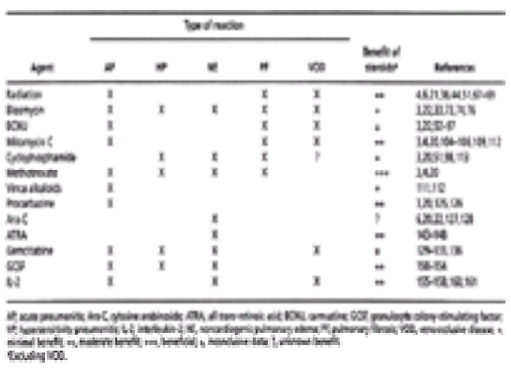
CARDIOPULMONARY TOXICITY OF CANCER THERAPY

MARIANNE J. DAVIES
MICHELLE Z. SCHULTZ
JOHN R. MURREN

Advances in cancer therapy have produced increasingly complex combinations of chemotherapeutic agents, radiation therapy, and biological-response modifiers. New methods of providing hematopoietic support with growth factors and marrow products have minimized myelosuppression as a barrier to the dose intensification of chemotherapy. As a result, many patients are now at increased risk for cardiopulmonary toxicity. Some of these side effects develop rapidly after exposure to the inciting agent, whereas others take years before becoming evident. Consequently, the need for vigilant supportive care has intensified. Fortunately, progress also has been made in prevention and management of treatment-related toxicity. Optimal management depends on the early recognition of treatment-related toxicity so that the inciting agent can be withdrawn and the appropriate therapy instituted. In addition, patients who are successfully treated for a malignant disease need to be informed that they remain at risk for potentially late cardiopulmonary toxicity and strongly counseled to avoid smoking and other toxic exposures. With appropriate supportive measures, cardiopulmonary risks to patients who are undergoing intensive cancer therapy can be minimized despite the narrow therapeutic index of this treatment.

PULMONARY TOXICITY

Severe pulmonary injury can result from radiation therapy or chemotherapy alone or in combination (Table 29-1). The incidence of treatment-related pulmonary toxicity is variable and difficult to establish precisely (1). A small number of agents predictably cause toxicity, whereas most do so exceedingly rarely. Because chemotherapy is usually given in multi-drug combinations and is often given concurrently with radiation, there may be additive or synergistic toxicity (2). The severity of toxic reactions varies widely, ranging from incidental asymptomatic cases to life-threatening respiratory insufficiency. The predominant patterns are interstitial pneumonitis with pulmonary fibrosis, acute hypersensitivity reactions, and noncardiogenic pulmonary edema. Other, less common acute pulmonary syndromes are pleuritis and bronchospastic anaphylactic reactions (3,4,5 and 6). Interstitial infiltrates may also be the presenting feature of a wide variety of other complications of malignancy, infectious as well as noninfectious (Table 29-2).



Agent	Type of reaction: AP	HP	NE	PF	VOD	Benefit of steroids*	Reference
Radiation	X			X	X	**	4,6,71,78,44,51,97–99

TABLE 29-2. DIFFERENTIAL DIAGNOSIS OF DIFFUSE INTERSTITIAL INFILTRATES IN CANCER AND BONE MARROW TRANSPLANT PATIENTS

APPROACH TO THE PATIENT WITH PNEUMONITIS

Typically, a subacute onset of progressive dyspnea, nonproductive cough, anorexia, and low-grade fever develops 1–3 months after treatment with chemotherapy and radiation (6). High fever (>40°C), purulent sputum, and hemoptysis are rarely seen and suggest an infectious etiology (7,8 and 9). Physical findings include tachypnea, tachycardia, diffuse rales, and occasionally cyanosis. Hypoxemia with respiratory alkalosis may ensue.

Chest radiographs usually reveal diffuse interstitial or alveolar infiltrates, particularly prominent at the lung base (3). However, infection is the most common specific diagnosis that is confirmed when diffuse infiltrates are manifested (10,11 and 12). Pulmonary function tests may display a restrictive pattern and decreased diffusing capacity (3). Decisions regarding the need for more invasive diagnostic procedures should be individualized. Patients who are neutropenic and those who have received prolonged corticosteroid therapy have a high risk of infection with bacteria and *Pneumocystis carinii*, respectively, and may be candidates for empirical therapy. Treated leukemia patients and bone marrow transplant (BMT) patients, on the other hand, may benefit from a more accurate diagnosis (13,14). Consideration of whether drug or radiation-related toxicity is present is made by assessment of the timing, risk factors, and agents involved and usually requires further confirmation by biopsy. Bronchoscopy is the preferred method for biopsy, as it is the least invasive. However, open-lung biopsy is sometimes necessary.

For infectious agents and malignant lesions, bronchoalveolar lavage (BAL) has a high diagnostic yield, although false-positive results have been seen with fungi and cytomegalovirus (15,16). Protected nonbronchoscopic BAL can be used effectively for intubated patients, and for severely immunosuppressed individuals it poses less risk of bleeding compared with transbronchial biopsy (12,17,18). Nonetheless, transbronchial forceps biopsy yields more tissue for histopathologic evaluation, which may increase the diagnostic yield in noninfectious processes.

If a diagnosis cannot be established by bronchoscopy, a thoracoscopic or open-lung biopsy may be required. Because a thoracoscopic procedure requires that

collapse of the lung be evaluated, it may not be feasible in some critically ill patients with limited pulmonary reserve. A trial comparing the relative usefulness of thoracoscopic and open-lung biopsies in noncritically ill patients found that equivalent amounts of tissue could be obtained with either method, producing similar diagnostic accuracy. Less morbidity occurred with thoracoscopy, however, and therefore this is the preferred procedure in patients who can tolerate single lung ventilation (19).

The histopathology of treatment-related interstitial pneumonitis incorporates nonspecific features that are common to drug- and to radiation-induced lung injuries. Capillary damage is present, characterized by endothelial swelling with fibrinous alveolar exudate in the interstitial and alveolar spaces. Type I pneumocytes are destroyed, and thus type II pneumocytes proliferate, sometimes with atypia. Characteristically, a paucity of mononuclear inflammatory cell infiltration is present. Release of inflammatory cytokines such as transforming growth factor-b recruits and activates fibroblasts. This culminates in thickening of alveolar septa by collagen and the development of fibrosis (3,6,20,21). In addition, hypersensitivity reactions may show eosinophilic infiltrates or granuloma formation (3,20,21 and 22). Leakage of plasma proteins into the alveolar space contributes to a loss of compliance and abnormal gas exchange.

Most patients in whom clinically evident pulmonary disease develops present several months after completion of treatment. Aggressive therapies have improved survival for many patients, leading to an increase in observed late toxicities. Evaluation of delayed toxicities has been extensively reviewed in patients with childhood acute leukemia and Hodgkin's disease (23,24,25,26,27,28,29 and 30). Risk factors for delayed toxicity were dose-intensified therapy and spinal irradiation (24,25). Asymptomatic restrictive lung disease may be evident by pulmonary function testing at the completion of therapy and may persist for greater than 10 years (23,24 and 25,27).

DELAYED-ONSET PNEUMOPATHIES

Syndromes that have a delayed onset include pulmonary fibrosis, pulmonary veno-occlusive disease (VOD), and bronchiolitis obliterans with organizing pneumonia. Pulmonary fibrosis usually develops as a progressive disorder in patients who have had acute pneumonitis. The fibrotic process generally plateaus after several months, but if a sufficiently large amount of lung is affected, it may lead to the development of cor pulmonale.

VOD is a rare disorder that is characterized by endothelial damage and intimal fibrosis of pulmonary veins and venules, resulting in pulmonary hypertension. Clinical presentation includes progressive dyspnea, hypoxia, and signs and symptoms of cor pulmonale. Pulmonary VOD typically occurs 2–4 months after therapy (31). However, isolated cases of early-onset pulmonary VOD have been reported (32). Diagnosis typically requires open-lung biopsy with special stains for elastic tissue. Although several etiologic factors have been associated with this syndrome, a handful of cases have been attributed to radiation and chemotherapeutic agents, including bleomycin, BCNU (carmustine), mitomycin C, and possibly cyclophosphamide (8,33).

Bronchiolitis obliterans is a circumferential inflammation of the terminal air spaces that can be caused by a diverse array of causes, including infections, toxins, medications, and autoimmune and other inflammatory conditions. A limited number of reports have been published of bronchiolitis obliterans complicating chemotherapy or radiation. Patients usually present several months after completion of therapy with fever and cough in addition to dyspnea. Most cases of bronchiolitis obliterans that are associated with radiation have occurred in patients who were treated for breast cancer (34,35). Radiographic findings may be minimal or may include acinar or reticular infiltrates. In contrast to the typical pneumonitis that is associated with radiation, the infiltrates extend outside the radiation port.

Patients must be educated about the risks of delayed effects of aggressive treatment regimens. It is essential to encourage continued screening for late effects and avoidance of detrimental health behaviors (smoking, respiratory exposures). Early detection and intervention can lead to minimization of delayed effects of therapy.

SPECIFIC CAUSATIVE AGENTS

Radiation Therapy

Irradiating the lung parenchyma results in acute as well as chronic lung injury, consisting of acute respiratory toxicity, interstitial pneumonitis, and later pulmonary fibrosis (4,21,36). Deaths due to pneumonitis have been reported (37). Overall, the incidence of symptomatic pneumonitis ranges from 5% to 10% of patients treated with mediastinal irradiation (6,38,39 and 40). The risk varies widely depending on the treatment plan, however, and approaches 20% in patients who are treated for lung cancer, whereas it is only 1% in individuals irradiated for breast cancer (41,42). Interstitial pneumonitis can occur within hours of treatment but typically is observed 2–3 months after completion of radiotherapy (43).

The risk of injury is dose and volume related. In nearly all patients, subtle changes on x-ray and pulmonary function can be detected (41). For clinically significant toxicity, however, there appears to be a threshold effect, with symptoms unlikely unless the volume of lung irradiated exceeds 10% or >200 cm^2. In addition to the volume of lung treated, the total dose of radiation and the number of fractions are important factors. Risk increases if daily dose fractions of radiation exceed 2 Gy or if the total dose to the lung is greater than 60 Gy using conventional fractionation and two-dimensional treatment planning (4,43,44).

Approaches that have been developed to enhance the effectiveness of radiation include the delivery of multiple doses of radiation daily, three-dimensional treatment planning, and administration of radiation concurrently with chemotherapy. Delivery of smaller doses of radiation two or three times a day is defined as a *hyperfractionated schedule*. Although the use of smaller fractions should decrease the risk of fibrosis, hyperfractionated schedules also deliver a higher weekly dose rate of radiation and frequently a higher total dose. These factors can negate any benefit from the use of smaller fractions (45).

Three-dimensional conformal radiotherapy uses computed tomography (CT) to contour treatment volumes and delivers the radiation beams from multiple portals. Multiple CT images are used to delineate the target and the normal structures, and the dose is delivered by several cross-firing beams that intersect at the target center from multiple angles. This approach reduces the amount of radiation that is delivered to normal lung surrounding the tumor and allows for the delivery of higher doses without increasing complication rates (39,46).

Several studies suggest that the delivery of chemotherapy concurrently with radiation is more effective than treatment with chemotherapy followed by radiation for patients with lung cancer (47). Concurrent delivery of chemotherapy with radiation can potentiate the risk of pulmonary toxicity (6,48,49 and 50). Chemotherapeutic agents that are particularly likely to increase the risk of pulmonary toxicity of radiation include dactinomycin, bleomycin, cyclophosphamide, cisplatin, vincristine, and recombinant interferon-a. For cisplatin, small daily doses or continuous infusion schedules appear to be safer than larger intermittent bolus dosing, suggesting that the risk may be related to peak plasma concentration (51).

