curative and palliative roles. To the extent that this separation allows the intensivist to withdraw from involvement as death approaches, it may represent a strategy to cope with feelings of helplessness, failure, and grief (20). The alternative, to assert that all patients at high risk of dying need palliative care, asks the intensivist simultaneously to be an advocate of rescue and palliative medicine (15,21). To assume both these roles is to move far beyond the transition model.

ADAPTING PALLIATIVE CARE TO THE INTENSIVE CARE UNIT

Palliative care in or out of the ICU starts with adequate symptom control. Symptom control is essential because pain and suffering without purpose are destructive, because untreated pain may adversely affect outcomes (22,23), and because unrelieved pain and suffering interfere with the patient's ability to address important life issues that may be brought to closure before death. Palliative medicine promises more than symptom control, however. It emphasizes the possibility of growth at the end of life. Palliative care means acknowledging and addressing psychological suffering (depression, anxiety), existential suffering (estrangement, alienation, lost opportunities, the meaning of one's life), and spiritual suffering (Why am I dying?) (24). This ideal of palliative care depends upon a predictable disease course that allows time to plan and a patient who is alert enough to speak for himself and to participate in discussions of both medical planning and personal growth with a provider who has a relationship with the patient and, preferably, has known the patient and the family over time. Critical care medicine violates this model in almost every respect (Table 79-3) (25).

The *raison d'être* of critical care medicine is to push the limits of what medicine can accomplish. Success is measured in lives saved. Lives lost may be accounted as failure. The importance of the quality of death is not part of the culture.[a]
ICUs are different from other hospital locations in that the organizing principle is the acuity of illness. Geographically and organizationally, the focus of care is on technology and interventions rather than on interpersonal relations.[b]
The ICU environment is characterized by acute illnesses with unpredictable outcomes.[c] Clinical status may change rapidly, necessitating rapid decision making about life and death issues.
Patients rarely have a preexisting relationship with their providers. Most patients who die are too ill to participate in discussions of their needs and wishes. Communications with family and surrogates are strained by lack of prior relationships, time-pressured decision making, and uncertainty of prognosis.[d]
Critical care education has emphasized the core mission of aggressive treatment of the acutely ill or injured, with little attention to palliative medicine. As a result, there is a lack of knowledge of palliative medicine.

TABLE 79-3. SOME OBSTACLES TO PALLIATIVE CARE IN THE INTENSIVE CARE UNIT (ICU)

Some of the barriers to palliative care listed in Table 79-3 actually contribute to the success of critical care medicine. An emphasis on technology, and expert providers willing to push its limits, are desirable if they help the desperately ill and injured. Other barriers seem inevitable if less desirable. In an environment dedicated to treating the sickest patients, prognostic uncertainty dictates that some patients will die under aggressive therapy in order successfully to treat those who survive. This is neither a mistake nor necessarily a failure but an expected consequence of not knowing who will respond to treatment (21). The nature of critical illness is that clinical situations change rapidly and decisions must be made quickly. Pervasive prognostic uncertainty, pressure to make decisions, and significant mortality seem inescapably part of the ICU environment. Some barriers in Table 79-3 are cultural and, therefore, subject to change. Struggling to save lives is fully consistent with acknowledging that the quality of death can be as important as the quality of life (26). To teach the importance of interpersonal relations and communications skills need not devalue the technical and scientific accomplishments that distinguish modern critical care. Technology does not imply dehumanization; intensivists can be full participants in the human stories being played out under their care.

There are key elements of palliative care that are adaptable to the ICU in a way that improves the care of patients while respecting the critical care provider's appropriate role as advocate for the desperately ill. These features of palliative medicine are not inconsistent with good ICU practice. They are increasingly seen to define good ICU practice (13,21,27,28 and 29). The internist or oncologist whose patient is admitted to the ICU may reasonably expect this degree of expertise from their ICU staff, if not now, at least as a goal to be reached in the near future.

First, as mentioned, it is absolutely essential that adequate attention be paid to symptom control. There are very few situations in which attention to the physical and psychological needs of patients conflicts with curative treatment. Palliative care can teach the intensivist about good symptom management.

A second aspect of palliative care applicable to the ICU is to recognize that each individual patient lives within a web of human relationships. To care for a critically ill patient is to have a relationship not only with the patient but also with all those people to whom the patient is connected. Regardless of the caregiver's interest or willingness to explore those relationships, he or she cannot escape the complex and frequently difficult communications environment that those relationships create. The ability to communicate effectively with groups of people is absolutely essential to the intensivist. Since uncertainty about prognosis is pervasive and colors everything else that occurs in the ICU, a communication strategy that diffuses the power of uncertainty by acknowledging it directly facilitates good ICU care while opening the door to good palliative care.

Third, a fundamental principle of palliative care is acceptance of impending death, by the patient, by loved ones, and by the health care provider. In the ICU, the unexpected nature of illness or injury combined with prognostic uncertainty leads to common self-protective strategies. In their hope of recovery, family members may deny the possibility of death while physicians may avoid discussion of death. The approach from palliative care means acknowledging the possibility of death in an ongoing discussion with the family and, when appropriate, moving to limit life-sustaining treatments. It is in the area of withdrawal of life support that intensivists have most clearly changed their practice and where the most concrete recommendations can be offered.

PAIN AND SYMPTOM CONTROL IN THE INTENSIVE CARE UNIT: GENERAL PRINCIPLES

There are multiple reasons for patients to experience pain, anxiety, dyspnea, and other distressing symptoms during treatment in the ICU. Operative surgical procedures, bedside instrumentation, placement and maintenance of an endotracheal tube, including endotracheal suctioning, and prolonged immobilization, in addition to the trauma or serious illness that warranted hospitalization in the first place, all may cause significant physical and psychological symptoms (30,31). Patients

report significant distress associated with pain that may manifest as anxiety or agitation (32). Hunger, thirst, and disruption of sleep were reported as moderate or severe by more than 50% of ICU patients in a recent survey (33). The act of weaning patients from mechanical ventilation may be associated with significant anxiety even in patients who are clinically improving (34). The overall symptom burden may be particularly high in dying patients (35).

Despite the apparent prevalence of pain and other symptoms, rigorous research into prevalence and control of symptoms has been scarce. In part, this lack of research reflects the difficulty of symptom assessment in ICU patients. Critically ill patients frequently have altered cognition, they may be heavily sedated, and a significant proportion are endotracheally intubated, which renders them speechless. Although there are symptom assessment tools that can assist providers in obtaining information in many patients (36,37), including intubated and dying patients (33), these tools are time and labor intensive, and have not generally been tested for both reliability and validity (38,39). In the routine practice of critical care medicine, symptom assessment has been subjective and poorly standardized (40).

The most basic principle in the assessment of pain is that pain is irreducibly subjective (36). Therefore, the best indicator of pain is the patient's own report. Patients who can report their pain should be treated accordingly, even though their cognition may be altered by illness or medication, and the stress of critical illness may significantly change their ability to cope with or to describe pain. Appropriate treatment always requires a careful pain history, particularly a history of chronic opioid use, to dose analgesics correctly. Instruments available for patients who can communicate range from a simple linear scale to quantify the pain, to more intricate inventories of psychological states such as the McGill Pain Questionnaire (41). Visual analog scales require less cognitive processing than visual descriptors or numerical rating scales but do require that the patient be able to see (36). None of these scales has been validated in critically ill patients.

Patients who cannot describe pain may manifest it as “agitation.” Agitation is not a diagnosis but a description of excessive or inappropriate motor activity. Despite the difficulty of identifying a specific etiology, a diagnostic review of the agitated patient is essential before instituting therapy. Anxiety, fear, frustration with inability to communicate, pain, delirium, dyspnea, and ventilator dyssynchrony all may manifest as agitation. Failure to search for an etiology may lead to inappropriate treatment. To treat pain with sedatives that have no analgesic properties may require excessive sedation to the point of general anesthesia. Delirium may be exacerbated by opioids or benzodiazepines and is best treated with haloperidol.

In the 50% or more of ICU patients who cannot report their subjective experience, assessment is particularly dependent on careful physical examination for potential sources of pain, such as early decubiti, pressure points, intravenous lines, surgical wounds, traumatic fractures, and constricting bandages or restraints. Assessment of the nonverbal patient also depends on observation of nonspecific physiological data, such as changes in blood pressure and heart rate, tearing or diaphoresis, along with a subjective assessment by the provider of the patient's appearance and how the patient responds to specific treatments such as turning, positioning, and suctioning (36,42). Observational methods that do not elicit information directly from the patient lack sensitivity and specificity (33,40). Family members may help interpret nonverbal information in such patients, although the validity of such surrogate interpretations is unknown.

Virtually all ICU patients require sedation, analgesia, or both to protect them and facilitate their treatment (43). To administer sedating agents presupposes a therapeutic goal and a way to determine when that goal has been reached. These goals are sometimes poorly defined, the assessments may be made subjectively, and documentation of both is frequently poor. A recent systematic review of sedation scoring systems (38) identified 25 sedation instruments, of which only four (one pediatric scale) had been tested for both reliability and validity. The oldest and most widely used scale in adult ICU patients is the Ramsay Scale (44). In many institutions, this has been superseded by instruments that discriminate better among levels of agitation (Table 79-4). A first step in improving sedation practice is to standardize assessment of therapeutic goals and patient assessment using one of these instruments. Systematic assessment can be combined with therapeutic algorithms to perform continuous quality improvement (45). Nonpharmacological strategies to manage agitation may be underutilized (46,47).

Rating	Ramsay scale[a]	Sedation-agitation scale[b]	Motor-activity assessment[c]
0	NA	Minimal or no response to noxious stimuli	Unresponsive to noxious stimuli
1	Asleep, no response to light glabellar tap	Arousable by physical stimuli but does not follow commands	Responsive only to noxious stimuli
2	Asleep, sluggish response to light glabellar tap	Difficult to arouse but follows simple commands	Responsive to touch or name
3	Asleep, brisk response to light glabellar tap	Calm, awakens easily, follows commands	Calm and cooperative
4	Awake, responds to commands only	Anxious or mildly agitated, but calms to verbal instructions	Restless and cooperative
5	Awake, cooperative, oriented and tranquil	Very agitated, does not calm with verbal instructions	Agitated
6	Awake, anxious, agitated or both	Dangerously agitated, uncooperative	Dangerously agitated, uncooperative

NA, not applicable.

TABLE 79-4. QUANTITATIVE ASSESSMENT OF SEDATION IN CRITICAL CARE

Current Practice

Most of the data regarding symptom control are found in studies of pharmacological management of pain and agitation. There is a paucity of data on nausea, dyspnea, sleep deprivation, etc. Studies of pain management in the ICU suggest systematic undertreatment. The SUPPORT study (2) is a major reference point for the management of pain in severely ill, hospitalized patients, half of whom were treated in ICUs during their hospitalizations. Twenty-two percent of patients interviewed in the second week of the SUPPORT study reported that they had had “moderate or severe pain all, most, or half the time.” Family members of patients who died reported that their loved ones had been in moderate or severe pain 50% of the time. Puntillo reported a series of 24 primarily surgical ICU patients in which 63% of patients reported moderate to severe pain (48). Whipple et al. investigated the different perceptions of physicians, nurses, and 17 ICU patients admitted to the ICU after traumatic injury (49): 95% of house staff and 81% of nurses reported the patients received adequate pain control but 74% of patients reported significant pain (27% moderate and 47% severe). The conclusion seems inescapable: Intensivists systematically undertreat pain.

On the other hand, a number of recent papers have raised questions about systematic oversedation. Kress and colleagues reported the results of a randomized controlled trial in 128 medical ICU patients (50). In the intervention group, sedative infusions were interrupted each morning until the patients were awake or uncomfortable; in the control group, the infusions were not interrupted routinely but at the discretion of the ICU clinicians. The investigators found a shorter duration of mechanical ventilation and shorter ICU length of stay in the intervention group, along with fewer diagnostic studies to assess altered mental status. No measure of patient distress or satisfaction was reported in the original paper. The authors have subsequently published in abstract form a summary of patient interviews that does not reveal any difference in psychological wellbeing, depression, or posttraumatic stress disorder between intervention and control patients (51). Only one patient of twelve recalled awakening from sedation; that patient was a control subject. These data suggest that, in a medical ICU, the current standard of practice sedates mechanically ventilated patients so heavily that it may prolong their ICU stay.

It is not yet clear how to reconcile these findings with data that pain is undertreated. Sedation may be given excessively while analgesics are underdosed. In particular, continuous infusion of sedatives and analgesics may prolong mechanical ventilation but the constant levels so achieved may not suffice for procedural pain from suctioning, turning, and other aspects of ICU care that patients report are uncomfortable (52). Given the paucity of data on patient distress or satisfaction, it may be that adequate symptom control requires medication that itself prolongs ICU treatment (33).

There are even fewer data about the management of pain and sedation in ICU patients at the end of life. This clinical context is very specific: The majority of patients who die in ICUs have life support withheld or withdrawn. The usual considerations of balancing adequate sedation with hemodynamic stability or avoiding prolongation of mechanical ventilation are no longer issues. There may be new considerations. Some patients may want to remain alert as long as possible to be able to communicate with their families. Some providers may worry about administering large amounts of opioids or sedatives to a patient who will die soon afterwards, for fear that such practice blurs the line between withdrawal of life support and active euthanasia.

Two studies speak to this question. In 1988–89, Wilson and colleagues retrospectively reviewed all patients over 1 year who had life support withheld or withdrawn at San Francisco General Hospital (53). They randomly selected an equivalent number (N = 22) of patients from their affiliated University Hospital. Seventy-five percent (33/44) of patients received sedation or analgesics or both, at doses that were significantly increased from baseline once the decision was made to withdraw life support. All the patients died. The minority who did not receive sedation were deeply comatose and died faster that those who did receive additional medication. The authors concluded that administration of opioids and sedatives was common in the withdrawal of life support from ICU patients and did not appear to hasten death. The latter conclusion was seriously weakened by significant clinical differences between the two patient groups.

Hall and Rocker reviewed charts from 174 consecutive patients who died over a 1-year period in 1996–97 (54). Seventy-nine percent (138/174) had life support withheld or withdrawn, while 21% (36/174) had aggressive therapy continued up to the time of death. Doses of morphine and lorazepam were fivefold higher in patients from whom life support was withdrawn, and most of this increase occurred in the 4 hours prior to death. Of interest, neuromuscular blocking agents (NMB) were

administered in the final 12 hours of life to 25 patients, of whom 17 had it started in the last 12 hours of life. In 20% (5/25), there was a single dose to facilitate endotracheal intubation. Nine patients had a NMB infusion at the time of death, 5 of whom had life support (but not mechanical ventilation) withdrawn. Sixteen percent (4/25) of patients receiving NMB were receiving intermittent sedation/analgesia but not continuous infusions.

These and other studies show that the range of opioid doses necessary to control acute pain or dyspnea is very wide; large doses may be necessary. However, the milligram dose is much less relevant than careful administration. It is entirely appropriate to give large amounts provided that these doses are carefully titrated to specific effects. In rare cases, it may only be possible to control symptoms with doses that hasten death. Provided that the intended effect is relief of suffering and the doses are carefully titrated to that effect, there is broad consensus in bioethics and the law that ameliorating symptoms is not euthanasia, i.e., not the deliberate administration of drugs with the intent to terminate the patient's life (55,56). One of the most egregious failings in end-of-life care is the systematic failure adequately to treat pain and dyspnea, based on a misunderstanding of this distinction (57).

Specific Recommendations

There is a modest amount of data describing current practice in pain and symptom management in ICUs. There is much less data to clarify how effective this therapy is in order to make specific treatment recommendations. A recent, systematic review of randomized, controlled trials comparing at least two different agents for the sedation of ICU patients found a discordance between the prevalence of use of sedatives (multiple reviews identified between 11 and 23 different agents used in the United States and United Kingdom) and a paucity of data (58). Of 49 studies identified, only 32 met minimal criteria for adequacy of study design, and of these 32, 20 compared propofol to midazolam. This literature is largely driven by pharmaceutical companies seeking data to support the use of specific medications. If the measure of efficacy is patient/family satisfaction, then there is little information to guide practice. Any recommendations are at the level of consensus guidelines and expert opinion (40).

First, and logically necessary to any improvement in practice, is that intensivists need to place a higher emphasis on specific symptom control. The first step is to incorporate systematic symptom assessment into their routine practice (33).

Second, intensivists must be expert in the use of a fairly small number of analgesic and sedative agents. Expertise includes understanding the pharmacokinetics and metabolism of these agents. With opioids and some benzodiazepines, the plasma elimination half-life is a poor measure of clinical effect because the onset of activity and duration of effect are more closely tied to distribution and redistribution of the drug into and out of the central nervous system. One must also understand how these properties are altered in the setting of advanced age (59) and critical illness (60,61). The presence of increased extravascular water increases the volume of distribution of many drugs. Changes in plasma protein levels will affect protein binding and may increase concentration of free drug. Impairment of hepatic and renal function affects metabolism and clearance. Agents (midazolam) that undergo oxidation-reduction are affected by age, disease states, such as cirrhosis, and competing pharmaceuticals far more than drugs (lorazepam) that undergo glucuronidation (62). Pharmacokinetic data are obtained in studies of healthy volunteers and may not be applicable to critically ill patients (Table 79-5 and Table 79-6).

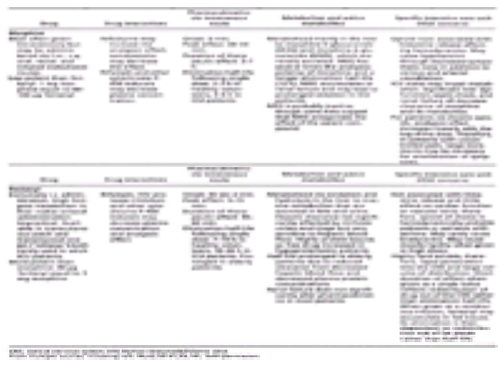

TABLE 79-5. OPIOID ANALGESICS COMMONLY USED IN INTENSIVE CARE

TABLE 79-6. AGENTS COMMONLY USED FOR SEDATION IN INTENSIVE CARE

As a practical matter, intravenous administration is preferred in the ICU. Virtually all patients have intravenous access, and many have central venous access that permits administration of agents that are irritating when given by peripheral vein. Intravenous administration reduces the variability in absorption seen in enteral or subcutaneous routes. Enteral administration is complicated in the ICU patient by impaired gastric emptying, decreased intestinal motility, nasogastric suctioning, diminished intestinal blood flow either due to illness or administration of vasoactive agents, and reduced absorptive surface area (63). Because the exact dose of analgesics or sedatives is less important than titrating the dose to clinical effect, some agents that are well-absorbed enterally (lorazepam, diazepam, and haloperidol) can be given via that route. Most medications are dosed by continuous infusion, however. In the case of pain, it is essential to control the pain adequately with bolus dosing before relying on a continuous infusion.

Opioids have a variety of beneficial effects in ICU patients (Table 79-5). Opioids have potent analgesic properties but are only mild sedatives and do not have specific anxiolytic effects apart from those consequent to reduced pain. Opioids may cause euphoria but do not produce amnesia. They are potent antitussives that depress upper airway and tracheal reflexes, facilitating tolerance of an endotracheal tube without coughing or fighting against the ventilator.

Opioids are potent respiratory depressants. They produce dose-dependent inhibition of respiratory rate, tidal volume, minute ventilation, and ventilatory response to CO_2 (64). This effect is potentiated by concomitant administration of benzodiazepines (65). Chronic administration of opioids is associated with tolerance to the respiratory depressant effects of opioids but this process takes many months (66). Therefore, ICU patients typically are sensitive to respiratory depression though it is rarely a pressing concern in patients who are intubated. At equianalgesic doses, no opioid is more or less likely than another to produce respiratory depression. Opioids cause urinary retention, decreased intestinal motility, and delayed gastric emptying. At high doses, they may cause adynamic ileus. Tolerance does not develop to constipation. Opioids may cause nausea through direct stimulation of the chemoreceptor trigger zone.

Benzodiazepines are safe and inexpensive medications that have become the drugs of choice for sedation in intensive care patients (Table 79-6). Benzodiazepines have potent anxiolytic and amnestic properties and are mild hypnotics. At higher doses, they are effective at preventing and treating seizures. They may have some antiemetic effects but this is not a potent property. They have no intrinsic analgesic properties and so are commonly given with an opioid for better control of symptoms at lower doses. Benzodiazepines do not have significant hemodynamic effects at usual doses though midazolam may precipitate hypotension in some patients. They do have mild central respiratory depressant effects that are synergistic with opioids (65). Midazolam has the most effect on the ventilatory response to CO_2 and can cause apnea when given at higher doses (induction of anesthesia) or in susceptible (principally elderly) patients. Lorazepam and, especially, diazepam cause venous irritation when given intravenously. Midazolam is prepared as a water-soluble solution and does not cause phlebitis.

Propofol is a potent intravenous hypnotic and anesthetic that is increasingly used in the ICU for short-term, titratable sedation (Table 79-6). Propofol causes a dosedependent fall in blood pressure through both direct depression of cardiac output and peripheral vasodilation. This effect is much more pronounced when given as

a bolus than when given as a continuous infusion. The hypotensive effect is augmented by concomitant opioid administration. Propofol is a respiratory depressant that causes dose-dependent depression of tidal volumes, minute ventilation, and ventilatory response to carbon dioxide. Apnea is common after induction of anesthesia with propofol. Propofol has demonstrated antiemetic properties during maintenance of anesthesia (67) to reduce postoperative nausea and vomiting after standard anesthesia (68) and to reduce chemotherapy-induced emesis (69,70). Haloperidol is a high-potency, nonspecific dopamine antagonist that is the agent of choice for management of delirium and psychosis in intensive care (Table 79-6) (71).

COMMUNICATIONS: GENERAL PRINCIPLES AND CURRENT PRACTICE

Multiple aspects of critical illness make the ICU a difficult communications environment. Most ICU patients were not terminally ill and many were healthy before an unexpected catastrophic illness or injury. The ability to predict outcome, though excellent across populations, is very limited in individuals (16). The threat of death or significant disability is real but intensivists rarely have an established relationship with their patients. In many cases, they never have the chance to speak to them because most patients are unable to participate in their treatment decisions (18,72,73). Patients admitted to ICUs rarely have completed advance directives (74,75), and the advance directives that are written are frequently too general to be helpful (76) or contain internal inconsistencies (5).

Family members of ICU patients confront difficult choices in a complex and unfamiliar environment. Surrogate decision makers are called on to make decisions about continuing or withdrawing life support, despite the fact that correlation between the patient preferences and their relatives' predictions of those preferences is poor (77,78). When asked about their needs, family members emphasize communication of information (Table 79-7). Despite the importance to families of clear communication, this does not appear to be a strength of critical care practice. Fifty-four percent of families of ICU patients in one study had significant misunderstandings of diagnosis, treatment, or prognosis (79). This lack of comprehension occurred despite the ability of physicians to identify family members who did not understand and despite a positive correlation between understanding and the amount of time physicians spent with the family. Of interest, for the readership of a textbook of supportive oncology, there was a high correlation between family misunderstanding and referral from hematology or oncology.

To have questions answered honestly
To know specific facts about what is wrong with the patient
To know the prognosis for recovery
To be called at home about changes in the patient's status
To receive information from the physician (at least) once daily
To receive information in understandable language
To believe that hospital personnel care about the patient
To be assured of the patient's comfort
To be comforted
To express emotions
To find meaning in the death of their loved one
To be fed, hydrated, and rested

Adapted from refs. 27,28,89,90,140, with permission.

TABLE 79-7. A DOZEN NEEDS OF THE FAMILY IN THE SETTING OF CRITICAL ILLNESS

In addition to the lack of skill or unwillingness to convey medical information to family members, intensivists may not listen carefully to the patient's and family's needs. Twenty-five percent of bereaved families in one study believed that neither the patient nor the family was part of the discussion about end-of-life decisions (80). Only 29% of patients in SUPPORT who preferred palliative care thought that the care they received was consistent with their wishes (81), and they reported low rates of discussions with physicians about their prognoses and preferences. In a survey of American Thoracic Society members, 34% of intensivists reported continuing therapy that the patient/surrogate requested be discontinued, and 82% of physicians made unilateral decisions to withdraw therapy, often without the knowledge or consent of the patient/surrogate and sometimes despite their objections (82).

Prognostic uncertainty and strained communications around unpredictable problems create fertile ground for disagreement. Disputes about management are not the exception in the ICU; they are ubiquitous—an integral part of the critical care environment (83,84 and 85). It remains unknown how many physician-family disputes are the result of ineffective communications by physicians. Disputes arise as often among physicians as between physicians and families (18). Despite the common assumption that nurses are more effective communicators than physicians, there is evidence that skills are not different between these groups (86).

Recommendations for Practice

Patients and families express needs for better communications with their physicians. In the ICU, this means that intensivists are called to build relationships, facilitate decision-making, and negotiate disagreements, in addition to learning how to deliver bad news (87). There are two problems with making concrete recommendations for improved practice in this area (88). First, much of the literature is based on expert opinion and is not grounded in empirical research. Second, the research that exists is written largely from the perspective of the caregiver. Perhaps the most important recent development in this area is the appearance of many attempts to elucidate the patient's and family's perspective (32,79,89,90 and 91). A first step toward improved ICU communication is to acknowledge this literature and, thereby, the importance of illness (i.e., the patient/family's subjective experience of their biomedical disease) (90). A second step is to eradicate the implicit and false assumption that communication with patients and families is a skill that every nurse and physician possesses. In fact, there are approaches to patients that are demonstrably more and less effective at facilitating communication (92,93). These approaches are skills that can be learned (94,95,96 and 97). Acknowledging the need for training may be difficult because physicians tend to believe that they are communicating effectively despite evidence that they are not (98,99).

A second development that gives hope for improved communications in the ICU is empirical research into the extraordinary complexity of treatment discussions, particularly those surrounding withholding and withdrawal of lifesustaining therapies. Recent work confirms that the act of withdrawing life-sustaining therapy from a patient is not the result of a single decision but emerges from the process of ongoing care (100,101 and 102). One implication of this work is that intensivists must recognize not only how important family discussions are to families but also how essential they are to the practicing intensivist (103,104).

The astute intensivist sees in the critical care setting opportunities for creating relationships. One rationale for advance directives is an underlying mistrust of physicians (105,106), and one task in discussing end-of-life care is to overcome that mistrust. In the outpatient setting, it takes a special effort on the part of physicians to establish a relationship that allows meaningful advance care planning. Insofar as ICU care is an emergent, unexpected event, the lack of previous relationship may open an opportunity to bypass mistrust. The clinician and the patient are brought together under extraordinary circumstances. There is often a sense of shared goals. Family and physician both seek the best possible care for the patient leading to recovery, if possible. Most want to avoid overtreatment if recovery is not possible. These shared goals form the basis of a natural alliance that the skilled intensivist can build upon to facilitate communications (106).

Preferences for end-of-life care are not fixed qualities that a patient discovers upon reflection. A decision to pursue risky therapy or to forego further intensive care is not made in the abstract. Preferences for care emerge from a process of discussion and feedback within the network of the patient's most important relationships (100). Such decisions are inevitably embedded within a social context. The ICU environment can make this communication easier, not harder, because there is a natural iterative pattern in meeting with a family through the course of a critical illness. The ability to meet repetitively over time provides an opportunity to build trust. These meetings also create a new social context in which the intensivist plays an important role in the ongoing development of preferences for care. These conversations hold the key to end-of-life decision-making in the ICU (102,105,107).

WITHHOLDING AND WITHDRAWAL OF LIFE SUPPORT: GENERAL PRINCIPLES

The majority of patients who die in North American ICUs now die following a considered decision to withhold or withdraw some form of life-sustaining therapy (4,54,108). This represents a recent, secular trend in North America toward more active management of dying ICU patients (18,109,110) as well as a dramatic change from earlier practice (Table 79-1). There is a broad ethical and legal consensus that withdrawal of life-sustaining therapy is appropriate in many circumstances (55,56,111,112,113,114 and 115). Nonetheless, there remains significant variation in practice (Fig. 79-1). The reasons for this variation are not clear, but it does not appear to be associated with size, type of ICU, or the number of admissions (4). The attending physician's status may be a relevant factor (116).

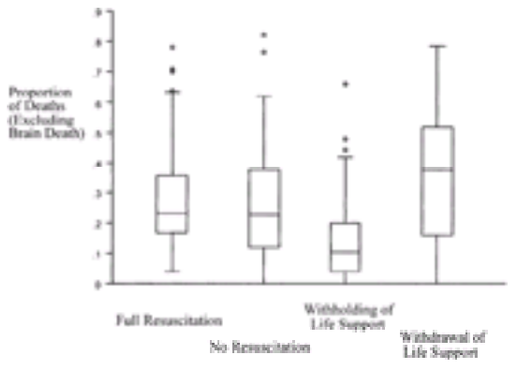

FIGURE 79-1. Variation in the practice of withholding and withdrawal of life support among 131 American intensive care units. Actual mean percentages (range) are as follows: full support, including cardiopulmonary resuscitation (CPR), 26% (4–79); do not resuscitate (DNR), 24% (0–83); withholding, 14% (0–67); withdrawal, 36% (0–79). (From Prendergast TJ, Claessens MT, Luce JM. A national study of end-of-life care for critically ill patients. *Am J Respir Crit Care Med* 1998;158:1163–1167, with permission.)

There is a great deal of descriptive research on the process of withdrawal of life-sustaining therapy (53,54,73,76,117,118 and 119). Any therapy that sustains life can be withheld or withdrawn. The most common therapies are, in the approximate order of frequency with which they are withdrawn: blood products, hemodialysis, vasopressors, mechanical ventilation, total parenteral nutrition, antibiotics, intravenous fluids, and enteral feedings. The majority of physicians opt to withdraw therapies in a sequence; the therapies most likely to be withdrawn first are those that are scarce, expensive, or invasive. Many physicians will first withdraw the therapies with which they are most familiar. There are many suggested algorithms for withdrawing different technologies (120,121,122 and 123). These recommendations are based on expert opinion. Few studies report patient comfort, family satisfaction, or the experience of caregivers on which to base a recommendation (124).

Patients and surrogates, or clinicians, or both, may pursue intensive care too long before acknowledging the appropriateness of limiting therapy. Patients and physicians usually move to limit therapy when hope for recovery is outweighed by the burdens of continuing treatment. Most disagreements about continuing therapy are not about the merits of treatment in the face of incontrovertible evidence that it has failed. Physicians and families most often disagree about how to value a small chance of improvement, or how to weigh the continuing burdens of treatment, be they physical, emotional, financial, or in loss of dignity. The difficulty in making such judgments in the face of inadequate information naturally leads to disagreements. Most often, these disagreements are handled through an intuitive process of negotiation. The parties agree on a time-limited trial of therapy, followed by review and withdrawal if the patient has not improved. In a small percentage of cases, the perspectives of the patient/surrogate and the treating physicians are difficult to reconcile, and one party may insist on treatment against the strong recommendation of the other. Many physicians attempt to apply the concept of medical futility to such requests to reassert the prerogative to make the decision they favor (125). Because there is no consensus definition of medical futility, this approach should be avoided. The Council on Ethical and Judicial Affairs of the American Medical Association has recently suggested an alternative, procedural approach based upon the experience of researchers in Denver and Houston (126). It is important to recognize that while each side—the medical community and patient advocates— accuses the other of demanding overtreatment, the evidence suggests that physicians and families are about equally responsible (85).

Suggested Protocol for Withdrawal of Life Support

A. *Clarify the decision.* Establish consensus on withdrawal among the medical team members. Responsibility to proceed with withdrawal remains with the patient/surrogate in consultation with the attending physician, but it is essential to know if there are significant concerns among consulting physicians, nursing, respiratory care, or other members of the critical care team. Members of the team may reach the conclusion that therapy should be discontinued at different times. Unanimity is not to be expected in all cases. Common areas of disagreement include misunderstandings of legal responsibility and liability, disputes over prognosis, and a tendency to focus on survival to ICU discharge that neglects the patient's long-term survival. If disagreements among the critical care team cannot be resolved in advance of the decision, their concerns must be noted as a sign of professional respect.

   Identify the appropriate decision maker, patient, or surrogate. Establish consensus on proceeding among patient/family. As with the medical team, unanimity is the goal but is not to be expected in all cases. All critical care providers should hone their skills in understanding the dynamics of family discussions. In particular, speculation as to motivations of family members should be discouraged while encouraging an appreciation for the difficulty of allowing a loved one to die. Providers should be particularly sensitive to framing discussions that suggest that the family's or surrogate's decision is responsible for the patient's death. In almost every case, this is simply inaccurate: The decision is made in accordance with the patient's wishes.

   Document the discussion as well as the plan in the medical record.

B. *Identify patient/family goals.* Nearly all patients who have life support withdrawn in a critical care setting die soon thereafter. This is usually not in doubt but should be made clear if it is not already.

   Some patients and most families ask for comfort above all else. Ensuring comfort often comes at the cost of diminished level of consciousness. Occasional patients will want to visit with loved ones and are prepared to tolerate some physical distress in order to be present to them. Others simply want to be asleep. In order to provide excellent care, it is essential to establish with the patient or surrogate the primary treatment goals following the withdrawal of life support.

C. *Review the process with family, and patient, if awake* .Emphasize comfort consistent with patient goals (above). Describe the plan to deal with any complications of withdrawal. Do not make promises that you cannot keep, e.g., adequate analgesia and sedation may not prevent some gasping or gurgling of secretions. Reassure the patient/family that you have a plan to treat these signs should they appear.

   Address length of survival. Family members frequently ask how long a patient will live after the withdrawal of life support. They deserve an answer, even if it is only an educated guess. In most cases, it is possible to put a patient's prognosis into categories of minutes to hours, hours to days, days or more. Often, the clinician can be much more specific. Of course, there will always be patients who will surprise their caregivers and prove their predictions wrong. They are few, and it is better to be helpful to the vast majority of families and risk the occasional mistake than to refuse to answer a legitimate question.

D. *Create a calm environment.* To the extent possible, isolate the patient from the noise and activity of the ICU. Provide a private room or draw curtains. Liberalize visiting rules. Allow children at the discretion of the patient/family.