Additional factors that are associated with increased risk of pulmonary toxicity following radiation are withdrawal of steroids and prior radiation to the lung (47). Continued tobacco use during treatment has actually been associated with a decreased risk in some studies (52,53).

A number of approaches to predict which patients will develop symptomatic pulmonary toxicity following radiation have been developed. Mathematical models that estimate the dose and distribution of exposure to normal lung based on the CT images (dose volume histograms), with or without inclusion of perfusion imaging to correct for the functionality of this lung volume, are useful for evaluating competing three-dimensional conformal treatment plans. Some models have been helpful in predicting increased risk of pneumonitis (39,54,55 and 56). The baseline pulmonary function, especially the diffusing capacity of carbon dioxide, has been shown to predict risk of postradiation impairment, and algorithms that incorporate baseline physiological function and the magnitude of normal lung irradiated are being developed (55,56 and 57). Serum markers that reflect the extent of parenchymal damage or the inflammatory response to radiation are also being evaluated. Baseline or posttreatment changes in the serum concentration of surfactant, tumor growth factor-b, and thrombomodulin have been shown in small studies to predict patients in whom pulmonary toxicity will develop and may play a role in determining which patients can be safely given higher doses of radiation (58,59,60,61,62 and 63).

The clinical features of radiation pneumonitis are nonproductive cough, dyspnea, fever, pleuritic or substernal chest pain, malaise, and weight loss. On examination few physical findings are usually found, although some patients have rales or a pleural rub. Purulent sputum or a leukocytosis is uncommon and is helpful in differentiating radiation injury from pneumonia. Frank hemoptysis is rare at presentation but has been observed as a late complication of radiation (64,65). The diagnosis is suggested by chest radiography demonstrating abnormalities within the radiation port. Typically, a diffuse haze is identified within the treatment area that progresses to patchy alveolar infiltrates and air bronchograms (66,67) (Fig. 29-1). CT, especially with a high-resolution protocol, is more sensitive than plain radiography in identifying subtle changes early in the course of the disease (4). Gallium scanning may also demonstrate abnormalities before the chest radiograph does. The magnitude of decline in pulmonary function tests often corresponds with the clinical symptoms and consists of reduced lung volumes and compliance and abnormalities in gas exchange (68).

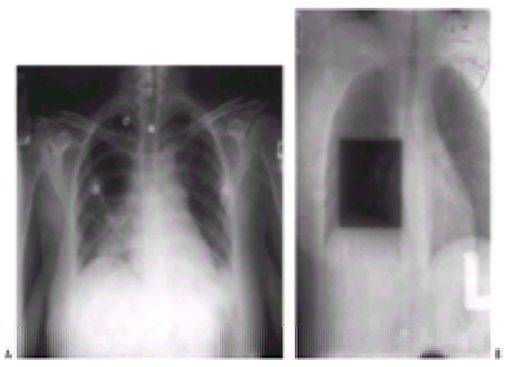

FIGURE 29-1. Radiation pneumonitis. Unilateral alveolar infiltrate in a woman following radiation treatment for recurrent Hodgkin's disease (A). This opacity corresponds with the radiation port (B).

Treatment with corticosteroids can reduce the acute inflammatory response of pneumonitis. Prednisone is administered at 60 mg/day for 2 weeks and then gradually tapered. This produces improved symptoms and resolution of pulmonary infiltrates in most patients (6,68,69). The sudden withdrawal of corticosteroids, as is done in some chemotherapy protocols, may precipitate acute pneumonitis in patients who are receiving radiation. This should be avoided by tapering the corticosteroids after each cycle (47). Amifostine reduced the incidence of acute pneumonitis in one small randomized study from 23% to 4% in patients aggressively treated for lung cancer with hyperfractionated radiation and concurrent chemotherapy (70). In animal models, angiotensin-converting enzyme inhibitors, pentoxifylline, a-tocopherol, and antibodies against CD40 ligand have been shown to ameliorate radiation pneumonitis but have not yet established a role in the clinic (71,72).

Although acute pneumonitis sometimes resolves completely, with or without treatment, in most patients some degree of pulmonary fibrosis subsequently develops (47,67). Fibrosis is generally detected between 6 months and 2 years after radiotherapy. Symptoms are usually minimal, unless the patient had significant pretreatment lung disease or involvement of more than 50% of one lung (6). Symptoms include dyspnea, cyanosis, clubbing, and cor pulmonale. Chest radiographs reveal a dense infiltrate with volume loss; a characteristic feature is a straight border to the infiltrate delineating the radiation port. Corticosteroid therapy is rarely helpful in this chronic phase (47).

Chemotherapy

Bleomycin

Although it is one of the few cytotoxic agents that is not myelosuppressive, serious toxicity from bleomycin occurs in the form of dose-related pulmonary fibrosis, as well as hypersensitivity reactions that are unrelated to dose (3,22). At therapeutic doses, the incidence of bleomycin-related pulmonary fibrosis ranges from 3% to 5%, but rates as high as 40% have been reported for some intensive regimens (3,20,22,73,74). The cumulative dose is the strongest predictor of toxicity, and above 350–500 units, the incidence of pulmonary abnormalities rises sharply, to above 10% (3,6,20,73,74). Other risk factors for the development of toxicity include age older than 70 years; prior lung disease; radiation concurrent with, preceding, or subsequent to bleomycin administration; tobacco use; impaired renal function; and the use of high inspired concentrations of oxygen (3,22,75,76,77 and 78). Hematopoietic support with granulocyte colony-stimulating factor during treatment with bleomycin-containing chemotherapy has been associated with an increased risk of pulmonary toxicity in some, but not all, series (79,80,81 and 82).

Clinical findings include progressive dyspnea, dry nonproductive cough, tachypnea, basilar rales, and a pleural friction rub. Fever and peripheral blood eosinophilia may be present in acute hypersensitivity reactions (3,74). Chest radiograph findings range from fine infiltrates to nodular infiltrates and lobar consolidation (Fig. 29-2). Before the onset of symptoms or radiographic changes, a decrease in diffusing capacity and forced vital capacity can be detected. The presence of a polymorphonuclear alveolitis on BAL is supportive, but a biopsy is necessary to confirm the diagnosis.

FIGURE 29-2. Bleomycin lung.The chest radiograph shows bilateral reticulonodular infiltrates and pleural thickening (A). Computed tomographic findings include bibasilar air cysts, bronchiectasis, and reticular opacities associated with extensive bilateral pleural thickening (B).

Patients who are treated with bleomycin should have baseline pulmonary function tests before therapy. They should receive a test dose 12–24 hours preceding the first treatment dose to minimize the risk of a hypersensitivity reaction. Total lifetime dosing should not exceed 400 units. Pulmonary function tests should be repeated if an elevated creatinine develops (77). Bleomycin should be discontinued if pulmonary function declines by 15%. Most patients with early or mild abnormalities stabilize or improve with discontinuation of the drug, but those with severe toxicity (resting hypoxemia and extensive infiltrates on x-ray) have a high mortality. Corticosteroids are probably beneficial for patients with bleomycin-induced pulmonary toxicity, particularly for hypersensitivity reactions (3,20,22,83). Aggressive diuresis may be necessary in cases of acute pulmonary edema (84). Amifostine, urokinase-type plasminogen activator, angiotensin-converting enzyme inhibitors, niacin, and soluble tumor growth factor-b receptor have been shown to be useful in animal models but have not been tested in the clinic (85,86,87 and 88).

Patients who have been treated with bleomycin-based regimes should be monitored closely throughout their lifetime during any surgical procedures, as oxygen therapy can exacerbate bleomycin toxicity. Adult respiratory distress syndrome (ARDS) has been reported in patients following general anesthesia and occurs 3–10 days after surgery (89,90). The preoperative forced vital capacity is the best predictor of postoperative complications. Perioperative prophylactic steroids, concentration of intravenous fluids into the least volume possible, and use of the lowest possible oxygen concentrations during mechanical ventilation are measures that can reduce the risk of complications (84,89).

BCNU

The pulmonary toxicity of BCNU (carmustine) has been unambiguously documented, because it is used as a singleagent treatment of malignant brain tumors, which are a group of diseases that spare the lungs and often present in otherwise healthy patients. At conventional doses, the incidence of toxicity ranges from 20% to 30%, with a clear dose–response effect (3,20,91,92). Pulmonary toxicity develops in up to 50% of patients at cumulative doses that exceed 1500 mg/m^2 (20). Typical BCNU pulmonary toxicity has an insidious onset, similar to that of other subacute chemotherapy drug reactions. The median onset of presentation is within 90 days of treatment (91,92,93 and 94), but some patients are diagnosed as late as 10–20 years after the completion of chemotherapy (95). Radiographic abnormalities occur late, if at all. BAL may reveal interstitial pneumonitis, but a lung biopsy is required for definitive diagnosis (93,94).

High-dose BCNU is commonly used in conditioning regimens for BMT. At single doses greater than 450 mg/m^2, there is a precipitous increase in the risk of acute interstitial pneumonitis (96,97). When used in preparative regimes that include other alkylating drugs, BCNU doses of 600 mg/m^2 result in symptomatic pulmonary toxicity in more than half of the patients treated (68,93,98).

Patients should be periodically monitored with pulmonary function tests and the drug withdrawn if a decline in function is noted. For patients who are already taking steroids for their underlying malignancy, discontinuation of BCNU is the mainstay of treatment for pneumonitis (3,20,99,100). Mortality in this setting is approximately

16% (101). In contrast, the pulmonary toxicity due to BCNU-based dose-intensive regimens responds well to steroids and has a better prognosis (94,102). Patients are generally treated with prednisone at doses of 1 mg/kg for 10 days and then slowly tapered to avoid a reexacerbation of symptoms (94,103). Complete recovery can be expected in the majority of these patients.

Mitomycin C

The incidence of severe mitomycin C pulmonary toxicity ranges from 3% to 29% (8,20,104,105 and 106). Patients usually present with the insidious onset of dyspnea and a dry cough 3–6 months after completion of therapy. In some cases, bronchospasm, pulmonary edema, or hemorrhage ensues (4,107,108). Diffuse pulmonary infiltrates are evident radiographically. Pulmonary function tests reveal decreased diffusing capacity and restrictive ventilatory defects. Toxicity is related to cumulative dose and usually develops after four cycles of therapy when the total dose exceeds 20–30 mg/m^2 (109,110). Underlying lung disease, tobacco use, oxygen therapy, and chest irradiation increase the risk of pulmonary side effects (3,8). Synergistic toxicity is observed when mitomycin is used in combination with vinca alkaloids (111,112). Although most patients respond initially to steroid therapy, many go on to develop chronic pulmonary dysfunction (110,112). Increasing the steroid dosage is effective in some cases (104,110). Patients who are able to taper off of steroids within 1 month have a decreased risk of developing chronic dysfunction. Those who require a more protracted tapering schedule are more likely to have progressive toxicity (110). Mortality approaches 50% (3,20). In addition to causing direct lung injury, mitomycin is associated with a hemolytic-uremic syndrome, which is rarely complicated by pulmonary hemorrhage (108).