   Any technology that is not providing comfort to the patient should be removed. Remove lines and tubes, turn monitors off, disable alarms, discontinue routine measurement of vital signs. Discretion will be needed with urinary drainage catheters because removal may be uncomfortable and obstruction may ensue. At least one intravenous catheter should remain in place for the administration of sedatives and analgesics.

E. *Principles of symptom management in withdrawal:*
   1. A physician should be at the bedside at the start of a process of withdrawal, regardless of the therapy withdrawn. Most decisions to allow a patient to die are distressing for the family and fraught with secondguessing. The continued presence of the attending physician at the time of withdrawal makes a strong statement to the family of nonabandonment in the face of death, of continued involvement, while dying, to ensure comfort, and of the importance to the medical team and, by inference, to the hospital of the importance of a good death. The absence of the attending physician may send the opposite message. The presence of the attending physician is also valuable to any trainees or students who may have participated in the patient's care. Obviously, a clinician should be available to assess and to respond to significant changes in the patient's status as therapy is withdrawn.
   2. Medications must be immediately available at the bedside.
   3. Administration of medications should be guided by anticipatory dosing, particularly when making changes that are highly likely to cause distress such as discontinuation of assisted ventilation or removal of an endotracheal tube.
   4. Medications should be titrated to effect. The effect is comfort, not apnea. There is no *a priori* maximal dose. It is difficult to assess discomfort in comatose patients. If a patient appears uncomfortable, it is acceptable practice to administer analgesic and/or sedatives under the assumption that he may experience something. Family suffering in the presence of an uncomfortable patient may be palpable. It is acceptable practice to administer medication to make the patient appear more comfortable provided that the intent is not to hasten death.
   5. Continuous infusion is preferable to bolus dosing although a bolus is often appropriate prior to increasing a continuous infusion dose, particularly for drugs with a longer time to onset (e.g., lorazepam).
   6. If a physician is not present, the nurse should be given appropriate latitude to increase dosing to achieve specific goals, such as to reduce tachypnea to less than 25 breaths per minute.

F. *Orchestrating withdrawal of therapies.* There is great variation in how clinicians proceed with the withdrawal of life support. There are, however, a few common principles to guide clinicians.

   First, any medical treatment that is not essential to the comfort of the dying patient may be withheld or withdrawn. Artificial nutrition and hydration is a medical

treatment like any other but, unlike most, has strong cultural associations with nurturing and caring. It is important to be aware of the strong feelings that nutrition and hydration carry for many people, including caregivers. Although the medical evidence suggests that there is no additional benefit to continuing artificial nutrition and hydration, families may have cultural traditions of caring for the dying that make a decision to forego such therapy very troubling.

Once a decision has been reached to withdraw life support in a critically ill patient, one must neither prolong dying unnecessarily nor act to hasten it. The former is the more common mistake. A piecemeal withdrawal of therapies that stretches over hours to days is inappropriate (127). In the vast majority of cases, the patient cannot survive without the technology in question, and death is not only expected but imminent. When a decision is made to withdraw life support, then life support should be withdrawn—all of it. Removal of most therapies does not cause distress. These therapies, therefore, should be stopped rather than gradually reduced. The only therapy in which removal commonly results in exacerbation of symptoms is mechanical ventilation (see below).

One reason for the gradual withdrawal of therapies over days is to create distance between the removal of the medical intervention and the patient's death. Such space is neither legally nor ethically necessary (55,56). However, too close an approximation of death to the withdrawal of therapy is frequently uncomfortable for caregivers and may contribute to a sense of guilt among family members. More important, the time between withdrawal and death is frequently an important vigil for the family: Having made the decision to stop therapy may allow them to sit in the presence of the dying.

Withholding and withdrawal are supported by a broad ethical and legal consensus. Euthanasia is nearly as universally condemned. It is also illegal in Canada and the United States. Medications that hasten death but have no role in providing comfort, such as potassium chloride, should not be given. Similarly, if not quite so starkly, large bolus doses of sedatives and analgesics should not be given unless and until routine doses have proved ineffective in controlling symptoms. These medications should be titrated up to effect from below, not down from doses that may induce hypotension or apnea. NMB are frequently used in critical care to facilitate mechanical ventilation. Their therapeutic effect makes symptom assessment all but impossible. Their use at the end of life, when symptom control is paramount, is discouraged. There is some evidence that they are used, and sometimes started, in anticipation of withdrawal of life-sustaining therapy (54). Most intensivists recommend stopping any NMB when the decision is made to withdraw life support and in advance of withdrawing mechanical ventilation (128).

G. *Removal of mechanical ventilation.* Removal of assisted ventilation or an endotracheal tube commonly causes visible signs of distress even in patients comatose from their illness. The goal of ventilator withdrawal is to remove support efficiently over 15 to 30 minutes while maintaining patient comfort. In general, all other lifesustaining therapies should be removed first (Table 79-8). A common concern is whether to leave the endotracheal tube in place (sometimes referred to as *terminal weaning*) or remove it (extubation) (127,129). In patients who can support their own ventilation, even briefly, extubation may improve patient comfort. It allows closer contact between the patient and loved ones, and may improve communication. It is recommended to leave the endotracheal tube in place in patients on high levels of ventilatory support, who may die immediately if extubated, and in those with difficulty clearing secretions or protecting their airway, who may struggle and gasp when extubated (121).

TABLE 79-8. WITHDRAWAL OF MECHANICAL VENTILATION

H. *After-death care*. A physician should acknowledge and confirm to the family when the patient has died. Every intensivist should understand the nature and management of grief and bereavement (130). Recognize that families may second-guess themselves and may need reassurance that their decision was appropriate and correct.

A multidisciplinary team should debrief after every death, to review the technical details of the outcome, to examine the process of decision-making among the team members and to allow the team itself to express grief over the death of a patient. This is particularly important in cases where the decision was particularly difficult (young person, tragic circumstances, a person connected to the medical community) or where there was disagreement over the decision.

SUMMARY: IMPLEMENTING PALLIATIVE CARE IN THE INTENSIVE CARE UNIT

Institute mandatory family meetings with the attending physician within 24 hours of admission. Goals of this meeting are

A. To convey information about the patient, specifically, to review the reason for admission, the treatment plan, and the expected prognosis, along with anticipated decision points;
B. To orient the family to the ICU. Clinicians may avail themselves of novel technologies, including written brochures, videotapes, and interactive CDs, to help families understand the people and routines of the ICU (79);
C. To convey a strategy about future communications. The clinicians should identify the responsible physician(s) and nurse(s) and establish a plan for ongoing communications. This plan should offer daily communication between the family and a designated physician, preferably the attending or a critical care fellow; and
D. To reassure the family of their access to information about sudden changes in the patient's condition. The family should be able to call into the hospital at any time to obtain information about the patient. The hospital must be able to contact the family in the event of a change in status. This may involve loaning a beeper/ pager to the family.

Highlight the value of good communications skills. Specific areas of need include communicating bad news, group dynamics, how to conduct a family meeting, and how to invite patients into the process of decision making without making them responsible for decisions that may end with the death of the patient (131). Explicit attention needs to be paid to the dynamics of conflict and the importance of negotiating rather than imposing resolution to disagreements.

ICU staff should recognize that the same structural issues that affect communications with families—uncertainty, rapid changes in status, intense personal relationships, exposure to many patient deaths—also affect communication among physicians and between physicians and nurses. A hierarchical model that devalues the input of some members of the multidisciplinary team leads to dissension (3,132). Such dissension may adversely affect patient care (27).

Emphasize the importance of symptom management.One mechanism to accomplish this is to institute regular use of pain and sedation scales. Quantitative attention to symptoms will be especially needed if practice evolves toward reduced sedation to avoid prolonging ICU length of stay. As part of the emphasis on evidence-based symptom management, physician and nursing staff will need periodic reviews of pharmacology of opioids and sedatives and how their properties are altered in critical illness.

Formalize recognition of the importance of quality of dying and bereavement support through a systematic review of every ICU death. A senior physician and a nurse should institute a quality improvement project based on the review of the first 20 deaths. Bereavement training is essential for ICU staff to help them to recognize and to assist patients/families, as well as attend to the grief reactions that affect professionals who work with many dying patients (133).

MEASUREMENT OF QUALITY OF LIFE OUTCOMES

ROLAND T. SKEEL

IMPORTANCE OF QUALITY OF LIFE OUTCOMES

Patients regularly ask physicians and nurses for quality of life information about their cancer and its treatment: “How much pain will I have? How much nausea and vomiting will the chemotherapy cause? How long will it last? Will I have enough energy to work? Is it safe for me to have sex? Will all my hair fall out? Will it come back? How much time will I have to spend in the hospital? How much is this all going to cost? When is my appetite going to come back? Why am I feeling so depressed? Will I ever stop being so nervous?” And they often ask the ultimate question that requires the physician to integrate knowledge of the anticancer treatment, the supportive care efforts, and the quality of life effect of the disease and the treatment: “Will I be better off because of this treatment?” Too often the answers given are limited to anecdotal, incomplete, or misinformed replies, because quality of life evaluations in cancer clinical trials and in palliative care have been uncommon, limited in scope, or difficult for the clinician to interpret (1).

The goal of supportive care in oncology—as is the goal of palliative care in any medical specialty—is to make patients function and feel better than they would have without that supportive care. This goal is explicitly different from that of curative or life-extending therapy, in which there is regularly a moderate to high tolerance for side effects and temporary functional impairments (2). Even with curative or life-extending therapies, supportive care measures are necessary, and the success of the palliative aspects of care may determine whether the patient is willing to tolerate repeated courses of the treatment, as is usually necessary with chemotherapy. Whether the care is given in conjunction with other cancer treatments or is used exclusively to palliate the effects of the cancer, the criteria for success are that the patient feels and functions better. When patients are less pleased with how they are feeling or functioning—that is, when they believe their quality of life is not better—then the supportive care has not been successful. The patients' personal, subjective perception of how they are feeling and how they are functioning thus becomes a critical outcome measure of this aspect of cancer care. As stated by Roy, “Quality of life studies and measurements are a systematic way of paying attention to the details in which effective compassion will be found or found wanting”(3).

HEALTH-RELATED QUALITY OF LIFE

Subjectivity of Assessments and Multidimensionality of Dimensions

Quality of life measurement is neither a concept nor a procedure with which nurses and physicians caring for patients with cancer are really comfortable, because it seems so difficult to define the meaning of the phrase “quality of life.” This is not to say that there is disagreement over the importance of quality of life. In two separate surveys of physicians in the Eastern Cooperative Oncology Group (ECOG), 63–89% of ECOG physicians said that they felt more satisfied when they could improve the quality of their patients' lives rather than simply prolong survival (1,4). Thus, even clinicians who have been self-selected to perform clinical research to find more effective cancer therapies value the notion of quality of life, despite lack of agreement on a precise meaning of the concept or the ability to measure it directly.

“Quality of life” is a phrase and a concept that also has crept into common parlance. When used in everyday language, it is assumed to cover many aspects of life, including the availability of food and shelter, climate, occupation, and other aspects of economic well-being, as well as social, psychological, and physical health. An article about the Federal Emergency Management Agency's report on “Nuclear Attack Planning Base—1990” discussed optimistic and pessimistic predictions about “the quality of life after World War III” (5). When measured in general populations by social scientists, “quality of life” usually refers to these broader terms. Domains that national surveys have identified as important to quality of life include the following:

- Physical and material well-being (which includes health and personal safety)
- Relations with other people
- Social, community, and civic activities
- Personal development and fulfillment
- Recreation (6)

Specific instruments used to measure quality of life determine the precise meaning for an individual study more definitively, and it is important to recognize that a single definition does not apply equally to all quality of life measurements. It is of interest that health and personal safety were ranked as important or very important by 95–98% of a sample of 3000 30- to 70-year-old subjects from the general U.S. population, higher than any other of the 15 different components that were ranked for importance to their quality of life. Only fifteen to 20% reported that this component was moderately, only slightly, or not at all well-met in their lives (6).

When limited to the narrower realm of illness and health, “quality of life” takes on more specific meanings, although it remains multidimensional and is clearly affected by factors that may be included in the more broadly designated “quality of life.” For the remainder of this chapter we use the term *health-related quality of life* (HQL) to designate a more focused concept related to the impact of a medical condition or its treatment on a person's expected physical, psychological, and social well-being. Calman has posited that quality of life evaluations measure the difference between the “hopes and expectations of the individual and that individual's present experiences” (7). This postulate carries the implication that the perceived quality of life could be improved either by reducing expectations or by improving the actual symptoms, functional status, and psychological well-being that the patient compares with his or her expectations. The reduction of expectations in HQL may be closely related to adaptation to changing health, as discussed by Schwartz and Sprangers (8).

Implicit in these definitions of HQL is that the designation of the extent of variation from that expected by the patient must be determined by the individual to have the greatest validity. Perceptions are, by their very nature, subjective. Therefore, reliance on family members or health professionals may produce misleading information on what the patient's quality of life is (9,10,11 and 12). In contrast to this general caveat, when treatment-related symptoms are focused on, others have found that, at least with some instruments, there are minor differences in HQL (13).

Although it is possible—and logical—to draw some conclusions about relative HQL impairment from certain symptoms or objective functional impairments, what appears logical may not in fact be the case. Two studies in patients with advanced cancer demonstrate this (14,15). In these studies, despite increased side effects from a more aggressive regimen (colon cancer) or a more prolonged regimen of chemotherapy versus shorter radiotherapy (lung cancer), patients did not report greater impairment of quality of life. It has been suggested that the overall improvement in quality of life in such active therapy may be related to “optimism and support provided by close medical supervision”(16).

It becomes even more hazardous to try to extrapolate the effect on psychological or social components of perceptions of HQL from objectively measured impairments. The subjectivity of HQL comes about in part because a person's designation of perceived HQL is psychologically derived from both his or her current (momentary) self-observed quality and the current quality that the person expects. The current quality expected is not static, but varies with many factors, including psychological adjustment to disease (e.g., the long-term paraplegic who is quite satisfied with his or her quality of life), culture, and personality. The momentary self-observed quality

of life is itself derived from a complex integration of factors that constitute the multidimensionality that is commonly assessed in quality of life measures (17,18 and 19):

1. Physical symptoms of the disease or its treatment or concurrent illness
2. Functional capacity (ability and energy) for daily routine, social interactions, intellectual activity, emotional reactions and adjustments, economic independence
3. Self-perceptions of wellness or its absence

The physical symptoms of disease and side effects of treatment that are common include fatigue, pain, nausea and vomiting, hair loss, and anorexia. Other symptoms of disease and treatment are quite specific to a disease or treatment and include problems such as incontinence of stool or urine, dyspnea from congestive heart failure or pulmonary toxicity, and peripheral neuropathies. Although these are discrete elements that contribute to global HQL, they also have an impact on functional capacity. The latter is usually separated into three distinct domains: psychological functioning, social functioning, and physical functioning. Psychological functioning includes anxiety, depression, adjustment to the disease and its treatment, and satisfaction with care. Physical functioning includes mobility, ability for self-care, and ability to carry on daily routine (e.g., child care or work activities). Social functioning includes family interactions, relationships with friends, and ability to function on the job beyond the physical level. Additional considerations in HQL may relate to spiritual concerns, sexual functioning, and body image (20). Variability among respondents may also occur because of the assessment environment, and the manner and form of evaluation (21). Thus, subjectivity and multidimensionality are two critical factors in understanding and measuring HQL and in interpreting data from HQL assessments.

QUALITY OF LIFE OUTCOMES IMPORTANT TO CANCER PATIENTS

Somatic and physiological symptoms and complaints are generally the most immediate concerns of patients with cancer. Dame Cicely Saunders, the founding director of St. Christopher's Hospice, London, England, stated at a lecture at Yale in the early 1970s that when a patient is in pain or lying in a bed of feces, it is difficult to converse with family and friends and to reminisce about the good times. The simple physical problems must be addressed first. “Successful symptomatic treatment should enable a patient to be so relieved of physical distress that he is freed to concentrate on other matters” (22).

Physicians and nurses are usually attuned to the physical, symptomatic distress expressed by patients. How likely it is that the range of HQL effects of this distress will be addressed depends on a willingness to take time with the patient and to ask appropriate questions that are relevant to the patient's disease. Even with the emphasis of the importance of HQL in cancer care over the past 10 years, patients express more concern and spend more time trying to discuss palliative care questions than physicians, who tend to focus on medical and technical issues (23). Asking the appropriate questions requires a knowledge of how specific factors about the disease and its treatment are likely to affect the patient's HQL. It also takes a recognition that these issues are paramount to many patients, and willingness to spend the extra time is needed to listen and offer thoughtful supportive responses.

Influence of Cancer Characteristics on Health-Related Quality of Life

The types of symptoms and physical distress experienced by patients are greatly influenced not only by the type of cancer but also by the stage of the disease, the specific organs and tissues involved, and the current or most recent treatment. For example, in early breast cancer, paresthesia on the chest wall consequent to surgery, nausea and vomiting, hair loss, or weight gain from chemotherapy may be important quality of life concerns. In advanced breast cancer, bone pain, loss of appetite and cachexia, or shortness of breath may be predominant physical quality of life concerns. For any patient who has completed active therapy, primary physical concerns may be persistent lack of energy with its resultant functional deficits, loss of organ function (e.g., of speech or swallowing), or the potential for second malignancies. As with other dimensions of HQL, patients' expectations about how they should feel play an important role in the degree to which their physical problems affect their reported HQL.