Cyclophosphamide and Other Alkylating Agents

Cyclophosphamide is one of the most frequently prescribed chemotherapeutic drugs, and at standard doses the associated incidence of symptomatic pulmonary toxicity is <1% (3). However, if sought, physiological changes in lung function can be demonstrated in many patients. For example, in a study of 150 patients with breast cancer who received the combination of cyclophosphamide, doxorubicin, and 5-fluorouracil (5-FU), the mean diffusing capacity of the lungs for carbon monoxide was decreased by 12% after three cycles (98). The risk of toxicity increases when higher than standard doses are used or when cyclophosphamide is administered with other DNA–damaging drugs or radiation. Treatment of small cell lung cancer with high doses of cyclophosphamide followed by radiation led to symptomatic pulmonary fibrosis in 74% of patients (113). Currently, pulmonary toxicity is most commonly seen in the setting of BMT (98). Clinical features are similar to those of other drugs, although fever is often prominent (3). Radiography typically shows a basilar reticular pattern; occasionally, a pattern of diffuse pulmonary edema is observed. BAL demonstrates a cellular inflammatory response (98). Corticosteroids may hasten improvement in some cases, and the overall recovery rate is approximately 60% (3,20,47). A closely related agent, ifosfamide, has rarely been associated with interstitial pneumonitis (114).

Although the therapeutic applications of other alkylating agents, such as chlorambucil, busulfan, and melphalan, are not as broad, each has been reported to cause pulmonary toxicity. All have been associated with the insidious onset of dyspnea and reticular infiltrates months to years after therapy. Unlike cyclophosphamide, chlorambucil and busulfan toxicity appear to be dose related (3,6). The role of corticosteroids for pulmonary toxicity from these agents is equivocal, although a trial of therapy in symptomatic patients is indicated (3,20).

Vinca Alkaloids

During or shortly after the infusion of vinca alkaloids, bronchospasm can occur. The chest radiograph may show evidence of interstitial infiltrates. Treatment consists of bronchodilators, steroids, and other supportive measures. The incidence of this reaction has been reported to be as high as 5% for vinorelbine and is less common with other vinca alkaloids (115,116). The risk of pulmonary toxicity is increased when vinca alkaloids are given with mitomycin (111,112,117,118 and 119). For example, Rivera et al. (112) reported an incidence of 4% for severe acute respiratory distress within 4 hours of receiving a dose of vinca alkaloid in 378 patients treated for advanced non–small cell lung cancer. Mitomycin C was administered on the same day in only one-third of the cases. Most patients had wheezing, rales, rhonchi, and new diffuse interstitial infiltrates on chest radiography. Significant improvement occurred within 24 hours in 21 of 25 patients who were managed with supplemental oxygen and bronchodilators. Eight patients who received corticosteroids for persistent dyspnea all improved; however, residual chronic dyspnea was worse than before treatment in 63% of patients, and one patient died (112). Rechallenge with vinca alkaloids has resulted in recurrence of symptoms (111,112).

Doxorubicin

When administered alone, doxorubicin is not associated with pulmonary injury. It may, however, reduce the tolerance of the lung to radiation. Enhanced toxicity has been identified in patients with Hodgkin's disease, breast cancer, and small cell lung carcinoma treated with doxorubicincontaining regimens and with irradiation (8,120,121). When doxorubicin is administered after chest irradiation, severe pneumonitis can occur, even outside the radiation port (122). This phenomenon, termed *radiation recall*, was described in a report of 71 patients who received combined radiation therapy and chemotherapy with cyclophosphamide, doxorubicin, and vincristine. Pneumonitis was the primary toxicity, with a 15% incidence of ARDS and a mortality of 10% (122). A 7% incidence and 4% mortality from ARDS were reported when a doxorubicin-containing combination was resumed after a course of radiation (123). Corticosteroids have been reported to be effective treatment for radiation recall pneumonitis (122).

Methotrexate

Methotrexate has been associated with hypersensitivity reactions, pulmonary fibrosis, noncardiogenic pulmonary edema, and pleuritis. These reactions may develop after oral, intravenous, or intrathecal administration, and synergism with other toxins may occur (3,124). The presentation of methotrexate pulmonary toxicity may be fulminant, with fever, blood eosinophilia, rash, and rapid onset of respiratory failure (Fig. 29-3). The onset may be as early as 12 days and as late as 18 years after treatment (4). Pulmonary eosinophilia may occur, and histopathology often reveals a marked inflammatory infiltrate with granulomas. Nonetheless, the prognosis is favorable. Dramatic responses to corticosteroids have been reported (3,20).

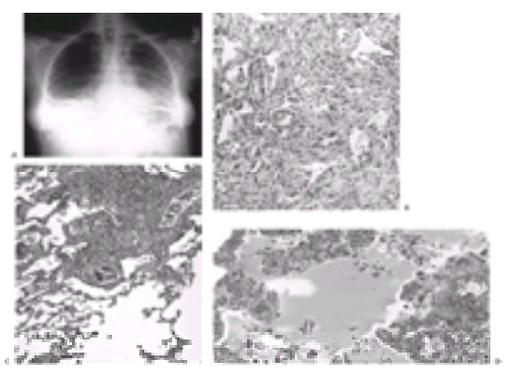

FIGURE 29-3. Methotrexate pulmonary toxicity. Alveolar infiltrates, primarily in the bases and bilateral pleural effusions, characterize this disease (A).These radiographic findings are consistent with either acute pneumonitis, hypersensitivity pneumonitis, or noncardiogenic pulmonary edema. These entities can be distinguished only by the clinicopathological findings (B–D). Acute pneumonitis produces expansion of the alveolar walls by a polymorphous inflammatory cell infiltrate. In this section, the pneumocytes exhibit moderate atypia (B). With hypersensitivity pneumonitis, there may be patchy interstitial lymphocytic infiltrates and associated bronchiolitis and granuloma formation (C). The pathological findings of pulmonary edema include expansion of the alveolar spaces by proteinaceous fluid (D).

Procarbazine

A hypersensitivity reaction characterized by the abrupt onset of respiratory distress along with fever, rash, arthralgias, and peripheral blood eosinophilia has been described in association with procarbazine therapy (3,20). The subacute onset of dyspnea over 1–2 weeks, without other signs of hypersensitivity, has also been reported (125,126). Corticosteroids appear to be beneficial in most cases (3,20,125,126).

Cytosine Arabinoside

Noncardiogenic pulmonary edema and ARDS have been associated with cytosine arabinoside (6,20,22,127,128). Pleural and pericardial effusions are present in a minority of cases. A dose–response effect appears to occur, with a 20–30% incidence after cumulative doses above 24 g/m^2. Management consists primarily of aggressive supportive care. The role of corticosteroids is unclear (22).

Gemcitabine

Pulmonary toxicity that is associated with gemcitabine is usually mild and self-limiting. However, it may produce life-threatening toxicity presenting as pneumonitis (129), acute hypersensitivity reaction with bronchospasm (130), ARDS (131,132), or capillary leak syndrome (133). Clinically evident toxicity occurs in 4–10% of patients (134,135). Symptoms usually develop within the first 24 hours after administration, but delayed reactions of up to 1 week have been reported (136,137). An increased risk of gemcitabine toxicity occurs when it is administered in regimens with docetaxel (138), concurrently with radiation therapy as a radiation sensitizer (135,139,140), or in patients with a prior history of reactive airway disease or previous radiation therapy to the mediastinum (135). Symptoms include dyspnea, cough, hypoxemia, and fever. Diffuse infiltrates on chest radiography are consistent with pulmonary edema. Transbronchial biopsies may reveal interstitial pneumonitis (132). Symptoms usually resolve with discontinuation of treatment. Corticosteroids, bronchodilators, and diuretics are effective in some patients (129,132,133,141,142).

Retinoic Acid Syndrome

All *trans*-retinoic acid (ATRA) syndrome is a life-threatening toxicity that occurs in up to 25% of patients with acute promyelocytic leukemia treated with ATRA. It resembles a capillary leak syndrome. It is characterized by fever, respiratory distress, and interstitial pulmonary infiltrates, often accompanied by weight gain, peripheral edema, pleural and pericardial effusions, and hypotension (143,144). Chest radiography shows bilateral interstitial and alveolar infiltrates (Fig. 29-4). Onset has varied from 2 to 35 days after the start of therapy. Although most affected patients have an elevated white blood cell count to ³20,000/µl, a significant percentage do not have a leukocytosis. In a review of 413 patients who were newly diagnosed with promyelocytic leukemia, ATRA syndrome developed in 64, 13 required mechanical ventilation, and four deaths were reported (145). Once respiratory distress is established, leukapheresis, chemotherapy, or cessation of ATRA provides no benefit. The early institution of high-dose steroids (dexamethasone, 10 mg intravenously every 12 hours for at least 3 days) results in prompt recovery in most patients (146,147 and 148), although respiratory failure can occur (149).

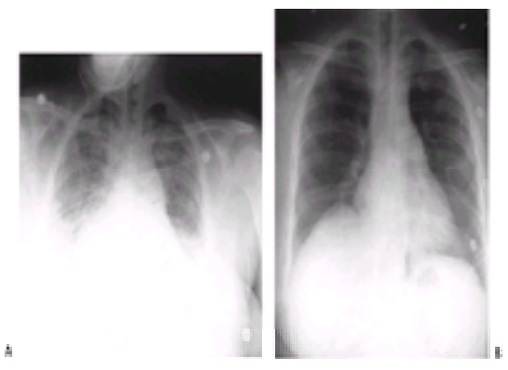

FIGURE 29-4. Retinoic acid syndrome. Rapid onset of bilateral pleural effusions and diffuse parenchymal infiltrates (A) that resolved with supportive measures (B).

Biological Response Modifiers

The availability of hematopoietic growth factors during the past decade has allowed the doses of chemotherapy to be further intensified. Sporadic reports of interstitial pneumonia (150,151), ARDS, and acute respiratory insufficiency (152,153) have appeared, generally in patients who also received chemotherapy that may have contributed to toxicity (80,151,154). Symptoms develop approximately 10 days after chemotherapy administration and coincide with recovery of the leukocyte count (150,151). The risk of toxicity increases above the age of 60 and does not appear to be dose related, although it is correlated with an elevated neutrophil count (124,150,151). Symptoms include abrupt onset of dyspnea and fever (150,152). Treatment with corticosteroids usually yields a prompt recovery. However, Couderc and associates (152) report that, despite high-dose corticosteroid therapy, two patients experienced progressive dysfunction and died of pulmonary fibrosis.

High-dose interleukin-2 (IL-2) is reported to cause severe respiratory distress with diffuse interstitial infiltrates (155). Pulmonary toxicity may also present as capillary leak syndrome leading to pulmonary edema (156,157,158 and 159). The risk of toxicity is dose dependent, occurs most frequently after the first intensive dose of therapy, and declines with subsequent dosing (160). Presenting symptoms include acute-onset shortness of breath, dyspnea, fever, eosinophilia, hypoxia, and pulmonary congestion. Onset is within 40 hours of dose administration (160). Treatment is supportive, with oxygen, diuretics, and steroids that usually produce a complete response (161).

Miscellaneous

Sporadic reports of life-threatening pulmonary toxicities have appeared for fludarabine (162,163), mitoxantrone (164), nilutamide (165,166), irinotecan (CPT-11)(167,168), and antithymocytic globulin (169). Oral etoposide has been associated with interstitial infiltrates and respiratory failure. Onset may occur within 14 days of treatment and has been effectively treated with steroids (168,170,171). The taxanes (paclitaxel and docetaxel), or the cremophor vehicle, have been associated with anaphylactoid reactions characterized by hypotension, dyspnea, bronchospasm, and urticaria (5,138,172). Reactions may develop during or within hours of completion of the infusion. Premedication with corticosteroids, antihistamines, and H2-antagonists have markedly reduced the incidence of this reaction (4,173).

Pulmonary Complications of Bone Marrow Transplantation

Pulmonary complications affect 40–60% of BMT recipients and are responsible for more than 30% of transplant-related deaths (174,175). In addition to the multiple infectious and noninfectious pulmonary side effects discussed already, there are further complications that are unique to these patients.

In the early phase of bone marrow recovery, diffuse alveolar hemorrhage may occur in up to 20% of patients and is associated with a mortality of as high as 80%. Symptoms and signs include progressive dyspnea, hypoxia, and diffuse patchy infiltrates, but rarely hemoptysis. The diagnosis is confirmed when BAL yields recovery of progressively bloodier aliquots that demonstrate hemosiderin-laden macrophages (175). Diffuse alveolar hemorrhage is associated with white blood cell recovery with or without thrombocytopenia. Risk factors include advanced age, underlying solid tumors, irradiation, severe mucositis, and renal insufficiency. Prompt diagnosis and institution of high-dose corticosteroids may be beneficial (175,176).

Interstitial pneumonitis is the most common pulmonary complication of marrow transplantation, occurring in 40% of allogeneic, 17% of syngeneic, and 10% of autologous transplant recipients (31). Cytomegalovirus accounts for most infectious cases. In 30–50% of patients, no infectious cause is identified. This noninfectious pneumonitis, termed *idiopathic pneumonia syndrome*, generally occurs after engraftment and is thought to be related to immunological reactions coupled with toxicity from conditioning regimens. Corticosteroids have no proven benefit, and the mortality remains close to 80% (31,68,175,177). A less severe interstitial pneumonitis has been observed with some of the preparative regimens that are used for autotransplant. This pneumonitis may respond to corticosteroids and is rarely fatal (68).

Acute graft-versus-host disease (GVHD) principally affects the skin, liver, gastrointestinal tract, and immune system; however, respiratory tract involvement may occur as well. Lymphocytic bronchitis is a controversial entity described in up to 25% of patients with acute GVHD (174). Whether it is a specific manifestation of GVHD, however, remains unresolved. Lymphocytic bronchitis presents with dyspnea and nonproductive cough, with a normal chest radiograph and without evidence of airflow obstruction. Bronchoscopy reveals diffuse inflammation of the airways. Pathological evaluation demonstrates small lymphocytes infiltrating the proximal bronchial mucosa, with loss of cilia and damage to the submucosal glands and goblet cells, predisposing to bacterial tracheobronchitis and pneumonia. Increased immunosuppressive therapy for the associated acute GVHD generally improves the syndrome (174,178).

The leukoagglutinin or pulmonary transfusion reaction is noncardiogenic pulmonary edema caused by activation of the recipient's neutrophils by donor leukocyte antibodies. The clinical presentation is respiratory distress, tachycardia, fever, chills, and often cyanosis and hypotension developing during administration of blood products. After discontinuation of the transfusion, treatment is supportive, and in most cases recovery is complete within a few days (179).

Bronchiolitis obliterans has been described in 10–20% of BMT patients, associated with chronic GVHD in most cases (31,174,178). This complication usually occurs 4–12 months after BMT and is manifested by exertional dyspnea, nonproductive cough, and wheezing. Because of airflow obstruction with gas trapping, physical examination may demonstrate late inspiratory rales, and pulmonary function tests may show obstruction in addition to restriction. BAL demonstrates lymphocytosis and excludes infection. Pathology resembles that of lung allograft rejection. Although mortality is as high as 65%, treatment with increased immunosuppressive therapy

appears to be beneficial if administered early in the course of disease (31,178,180).

Interstitial pulmonary fibrosis occurs in 20–30% of patients within 12 months of allogeneic BMT (174,178). Factors that contribute to diffuse lung injury and lead to fibrosis may include conditioning regimens (e.g., BCNU, busulfan, cyclophosphamide, and total body irradiation), immunosuppressive therapy (methotrexate), transfusion reactions, pulmonary hemorrhage, and hyperleukocytosis. Treatment is supportive, and the mortality remains high (174). In severe cases, successful lung transplant has been performed (27,181).

CARDIAC TOXICITY

Mediastinal irradiation and many chemotherapy drugs can produce cardiotoxicity (Table 29-3). Advances in radiation techniques along with the development of cardioprotective agents have reduced the risk of heart damage from some of these therapies. As new treatment modalities are introduced, however, predicted or unanticipated cardiotoxicities may be observed. As a result, vigilance for and management of cardiac side effects will remain an important component of supportive care for the foreseeable future.

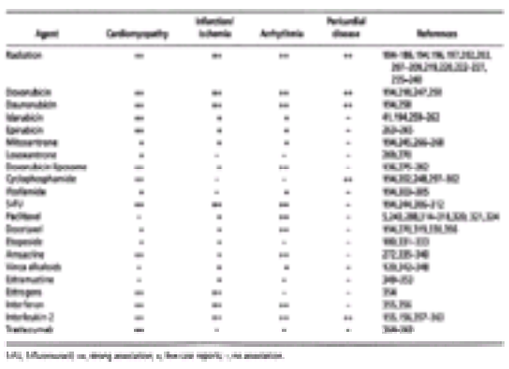

TABLE 29-3. CARDIOTOXICITY OF CANCER THERAPEUTIC AGENTS

Radiation Therapy

Mediastinal radiation therapy is an integral part of the treatment for Hodgkin's disease and other lymphomas and lung and breast cancer. The risk of damage to the heart from radiation therapy is related to the volume of the heart that is irradiated and the total dose received (182,183,184,185,186 and 187). Radiation therapy potentially can damage the pericardium, myocardium, coronary arteries, and conduction system. However, the incidence of all these toxicities is declining, with current dose fractionation and cardiac-shielding techniques that limit exposure (188,189).The use of anteroposterior and posteroanterior ports for Hodgkin's disease has minimized cardiac exposure (190). Minimizing exposure of the internal mammary node chain in patients with breast cancer has also limited cardiac exposure (191). The cardiotoxic effects of irradiation may be manifested early after completion of therapy, as with acute pericarditis, or delayed for years, as with coronary artery disease. Table 29-3 discusses the cardiotoxicity of cancer therapeutic agents.

Pericardial Disease

The diagnosis of toxicity can be made by chest radiography, CT scan, magnetic resonance imaging, echocardiography, angiography, electrocardiography (ECG), or biopsy. On chest film, the transverse diameter of the heart may be decreased, with narrowed or straight borders indicating fibrosis (192), or the cardiomediastinal ratio may be decreased, indicating cardiomyopathy or pericardial effusion (193). However, a normal chest radiograph does not exclude injury, as the majority of patients have no changes. Echocardiography, CT, and magnetic resonance imaging are more sensitive to evaluate the pericardium (192).

Although pericardial disease is the most common cardiotoxicity of mediastinal radiation, this complication occurs less often with modern treatment techniques (184,185,194,195,196,197 and 198). Pericardial disease, previously identified in up to 20% of patients when the entire pericardium was irradiated, was reduced to 7.5% with partial cardiac shielding and 2.5% with the addition of subcarinal blocking (199). During the course of treatment of a radiosensitive mediastinal mass, an acute pericarditis may occur, which is believed to be directly related to tumor response rather than pericardial damage. The patient usually presents with acute chest pain, fever, and ECG changes. Symptoms resolve despite continued treatment, and there is no correlation with the development of chronic pericarditis (190,196).

Typically, the onset of symptomatic pericarditis, pericardial effusion, or constriction is delayed for 4–9 months, but it may develop as late as decades after treatment (186,190,200,201 and 202). Symptoms include fever, pleuritic chest pain, and pericardial friction rub. The risk of developing a delayed pericardial effusion ranges from 2% to 10% at doses >4000 cGy (192,203). Factors that contribute to the development of the effusion are an elevated lymphocyte count >1500/µl, the presence of a large mediastinal mass, and concomitant chemotherapy (204). Most cases of radiation pericarditis resolve spontaneously within 16–20 months (185,194,205). Nonsteroidal antiinflammatory drugs can be used to provide symptomatic relief (185,186). Steroids may help in resolution of symptoms, but withdrawal may trigger relapse or identification of other inflammatory cardiac processes (201,206). The development of a pericardial effusion increases the risk of chronic pericardial disease. Of patients who become symptomatic, tamponade develops in 10–30%, usually within 2 years of treatment. Up to 20% progress to constrictive pericarditis within 5–10 years, although a 45-year latency period has been described (185).

In a few patients, the pericarditis is effusive and constrictive. This entity presents with signs and symptoms of pericardial tamponade. Right atrial pressure is persistently elevated after pericardiocentesis due to fibrosis of the visceral pericardium. Pericardectomy is required in most symptomatic patients with effusive-constrictive pericarditis (195). Despite aggressive surgical intervention, deaths have been reported due to persistent constriction and restrictive cardiomyopathy (207).

Myocardial and Valvular Disease

Myocardial damage, when detected, is usually mild and asymptomatic (185,198,208). The mechanism of injury is thought to be due to injury of the capillary endothelial cell, leading to obstruction of capillary blood flow, microvascular insufficiency, and myocardial fibrosis (186). Impaired exercise capacity with reduced resting ejection fraction may be identified on echocardiogram after completion of mediastinal radiation (193,202,209,210). Most patients have return of function within 2–6 months of completion of therapy (193,211,212). However, subtle changes have been reported several years after completion of treatment for Hodgkin's disease (213). Clinically evident heart failure is rare with the use of modern techniques (186,187). The concurrent or sequential use of anthracyclines may cause additive or synergistic toxicity to the myocardium (185,188,214,215). When radiation is delivered with doxorubicin, toxicity occurs at a dose that is 1000 cGy lower than when radiation is delivered as a single modality (216). Doxorubicin is also known to persist in myocardial tissue for months and may produce a “recall phenomenon” when radiation is delivered (217). Reduction of the anthracycline dose when used in combination therapy is recommended (218). If heart failure develops, treatment includes the use of inotropes and afterload reducing agents (187).

Valvular damage, although rare, may occur as a result of valvular thickening (185,186,196,197,219,220). The aortic valve followed by the mitral valve is most frequently involved, and stenosis and regurgitation can occur (207,219,220). In an analysis of 635 patients who were treated for Hodgkin's disease, 29 patients developed murmurs in follow-up (196,197). Women who receive radiation for breast cancer are at higher risk of developing valve disease when they are irradiated for left-sided lesions (221). Although most patients are asymptomatic (196,197,221), deaths due to valve failure have been reported (196,197). The onset of detection is between 11 and 16 years after completion of the radiation (219). Diagnosis is best made by echocardiogram (219). Valve replacement is sometimes necessary; however, the procedure may be complicated by fibrosis of surrounding tissue (219).

Coronary Artery Disease

Long-term follow-up studies indicate that patients who have received mediastinal irradiation characterized by accelerated atherosclerosis and vessel fibrosis have an increased risk of developing coronary artery disease (184,189,194,196,197,207,222,223). The vessels that are most commonly involved are the right coronary, left main, or left anterior descending coronary artery (189). The incidence of ischemic heart disease ranges from 2% to 12% (196,198,203,224,225,226 and 227). The risk, which is related to dose and volume of the heart exposed (203,225), has been reduced with modern techniques and smaller doses of radiation delivered to the coronary arteries (224). Occlusive coronary lesions are usually identified 6–12 years after therapy (224,227,228). Coronary artery disease may present in patients with no other cardiac risk factors (207). Coronary spasm may also occur (229). In an autopsy series that involved patients younger than the age of 35, 25% of irradiated

individuals versus 2.5% of age- and sex-matched nonirradiated control subjects had significant coronary artery disease (230). Large studies demonstrated a 2.6- to 8.8-fold relative risk of mortality from myocardial infarction after mediastinal radiation for Hodgkin's disease (194,198,203,224,225,231). The increase in mortality is not apparent until 10 years after irradiation. Patients at the highest risk of death from myocardial infarction are those who receive radiation at an age less than 20 years (196,197). Rutqvist et al. (232) found a threefold relative risk of death from ischemic heart disease in women with cancer of the left breast who received a highdose volume of radiation before mastectomy compared with surgical control subjects. No increased risk was found for those who received radiation to the right breast or those treated with electrons postoperatively and received lower doses to the myocardium (232). Monitoring and early intervention for signs of coronary artery disease are warranted for patients who have received irradiation to the chest. Every attempt should be made to reduce other risk factors for arthrosclerosis in patients who have received mediastinal radiation. Coronary artery bypass surgery and balloon angioplasty have been successful in patients with radiationinduced coronary artery disease (228,233). The growth factor fibroblast growth factor-b, administered during mediastinal radiation, decreased blood vessel stenosis and increased survival in an animal model but has not yet been tested in the clinic (234).