The influence of the cancer, its stage, and its treatment on the social and psychological domains of HQL are not as evident as with the physical domains. In contrast to somatic and physiological symptoms and complaints, social and emotional issues get inadequate attention from physicians and are underemphasized in many HQL measures (23,24). Physicians often feel that emotional support is better relegated to other health professionals, whereas many patients prefer to get their support from their primary oncology physician (16). The emotional benefit of psychological interventions for patients with cancer in reducing emotional distress, enhancing coping, and improving “adjustment” have been well demonstrated (25). There is even some suggestion that there is a physical, lifeprolonging benefit as well (26), although this is far from being established (27).

Influence of Age and Other Factors on Health-Related Quality of Life

Any discussion of HQL measurement must also recognize that HQL is influenced by considerations other than the disease in question and its therapy. Because the measured quality of life is dependent on expectations as well as the patient's current situation, anything that can affect expectations can have an influence on the measured quality. Younger people have different expectations regarding life expectancy than do older persons; they may also have different expectations about functional ability, pain, or other symptoms that could affect their perceived HQL. Age has been found to affect decision making by patients with cancer when they are presented with scenarios in which survival can be traded for quality of life: Younger patients are more likely to accept a treatment with more severe side effects to gain an increment in survival than are older patients, who have a greater interest in maintaining their current quality of life (28). In addition, patients with higher scores on the social well-being subscale of the Functional Assessment of Cancer Therapy (FACT) assessment, as well as those with children living at home, were more willing to have aggressive cancer treatment (29). Debilities from the disease or comorbid conditions may be greater in older patients and result in a worse baseline quality of life.

It has been found that older patients with cancer had lower HQL scores when uncorrected data were used. However, once complicating comorbidities or performance status were controlled for, the older patients had a quality of life similar to that of younger patients, according to various physical and psychosocial scales (30). Because the results obviously reflect how the analysis is designed and what measure is used, it is not possible to generalize from these data that age was not a factor in HQL measurement or perception. In fact, the opposite might be true, because only after “correction” for performance status or comorbidities or functional status were the HQL scores similar. Age is clearly a potentially important patient variable to be taken into consideration and controlled for when possible.

Similar arguments can be made for socioeconomic status, which has a significant effect on overall health (31). Because the cultural context in which the HQL is being evaluated is important, a determination of cross-cultural validity of HQL assessments is essential (32). Finally, personality factors, such as ability to adjust to and cope with stressful situations, can also have an impact on the patient's perceived quality of life, as they impinge on the patient's expectations (8).

Evolution of Health-Related Quality of Life Measurements from Curiosity to Commonplace

When Spitzer reviewed the state of the science of quality of life, he found only four papers in the medical literature (by physicians and surgeons) with “quality of life” in their titles between 1966 and 1970 (33). In the next 5 years there were 34, and since then the rise has been seemingly exponential: In 1993 alone, 165 articles met the specific criteria of focusing on HQL and were believed to be significant contributions to the HQL literature (34). In 2000, more than 5100 titles indexed in Medline's PubMed (National Library of Medicine, Bethesda, Maryland) contained the phrase “quality of life.” The growth of the area is further attested to by the fact that there is now a dedicated journal, *Quality of Life Research*, to deal with this topic.

Along with the growth in the research has been a concomitant growth in instruments to measure quality of life. Even 10 years ago, a review of a quality of life bibliography and measurement instruments found that over 170 different HQL instruments were reported as being used (34).

Many HQL instruments are designed for use either in the general population, to assess health status, or in patients with disease states, but they are not directed specifically at any one health problem (35,36). Other measures are much more specific and are designed with a limited population in mind, such as patients with systemic lupus erythematosus, chronic lung disease, or cancer. Even within disease groups, there are specific measures that aim to address the particular problems posed by a unique group of patients. For example, within cardiovascular diseases, there is a questionnaire for patients with chronic heart failure. Whether the approach is broad and general, or narrow and specific, the aim is to gain information that enhances understanding of the disease process, the illness that people experience from their diseases, the consequences of the therapy for the diseases, and the predictive value of the information about groups or individuals with disease.

Just as there is often a gap between patients' expectations about their HQL and current reality, there is also a gap between the health profession's affirmation of the importance of quality of life in medical care and how the outcomes from measurements of HQL using standardized instruments are used to inform patients, shape clinical decisions, and establish health policy. As a consequence, physicians continue to use unsystematic approaches to learn about their patients' perceived quality of life and to apply this knowledge to clinical decisions.

Although HQL evaluations in oncology, particularly in clinical trials (37,38 and 39), became prevalent somewhat later than HQL evaluations in cardiovascular (40) or chronic lung disease (41), there has been a flurry of activity in the past 10–15 years that has resulted in HQL evaluations being companion studies or an integral component of many clinical trials in oncology (38,39,42,43).

The most prevailing use of HQL assessment in oncology is as an end point in clinical trials (20,21,32,37,38,42,43,44,45,46,47,48,49 and 50). Gotay and colleagues (44)

suggested that for HQL to serve as a study end point, two conditions must be met:

1. The predicted survival differences between treatment arms are expected to be small.
2. Moderate to large differences are expected on at least one quality of life dimension.

This set of conditions describes one important situation in which HQL should be an end point, but if applied strictly it may be unduly restrictive to investigators who may have valid reasons to study HQL effects in other situations. For example, significant differences in HQL could be important to some patients despite substantial (or at least statistically significant) differences in survival. A determination of what is a “small” difference in survival, after all, requires a value judgment: a judgment of the relative importance of survival and quality of life to the patient. Importantly, a significant change in survival or HQL as seen through the eyes of the statistician may not be viewed as clinically important by the patient or physician. As pointed out by Edlund and Tancredi (51), to understand quality of life measures we need to know “who is talking about quality of life? What sort of quality is being specified? Defined by whom, for whom? Decided by whom? One must consider the different social and economic (or bureaucratic) groups who use the phrase, when they use it, how they use it, and finally, why they use it.” Predictability about preferences is treacherous, and contrary to some expectations, patients with cancer may forego a better quality of life and choose a more radical treatment with minimal chance of benefit than those without cancer, including medical professionals (52).

Use of Health-Related Quality of Life to Inform and to Develop Health Care Policy

Once HQL data have been derived from clinical trials that are deemed valid and generalizable, several uses can be made of the information. One obvious and direct use is to enable health care professionals to better inform patients about the risks and benefits of a proposed treatment, particularly if the alternatives being considered are the same as those that were compared in a clinical trial. Because HQL data may be a useful prognostic variable (53,54,55 and 56), they can be of further benefit to clinicians and patients in helping them to make informed treatment decisions. HQL data may also be used to evaluate the impact of socio-economic or ethnic factors on quality of life (57). HQL data have also been used—and some think misused—to influence an increasingly involved and interested public through mass public advertising for products as diverse as allergy medicine, hematopoietic growth factors, and therapy for impotence. The jury is still out regarding whether the net effect of this will be improvement in health or public HQL.

Thus far, most HQL evaluations have been attempts to learn about the impact of cancer and its treatments on groups of patients. This has led to a focus on disease rather than individual patient outcome. As familiarity with HQL assessments increases and their value and limitations become clearer, it is anticipated that they will become an aid in patient management, because (a) they have prognostic value, (b) they can be used as independent outcome measures that help determine the benefit or harm of current antineoplastic or supportive therapy, and (c) they can be used as clinical tools to direct earlier initiation of psychological, social, or physical support or rehabilitative measures.

Quality of life data can also be used to determine health policy (58). The information might be used to select alternatives for additional clinical trials or to make decisions about approval of new drugs for marketing. The U.S. Food and Drug Administration has declared that “a favorable effect [of an anticancer drug] on survival or quality of life is generally required for approval” (59). Assessments of HQL have the potential to enhance decision-making about the use of health care resources, but because of the pervasive issues of value that are associated with various HQL outcomes (or lack thereof), the information thus gained is open to misuse. As pointed out by Ganz, it will “be imperative that the QL data incorporated into policy decisions be of high quality and that both patient advocates and clinicians play an important role in their interpretation” (20). “The diffusion of process and outcome measures into practice; the practicality, reliability, and validity of these measures; and the impact that these indicators have on practice patterns and the health of populations will be key to evaluating the success of such quality-of-care paradigms” (60).

MEASUREMENT OF HEALTH-RELATED QUALITY OF LIFE

Clinical Assessment

Physicians have placed a premium on the quality of life of their patients throughout the history of medicine. Hippocrates wrote: “I will define what I conceive medicine to be. In general terms, it is to do away with the sufferings of the sick, to lessen the violence of their diseases, and to refuse to treat those who are overmastered by their disease, realizing that in such cases medicine is powerless” (61). In most clinical oncology offices, physicians regularly obtain HQL information from their patients when they ask “How are you?” or “How's it going?” This question is equivalent to the global HQL evaluation that asks, “How would you rate your quality of life today?” or “How satisfied are you at present with your life?” (62). The physician then follows up this question with further questions that probe the ways in which quality of life has been affected by the cancer and its treatment. This assessment is usually qualitative rather than quantitative, but it explores those domains that patients believe have an impact on their quality of life. For example, one patient may have low satisfaction with his or her current quality of life because of persistent nausea, another because of pain, and another because of a disinterest in talking with friends. These clinical assessments are essential in dealing with individual patient concerns, but they are of little value in collating information about the general and particular effects of cancer and its treatment on the “average” patient. For these purposes, standardized evaluation instruments are needed.

Standardized Instruments

To obtain useful information from groups of patients about HQL, standardized instruments are necessary (24,32,37,38,62,63,64,65 and 66). Questions that are asked of patients can fall into two major categories: They can be *open questions* to which the respondent may make any response, or *closed questions*, in which the respondent is supplied with a list of responses or a fixed scale on which to indicate a response. Open questions are less likely to restrict possible responses, but they are more difficult to categorize and analyze than responses to closed questions and may not cover all important areas because of the patient's reluctance, memory lapses or impairments, or lack of understanding of the scope of acceptable responses (66,67).

Psychometric and Utility Approaches to Health-Related Quality of Life Evaluation

Cella has emphasized that there have been two different approaches to measuring quality of life: *psychometric* and *utility* (68). With the *psychometric approach*, instruments are used to measure the impact of the disease, condition, or treatment on the physical, psychological, social, and functional domains of HQL and on overall perceived wellbeing. This approach does not quantify the weight or importance that patients place on these HQL domains or individual components when it comes to making decisions about alternative treatments, nor does it assess the impact of each component on their overall quality of life. For example, nausea and vomiting or anxiety may be rated by the patient as severe, but that alone does not tell the investigator how important it is to the patient's feeling of (or absence of) well-being, and further, how that will affect choices of therapeutic alternatives.

The *utility approach* is concerned with decision making and a comparison of two different conditions or treatment approaches in which an assessment is made by the investigator or the patient of the cost-benefit ratio of therapy. When utility measurements are made, there is always an explicit or implied evaluation of relative importance. The psychometric approach assesses intensity of symptoms, ability to function, and the psychological state of the patient; the utility approach tries to assess the importance of these factors, relative to each other or other factors, and the impact that they have on practical decisions (69). Utility assessments may involve

1. Offering theoretical choices between the patient's current state of health and various probabilities of cure or death
2. Asking the patient how much time he or she would be willing to give up to live the rest of life in perfect health
3. Having the patient subjectively assign the effect of specific HQL impairments on overall quality of life (24)

One current area of development in standardized instruments is to blend the psychometric data with utility estimates in the anticipation that the results will facilitate more informed decision making by individual patients, physicians, and policy makers. This kind of extension of HQL data permits formal assessments of various derived costutility parameters. In one type of analysis, total survival is adjusted for quality of that survival to obtain a measure called *quality of life years* (QALY). One can then compare treatments and calculate the cost for the gain in QALYs. This information can be used to address broad societal questions that involve comparisons between the value of incremental years lived and the costs for interventions under consideration relative to other health care or societal costs. One criterion states that treatments are reasonably cost-effective up to $50,000 per QALY gained (58). When patients themselves are asked about preferences for therapy, there is a reluctance to trade off survival for quality of life (70). This is consistent with the results of Slevin (52), who found that patients were more likely than doctors and nurses to accept radical treatment for minimal benefit.

The majority of HQL instruments in use today are based primarily on the psychometric approach. Examples of 17 generic, cancer-specific, and cancer site–specific instruments are reviewed elsewhere (71). Their application to cancer clinical trials has been reviewed by Moinpour et al. (38) and Maguire and Selby (72).

Development and Testing of Instruments

The design of a valid, reliable, and useful instrument is not as simple or straightforward as picking some questions that are thought to be important to quality of life,

applying a scale, and administering the instrument to patients. In the best-tested instruments there is a systematic process of item generation, item review and reduction, scale construction and piloting, and initial evaluation. Included in the initial evaluation are item analysis, factor analysis, creation of subscales (if there are to be any), and validity testing. Additional evaluation includes test-retest reliability and measurement of sensitivity to change. Validity testing tries to answer this question: Does the instrument measure what it is intended to measure? Measures of validity include

1. Content validity—does the measure cover all of the issues of interest and appear to be applicable for the stated purpose?
2. Construct validity—does the measure correlate with other similar measures completed at the same time, and do the results diverge from dissimilar measures completed at the same time?
3. Clinical validity or interpretability—are there correlations with other measures of health status, is there a responsiveness to a change in health status over time, and do the results have clinical relevance?

Once the instrument has undergone development and initial assessment, repeated evaluations over time in different populations are required to determine its specificity for unique populations and generalizability to broader categories of patients or healthy people.

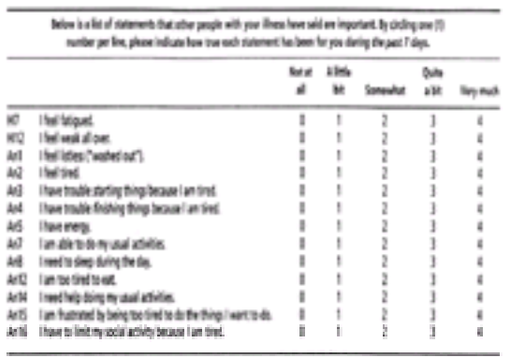
Generic versus Specialized Instruments

In the search for a gold standard, it was once believed that the choice was between either a broad generic instrument that gave information about general health status and HQL but was not specific enough to detail information relevant to a disease or treatment, or a specific instrument designed for each disease or stage or treatment. Aaronson (73) suggested an alternative modular approach whereby one could design an instrument with a number of general questions that would apply to many situations (e.g., to all patients with cancer) and append to this a module of diseasespecific or even trial-specific questions of disease symptoms and treatment side effects. This approach has been carried out by Cella and colleagues (24) and Aaronson and colleagues (32). A related approach uses an established general health measure, such as the Short-Form Health Survey: Medical Outcomes Study (35) and combines this with a global measure of quality of life and specific measures for anticipated disease and treatment-specific HQL outcomes, such as unique symptoms.

Examples of Health-Related Quality of Life Instruments in Cancer

The FACT measurement system is an example of a psychometric instrument (24). The FACT measurement is a 34- to 50-item compilation of a generic core of 34 items and specific subscales that can be appended for specific diseases. These subscales reflect symptoms and other problems that may be associated with disease sites (e.g., lung, breast, bladder, cervix, colon/rectum, head and neck, ovary, or prostate) or with human immunodeficiency virus infection. Table 80-1 provides an example of one of these instruments, the FACT-L (Lung) (74). The first 27 items correspond to the FACT-G (General), which can be given to any patient with cancer. The second set of ten items are specific for patients with lung cancer. The FACT is broken into five components from which subscales can be derived: (a) physical well-being, (b) social/family well-being, (c) emotional well-being, (d) functional well-being, and (e) additional concerns (disease-specific, treatment-specific, or both). A special concern has been the evaluation of fatigue, which is a common symptom associated with many cancers and cancer therapies. Fatigue may be amenable to therapy, such as weekly injections of erythropoietin for those with anemia-related fatigue. Table 80-2 provides an example of a specialized stand-alone instrument (The Functional Assessment of Chronic Illness Therapy—Fatigue) to evaluate fatigue, which has been validated in anemic patients with cancer (75).

TABLE 80-1. THE FUNCTIONAL ASSESSMENT OF CANCER THERAPY-LUNG (FACT-L) HEALTH-RELATED QUALITY OF LIFE INSTRUMENT



Below is a list of statements that other people with your illness have said are important. By circling one (1) number per line, please indicate how true each statement has been for you during the past 7 days.						
		Not at all	A little bit	Somewhat	Quite a bit	Very much
HI7	I feel fatigued.	0	1	2	3	4
HI12	I feel weak all over.	0	1	2	3	4
An1	I feel listless ("washed out").	0	1	2	3	4
An2	I feel tired.	0	1	2	3	4
An3	I have trouble starting things because I am tired.	0	1	2	3	4
An4	I have trouble finishing things because I am tired.	0	1	2	3	4
An5	I have energy.	0	1	2	3	4
An7	I am able to do my usual activities.	0	1	2	3	4
An8	I need to sleep during the day.	0	1	2	3	4
An12	I am too tired to eat.	0	1	2	3	4
An14	I need help doing my usual activities.	0	1	2	3	4
An15	I am frustrated by being too tired to do the things I want to do.	0	1	2	3	4
An16	I have to limit my social activity because I am tired.	0	1	2	3	4

TABLE 80-2. THE FUNCTIONAL ASSESSMENT OF CHRONIC ILLNESS THERAPY-FATIGUE (FACIT-FATIGUE) HEALTH-RELATED QUALITY OF LIFE INSTRUMENT

Questionnaires such as FACT are usually completed by the patients themselves, with instructions by a research assistant or nurse, but without assistance in completing the questions. The importance of patient-assessed HQL has been confirmed in cardiovascular disease (10) and cancer (11,76). After completion of the questionnaire, the nurse or research assistant reviews the responses to help ensure that all questions are completed (if possible) so as to minimize the number of unanswered questions. For patients who have difficulty in completing the questionnaire by themselves, it is preferable to have a nurse or research assistant help with the questions, because family members are more likely to insert their own biases about patients' responses than a person who has been trained to be neutral. Results are then analyzed by use of a manual provided by the developer of the instrument.

Although instruments such as the FACT are not widely used in the clinic to inform health care professionals about their patients' ongoing quality of life concerns or to make individual decisions about patients, adaptation of these selfadministered instruments to this purpose should be feasible, particularly as the health care professionals become more familiar with the instrument and with the interpretation of individual responses.

The European Organization for Research and Treatment of Cancer (EORTC) QLQ-C30 (32,77) is a similar core questionnaire developed by the EORTC. It has an additional virtue of having consistent reliability and validity across three language-cultural groups: patients from English-speaking countries, those from northern Europe, and those from southern Europe. It does not ask patients to render a judgment regarding how much each of the domains (e.g., social well-being) affects their quality of life, although it does ask global questions about how patients rate their overall physical condition during the past week and how they rate their overall quality of life during the past week. The selection of the question time frame is influenced by the disease and treatment under study: If one is looking at a relatively short duration of side effects, then there must be a clearly defined time of interest in the questions. This also relates to the timing of administration of the instrument relative to the treatment. As pointed out by Aaronson, even in the case of long-term effects, the use of a relatively short time frame, such as a week, minimizes problems associated with memory loss or a tendency over time to minimize or exaggerate symptoms or functional impairment (73).

A different type of instrument used in patients with cancer is the Cancer Rehabilitation Evaluation System, developed by Schag, Ganz, and others (64,78). This is a comprehensive list of 139 problems encountered by patients with cancer. Patients rate each problem on a 5-point scale. The first 88 items apply to all patients. The remaining questions apply to subgroups of patients. For instance, if a person does not have children, that section is skipped; if the person has not been employed, that section is skipped. A short form with 59 items has also been developed. It is intended particularly for use in research protocols in which repeated measures may be

needed and too much time needed for completing an instrument would be undesirable.

A third example of a quality of life instrument is a newly developed Hospice Quality of Life Index (79). This is a 25-item satisfaction questionnaire that has visual analog scales with adjectival anchors on each end of a 100-mm line on which the patient must make a single mark. Each item is then weighted by the patient relative to its importance for his or her quality of life. This instrument has been less rigorously tested and validated than the first two, but it may have broader validity for patients approaching the end of life who are receiving only supportive care. Even less studied are measures to evaluate quality of life in terminally ill patients (80). Additional validation is necessary to learn the most helpful ways to assess quantitatively HQL in populations of patients not on clinical trials, but for whom maximizing functional and sense of well-being is of paramount importance.

QUALITY OF LIFE OUTCOMES IN PATIENTS WITH CANCER

Quality of life outcomes in patients with cancer that have been assessed by well-validated instruments have become much more common in the past several years, although their interpretation and usefulness to the oncology community has not yet been fully realized (81,82). The largest number studies have been in breast cancer, with fewer studies in other types of cancer, and fewer yet in the supportive care or palliative care settings. Some have addressed palliative care offered by cancer treatment. Because HQL evaluations have mostly been developed for patients with specific cancers, some examples of what has been done and the types of results achieved are discussed in this section, followed by a description of the development of HQL in assessing palliative care and the potential for future directions both in research and in clinical care.

Health-Related Quality of Life in Breast, Lung, and Other Cancers

Breast Cancer

One early study of HQL was an evaluation of patients receiving treatment for advanced breast cancer using a linear analogue self-assessment (LASA) by Priestman and Baum (83). In one group of women with breast cancer, they evaluated HQL with this technique before and after 3 months of endocrine therapy. In another group, they compared subjective toxicity with two different cytotoxic regimens. Although the analysis was not highly sophisticated, they reached the following conclusions:

1. Patient age does not greatly influence the degree of subjective disturbance.
2. A smaller fall in the LASA score during the second cycle of chemotherapy suggested that patients tend to adjust to their side effects with time.

The National Institutes of Health Consensus Development Conference Statement, “Adjuvant Chemotherapy for Breast Cancer,” stated that: “The goal of adjuvant therapy is to significantly prolong survival while maintaining an acceptable quality of life” (84). Many HQL studies that have addressed primarily “psychosocial” problems have been done in patients receiving adjuvant therapy for breast cancer. For example, Meyerowitz (85) studied 50 women receiving adjuvant chemotherapy and found that 88% reported a decrease in activities from the adjuvant chemotherapy, 54% reported an increased financial burden, and 41% said their treatment had an adverse effect on their family or sexual life. Seventy-four percent said they would definitely recommend the treatment to their friends. This disparity demonstrates that the psychometric analysis (how much of a problem they have experienced) without the utility analysis (the relative importance of the symptoms versus possible benefits from treatment) gives incomplete information. A 2-year follow-up of 35 of these patients 21 months after treatment ended found that there were significant improvements in quality of life in most areas, although there were continuing problems in the physical area (86). Anxiety levels were found by Cassileth et al. to be similar in patients randomized to adjuvant chemotherapy versus observation in women in two Eastern Cooperative Oncology Group studies (87). Although the sample was small, the data were sufficient to rule out major differences in anxiety levels among women randomized to each arm.

The effectiveness of supportive care, such as for nausea and vomiting, clearly can make a difference in HQL outcome. The investigators in one early study of adjuvant chemotherapy in breast cancer and its effects on quality of life believed that the side effects from multiple drug regimens were so severe that they decided to stop a study of doxorubicin, vincristine sulfate, fluorouracil, methotrexate, and chlorambucil. Major side effects were nausea and vomiting, alopecia, and feeling “off color.” Nearly 30% of the patients said the treatment was unbearable or that they would “never again” undertake it (88).

Kemeny and associates looked at psychosocial outcome in 52 (62%) of 83 patients randomized to mastectomy versus segmentectomy (89). They found that women with segmentectomies felt less anxious, less sad, and more in control of their lives. Even the fear of recurrence was less in the segmentectomy group. Offering a choice of surgery in early breast cancer has been shown to reduce anxiety in both patients and their husbands (90).

Coates and others (46) looked at the HQL effect of intermittent versus continuous treatment strategies for advanced breast cancer and concluded that continuous chemotherapy was better than intermittent chemotherapy. In other words, it does not help to take a break and wait for the disease to progress. The implication is that cancer (or the concern about doing nothing for the cancer) has a greater adverse effect on HQL than does chemotherapy. Coates and colleagues have also looked at whether quality of life scores predict outcome in breast cancer. They found that there was minimal prognostic significance in the adjuvant setting, but that with relapse, poor HQL scores were strong predictors of shorter survival. They suggested that the patient's perception of disease severity influences HQL scores (91).

A different approach that tried to put some relative value on health states regarding adjuvant therapy of breast cancer was pioneered by Gelber and associates, who coined the concept “time without symptoms or toxicity” and a modification of it, the “quality-adjusted time without symptoms or toxicity” (47,92,93). Their studies supported adjuvant therapy as providing more quality time to patients, even when the toxic periods were subtracted from the total survival.

The palliative benefit of pamidronate disodium as a supplement to antineoplastic therapy has been evaluated in women with breast cancer and osteolytic metastases (94). Skeletal complications were reduced and pain scores better in the group that received pamidronate disodium. Fatigue has been increasingly studied in breast cancer as well as other cancers and therapies. In one study of breast cancer survivors, fatigue was found to be severe and persistent in approximately one-third of the women studied (95). Determination of the mechanisms underlying fatigue in this and other populations will aid in both prevention and more successful treatment. Menopausal symptoms occur earlier in women younger than 50 years of age when they receive cytotoxic adjuvant therapy for breast cancer. A comprehensive menopausal assessment and intervention program has been shown to be feasible and acceptable to breast cancer survivors, resulting in a reduction of symptoms and sexual dysfunction, but no demonstration of improvement in the RAND Short Form Health Vitality Scale (96).

Lung Cancer

In lung cancer, Cella et al. found that the psychological distress was correlated with worsening performance status and that when the performance status was poor, the extent of disease was also a determinant of distress (97). An early study in lung cancer using the Functional Living Index— Cancer found that when patients did not complete the instrument, not enough information was obtained for rigorous analysis (98), but correlations were found, as might be expected, between HQL and performance status. Compliance problems are not trivial, but there appear to be methods that minimize their occurrence (99). Psychological response has been compared in patients with lung cancer receiving either intravenous methotrexate, doxorubicin, cyclophosphamide, and oral lomustine (repeated in 21 days) or intravenous cyclophosphamide, doxorubicin, vincristine sulfate, and oral lomustine (with the doxorubicin and vincristine sulfate repeated in 21 days) (50). This study showed a “strong trend” to more fatigue and depression in the second group, which was hypothesized to be due to the vincristine sulfate, despite no differences in clinical response. It demonstrated the value of HQL studies in lung cancer or other cancers, although the conclusions themselves have no importance for current lung cancer therapy. Other studies, as mentioned previously, have shown that assessment of HQL can be a predictor of survival in lung cancer. Assessment of HQL by the Functional Living Index—Cancer is superior to performance status for predicting survival in patients with lung cancer (53,54). Other studies have failed to show that HQL is predictive of survival in lung cancer after adjustment for other factors, such as pain (100).

Systematic evaluation of symptoms at presentation in patients with lung cancer has shown that the chest symptoms commonly inquired about are not the only issues of concern to patients. Tiredness, lack of appetite, worry, and anxiety, as well as cough and shortness of breath, are most common, and are equally present in patients with both small cell and non– small cell carcinomas of the lung (101). The authors suggest that all symptoms at the outset of disease must be taken into account when the benefit of palliative therapy is assessed.

Other Cancers

Other cancers have been studied less regularly, although each common cancer, modality of therapy, and age group has probably had some HQL or psychosocial evaluation (49,102,103,104,105,106 and 107). Prostate cancer probably deserves special mention, as its potential prevention, diagnosis, and treatment have catapulted to prominence in recent years. Patients receiving a luteinizing hormone-releasing hormone agonist and flutamide in remission were studied using the EORTC questionnaire C30 and the Medical Outcomes Study Short Form Health Survey SF-36 (108). They were found to have a HQL that was not distinguishable from a matched male population without prostate cancer, but significantly better than men who were in progression from androgen resistant disease.

Health-Related Quality of Life in Symptomatic Care

In contrast to the burgeoning development of HQL assessments in clinical trials of cancer therapy, there has been less systematic advancement in the design of specific instruments or the use of standardized instruments for patients receiving supportive, palliative, or posttreatment follow-up care (80,109,110,111 and 112). In their literature review of the psychologic and psychosocial implications of survivorship of cancer in adults, Welch-McCaffrey and associates (113) point to significant psychosocial concerns of patients who have had cancer and are no longer undergoing active treatment. They include fear of recurrence and death, relationships with the health care team, adjustment to physical compromise, alterations in customary social support, isolationism, psychosocial reorientation, and employment and insurance problems. For many patients who are no longer undergoing active therapy, psychological and social support are necessary for optimal rehabilitation. Survivors of various cancers have been studied in a systematic fashion by use of validated instruments (114). One conclusion has been that patients who survive cancer do not return to a state of normal health, which emphasizes the need for continuing supportive care after active cancer treatment has ended. The relative absence of good prospective studies, however, has meant that retrospective studies, case reports, and legal overviews have been the primary source of information about such effects (113).

Farncombe (115) has suggested that the model for palliative care has shifted in recent years from one in which there was a sharp break between active aggressive therapy and palliative therapy to one in which there is a gradual shift in the balance between the approaches. This means that the HQL evaluations of palliative care must not be relegated only to patients who will no longer be offered active antineoplastic therapy, but can, in fact, take place throughout the course of management of the cancer (110,111,116,117). The need for supportive care as a key ingredient of total cancer care is being recognized by many National Cancer Institute–designated cancer centers that have ongoing research programs in supportive care (118). The prevalence of symptoms has been shown to be highly associated with psychological distress and poorer quality of life (119). This association highlights the need for regular assessment of HQL in the evaluation of symptom management during all phases of cancer care.

Occasional chemotherapy studies have been done in which palliation was the primary end point of therapy. Moore and coworkers (120) treated hormone-resistant prostate cancer with mitoxantrone hydrochloride and prednisone and used HQL as the end point. Evaluation tools included a pain intensity score and a modification of the EORTC core questionnaire. By these criteria, 9 of 25 patients achieved a palliative response lasting 6 weeks or more, despite the fact that only one patient had a measurable objective partial response. A larger study has confirmed these results (121). The drug gemcitabine hydrochloride was approved as firstline chemotherapy for cancer of the pancreas, primarily on the basis of its greater efficacy in achieving “clinical benefit response” (a composite of measurements of pain) than the previous standard agent, fluorouracil (122).

HQL has been compared in patients with terminal cancer who were dying in palliative care units or in the hospital. Using a variety of psychological scales, Viney and associates (123) looked at uncertainty, anxiety, depression, anger, helplessness, competence, sociability, and good feelings through content analysis of interview material. They found that patients in specialized palliative care units showed less indirectly expressed anger and more positive feelings. They also reported more anxiety about death, but less anxiety about isolation. Several studies have tried to determine whether palliative care has a positive effect on patients' HQL, but aside from patient and family satisfaction, benefit has been difficult to demonstrate (124,125,126 and 127).

A special problem pertains to children who are at the end of life. Many of these children die in the hospital, often in an intensive care unit. Parents reported to Wolfe et al. that 89% of the children suffered “a lot” or “a great deal” in their last month of life, most commonly from pain, fatigue, or dyspnea (128).

HQL has been found to deteriorate in most patients during the last weeks of life (129,130), although a substantial group (20%) of patients cared for in hospices felt that they had a good quality of life even toward the end of life (131). This suggests that attention to patients' concerns could play a role in the maintenance of HQL as perceived by the patients and that factors other than physical function are contributors to HQL in terminal cancer. When patients with varying prognoses were compared by use of the EORTC QLQ-C30, the main effect of prognosis was on the general quality of life scale and the physical aspects of HQL, with little effect on social or psychological functioning (116).

Compliance can be a major problem when trying to study patients who are at the end of life. Jordhoy et al. found that compliance in completing HQL questionnaires was good up to one month before death, but fell significantly in the last weeks of life (132). Because of the weak physical state of most patients who are terminally ill, Cohen and Mount (110) have suggested that the ideal palliative care HQL instrument is one that can be administered verbally (orally) in 10–15 minutes. They believe that the measure should determine how satisfied the patients are with the various aspects of their lives that are evaluated, and that they should be asked how important that aspect is to them (utility weight).

Single-problem issues can be important and legitimate foci for HQL evaluations in palliative care. In such circumstances, the HQL instrument may be limited to various facets of the single problem, such as the response of anorexia to megestrol acetate, which was reported to improve appetite and increase weight and food intake (133). Pain relief has been a common single-problem focus in the HQL arena. Studies of palliative pamidronate disodium in the treatment of patients with bone metastasis from breast cancer exemplify this (94,134). As an alternative to the study of only one symptom, broader instruments may be used to determine the impact of one problem on overall HQL.

Issues of feeding, nutrition, and hydration are among those that will benefit from more systematic evaluation of HQL. Patients who have been monitored during terminal illness to determine the frequency of hunger and thirst reveal that hunger is infrequent and can be usually be palliated by small amounts of food (135). Thirst can be relieved by careful mouth care and sips of water—less than would be ordered to prevent hydration. It is concluded that attention to what the patient requests is probably of greatest benefit to most patients. If patients have stopped eating, the production of ketones may lead to suppression of hunger and mild euphoria. Administration of carbohydrates (as in 5% dextrose and water) could serve to reverse this and reawaken hunger (136). If artificial feeding is deemed appropriate, the enteral approach should be used, if possible. Padilla and Grant (137) reported that even in those who had lost the normal ability to eat, enteral tube feedings gave patients more perceived control, were less stressful, and produced fewer psychosocial problems than parenteral feeding. Finally, vigorous attempts at hydration in patients whose heart and kidneys are failing may inadvertently lead to fluid overload, pulmonary congestion, and a more uncomfortable death than if the natural processes are allowed to take place.