Conduction System Disease

Atrioventricular blocks are the most commonly reported conduction disorders following mediastinal radiation (202,235). Conduction disturbances, ECG changes (ST-T segment changes, decreased QRS voltage), and arrhythmias have been reported (185,190,236,237,238 and 239). In an estimated 20–30% of patients who are treated with mediastinal radiation, conduction disorders develop within 10 years of treatment (185,240). ECG changes are evident in 10–15% of patients with Hodgkin's disease who are treated through a single port (196,197). This is decreased to 2.5% when more conventional divided ports are used (241). In some patients with breast cancer who are treated for a left breast lesion, evidence of heart block develops (221). The risk increases at doses greater than 40 cGy and in those patients with preexisting coronary risk factors. Patients with pacemakers are at particular risk for development of arrhythmias due to damage to the device and interference in conduction signals (194,242).

Chemotherapy

Doxorubicin

Doxorubicin generates free radicals intracellularly that can cause myocardial membrane damage. The damage is complicated by chemotherapy-induced reductions of glutathione, which serves as a free oxygen scavenger (243). Doxorubicin exposure and cardiotoxicity have a welldocumented dose–response relationship. Von Hoff et al. (218) reviewed 4018 patients who were treated with doxorubicin and identified an exponential increase in cardiac toxicity with increasing cumulative doses. The probability of developing congestive heart failure (CHF) increased from 3% at 400 mg/m^2 to 18% at 700 mg/m^2 (218). Other studies have confirmed this dose–response effect (244,245). However, there is some degree of interpatient variability. CHF has been reported after total doses of only 40 mg/m^2, whereas other patients have received more than 1000 mg/m^2 without complication (218). Risk factors that have contributed to toxicity are a bolus schedule of administration (246), previous or concurrent mediastinal irradiation (247), very young or advanced age, a history of cardiac disease, female sex, and concomitant cyclophosphamide administration (218,244,248). Doxorubicin that is administered to children younger than age 4 is associated with thinning of the left ventricular wall as a result of inhibition of myocardial growth (249).

Toxicity may develop as acute, subacute, or late cardiotoxicity. Acute toxicity occurs within hours or days of dose. Patients may present with ECG changes, arrhythmias, pericardial effusion, CHF, and pericarditis with myocardial dysfunction (247,250) (Fig. 29-5). ECG changes have been identified in 20–30% of patients who receive doxorubicin. Rarely, sudden death following administration has been reported (251). Patients with symptomatic atrial or ventricular arrhythmias should not receive antiarrhythmic therapy (248).

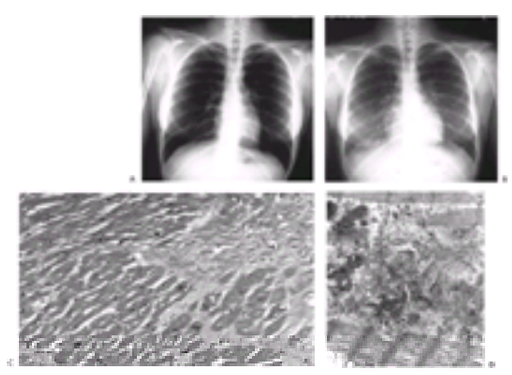

FIGURE 29-5. Doxorubicin cardiomyopathy. Films taken 3 weeks apart show the development of cardiomegaly and the ground glass infiltrates of pulmonary edema secondary to doxorubicin cardiomyopathy (A, B). Biopsy (C) depicts myocytes with enlarged and atypical nuclei associated with interstitial fibrosis. Electron microscopy (D) shows myofibril fragmentation, mitochondrial degeneration, and the accumulation of whorls of membrane proteins (×15,300) (C).

The peak time for the onset of subacute toxicity is 3 months after the last dose of therapy (218,252). Patients may present with evidence of CHF, such as tachycardia, fatigue, dyspnea, or pulmonary edema. A careful evaluation can reveal underlying abnormalities even in asymptomatic patients. Of asymptomatic patients who receive 500–600 mg/m^2 doxorubicin, subacute toxicity develops in 2–20% (218,244,250). Mortality ranges from 30% to 60% (253,254 and 255). With aggressive medical management, cardiac dysfunction usually slowly improves (245,256).

Late toxicity presents 5 or more years after the chemotherapy (194,256,257). It may be due to decompensation of a previously identified toxicity or it may develop in patients who have been without previous symptoms (194,256,257). Patients may present with arrhythmias, fibrosis, and hypertrophy. Late toxicity correlates with increased cumulative doses of doxorubicin and mediastinal irradiation (194,247). Reports of death have occurred up to 15 years after treatment (256,257).

Other Anthracyclines and Related Drugs

The cardiotoxicity that is caused by other anthracyclines has clinical and pathological features similar to those observed with doxorubicin. The clinical spectrum ranges from asymptomatic decreased myocardial contractility to heart failure or myocardial infarction. The threshold at which the risk of toxicity significantly increases is approximately 600 mg/m^2 for daunorubicin (258), 150 mg/m^2 for idarubicin (41,259,260,261 and 262), and 900 mg/m^2 for epirubicin (263,264). Epirubicin toxicity may occur as early as 8 weeks after treatment; however, a decline of left ventricular ejection fraction (LVEF) is uncommon earlier than 4 years (265) and often returns to normal limits after completion of treatment (263).

Mitoxantrone is an anthracenedione with antitumor activity similar to that of doxorubicin. Although mitoxantrone has been touted to be less cardiotoxic than doxorubicin, the nonhematological dose-limiting toxicity is also cardiotoxicity (266,267). This cardiotoxicity is cumulative, with a rapid increase in risk observed above a total dose of 160 mg/m^2 . Prior anthracycline exposure of >250 mg/m^2 increases the risk of toxicity (245,268).

Losoxantrone, an anthrapyrazole, is similar in structure to the anthracyclines and was developed due to its lower potential for causing cardiotoxicity. No relationship appears to exist between the total cumulative dose of losoxantrone and change in LVEF. In one study of patients with breast cancer, CHF developed in 1%, and 4% experienced a >20% asymptomatic decline in LVEF (269). In a dose escalation study of losoxantrone in combination with paclitaxel, CHR developed in one patient, and a >10% reduction in asymptomatic LVEF developed in nine additional patients (270).

Strategies to Reduce the Risk of Anthracycline Cardiotoxicity

The primary mechanism of treatment is prevention. Baseline imaging of myocardial contractility should be obtained for all patients. Monitoring by echocardiogram or MUGA should begin as the cumulative dose approaches the threshold dose or earlier if other risk factors for cardiovascular disease are present (194,249,271). Patients with an LVEF of <30% should not be treated with an anthracycline. Furthermore, if the LVEF is reduced 10–15% during the course of treatment, anthracycline chemotherapy should be discontinued (194,271).

The risk of cardiotoxicity caused by anthracyclines is related in part to peak plasma concentrations of the drug. Continuous infusion schedules produce lower peak plasma levels than bolus infusion and as a result are less cardiotoxic (218,244,272,273). Shapira and associates (274) demonstrated a decline in LVEF of 6% when 6-hour infusions were used to administer a total cumulative dose of 400 mg/m^2. However, a 21% reduction in LVEF was identified when therapy was administered by

20-minute bolus infusion (274). It is unclear whether different administration schedules produce differences in efficacy (194). Other strategies that ameliorate anthracycline cardiotoxicity include encapsulation within liposomes and the concurrent administration of cardioprotectants such as dexrazoxane.

Compared with the bolus administration of free drug, liposomal encapsulation results in an improved pharmacokinetic profile with a longer plasma life and better drug delivery (275,276). Liposomal doxorubicin is taken up preferentially by the reticuloendothelial cells and tumors and is less likely to be deposited in cardiac muscle (277,278 and 279). The liposomal encapsulation permits the administration of high doses of doxorubicin, without increased cardiotoxicity (136,280). Following a median dose of liposomal doxorubicin of 500 mg/m^2 (range, 192–900 mg/m^2), only 1 of 41 patients had evidence of CHF, and in this patient a biopsy was consistent with a nonanthracycline etiology (280). Liposomal doxorubicin, however, may produce acute allergic reactions (275,276,281,282).

Dexrazoxane is approved for use with anthracyclines and mitoxantrone (169,283,284,285,286,287,288 and 289). It is rapidly taken up by myocytes and converted intracellularly into a chelating agent that binds to free and bound iron, reducing anthracycline-iron complexes that contribute to the generation of toxic oxygenfree radicals (290,291,292 and 293). In previously untreated patients, differences in cardiac function can be detected by radioisotope scans after a cumulative dose of doxorubicin of 150 mg/m^2 . Inclusion of dexrazoxane into regimens that contain anthracyclines may reduce the cardiotoxicity by as much as 50%, with the effect becoming apparent after a cumulative dose of 300 mg/m^2 (294). Cumulative doses of doxorubicin that exceed 1000 mg/m^2 along with dexrazoxane have been given to patients without resultant cardiac damage (283).

Although dexrazoxane allows the dose intensity of anthracyclines to be increased, in most studies this has not led to improvement in overall survival (290,292,295,296). Rather, patients experience increased noncardiac toxicities, particularly myelosuppression, secondary to the increased dose intensity (284). Whether dexrazoxane impairs the antitumor activity of the anthracyclines remains unsettled. Several randomized trials that involved patients who were treated with doxorubicin found no difference in response rates (287,296). However, two randomized trials of patients with breast cancer found a decrease in the response rate when dexrazoxane was administered to individuals who had received cumulative doxorubicin doses of <300 mg/m^2 (291,294). As a result, dexrazoxane currently is indicated only for patients who have received a total dose of doxorubicin of >300 mg/m^2 for whom continued therapy is warranted. The recommended dose of dexrazoxane is 10:1 with doxorubicin and 30–60:1 with mitoxantrone. Dexrazoxane should be infused over 15 minutes, beginning 30 minutes before the anthracycline (287,288,294,296).

Cyclophosphamide

The dose–response relationship between cyclophosphamide and cardiac damage is noncumulative. As a single agent, cyclophosphamide is associated with cardiac complications almost exclusively at the doses used for BMT (120–270 mg/kg, in divided doses, over a few days). Cyclophosphamide toxicity may begin with transient ECG changes that include low voltage, depressed ST segments, elevated cardiac enzymes, and a reduced LVEF (297). More advanced toxicity consists of a myopericarditis that is characterized by coronary artery vasculitis, heart failure, hemorrhagic pericarditis, and effusion (298,299 and 300). Myocardial biopsy reveals capillary endothelial damage, myocardial hemorrhage, and necrosis with edema and serosanguineous pericardial effusion (202,299). The onset is fulminant, within 1 week of beginning treatment; the mortality is 20–40% (202,248,301).

Factors that influence the development of cardiotoxicity include dose, rate of drug delivery, previous exposure or concurrent administration of anthracyclines, underlying cardiac dysfunction, and mediastinal radiation therapy (194,297,298,302). Gottdiener et al. (202) evaluated 32 patients with hematological malignancies who were treated with 180 mg/kg cyclophosphamide over 4 days as part of a conditioning regimen for allogeneic BMT. Cardiotoxicity was common, with a 28% incidence of CHF, 19% incidence of pericardial tamponade, and 19% mortality. Furthermore, for patients who had received prior anthracycline therapy, the incidence of CHF was 50%. Goldberg et al. (301) reported on a series of 80 children who underwent allogeneic BMT for aplastic anemia or immunodeficiency syndromes, none of whom had prior anthracycline therapy or mediastinal irradiation. CHF developed in 25% of the patients who received more than 1.55 g/m^2 /day cyclophosphamide for 4 days, compared with 3% of patients who received <1.55 g/m^2 /day; nearly half of the cases were fatal.

With aggressive supportive care with diuretics, inotropic agents, and afterload reduction, patients who recover have no long-term sequelae (194,248). A baseline MUGA scan and continuous cardiac monitoring are indicated for patients who receive high-dose cyclophosphamide. Amifostine may offer protection against the cardiotoxicity that is associated with high-dose cyclophosphamide (85).

Ifosfamide

Although ifosfamide is an alkylating agent that is structurally related to cyclophosphamide, it produces a different pattern of cardiotoxicity. Supraventricular arrhythmias have been reported at doses of 6.25–10.0 g/m^2 over 3–5 days (303). In one patient, rechallenge with the drug resulted in a refractory arrhythmia (304). Ifosfamide is frequently used as part of the conditioning regimen for stem cell transplantation, and at these higher doses, more cardiac side effects are observed. In a retrospective study of 52 patients who were undergoing autologous transplant, cardiotoxicity developed in 17%. Although most patients had received prior treatment with doxorubicin, none had a history of CHF, angina, or arrhythmias before the chemotherapy. Symptoms occurred at 10–12 days. An elevated serum creatinine preceded the onset of CHF, suggesting that a delayed elimination of the drug may have contributed to the observed toxicity. Most patients required intensive care; one patient developed cardiogenic shock and died (305). Patients who receive ifosfamide should have kidney function tests frequently monitored to assure proper drug excretion.

5-Fluorouracil

Angina is the most common symptomatic reaction, occurring in 64% of patients who experience cardiac toxicity due to 5-FU (306). Arrhythmias, CHF, infarction, cardiogenic shock, and sudden death have been reported (307,308). Although the overall incidence of cardiotoxicity is low, it appears to be significantly higher in patients with underlying coronary artery disease (approximately 5% vs. 1% in patients without such a history). This is probably due to increased coronary vasomotor tone and spasm (244,309,310). Life-threatening ischemia has occurred among patients with normal coronary arteries (194,311). Mediastinal radiotherapy and continuous infusion schedules of 5-FU are risk factors for ischemia (309). The addition of leucovorin to 5-FU also increases the risk (312).

Most patients have reported typical precordial pain, sometimes radiating to the arms or jaw, which can be associated with nausea, vomiting, and diaphoresis. Abnormalities on ECG may include diffuse ST-segment depression or elevation, peaked T waves or T-wave inversions, prolongation of the QT interval, and atrial or ventricular arrhythmias. Toxicity can be progressive with repeated dosing (307,309). Clinical toxicities are usually identified after the third cycle of bolus infusion and during the first 3–4 days of a continuous infusion schedule (309). Symptoms generally start within hours of exposure to the drug and resolve after discontinuation of the 5-FU, spontaneously or after the administration of nitrates. Aggressive supportive measures with intravenous inotropic agents, diuretics, and vasodilators may be necessary. Although the ECG returns to normal in most patients, continued administration of 5-FU can lead to infarction. Reversible regional or global left ventricular wall motion abnormalities have been demonstrated. Although symptoms may improve with drug cessation, cardiomegaly is not always reversed (313). Neither nitrates nor calcium channel blockers have reliably demonstrated efficacy in preventing 5-FU–related ischemia (307,309). Relapses on reinstitution of therapy are frequent, and thus the risks and benefits of further treatment with 5-FU should be weighed carefully (194,311).

Paclitaxel

Initial reports of cardiotoxicity due to paclitaxel administration have been attributed to severe hypersensitivity reactions that occur within the first few minutes of infusion (314). Hypotension developed in as many as 25% of these patients and was linked to the cremaphor vehicle (5,315). The prophylactic use of steroids and histamine blockers has significantly reduced the severity of these reactions (316,317). Cardiotoxicity may also present as CHF, hypotension, arrhythmias, conduction disturbances, and ischemia (316,318,319 and 320). The most common finding is asymptomatic sinus bradycardia (318,320). This complication requires no treatment and does not preclude further use of the drug. Whether preexisting cardiac dysfunction is a predictor of toxicity remains controversial. Nevertheless, the risk for patients without cardiac risk factors is minimal. In a retrospective review of 3400 patients who were treated with paclitaxel as a single agent, the incidence of advanced heart block, atrial or ventricular arrhythmias, and myocardial infarction or ischemia was below 1% for all (318). The risk of toxicity does not appear to be related to cumulative dose (318). Patients in whom symptomatic arrhythmias or heart block have developed have been rechallenged safely under controlled conditions, which may include the use of continuous cardiac monitoring and pacemaker placement (318,320).

In contrast, if paclitaxel is given in combination with doxorubicin, the observed toxicity is dramatically increased, with ventricular dysfunction developing at significantly lower cumulative doses of doxorubicin (243). One way that paclitaxel potentiates the cardiotoxicity of doxorubicin is by decreasing doxorubicin clearance (288,321,322). Paclitaxel also increases cellular retention of doxorubicin (243,323). After just four cycles of chemotherapy (200 mg/m^2 paclitaxel each cycle and doxorubicin cumulative dose of 240 mg/m^2), 20% of patients experience a decline in LVEF below normal, and 4% have symptoms of heart failure. After eight cycles of therapy (doxorubicin cumulative dose of 480 mg/m^2), approximately 50% of patients have depressed contractility, and 20% experience symptomatic CHF (288). Results are similar for chemotherapy-naive individuals and for patients who are heavily pretreated with anthracyclines (324,325).

Different strategies have been used to decrease the pharmacokinetic interaction between paclitaxel and doxorubicin. Alteration in dose administration and substitution of epirubicin or losoxantrone for doxorubicin and docetaxel for paclitaxel have been recommended (270,319,326). The incidence of toxicity is reduced to <5% when the total cumulative dose of doxorubicin is kept below 360 mg/m^2 (321,323,325). Controversy remains over whether the duration of the paclitaxel infusion influences the risk of cardiac toxicity. Some reports indicate that pharmacokinetic interaction is decreased when paclitaxel is administered as a 3-hour infusion (243,327). If a

minimum of 4 hours elapses between administration of the agents, the toxicity is reduced (328,329). Because paclitaxel does not alter the pharmacokinetics of epirubicin, this is a less toxic combination than the paclitaxel-doxorubicin regimen (139,326). Another alternative is to use docetaxel rather than paclitaxel, since docetaxel does not alter the pharmacokinetics of doxorubicin (319,330).

Etoposide

A few reports of myocardial infarction and CHF during etoposide infusions have been published. Some patients had preexisting coronary artery disease, and others received doxorubicin, cisplatin, bleomycin, or mediastinal irradiation (180,331,332). Hypotension occurs frequently when etoposide is administered by an intravenous infusion that lasts less than 30 minutes but is reversible with intravenous fluids and lengthening of the infusion rate (333).

Amsacrine

Amsacrine (AMSA) is an agent that is used primarily in the treatment of acute nonlymphocytic leukemia. Toxicity results from the production of free radicals in a fashion similar to that of anthracyclines (334). Toxicity ranges from subtle ECG changes to arrhythmias, CHF, and myocardial infarction (272,335). The incidence of arrhythmias is below 1% but can result in sudden death (272,336,337). In one case, biopsy revealed infarction and myocardial necrosis in a patient who did not have underlying cardiac disease (338).

The risk of toxicity has been related to the total dose of AMSA, prior anthracycline exposure, and the rate of AMSA infusion (194). No evidence of cumulative dose effect has been found (336). In one series, when the combination of anthracycline and AMSA dose exceeded 900 mg/m^2 , abnormalities in cardiac function developed in most patients (339). Hypokalemia may be a risk for the development of arrhythmias (272,335). However, in a large review, most affected patients had normal serum potassium levels (336). In one study, AMSA was administered to patients with a prior history of arrhythmias, all of whom tolerated the infusion without incident if the potassium level was above 4.0 mEq/l (334,340).

Symptoms, usually presenting with the first course of treatment (336), may begin as the drug is being infused or within 4 hours (272,335). Echocardiographic changes and evidence of CHF appear within a week (339,341) and return to baseline on discontinuation of the drug (336,339,341). Symptoms of CHF may require the use of digitalis and diuretics (339).

Vinca Alkaloids

Several cases of myocardial ischemia or infarction have been reported in association with the combinations of vinca drugs with cisplatin and bleomycin (120,342,343). In some cases, cisplatin was believed to be the causative agent (120). In other reports, vincristine alone was associated with myocardial infarction (344,345). In addition to myocardial ischemia, vinca alkaloids have been associated with cardiac autonomic neuropathies that result in orthostatic hypotension and an abnormal heart rate response (346,347). These abnormalities were found more often among patients who received high cumulative doses (347) or inadvertent overdose (348).

Estrogens and Estramustine

Diethylstilbestrol, at doses of ³3 mg/day, is associated with CHF, myocardial ischemia and infarction, and thromboembolic episodes in up to 10% of patients (349,350 and 351). Lower doses (1 mg/day) retain activity against prostate cancer and are not associated with an excess incidence of cardiovascular events (350). Although the antineoplastic properties of estramustine are related to the inhibition of microtubule assembly, the cardiovascular toxicities appear to be linked to the estrogenic properties. The incidence of myocardial ischemia or infarction and cardiomyopathy is in the range of 10–30%, with the greatest risk reported in patients with prior cardiac disease (351,352 and 353). Cardiac complications are most evident during the first year of therapy and have been correlated with elevated luteinizing hormone levels (354).

Biological Response Modifiers

Interferons (a and g) and interleukins (IL-2) can produce cardiotoxicity (155,355,356,357,358 and 359). Interferon has been associated with supraventricular and ventricular arrhythmias, myocardial infarction, cardiomyopathy, and sudden death. Neither the dose nor the duration of therapy has been correlated with toxicity (355). The risk appears to be increased among patients with a prior history of coronary artery disease and in individuals who were previously treated with an anthracycline (360). Although most patients who experience atrial arrhythmias or myocardial ischemia have underlying heart disease, those in whom ventricular arrhythmias or cardiomyopathy develop may have had no such history. Onset of symptoms usually occurs within 5 weeks of treatment (355). Most toxicities resolve after discontinuation of the drug if the patient has no prior history of coronary artery disease (355), but irreversible cardiomyopathy has been reported in a patient who was previously treated with doxorubicin (356).

High doses of IL-2 cause a myriad of adverse events. The most serious event is the immediate onset of decreased systemic vascular resistance and capillary leak syndrome. This is characterized by hypotension, tachycardia, decreased LVEF, pulmonary and peripheral edema, oliguria, and renal failure (156,159). Cardiac toxicities have also included atrial and ventricular tachyarrhythmias, bradycardia, complete heart block, myocardial ischemia and infarction, myopericarditis, and, rarely, sudden death (155,156,357,359,361,362). Symptoms develop within 120 hours after the initiation of treatment and can last for up to several hours (363). Changes on ECG range from nonspecific ST-segment elevation (359) to arrhythmias in up to 10% of patients (155,156). No correlation has been found with prior cardiac dysfunction. However, a relationship appears to exist between IL-2 dose and arrhythmias. Elevations of the cardiac enzymes in plasma may precede the onset of arrhythmias and are not associated with ischemic vascular disease (155,359). A reduction in LVEF may be evident. Vasopressor support, mechanical ventilation, or antiarrhythmic therapy is often required during the course of treatment, but symptoms generally resolve rapidly after discontinuation of the drug (155,156,363).