An additional area of palliative care that is as least as difficult to study is the use of drugs for symptom control during the last days of life (138,139). Issues that must be addressed not only include the quality of the living and dying by the patient and the predominance of the patient's own wishes for the relief of suffering, but also the perceptions of the family about the patient's suffering and their own suffering. Consideration must also be given to ethical, social, and religious issues surrounding suffering and its relief by allowing death to occur in the process of relieving the suffering or withdrawal of mechanical ventilation and other life-support measures (140,141,142 and 143).

Although there is an obvious limit to when and under what circumstances HQL testing can be done, it may be possible to ask alert patients in the terminal stages of disease— using standardized questionnaires—how much relief or discomfort they experience from those things we do to try to help. Indeed, it has been suggested that many palliative care patients welcome the opportunity to participate in clinical research, because they recognize that they will receive stateof-the-art care and also that they will continue to provide meaning for their lives by contributing to society as they and their families deal with their life-wrenching illness.

One such study has been done by the Methylprednisolone Preterminal Cancer Study Group, which studied the effect of an 8-week course of methylprednisolone, 125 mg daily, in a double-blind, placebo-controlled trial (144). Assessment of HQL was made by use of the Nurses' Observational Scale for Inpatient Evaluation, the LASA, and the Physicians' Global Evaluation. In all scales, treatment was more effective in improving HQL but was associated with a higher mortality rate in females. The reason for the latter result was not established.

One problem in the evaluation of HQL in patients receiving cancer treatment is a high attrition rate (98). This is a particular problem in patients receiving palliative chemotherapy who may die during therapy or become too ill to be able to or wish to continue reporting on their HQL (132,145). This does not mean that HQL evaluations should not be done, but that the limitations of the population must be considered when studies are designed.

The Staunton Harold Sue Ryder Hospice used a method of assessing HQL at the time of patients' admission to their program that deliberately avoided standardized instruments. This was based on their opinion that standardized measures in the later stages of terminal illness were inappropriate because of poor patient acceptance, the “danger” of missing an aspect of suffering that was of most immediate concern to the patient, and the unreliability of observers' assessments of these patients' needs (146). They found this technique helpful in identification of previously unrecognized or underrated problems, particularly those that were psychosocial. They found that the use of the Patient Evaluated Problem Score was also helpful in evaluating progress and that it was acceptable to patients, even those who were within a week of dying. The authors recognized that this type of questionnaire cannot easily be used as a research tool, nor is it appropriate for inter-patient comparison.

Another approach to the evaluation of palliation is the “audit.” Such an approach can determine the perspective of health care providers on symptom relief, objective response, and improved activity status. This approach can be used to assess the cost-effectiveness of palliative therapy (147). Although this use of predetermined criteria for effectiveness is valuable and could be one component of the determination of effectiveness of symptom management, it is necessarily incomplete without

the patients' perspective obtained from HQL evaluations (148).

CONCLUSION

As society becomes more concerned about the cost of hightechnology care, legitimate questions can be raised about how to integrate the patient's subjectively determined quality of life into the formulation of total medical benefits and costs incurred with palliative care. The costs of care will be most problematic if the care given is seen as “futile” or “marginal” (149). Without a doubt, HQL measurements will be factored into clinical practice guidelines and policies by professional societies, insurance carriers, states, and perhaps the federal government.

It has been proposed that HQL tools will be more widely used in the future, so that oncologists will become as familiar with them as they now are with performance status and will find them equally useful (20). If standardized HQL scores are found to be reliable and clinically meaningful end points for groups of patients in clinical trials, they may become integral to the process of making individual patient treatment recommendations and decisions. The degree to which this happens will depend on the results of current clinical trials and the ease with which these results and their meanings are translated to individual patient scenarios by clinicians. Such a development is contingent on the maturation of HQL evaluations in clinical trials now under way, dissemination of the findings, and a demonstration of their discriminatory value for prognosis and for understanding the benefits and burdens of cancer therapy in cancer. If this comes about, such HQL evaluations may be able to identify problems that can be addressed immediately by the physicians or other members of the health care team. As Till et al. point out, it is not just those who are directly involved in HQL research who have legitimate priorities, nor even the health care providers, but especially patients and their advocates (81).

OUTCOMES ASSESSMENT IN PALLIATIVE CARE

JOAN M. TENO

Accountability has been called the “third revolution” in medical care (1). Health care providers are now often faced with new questions. For example, what are the outcomes of palliative care that justify its continued institutional support? Or, what is the evidence for the use of a certain medical intervention for a specific patient? Fundamental to answering these questions are defining quality of care for seriously ill patients and determining how care is measured.

Quality care at the end of life is different than during any other period of time. Dying persons, their families, and health care providers are often faced with decisions that involve tradeoffs between length of life and quality of life. Reasonable persons may differ in such decisions. Thus, preferences and values are important to shaping treatment decisions in ways unlike other time periods. Outcomes assessment for the dying must take this into consideration. In this chapter, a practical approach to examining outcomes, whether it is part of an audit prior to quality improvement efforts or for the ongoing assessment of institutional quality of care, will be discussed.

WHY EXAMINE OUTCOMES?

The first response of staff to auditing the quality of care is, “Why?” A typical response is that their work can't be measured. Yet, audits and ongoing quality monitoring through examining administrative data, reviewing medical records, and/or speaking with dying persons and families, leads to important opportunities to improve quality of care. Simply stated, “If you don't measure it, you won't improve it” (2).

The results of assessing the outcomes of palliative medicine can help create the needed attention to the issue of improving the quality of care. Such tension can create the awareness among health care providers of opportunities to improve and enhance their current practice. Examining the outcomes can be critical to detecting early problems with new medications or other unintended consequences from medical interventions. Examining outcomes can guide organizational efforts to improve the quality of care. For example, knowing that one in four persons now dies in a nursing home provides important information for the planning of new programs to meet the needs of the dying (3).

WHAT OUTCOMES TO MEASURE?

Reflecting on the thirtieth anniversary of St. Christopher's Hospice, Dame Cicely Saunders said, “We have never lost sight of the values that were so important to David: commitment to openness, openness to challenge, and the absolute priority of patients' own views on what they need” (4). Fundamental to palliative care is meeting the needs and expectations of patients and families. Quality in a 42-year-old with an acute myocardial infarction can be measured by whether interventions have been done that minimize infarct size such as the use of aspirin or percutaneous transluminal angioplasty. The vast majority of persons would want efforts to focus on restoring function under these circumstances. On the other hand, the circumstances of a 42-year-old dying of stage IV lung cancer are quite different. Technological interventions require weighting of their impact on both quality and quantity of life—decisions that require the input of an informed patient.

The importance of preferences is reflected in the Institute of Medicine definition of quality of care: the “degree to which health services for individuals and populations increased the likelihood of desired health outcomes and are consistent with professional knowledge” (5). This definition implies that conceptual models for quality care (as well as instruments measuring quality) must be based on both professional knowledge *and* informed patient preferences. To date, most conceptual models have been built either around expert opinion *or* qualitative data from patients, families, or health care providers.

Fortunately, both experts and consumers agree in many ways about what is important for end-of-life care—physical comfort, emotional support, and autonomy. However, they have significant areas of disagreement as well, e.g., unmet needs (Table 81-1). Family members want more information on what to expect and how they can help their dying loved ones. Patients and families emphasize the importance of closure at the end of life, including issues of personal relationships. Families often speak of frustration with a lack of coordination of medical care. It often isn't clear who is in charge; different health care providers provide conflicting information, and transitions can be fraught with confusion (6).

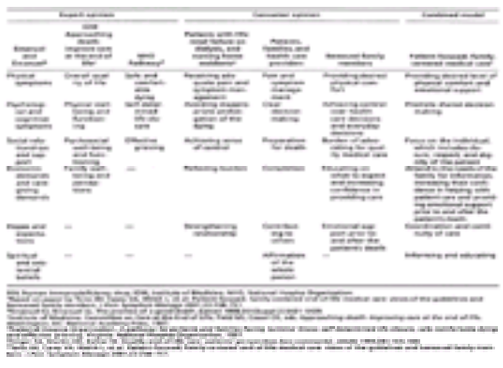

TABLE 81-1. COMPARISON OF DOMAINS OF EXPERTS, PATIENTS, FAMILY MEMBERS, HEALTH CARE PROVIDERS, AND PROPOSED COMBINED MODEL IN MEASURING QUALITY OF CARE AT END OF LIFE[a]

One conceptual model, Patient Focused, Family Centered Medical Care (Table 81-1) is based on a review of existing professional guidelines *and* results from focus groups conducted with family members (6). According to this model, institutions and care providers striving to achieve patient-focused, family-centered medical care for the seriously ill patient should

- Provide the desired level of physical comfort and emotional support
- Promote shared decision making, including advance care planning
- Focus on the individual patient by facilitating situations in which patients achieve their desired levels of control, staff members treat patients with respect and dignity, and patients are aided in achieving their desired levels of closure
- Attend to the needs of caregivers for information and skills in providing care for the patient, and provide emotional support to the family before and after the patient's death

Based on this model, a survey intended to be used as part of an initial quality audit of the quality of end-of-life care has been developed and validated.

HOW ARE OUTCOMES MEASURED?

Outcomes assessment refers to measuring the “end results”—the impact or effect of medical care on the dying person and/or family. Measuring outcomes allows you

to judge the effectiveness of medical interventions, innovative programs, and new medications. In addition to examining outcomes, process measures provide important information for quality improvement and examination of the effect of new programs. A *process measure* examines what a service or intervention does for patients and their families. For example, a process measure focuses on whether there is regular assessment of pain noted in the medical record, while an *outcome measure* examines whether patients report that they received their desired amount of pain relief. Both are important and critical to measure. Ultimately, the quality of medical care is judged by changes in outcome indicators. Yet, an organization will not achieve those outcomes if it does not implement key processes of care that are known to benefit medical care.

Key to choosing an outcome or process measure is the intended use of the quality measures. Table 81-2 notes the four potential uses of measurement tools.

TABLE 81-2. PURPOSES OF QUALITY MEASURES

The areas of emphasis and desired characteristics vary for measurement tools intended for different purposes (Table 81-3). For example, the intended audience for quality improvement measures is the institutional and quality improvement team, whereas the intended audience for public accountability is the health care purchaser and consumer.

	Purpose of measure			
	Clinical assessment	Research	Improvement	Accountability
Audience	Clinical staff	Science community	Quality improvement team and clinical staff	Payers, public
Focus of measurement	Status of patient	Knowledge	Understand care process	Comparison
Confidentiality	Very high	Very high	Very high	Purpose is to compare groups
Evidence base to justify use of the measure	Important, and the measure should have face validity from a clinical standpoint	Builds off existing evidence to generate new knowledge	Important	Extremely important in that proposed domain ought to be under control of true institution
Importance of psychometric properties	Important to the individual provider	Extremely important to that research effort	Important within that setting	Valid and responsive across multiple settings

Adapted from Solberg LI, Mosser G, McDonald S. The three faces of performance measurement: improvement, accountability, and research. *J Comm J Qual Improv* 1997;23:135–147, and reproduced from Teno JM, Byock I, Field MJ, Research agenda for developing measures to examine quality of care and quality of life of patients diagnosed with life-limiting illness. *J Pain Symptom Manage* 1998;15:75–82.

TABLE 81-3. AREAS OF EMPHASIS BASED ON THE PURPOSE OF QUALITY MEASURE

Measurement tools used for public accountability need further evidence that justifies their use. For example, given the intended audiences and implications of the use of measurement tools for public accountability, more stringent psychometric properties must be used for these measures. In addition, there must be either normative or empirical research that substantiates a claim that the construct being measured for public accountability is under the control of that health care institution.

Typically, measurement tools can review the medical record, examine administrative data (such as death certificate or billing data), or conduct interviews with a patient or a proxy such as a family member. Each potential source of data has strengths and limitations that should be considered when selecting a measurement tool or strategy.

Medical records are legal documents that should reflect the medical care that patients receive. Yet, medical records reflect staff perceptions, and their contents are subject to reporting bias. For example, a nurse may document that a patient understands how to take his/her medications on hospital discharge; this documentation reflects the nurse's perception. Yet, patients and families often report that they did *not* understand that explanation when interviewed after hospital discharge (8). Furthermore, not all discussions are documented in the medical record. Discussions about resuscitation preferences are usually only documented when the patient or family consents to a “do not resuscitate” order. Thus, a physician and patient may have talked about resuscitation preferences and decided *not* to forgo cardiopulmonary resuscitation, but there is nothing documented in the medical record because cardiopulmonary resuscitation is the default in the majority of U.S. hospitals.

Administrative data, such as death certificate data, billing data, or the Minimum Data Set, is readily assessable information that can provide invaluable information. Examining death certificate data that is published on the internet (see www.cdc.gov) and available in public use files can provide hospice and palliative programs with information about their “market share,” i.e., what proportion of persons for whom they provide medical care in a certain geographic area. This information can highlight areas that are underserved and opportunities for program expansion. Users of administrative data need to be aware that it can be inaccurate because of coding problems, key punch errors, or economic incentives to upgrade a patient's condition to get more reimbursement.

The Minimum Data Set is used in U.S. nursing homes to systematically collect information on more than 300 items on a quarterly basis. This instrument can provide institution-specific and national estimates of outcomes, such as pain management (9). Yet, these data reflect staff perceptions of patients' levels of pain. Thus, ascertainment bias is an important concern in the use of these data.

Surveys, either self- or telephone-administered, provide information directly from the patient and family perspective about the quality of care. Typically, satisfaction measures which ask a person to rate the quality of care with response categories that vary from “poor” to “excellent” have not yielded discriminating information about the quality of care. The respondents' task with these rating questions includes several steps: First, determine whether that event occurred; second, formulate their expectations regarding that aspect of care; and third, choose a category from the response categories. Often, persons have lowered expectations regarding their medical care, which, at least in part, explains the finding of high satisfaction in the face of indicators of poor quality of care, e.g., severe pain (10,11).

Newer methods have begun using either “patient-centered reports” or “preference-based questions” (i.e., unmet needs) to capture the consumer perspective (Fig. 81-1) (12). These methodologies, unlike typical satisfaction questions that rely on ratings questions, provide information that guide improvement of the quality of care. For example, knowing that 85% of patients believe a health care provider is “very good” does not tell that provider in what ways and specific processes of care that he/she can improve. On the other hand, knowing that 20% of patients did not understand a provider's directions for taking pain medications does provide a tangible target for improving and enhancing the quality of care. Moreover, patient-centered reports and preference-based questions have strong face validity with health care providers. In the future, surveys need to rely on all three methodologies—ratings, patient-centered reports, and preference-based questions—to capture the consumer perspective on the quality of care at the end of life.

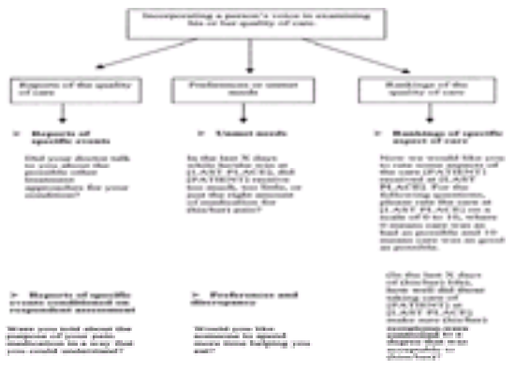

FIGURE 81-1. Proposed classification scheme for measuring a patient and family voice about the quality of medical care. [Adapted from Teno JM. Putting patient and family voice back into measuring quality of care for the dying. *Hosp J* 1999;14(3–4):167–176. Review, with permission.].

WHICH TOOL SHOULD BE USED?

Selecting a measurement tool should be guided by its intended use and the characteristics of the particular tool. The goals of measurement should be clear. As noted in Table 81-3, different psychometric properties (i.e., reliability, validity, and responsiveness of the tool) are needed for different intended uses. In addition, the intended audience is different for each of the four key purposes of measurement listed in Table 81-3. Measurement tools used for accountability, for example, have an intended audience of health insurers, the government, and other such institutions that pay for health care services. The focus of measurement is to compare health care institutions or plans. Given this purpose, it is very important that there is evidence that what is being measured is under the control of that health care institution and that the chosen instrument is reliable, valid, and responsive across the settings.

Reliability is necessary but not sufficient evidence of validity of an instrument or measurement tool. Reliability examines the degree to which the measurement tool is capable of reproducing the same results over time. Thus, a person should give the same response to a question if asked within a short period of time.

A measurement tool is valid if there is evidence that it measures what it purports to measure. In essence, one is asking whether the measurement tool is reporting the truth. Often, the intent of the measurement tool is to identify a perception or attitude of the respondent. In this case, there is not a “gold standard” by which to judge whether the measurement tool is accurately representing the construct that is being measured.

Content validity asks whether the measurement tool examines the correct concepts at face value. Were experts involved as advisors in the creation of the tool? Was the selection of concepts based on a theoretical model? *Construct validity* examines the degree to which the results from that measurement tool are associated with preestablished and known relationships. For example, a measure of overall satisfaction should be associated with consumer choice of health care plans.

Responsiveness examines the degree to which a measurement tool changes as a result of interventions or historical events. Often, responsiveness is not reported in the initial validation of a measurement tool. Rather, responsiveness is reported at a later date after the measurement tool has been utilized in intervention studies or research that tracks quality over time.