Trastuzumab

Trastuzumab (Herceptin) is a humanized monoclonal antibody that targets the HER2 receptor. Although the exact mechanism is unclear, trastuzumab has been associated with cardiotoxicity in 4–7% of patients when used as a single agent (364,365). Trastuzumab cardiotoxicity is additive and synergistic when given in combination therapy (366,367). When the drug is administered with paclitaxel, toxicity has developed in 11% (10 of 91 patients), whereas CHF developed in only 1% of patients with paclitaxel alone (368). The risk of toxicity increases further when trastuzumab is administered with an anthracycline. In a phase III study of individuals with metastatic breast cancer, patients were randomized to doxorubicin alone or in combination with trastuzumab. Heart failure developed in only 6% of patients treated with the single agent, versus 27% of those on the combination arm (367,369). Most patients in whom heart failure develops achieve symptomatic relief with discontinuation of the agent and appropriate medical management. Patients should be encouraged to undergo long-term follow-up for potential delayed toxicity, which is common to anthracycline toxicity. Caution should be used when administering trastuzumab to women with prior cardiac dysfunction.

MANAGEMENT OF ADVANCED HEART FAILURE

JOSEPH G. ROGERS
MICHAEL W. RICH

> Dropsy is usually produced when a patient remains for a long time with impurities of the body following a long illness. The flesh is consumed and becomes water . . . The abdomen fills with fluid; the feet and legs swell; the shoulders, clavicles, chest and thighs melt away. If you begin treatment at the beginning, before the accumulation of water becomes excessive, you must administer purgatives which evacuate water or phlegm...the regimen of food, drink, exercise and walking will be until the patient becomes thin and dry, but only until the flesh becomes as strong as possible. This illness is fatal, above all through the progression of ascites. [Regardless of cause] the treatment is similar, but few survive. —Hippocrates

This description, written long ago, provides an interesting and insightful historical picture of the clinical syndrome and management of heart failure (1). However, the later stages of this disease remain strikingly similar to those described by Hippocrates despite remarkable advances in our understanding of heart failure pathophysiology, cardiac diagnostics, and therapeutic modalities. The accumulated knowledge has left several notable voids: The majority of the management strategies have excluded patients with the most advanced stages of the disease, and end-of-life issues have not been adequately studied. This chapter defines heart failure as a public health crisis by virtue of its prevalence, incidence, cost, morbidity, and mortality. The rationale for heart failure therapy is outlined, and standard pharmacotherapeutic approaches are described. Comprehensive outpatient care strategies are reviewed and linked to palliative care. Newer heart failure treatments, including biventricular pacemakers, surgical techniques to improve cardiac performance, and mechanical ventricular assist devices, likely transcend the definition of palliative care and are beyond the scope of this chapter.

EPIDEMIOLOGY

The management of systolic and diastolic cardiac dysfunction remains a clinical challenge for primary care physicians and cardiovascular specialists. Heart failure is the only cardiovascular disease that is increasing in prevalence. Nearly 5 million Americans have heart failure, and approximately 550,000 new cases are diagnosed annually (2). The annual incidence of heart failure in the United States is expected to exceed 800,000 by the year 2010 (3). The etiology of this “epidemic” is multifactorial but can largely be attributed to the aging U.S. population and advances in the early diagnosis and treatment of other cardiovascular diseases, particularly acute myocardial infarction. Heart failure affects 1% of individuals in their fifth decade of life but nearly 10% of the octogenarian population (2). Frequent and recurrent hospitalizations are common. The 90-day readmission rate following an index heart failure hospitalization ranges between 36% and 57% (4,5 and 6). The cost of managing these patients has been estimated as high as $38 billion annually, with nearly 60% spent on inpatient care (7).

PATHOPHYSIOLOGY

The heart must perform two mechanical functions to provide adequate blood flow throughout the body: It relaxes to allow the ventricular chambers to fill and contracts to eject the blood into the peripheral vasculature. Heart failure may result from abnormalities of either left ventricular (LV) relaxation (diastolic dysfunction) or contraction (systolic dysfunction). Coronary artery disease accounts for the majority of systolic heart failure (8). Other important etiologies include hypertension, chronic valvular heart disease (particularly chronic mitral and aortic regurgitation), and other nonischemic cardiomyopathies, including idiopathic dilated cardiomyopathy, heritable cardiomyopathies, and alcoholic cardiomyopathy. Approximately 40% of cases are attributable to diastolic dysfunction (9). The prevalence of diastolic heart failure is higher in the elderly and is commonly associated with hypertension and LV hypertrophy, obesity, diabetes, ischemic heart disease, and infiltrative diseases such as amyloidosis. Familial hypertrophic cardiomyopathies also result in diastolic dysfunction. Although the. annual mortality from diastolic heart failure is lower than that associated with systolic heart failure, the symptoms, exercise limitations, and hospitalization rates are similar to those experienced by patients with systolic dysfunction (10).

PROGNOSIS

The two primary modes of death in heart failure are progressive pump failure and cardiac arrhythmias. The frequency of these events correlates with symptom severity. Patients with New York Heart Association (NYHA) functional class II–III symptoms (Table 30-1) are more likely to die of an arrhythmia, whereas those with class IV symptoms more frequently die of progressive pump failure (11). Etiology, ejection fraction (EF, a measure of systolic function), hemodynamic parameters, neurohormone levels, exercise performance, and symptom severity also influence prognosis and management (12,13,14,15,16,17 and 18). Arguably the most convenient tool for clinical use is the NYHA functional classification, which can be readily determined from a carefully obtained history (Table 30-1). The annualized mortality risk can be estimated using the NYHA classification and ranges from 5% to 50% depending on the symptom severity. These data are concordant with the Framingham Heart Study, which demonstrated a 1- and 5-year heart failure mortality of 43% and 75% in men and 36% and 62% in women (25). These mortality risks, which are higher than most forms of cancer, highlight the importance of end-of-life planning for patients with advanced heart failure (26) (Fig. 30-1).

NYHA class	Definition	Annualized mortality without therapy (references)
I	Evidence of left ventricular dysfunction but capable of performing all levels of exertion	5–10% (19,20)
II	Comfortable at rest and with normal exertion; vigorous exertion causes excessive fatigue, dyspnea, chest pain, or palpitations	10–15% (21–23; DIG, unpublished results)
III	Comfortable at rest, but limited activity results in symptoms	15–20% (21–23; DIG, unpublished results)
IV	Symptomatic at rest; symptoms worsen with minimal activity	50% (24)

DIG, Digitalis Investigation Group; NYHA, New York Heart Association.

END-OF-LIFE CARE: STUDY TO UNDERSTAND PROGNOSES AND PREFERENCES FOR OUTCOMES AND RISKS OF TREATMENTS (SUPPORT) TRIAL

Physicians and patients are less likely to discuss end-of-life issues in heart failure than in other serious illnesses, such as the acquired immunodeficiency syndrome and cancer (27). This may result from the perception that heart failure is more “treatable” than malignant disease. Further, the clinical course of heart failure negatively impacts end-of-life discussions (28) (Fig. 30-2). The terminal phase of malignant disease is typically heralded by failure of aggressive treatment modalities and a significant functional decline, at which point a philosophical change from aggressive therapies to palliation is contemplated. Heart failure produces a gradual decline in functional capacity, punctuated by symptomatic exacerbations that often result in hospitalization. Timing the implementation of palliative care practices in this setting is more difficult. The SUPPORT trial demonstrated the challenges of predicting heart failure mortality. More than half of the patients with heart failure who died in SUPPORT had a predicted 6-month survival that exceeded 50%, even 3 days before death (29).

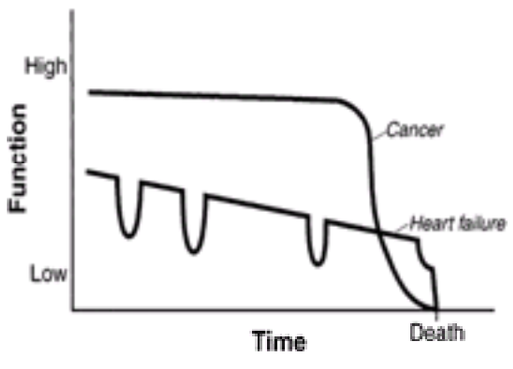

FIGURE 30-2. The clinical course of patients with cancer and heart failure. Individuals with malignancies often maintain a relatively high functional level until the disease progresses despite therapy. Heart failure is characterized by a slow functional decline punctuated by symptomatic exacerbations. (Redrawn from Lynn J. Serving patients who may die soon and their families: the role of hospice and other services. JAMA 2001;285:925–932, with permission.)

The SUPPORT trial provided meaningful insights into quality of life issues and the nature of treatment that was provided to 1404 patients with heart failure during the final months of life. Of these individuals, 38% died within the first year of follow-up. During the 6 months before death, patients experienced more daily activity dependencies and reduced activity levels but did not perceive a reduction in quality of life (29). These individuals remained capable of expressing their wishes, and pain relief and comfort care, rather than extension of life, became increasingly important. Twenty-three percent of the patients preferred to forgo resuscitation efforts (30). Only 25% reported this preference to their physician, and physicians incorrectly perceived the patients' wishes in 24% of cases. As death became imminent, dyspnea, confusion, and severe pain were prominent symptoms (31). Cardiopulmonary resuscitation, mechanical ventilation, or feeding tube placement was performed in nearly 40% of patients during the final 3 days of life. Of the octogenarians with heart failure who died in SUPPORT, 65% expired in a hospital or nursing home. Only 3% of heart failure patients died with hospice care, compared with 10% of those with malignant disease.

HEART FAILURE PHARMACOTHERAPY

Rationale

Our current understanding of the pathophysiology of heart failure is one of neurohormonal activation in response to cardiac injury or reduced cardiac output (32,33). Neurohormone activation is initially an adaptive response that is intended to improve cardiac output and maintain blood pressure and organ perfusion. However, chronic activation of the renin-angiotensin system and the sympathetic nervous system causes progressive LV dilation and further deterioration in cardiac performance. The current approach to heart failure pharmacotherapy is focused on inhibition of the deleterious effects of angiotensin II and norepinephrine on the heart and vasculature. Several other neurohormones and small peptides are maladaptively regulated in heart failure, and the effects of altering these substances are under investigation.

Overview

Table 30-2 provides a guide to the pharmacotherapy of systolic heart failure (EF £40%). The standard regimen includes an angiotensin-converting enzyme (ACE) inhibitor, b-adrenergic antagonist, digoxin, a loop diuretic, and spironolactone if the patient has NYHA class III–IV symptoms (34). Because several comorbid diseases may accompany heart failure, the treatment must be individualized, taking into consideration the complexity and cost of the medical regimen, tolerability, potential drug interactions, and compliance issues.

Agent(s)	NYHA functional class			
	I	II	III	IV
ACE inhibitors	+	+	+	+
Angiotensin II receptor blockers		+	+	
β-Adrenergic blockers	?+	+	+	?+
Spironolactone			+	+
Digoxin		+	+	+
Loop diuretics		+	+	+
Hydralazine/nitrates		+	+	?+
Positive inotropic agents				?+

ACE, angiotensin-converting enzyme; NYHA, New York Heart Association; +, agent(s) has demonstrated efficacy; ?+, fewer data support usage.