Over the past several decades, an increasing number of measurement tools have been developed for examining the quality of end-of-life care. A Web site maintained by the Center for Gerontology and Health Care Research at Brown University offers a structured literature review of existing instruments that focus on examining palliative care outcomes (see www.chcr.brown.edu/pcoc/toolkit.htm). This Web site is a good starting point for selecting measurement tools for quality improvement and research purposes. The site provides published instruments in ten domains and selects promising instruments for in-depth review, including psychometric properties and response burden.

For a seriously ill and dying population, the time burden on respondents and staff is an important consideration for selecting an instrument. Limiting the scope of domains covered and the number of individual cases for which data is collected can reduce time burden. For an interview respondent— especially a seriously ill patient—it is particularly important to limit the scope of domains that are covered in the interview. For the purpose of quality improvement, you do not need to collect a large number of cases. A small number of cases collected by a random sample can provide invaluable information to guide a quality improvement effort.

HOW IS THE SAMPLE SELECTED?

A fundamental, yet often perplexing, step is deciding who is to be included in the sample. This relates to the “denominator” for the outcome being measured. Simply stated, a rate is composed of a numerator and a denominator. Determining who is in the denominator can be difficult in palliative medicine. For example, three decades ago, most persons would have considered patients with childhood leukemia to be among those patients with a terminal illness. However, this no longer is the case due to the tremendous strides made in treating childhood cancers. Researchers and quality improvement teams, then, must make decisions about which patients to include in the overall group of interest (i.e., the denominator).

The difficulty of accurate prognostication is an additional issue. Physicians are often overly optimistic in their prognoses, resulting in uncertainty about patients' actual time before death. Even the best statistical models are inaccurate because they are applying historical information from a previous cohort of similar patients to predict the future. There is certain error in those estimates. Moreover, new treatments can invalidate even the best estimates by prediction models.

Although the timing of the interview is not as critical for certain domains, such as pain assessment, other domains are very sensitive to the time from death at which the interview takes place. For example, the timing of a discussion about stopping active treatment depends on the patient's prognosis and condition. The difficulty with prognostication also impacts the ability to compare different health care units or institutions. It is possible that institutions will interview persons at different time periods prior to death. This situation may result in differences in observed quality measures that reflect timing of the interview more than differences in the quality of care provided.

Given these prognostication issues, an institution may do frequent interviews to capture the same time period from death across patients or relies on retrospective interviews with bereaved family members to collect information on a certain time period. Doing a prospective patient data collection has important advantages. First and foremost, the results could improve the quality of care of that individual patient. Second, the information originates from the patient and not a surrogate. Yet, retrospective interviews with bereaved family members remain an important tool to examine the quality of end-of-life care.

If information is desired about the last week of life, often a family member is the only person that is able to provide a consumer perspective on the quality of end-of-life care delivered to the deceased and his/her family. The advantage of this “mortality follow-back” approach is that the denominator can be precisely defined, given that demographic information (including next of kin) is reported on death certificates to state-level departments of vital registries. Thus, data collection can occur quickly without the costs of case finding for the prospective sample of patients. Because of this, mortality follow-back surveys have been used by both the United Kingdom (13,14) and the United States to collect (15) information on the last year of life of decedents.

WHAT ARE THE NEXT STEPS?

The first step in improving the quality of end-of-life care is taking stock—identifying and understanding the opportunities to improve. Simply stated, if you don't measure it, you won't improve it (2). Measuring or conducting an audit is the first step (Fig. 81-2). The second step is to engage stakeholders and define the goal. Engaging stakeholders means to present the results of the audit in a way that does not assign blame, but rather looks for the shared opportunities to improve and enhance the quality of care. Key to the success of this second step is raising awareness and developing a shared goal.

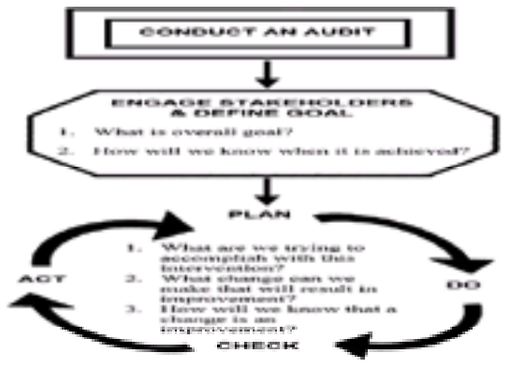

FIGURE 81-2. Quality improvement model.

The third step is actually improving the quality of end-of-life care through interventions and measuring whether these interventions succeed in creating change. Often, persons believe that education which provides knowledge and impacts attitudes will achieve change. Many times, though, knowledge is not sufficient to change behavior. Instead, changes must be made in the processes of care that provide the cues and default pathways that ensure persons will choose the right behavior. Often, this change can be achieved through a model of rapid improvement that utilizes multiple Plan, Do, Check, and Act cycles (PDCA) (16). PDCA cycles allow testing of interventions first on a small scale (sometimes as small as only one nurse with one patient). From the information learned, the intervention can be refined or a

different one can be tested.

Three key questions help to frame the work of the PDCA cycle. First, what is one trying to accomplish with this intervention? Just as an overall goal was identified in Step 2 of the quality improvement model, a goal must be stated for each PDCA cycle. Second, what change can one make that will result in improvement? This may involve brainstorming with a team of colleagues about what interventions can achieve the goal of the cycle. An effort should be made to be creative, yet don't be afraid to copy the success of others. Third, how will one know that change is an improvement? It is important to choose either a process or outcome variable that examines whether the goal of that cycle is being met and that data are tracked for the goal of that cycle, as well as the overall goal for the improvement effort. Often, a quality improvement team must test multiple interventions and conduct multiple PDCA cycles to achieve the overall goal.

CONCLUSIONS

Outcomes assessment is key to improving quality of end-of-life care. At this early stage of development of supportive and palliative care, we urgently need both research and quality improvement efforts that will contribute to the scientific evidence base. Care at the end of life is quite different than care at other time periods. Patients' informed preferences play an even more central role in decision making and outcomes. Not all persons with stage IV lung cancer, for example, will want experimental chemotherapy, and quality indicators must take into account that reasonable persons have different treatment preferences. Hence, measuring the quality of end-of-life care often requires interviews to examine the consumer perspective.

Even at this early stage, there are several promising measurement tools for quality improvement audits, for research, and for accountability. Selection of these measurement tools must be guided by the intended use of the data. The use of measurement tools for accountability carries two key requirements: an evidence base that suggests that the domain of interest is under the control of health care providers, and demonstration of satisfactory psychometric properties of the tool across settings of care.

With an increased focus on accountability, health care providers will need to become familiar with methods to improve the quality of medical care. Measurement plays an important role in quality improvement efforts—from the initial audit that raises awareness of an opportunity to improve, to ongoing assessments of whether interventions are achieving their goals. The ideal quality monitoring system for palliative care should strongly link guidelines and proposed quality indicators. Guidelines should be based on both normative and empirical research. Quality indicators can measure information about the structure of a health care institution (e.g., availability of certain services, existence of policies), about processes of care (i.e., the interactions of health care providers, patients, and family members), and about outcomes of care (i.e., the effectiveness of treatment).

Currently, most quality indicators measure either structure or processes of care. Outcome measures are intuitively more attractive, but they are more difficult to apply because of our limited ability to adjust for differences in patient characteristics and the relatively small numbers of people with a particular condition treated at institutions each year. One argument in favor of collecting process data is that they are a more sensitive measure of quality because adverse outcomes do not occur every time there is an error in the provision of medical care. Furthermore, important outcomes—both positive and negative—often appear months or even years after care has been given. Quality indicators based on measures of structure or process, however, are only as good as their ability to predict outcomes of importance.

RESEARCH ETHICS

DAVID J. CASARETT

The goal of good palliative care is to relieve suffering and to improve quality of life. However, it is apparent that access to palliative care is inconsistent, and standards to guide palliative care have not been established clearly. At least in part, these deficiencies exist because of a lack of solid evidence on which to base clinical decisions (1,2). Therefore, there is an urgent need for research that can provide evidence to define the standard of care and to increase access to quality care.

Recent years have seen a dramatic increase in palliative care research, defined broadly as activities that are designed to contribute to generalizable knowledge (3) about end-of-life care. This growth has created a heterogeneous field that encompasses both qualitative and quantitative techniques, and descriptive as well as interventional study designs (4). Although the past 10 years have seen impressive growth in all of these areas, this rate of growth appears to be particularly rapid for interventional research, including controlled trials of pain medications (5,6), interventional procedures for pain (7), and other nonpharmacological interventions to improve a variety of aspects of end-of-life care (8,9,10,11 and 12).

Despite the valuable knowledge that has been produced by this research and the promise of future important advances, its progress has been clouded by a persistent uncertainty about the ethics of these studies. Indeed, there have been concerns raised from several quarters about whether patients near the end of life should ever be asked to participate in any form of research (13,14). Others have objected to this extreme position (2,15). Nevertheless, many providers, Institutional Review Boards (IRBs), ethics committees, study sections, and even investigators remain uncertain about the ethical limits of research involving dying patients.

These concerns have considerable intuitive appeal and must be taken seriously. Indeed, it would be unfortunate if the progress of palliative care research were slowed by the sorts of ethical scandals that have threatened other fields of research that involve vulnerable populations such as those with mental illness (16). However, strict oversight and tight limits on palliative care research have the potential to do equal damage to a growing field. Therefore, to avoid potential scandals, without excessive regulation and oversight, it will be important that palliative care investigators and clinicians consider these concerns in a fair and balanced way.

This chapter discusses six ethical aspects of palliative care research that investigators and clinicians should consider in designing and conducting palliative care research. These include: (a) whether a study is research or quality improvement (QI); (b) the study's potential benefits to future patients; (c) the study's potential benefits to subjects; (d) the study's risks to subjects; (e) subjects' decision-making capacity; and (f) the voluntariness of subjects' choices to participate in research. Each of these is discussed, as well as opportunities to enhance the ethics of palliative care research in each of these ways.

DEFINING RESEARCH

The first, and arguably the most important, question that palliative care investigators face in designing an ethical study is whether it is research or QI. This decision is extremely important and has profound implications for the study's design and the ethical standards to which it will be held. For instance, federal law requires research projects to be reviewed by local IRBs to assure that informed consent is obtained from each subject, that research risks are reasonable in relation to expected benefits, and that subjects are recruited in an equitable fashion (3). In comparison, there are few widely accepted standards that govern QI.

In many situations, it is clear that a planned study is research. For instance, there is likely to be general agreement that randomized clinical trials comparing one or more pain medications or population-based studies of symptom prevalence, are research and should be held to the ethical standards for research. However, QI activities often share many of the attributes of research. For instance, both QI and research involve systematic data collection methods such as surveys and chart reviews. Both apply statistical methods to test hypotheses, establish relationships between variables, and evaluate outcomes. Both QI and research are designed to produce knowledge that could benefit patients other than those directly involved in the activity. In practical terms, therefore, QI and research activities are often difficult to distinguish. This can produce confusion and conflicting opinions from IRBs that review study protocols (17).

Unfortunately, the federal regulations that make the distinction between research and QI so important offer little practical assistance in distinguishing between the two types of activities. In those regulations, research is defined as “a systematic investigation, including research development, testing and evaluation, designed to develop or contribute to generalizable knowledge” (3). Although elegant in its simplicity, this definition may prove prohibitively difficult for palliative care investigators to apply. It is often not clear how systematic an activity needs to be in order to be considered research. Nor is it clear how generalizability should be defined, or how an investigator's intent should be measured.

In an effort to make the distinction between QI and research more clear, additional criteria have been proposed. These include the degree to which a study deviates from standard care, whether an activity requires identifiable recruitment practices, how individuals are selected to receive a particular intervention, the degree of uncertainty associated with the intervention, and whether the patients involved benefit from the knowledge to be gained (18,19 and 20). One of the most recent of these criteria (20) describes a two-step algorithm that investigators may find useful when the existing criterion of an intent to produce generalizable knowledge (3) fails to provide adequate guidance. This algorithm is based on the additional risks or burdens that are imposed by a study and on whether the patients involved in the study will benefit from the knowledge to be gained (Fig. 82-1). Briefly, this algorithm suggests that studies should be considered as research, rather than as QI, if they expose patients to risks in order to generate knowledge that will not benefit them.

FIGURE 82-1. An algorithm that examines when quality improvement is also research.

This algorithm may prove to be too restrictive, as some have argued (21). In any event, it should not take precedence over existing federal regulations (3). It is, at most, a guide that palliative care investigators may wish to turn to. When the status of a project is unclear, investigators should also seek guidance from their own IRB.

BENEFITS TO FUTURE PATIENTS: A STUDY'S VALIDITY AND VALUE

Palliative care research is designed to produce knowledge that will advance understanding of end-of-life care. Implicit in this goal is the expectation that this knowledge will eventually improve care for future patients. Therefore, the first ethical aspect of palliative care research that deserves consideration is its potential benefits for future patients. These benefits to others can be described in terms of validity and value.

Validity

First, all studies must be valid. That is, they must use techniques of design and data analysis that peer reviewers can agree are appropriate. In addition, all studies must be designed to produce knowledge that is generalizable. Indeed, generalizability is the cornerstone of the Common Rule's definition of research: “a systematic investigation, including research development, testing and evaluation, designed to develop or contribute to generalizable knowledge” (3). These requirements collectively describe a study's validity (22). Validity is a threshold requirement for all research because it is unethical to expose human subjects to risks in studies that peer reviewers agree cannot adequately answer a research question (23). Therefore, at a minimum, investigators routinely consider a study's validity.

Value

Above this threshold of validity, palliative care studies may offer more or less importance or “value.” Broadly, value can be defined as the likelihood that a study's results will improve the health and well-being of future patients (24,25). Like validity, value is an important measure of a study design's scientific quality, but it is also a measure of its ethical quality. Value is an essential aspect of a study's ethical design because a central goal of research is to produce knowledge that will ultimately be “important” (3,26), “fruitful” (27), or “valuable” (28). In fact, one reason that subjects participate in clinical research is to produce knowledge that will benefit others (29,30). Because subjects are willing to accept risks and burdens of research, at least in part, in order to benefit others, investigators have accepted an ethical responsibility to maximize the probability that a study will be able to do so. Therefore, in addition to widely accepted scientific arguments for valuable research, there are compelling ethical arguments as well.

Maximizing Validity and Value in Palliative Care Research

Space does not permit a comprehensive overview of ways in which a palliative care study's validity and value can be assessed and improved. Indeed, such a discussion moves quickly beyond ethics and into the technical language of study design and health measurement. Nevertheless, several broad recommendations are possible.

First, a study's sample size should be adequate to answer the research question that is posed. Problems of underpowered studies, and particularly clinical trials, are both widespread and well described (31). But issues of power and sample size are particularly relevant to pain and symptom research, in which random variation can be quite large (32). To minimize these problems, it may be useful to establish consortia or collaborative groups that can participate in multicenter studies. Such arrangements have been highly effective in promoting research on rare disorders and may be applicable as well to palliative care research, in which investigators are limited and available patients are often sparse.

Second, palliative care investigators can enhance the ethical quality of a study by taking reasonable steps to increase the generalizability of its results. These steps might include sample size calculations that permit subgroup analysis of groups of patients that have typically not been the focus of investigation such as patients with noncancer diagnoses or elderly patients. The generalizability of a study's results might also be enhanced by recruiting subjects outside academic medical settings because preliminary evidence suggests that these patients, and their needs for care, may be different than those who receive care in academic settings (33).

In addition, palliative care investigators can enhance the generalizability, and therefore the value, of their research by making reasonable efforts to include patients who are receiving care at home and, particularly, those who are enrolled in a home hospice program. Substantial barriers may make it difficult to include these patients in research. Nevertheless, few data exist to guide the management of home care patients near the end of life, and palliative care investigators can enhance the value of their research by including this population whenever possible (34).

Of course, all of these improvements in generalizability come at a substantial cost. For instance, studies that recruit subjects from several different settings require more elaborate designs for recruitment and follow-up. In addition, investigators who include plans for subgroup analysis in their sample size calculations face rapidly escalating sample size requirements and costs. Nevertheless, steps like these offer an important way to enhance a palliative care study's value and, therefore, its ethical quality. Therefore, it will also be important that funding agencies understand the ethical importance of generalizability and that generalizability comes with a financial cost.

BENEFITS TO SUBJECTS

Palliative care investigators can also enhance the ethical rigor of a study by maximizing the benefits that it will offer to subjects. Broadly, these benefits can be considered under two categories: benefits to subjects during the study and benefits from the data that are collected. Each of these is discussed below.

Benefits to Subjects during the Study

Investigators may have several opportunities to maximize potential benefits of research to the subjects who participate. Perhaps the first, at least in an interventional study, is in their choice of an intervention. Ideally, a new intervention to be studied should have a reasonable chance of success. More important, though, if it is to offer subjects a significant potential benefit, an intervention should offer the possibility of a meaningful improvement over other interventions that are available to subjects outside the study. For instance, a pain management algorithm that is expected to reduce cancer pain (35) would only offer potential benefits if it is qualitatively or quantitatively different than those that constitute the usual standard of care. On the other hand, a comparison of two medications that are commercially available, such as topical fentanyl and sustained-release morphine, would not offer subjects any potential benefit. This is true even if the study's results offer considerable clinical value (36).

The potential benefits of a study can also be enhanced by choosing an active control design, rather than a placebo (36,37). If a placebo is used, a study's potential benefits can also be improved by altering the standard 1:1 randomization scheme in a placebo-controlled trial in a way that increases subjects' chances of receiving an active agent (6). The potential benefits of a placebo-controlled trial can also be enhanced by using a crossover design, so that all subjects are offered potential benefits, if the medication's pharmacokinetic profile makes it possible to avoid carryover effects.

These suggestions should be tempered by two caveats. First, the potential benefits of research are never certain. If they were, a randomized trial would not be ethically acceptable. That is, a legitimate argument for the uncertainty that justifies a clinical trial, or equipoise, could not be made (38). However, investigators generally design studies of interventions for which there is at least some evidence of effectiveness. Therefore, even though these potential benefits are not certain, they are more or less likely, and this assessment of likelihood should be considered in the design of pain research.

Second, palliative care studies need not always offer potential benefits. Indeed, many, and perhaps most, will not. Nevertheless, when a study does offer potential benefits, investigators may consider enhancing a study's potential benefits in these ways. The importance of doing so is particularly great if other aspects of a study raise ethical concerns, which might be the case if subjects' decision-making capacity is limited, or if the study's risks are substantial.

Benefits from Data Collected during a Study

Although the opportunities to enhance potential benefits described above apply largely to studies involving interventions, another opportunity applies equally well, if not better, to research that is descriptive. A common ethical issue in the design of palliative care research and, particularly, descriptive research, is the possibility that data

gathered may contribute to a subject's care. For instance, data gathered during a descriptive study may identify pain that is inadequately treated (39,40,41 and 42), dissatisfaction with pain management (43,44,45,46 and 47), or related clinical problems like depression (48,49).

In anticipation of instances like these, investigators can design standard operating procedures that help to ensure that valuable clinical information is made available to the subject and his or her clinicians. At the least, these procedures should include data about the presence of unrecognized and untreated symptoms, and concurrent disorders like depression. This is arguably an ethical obligation of symptom-oriented research (15). Moreover, these procedures offer a significant opportunity for investigators to enhance the potential benefits of pain research.

Benefits to Subjects after a Study Has Ended

Investigators can also enhance the potential benefits for subjects after a study has ended. These sorts of post-study benefits are not usually included in assessments of a study's balance of risks and benefits. They are also components of a study's value because these benefits generally come from the knowledge that the study produced. Nevertheless, subjects may benefit from the knowledge to be gained from a study if the study's results are applied to their care. Investigators have numerous opportunities to ensure that these results are translated into subjects' care and, by doing so, can enhance the study's potential benefits to subjects.

For instance, subjects in palliative care research can benefit after a study if they learn from the study's aggregate results. This might be the case if a study comparing two pain medications found that one resulted in fewer side effects overall (36). Subjects in the study would benefit from these data because this knowledge should allow them to make a more informed choice among available medications. Subjects might also benefit from results that are specific to them. For instance, if a subject receives two medications in a blinded, crossover trial, and prefers one to the other, he or she would be better able to choose between these medications in future clinical situations, armed with the results of a blinded comparison of the two (50,51 and 52).

Finally, investigators can increase the likelihood that subjects have continued access to medications that are studied. If medications are not available, either due to high cost or because the medication has not yet received regulatory approval, subjects will not benefit (immediately) from the study's results. Thus, by arranging reduced rate programs or open label extension phases, investigators can increase a study's potential benefits for subjects by helping to ensure that subjects will benefit from the study's results.

This benefit may be particularly important in palliative care research because mortality rates in some studies are very high. This means that subjects may not live long enough to see a study medication's approval for clinical use or to see a study's results published and translated into improved care. For this reason, it is especially important that investigators consider mechanisms by which results can be applied to the care of research subjects in a timely fashion.

MINIMIZING RISKS AND BURDENS

Investigators can also enhance a study's ethical soundness by taking steps to minimize a study's risks and burdens. Although the distinction between risks and burdens is not always clear, a rough heuristic is useful. In general, a risk can be considered as the probability of an adverse medical event or undesirable outcome. Risks might include side effects of a medication, or increased pain during a study. The term “burden” can be used to describe those unpleasant features of participation in a study that are more certain, and which are better thought of as inconveniences. Additional clinic visits, time spent filling out questionnaires, or time spent waiting in clinic might be described as burdens.

Identifying Risks and Burdens

Attention to the ethical design of pain research and to the minimization of research risks and burdens requires a clear agreement about how they should be defined. The criteria by which study risks and burdens are identified and evaluated use the concept of incremental or “demarcated” risks imposed by participation in a study (53). The application of this standard to interventional pain research would mean that investigators designing a trial to compare the effectiveness of two opioids (36) need not go to great lengths to justify the risks of the opioids being evaluated if subjects in the trial would have received similar medications, with similar risks, off protocol. Of course, the risks of any medication in a clinical trial should be disclosed in the informed consent process (3). Nevertheless, investigators are not under the obligation to minimize or justify these risks as they would be if, for instance, the same medications were being given to patients with mild pain who would not receive them as part of standard care.

Minimizing Risks: The Choice of Control

Perhaps one of the most contentious and emotional questions in palliative care research (54,55), and, indeed, in research generally (56,57 and 58), is whether a placebo or sham control arm is ethically appropriate. The ongoing debates about the scientific merit of these controls, and the competing advantages of active control superiority trials and equivalency trials, are beyond the scope of this discussion. However, several general points can be made about the ethics of placebo- and sham-controlled trials. Each of these designs is discussed below.

Broadly, placebos can be defined as interventions that are “ineffective or not specifically effective” for the symptom or disorder in question (59) Increased attention to the ethical issue of placebo controls in recent years has produced a growing consensus that all subjects in a clinical trial should have access to the best available standard of care (60). Thus, in infectious disease research, for instance, all subjects with meningitis would have access to an antimicrobial agent that has proven effective. However, this requirement may be difficult to apply to studies of treatment for pain, other symptoms, or depression, in which the placebo response can be quite substantial. These difficulties are compounded when the symptom being studied is transient such as incident pain (6).

For these reasons, it may not be practical to prohibit placebos in palliative care research, and a placebo control may be ethically acceptable in several situations. First, placebos are acceptable if subjects receive a placebo in addition to the standard of care. For example, subjects might be randomly assigned to receive an opioid for pain or an opioid plus an adjuvant agent. Second, a placebo arm is justified if the symptom under study has no effective treatment. For example, the transient nature of incident pain often defies adequate treatment on an as-needed basis, and a placebo control might be justified in a randomized controlled trial of a novel agent for the treatment of incident pain. Third, a placebo control is justified if subjects have adequate access to breakthrough, or “rescue,” treatment. This may, in turn, alter a trial's end points. For instance, the free use of breakthrough dosing in a trial suggests the possible inclusion of these doses as a study end point either directly (61,62) or as part of a composite end point (5,63).

Concrete recommendations about sham procedures are somewhat more elusive, in part because sham procedures themselves are difficult to define. In general, though, sham procedures in palliative care research involve the use of a control procedure, such as a nerve block, which is administered in a way that makes it ineffective (7). These procedures create ethical concerns because some subjects, or all subjects, depending on the study's design, are exposed to the risks of the procedure without hope of its benefits (56). Like placebo controls, though, shams also have a role in research, because the nonspecific, therapeutic effects of surgery may be substantial. For instance, Leonard Cobb's research in the 1950s effectively debunked a widely used cardiac procedure that, if it had been widely disseminated, would eventually have put thousands of patients at risk.

Investigators have an opportunity to reduce these concerns substantially in the design of a sham-controlled study. For instance, investigators might conduct these studies in a setting in which the procedure itself (whether sham or real) poses few, if any, additional, or “incremental,” risks above and beyond usual care. Investigators might insert a sham epidural catheter that would then be used for postoperative analgesia (64). When this is not possible, investigators can choose a crossover design, in which subjects are assigned to receive either the sham or the real procedure, followed by the other. This design does not decrease the incremental risks of the sham procedure. However, it does ensure that all subjects who bear the risks of the sham procedure also have access to the real procedure's potential benefits. This crossover sham design has been used in other settings (65) and might be appropriate for pain research when the risks or discomforts of the sham procedure are substantial.

Minimizing Burdens

For the most part, opportunities to minimize burdens are readily apparent. For instance, it seems reasonable, wherever possible, to minimize surveys, interviews, and additional study visits (66). These are all burdens that investigators routinely consider carefully in designing studies. However, there may be other needs and concerns that may be unique to, or more common in, patients near the end of life.

Although it is intuitively obvious that all research subjects would like to avoid the added time commitment and inconvenience of travel to and from additional appointments, this concern may be especially important to patients near the end of life, for whom long periods of time spent sitting in a car can exacerbate discomfort. Similarly, patients may view surveys and questionnaires not only as timeconsuming but also as a drain on their energy. Therefore, investigators who conduct palliative care research may have an added reason to minimize the burdens of extra visits and data collection procedures and to rely on telephone data collection strategies whenever possible.

Palliative care investigators may also need to consider the burdens that a study creates for friends and family members who often take on substantial burdens as caregivers (67,68 and 69). Although most of the burdens of research participation are borne by the subject, the requirements of time, travel, and, perhaps, time off from work, create burdens for others. Patients may be very sensitive to these burdens and, for some patients with chronic pain, burdens to others can be influential in the decision whether or not to enroll in a study (30). By building flexibility into a study design (e.g., use of brief telephone interviews, multiple options for timing of clinic visits), investigators may be able to reduce the burdens of research participation on others.

ENSURING DECISION-MAKING CAPACITY

Patients who consent to participate in research should have adequate decision-making capacity, which refers to subjects' ability to understand relevant information, to appreciate the significance of that information, and to reason through to a conclusion that makes sense for them (70). These concerns parallel concerns in research involving patients with dementia (71), psychiatric illness (72,73), and patients in the intensive care setting (74), among others. However, deficits in decision-making capacity may create several additional challenges for palliative care investigators.

First, concern about capacity is reasonable given the prevalence of cognitive impairment at the end of life (75,76,77 and 78). Cognitive impairment occurs in 10–40% of patients in the final months and in up to 85% of patients in the last days of life (76,77). Cognitive impairment may be difficult to identify in palliative care research because decisionmaking capacity varies over time (79) and because impairment may result from the experimental or therapeutic medications themselves, such as opioids, benzodiazepines, or corticosteroids (80,81). Investigators who conduct trials of medications will encounter these challenges even more frequently if trials are designed to evaluate treatments for delirium, for which impairment is an inclusion criterion (82,83).

Second, the effects of cognitive impairment on comprehension may be complicated by clinical depression, which occurs in between 5% and 25% of patients near the end of life (48,49,84,85 and 86). Clinically, significant adjustment disorders may be even more common (48). It is possible that these disorders may impair either comprehension or decisionmaking, or both (72), but studies have not yet supported this conclusion.

Third, even in the absence of overt cognitive impairment or depression, it is possible that severe symptoms or affective disorders may impair subjects' ability to understand the risks and benefits of research participation. For some studies, particularly clinical trials, the presence of one or more of these intractable symptoms is an inclusion criterion (87,88 and 89). It is possible that severe symptoms may impair comprehension if patients are unable to concentrate on the information offered in the informed consent process (90).

Finally, these challenges may be compounded in prospective studies that require participation over days or weeks. In these studies, even if patients have the capacity to consent at the time of enrollment, they may not retain that capacity throughout the study. Thus, days or weeks after patients give consent to participate, they may be unable to understand changes in their condition clearly enough to withdraw. The result can be a “Ulysses contract,” of sorts, in which research subjects find it easier to enroll than they do to withdraw (91).

None of these challenges is easily remedied. Indeed, it is obstacles like these that lead some authors to argue that patients near the end of life should not be allowed to enroll in research (13,14). Nevertheless, palliative care investigators have several concrete opportunities to enhance the ethical quality of palliative care research when decisionmaking capacity is uncertain.

First, at a minimum, investigators whose research involves patients near the end of life, who are likely to lack decision-making capacity, might institute brief assessments of understanding. Although this strategy cannot assess decision-making capacity, a few simple questions in either open-ended or multiple choice format provide a brief assessment of understanding (92,93 and 94). In some situations, investigators may wish to assess decision-making capacity more formally using validated instruments (95).

These sorts of safeguards need not be employed in all studies. Instead, their use should be guided by the prevalence of cognitive impairment in a study population and by the balance of risks and benefits that a study offers (34). For instance, when palliative care research involves only interviews or behavioral interventions that pose minimal risks, informal capacity assessments are generally sufficient. “Minimal risks” are defined as those risks that are encountered during a patient's usual care, or in everyday life (3). When research poses greater than minimal risks, but offers potential benefits, some assessment of understanding may be appropriate. This research includes studies that involve a placebo (6) or invasive interventions such as nerve blocks (96) or epidural catheters (97). When a study that poses greater than minimal risks does not offer potential benefits or is conducted in a population in which the prevalence of cognitive impairment is high (e.g., an inpatient hospice unit), a formal evaluation of capacity should be considered. This research includes studies that involve a placebo when an effective agent is available (5) and some pharmacokinetic/pharmacodynamic studies that require repeated blood samples and prolonged observation, without potential benefits (98).

If a patient does not have the capacity to give consent, a legally authorized representative may be able to give consent for research. This follows from federal guidelines governing research involving children (3) and is justified by the argument that surrogate decision makers should be allowed to consent to research just as they are allowed to consent to medical therapy. However, as with other research that involves patients without capacity to consent, investigators should be aware of applicable state laws that may restrict or even prohibit surrogate consent for research. In addition, investigators in this field should be alert to possible future changes in federal regulations that have been discussed (99).

If a patient does not have the capacity to consent but is still able to participate in decisions, investigators should obtain assent from the patient and informed consent from the patient's surrogate (100,101). This “dual consent” ensures that patients are as involved in the decision as possible yet provides the additional protection of a surrogate's consent.

If a patient has decision-making capacity intermittently, or is expected to lose capacity, investigators may obtain advance consent. This approach has been used in a study of treatment for delirium in which informed consent was obtained from patients while they had decision-making capacity (82). Advance consent should be obtained only for specific studies and should be obtained close to the planned start of research, for instance, at the time of hospitalization or enrollment in a hospice or palliative care program.

PROTECTING VOLUNTARINESS

Another way that investigators can enhance the ethical soundness of a study's design is to examine ways in which subjects' voluntary participation can be protected. In general terms, a choice is voluntary if it is made without significant controlling influences (102,103). At first glance, assurances of voluntariness appear to be an issue of informed consent, and, in fact, for the most part they are. However, a study's design and plan for subject selection and recruitment may have as great an influence on subjects' freedom to refuse research participation as does the informed consent process. In particular, two features of a study's design are relevant. First, a prospective subject's choice must be made with full knowledge of available alternatives (3). Second, his or her choice must be made with the understanding that he or she can withdraw at any time (3). Each of these creates opportunities in a study's design to ensure voluntariness, which are discussed below.

Reasonable Alternatives to Participation

First, investigators can make sure that a study recruits subjects from an environment with excellent standards of palliative care. If patients generally receive excellent care, they will be best able to make a free and uncoerced choice about research participation. If, however, patients do not have access to a bare minimum of treatment options and expertise, they may view research participation more favorably, out of desperation.

One solution, albeit a somewhat draconian one, would be to require that palliative care research be conducted only in settings in which patients have access to a full range of services, treatment, and expertise. Although this requirement would reduce the potential for research participation out of desperation, it would effectively limit research to a small number of academic centers, with a possible loss of generalizability (33). Another more practical option might be to include a lead-in phase when clinical pain research is conducted in settings where the standard of care is poor (15). A lead-in phase allows an opportunity to optimize palliative care prior to recruitment. This strategy not only has ethical value but scientific value as well because it provides a uniform baseline prior to randomization.

Opportunities to Withdraw

Investigators can also enhance the ethics of a study's design by ensuring that subjects are able to withdraw at any time. Although a subject's ability to withdraw should be a fundamental aspect of any ethical research (3), there may be unique barriers to withdrawal from palliative care research. For instance, subjects who withdraw from clinical pain research that involves one or more medications will usually need access to a different medication on withdrawal. This problem may be straightforward in many cases but can be very challenging in an interventional study if the investigational medication is an opioid, which requires the subject to get a new prescription and get it filled. Most states have created considerable barriers to opioid prescribing, including triplicate prescriptions, which may make it very difficult for a subject to obtain

a new prescription and get it filled in a timely manner. If a subject has his or her medication available, the process may be easier. Nevertheless, considerable challenges of calculating an equianalgesic dose remain. For both of these reasons, investigators can enhance the ethical design of pain research by developing mechanisms to ensure that subjects who drop out continue to receive adequate pain treatment with as little interruption as possible.

CONCLUSION

The field of palliative care, and the standard of care that it represents, depends upon rigorous research to provide data that will guide clinical care. Although this research raises substantial ethical questions, these questions need not curtail what promises to be a valuable and highly productive area of research. Of course, the concerns discussed above should be taken seriously. To do otherwise risks the sorts of ethical missteps that have produced scandals in other fields. Nevertheless, these ethical questions can be addressed through careful planning, attention to the adequacy of a study's design, and to the informed consent process.