TABLE 30-2. MEDICAL THERAPY FOR SYSTOLIC HEART FAILURE

Angiotensin-Converting Enzyme Inhibitors

Activation of the renin-angiotensin pathway leads to accumulation of angiotensin II, a molecule with complex physiological actions, including vasoconstriction, salt and water retention, stimulation of thirst, and myocyte hypertrophy (35,36). ACE inhibitors prevent the production of angiotensin II via blockade of ACE. Numerous prospective, randomized clinical trials, involving more than 7000 patients with heart failure, have conclusively shown that ACE inhibitors slow disease progression, reduce hospitalizations, and decrease mortality (37). Importantly, ACE inhibitors provide these benefits across the symptomatic spectrum.

Angiotensin II Receptor Blockers

The angiotensin receptor blockers (ARBs) are a newer pharmaceutical class that inhibits the effects of angiotensin II by blocking its receptor. Inhibition at the receptor level theoretically provides more complete blockade, as non– ACE-dependent pathways also produce angiotensin II. Several clinical trials have evaluated the ARBs in heart failure. The second Evaluation of Losartan in the Elderly trial randomized 3152 patients ³60 years of age with an EF of <40% to receive either an ACE inhibitor (captopril) or an ARB (losartan) (38). Patients who received losartan had a similar 18-month survival to the captopril-treated group, and fewer permanent withdrawals occurred from losartan therapy. In the Valsartan Heart Failure trial, the combination of an ACE inhibitor and an ARB (valsartan) was compared to an ACE inhibitor alone. Overall, combination therapy was associated with a 13% reduction in the composite end point of death, hospitalization, resuscitated sudden death, or the need for intravenous inotropic or vasodilator support (39). The benefits of using both an ARB and an ACE inhibitor were limited to patients who did not receive a b-blocker. Until more data are available regarding the efficacy of the ARBs in heart failure, ACE inhibitors should remain first-line therapy.

b-Adrenergic Blockers

b-Blockers have become standard of care for the treatment of systolic heart failure. The b_1-selective b-blockers bisoprolol and metoprolol succinate and the third-generation agent carvedilol, a nonselective b-blocker with a-blocking and antioxidant properties, have been shown to improve heart failure outcomes (11,40,41 and 42). The b-blocker trials have consistently demonstrated symptomatic improvements, increased EF, reduced hospitalizations, and decreased mortality. The addition of a b-blocker to an ACE inhibitor produces an incremental mortality risk reduction of approximately 35% in patients with heart failure. To date, the majority of patients who have been enrolled in the b-blocker trials have had moderate symptoms (classes II and III). One trial evaluated the use of carvedilol in patients with stable class IV symptoms and was terminated prematurely because the carvedilol-treated patients had a 35% mortality reduction compared to placebo (43).

Spironolactone

The potassium-sparing diuretic spironolactone or placebo was added to an ACE inhibitor and a loop diuretic in the Randomized Aldactone Evaluation study (44). Spironolactonetreated patients with class III–IV symptoms experienced a 30% relative mortality reduction during a mean follow-up period of 24 months. The survival advantage that was demonstrated with this agent has been attributed to aldosterone antagonism, another of the maladaptively up-regulated neurohormones.

Digoxin

Digoxin, the oldest heart failure pharmaceutical, is a useful adjunct when added to a regimen that includes an ACE inhibitor and a b-blocker. The Digitalis Investigation Group trial randomized 6800 patients with systolic heart failure to receive either digoxin or placebo in addition to an ACE inhibitor and a loop diuretic (45). Digoxin did not reduce mortality, but it did reduce all-cause and heart failure hospitalizations. Digoxin also decreases the likelihood of symptomatic decline (46,47).

Diuretics

Diuretics are a critical component of heart failure therapy. Maintaining normal intra- and extravascular volume improves symptoms and exercise performance and reduces the hospitalization risk. Loop diuretics affect a high-volume diuresis when administered at appropriate doses. The addition of metolazone to a loop diuretic may further increase urine output. Patients with mild heart failure (class I) may require little if any diuretic on a daily basis. These patients can be taught to adjust their diuretic dose based on changes in body weight and the signs and symptoms of volume overload.

Hydralazine and Nitrates

The combination of hydralazine and isosorbide dinitrate is superior to placebo and the a-antagonist prazosin in reducing heart failure mortality (22). Compared to ACE inhibitors, hydralazine and nitrates have a similar effect on exercise tolerance but a less potent impact on mortality (23). Hydralazine and nitrates do not interfere with established neurohormonal pathways and therefore fit less well into our current understanding of heart failure pathophysiology. Nonetheless, this combination remains useful in patients with significant renal insufficiency and in those who are intolerant of ACE inhibitors and ARBs.

Inotropic Therapy

The role of inotropic therapy, including the b-adrenergic agonists (e.g., dobutamine) and the phosphodiesterase inhibitors (e.g., amrinone, milrinone), in patients with heart failure remains controversial. These agents increase myocardial contractility and improve hemodynamics, often resulting in symptomatic improvement. However, clinical trials of nondigitalis inotropic agents have consistently demonstrated excess mortality in the treatment arm (48,49,50 and 51). Cardiac arrhythmias mediate much of the excess mortality and are independent of the specific agent administered (49,51,52). Despite these observations, inotropic agents are administered to patients with severe heart failure to provide symptomatic relief and reduce hospitalizations. Aside from digoxin, none of the currently available inotropic agents can be administered orally. Intravenous b-adrenergic agonists and phosphodiesterase inhibitors can both be used as intermittent or continuous infusions. Intermittent infusions provide symptomatic palliation in up to 40% of patients with class IV heart failure (53,54) and have been shown to reduce subsequent hospitalizations in observational studies (55). However, intermittent inotropic therapy has not been tested in a placebo-controlled trial. The observed benefits in these studies may result from frequent encounters with health care providers, more intensive education, and the use of diuretics when early signs of volume. overload are detected. Continuous infusions of inotropic drugs have been used as end-of-life therapy for patients who are in cardiogenic shock or who have severe hemodynamic compromise. Inotropes are also used to “bridge” patients to other advanced heart failure therapies, including mechanical ventricular support and cardiac transplantation.

MANAGEMENT OF DIASTOLIC DYSFUNCTION

Evidence-based guidelines have been established for the management of systolic heart failure, but similar recommendations for the treatment of diastolic dysfunction are lacking. A major contributor to this knowledge deficit has been the lack of an inexpensive noninvasive method to diagnose diastolic heart failure reliably. Echocardiographic diagnostic criteria have been proposed that rely on measurement of blood flow characteristics across the mitral valve. Patients with mild diastolic dysfunction have evidence of impaired early LV relaxation, whereas individuals with more severe diastolic dysfunction exhibit a pattern of “restrictive” LV filling. In these patients, LV pressure is elevated, and left atrial contraction contributes relatively little to ventricular filling (56).

The primary strategy for managing heart failure with preserved LV systolic function is treatment of the underlying disease, which is most frequently hypertension or ischemic heart disease. Patients with diastolic heart failure are characteristically intolerant of atrial fibrillation, making restoration and maintenance of sinus rhythm important. Measures to control intravascular volume include dietary sodium restriction and the liberal use of diuretics. At present, no drug therapy significantly improves the relaxation properties of the heart. The pharmacotherapy of diastolic heart failure is therefore targeted at slowing the heart rate, controlling blood pressure, relieving ischemia, and promoting regression of LV hypertrophy. ACE inhibitors, calcium channel blockers (particularly the nondihydropyridines), b-blockers, and ARBs are most commonly used (57). A single agent or a combination of drugs with differing mechanisms of action is initiated and titrated to achieve symptomatic improvement. The treatment of diastolic dysfunction is often challenging, as symptomatic improvement may remain elusive despite multidrug therapy.

ROLE OF DISEASE MANAGEMENT IN END-STAGE HEART DISEASE

The concepts that underlie disease management are similar to those of a hospice in that a multidisciplinary, comprehensive, patient-focused approach is taken to the delivery of medical care. Further, heart failure disease management programs may also manage comorbid conditions. Several notable differences between hospice and disease management are evident. The emphasis of disease management is placed on reduction of resource use through aggressive follow-up targeted at early symptom detection and treatment. Disease management uses an evidence-based approach to medical therapy, including medication titration, and promotes patient education regarding dietary and fluid restrictions, self-monitoring techniques, and medication compliance. To date, little emphasis has been placed on providing comfort or palliative care in the context of heart failure disease management programs.

Multiple disease management strategies have improved outpatient heart failure outcomes. These protocols are typically initiated during a hospitalization, a time when patients may be more receptive to learning about heart failure and its treatment. This is followed in the outpatient setting by a period of enhanced patient contact, either through a clinic or by telephone. The educational efforts continue during the early posthospitalization period and are supplemented by queries directed at eliciting signs and symptoms of early clinical decompensation. As the patient demonstrates clinical stability, the frequency of contacts decreases. If he or she requires an emergency

room visit or hospitalization for heart failure, the cycle of intensive monitoring begins again.

A large portion of the published experience with disease management is from observational studies using patients as their own historical controls. These studies have included small numbers of patients followed for relatively short periods of time (58). Although such trials have inherent potential biases, outcome improvements have been consistent (58) (Table 30-3).

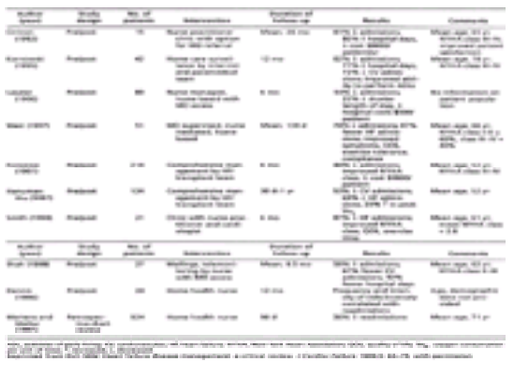

TABLE 30-3. NONRANDOMIZED TRIALS IN HEART FAILURE DISEASE MANAGEMENT

Fewer randomized trials of disease management have been published. Rich and associates (59) randomized 98 hospitalized geriatric patients to usual care or an intervention that included patient education, medication review, consultation with a social worker to expedite hospital discharge, dietary teaching, and close outpatient follow-up. Those who received the intervention had a 27% reduction in 90-day readmissions and fewer total hospital days than the usualcare group. A larger study using the same intervention randomized 282 patients and demonstrated a trend toward improvement in 90-day readmission-free survival in the intervention arm (60). The intervention decreased all-cause and heart failure readmissions, and fewer patients were readmitted multiple times. Quality of life measures improved more in the intervention group, and the cost of care was reduced by $460 per patient during this short follow-up period. Stewart and associates (61) studied 97 hospitalized patients who received predischarge education followed by a home visit 1 week later to assess patient knowledge and compliance and to detect clinical decompensation. Additional services and education were provided to those who demonstrated a knowledge deficit or noncompliance. Fewer intervention patients had unplanned hospitalizations, multiple readmissions, or out-of-hospital death. After 18 months, these patients experienced a nearly 50% reduction in the risk of hospitalization or out-of-hospital death (62).

Naylor et al. (63) evaluated comprehensive discharge planning in a geriatric population with heart failure or angina/myocardial infarction. The intervention included an assessment of patients' needs, patient and caregiver education, and coordination of postdischarge care. Nursing support was available by phone during the hospitalization and for 2 weeks following discharge. Patients who were randomized to the intervention had a 12% reduction in rehospitalizations. The effect of the intervention, however, was limited to the period during which the patient was being closely followed. To overcome this limitation, the period of observation was extended by adding outpatient services including home nursing visits and a prolonged period of contact in a broader population that included patients with heart failure (64). This intervention reduced 6-month readmissions by 45%, with fewer patients requiring multiple readmissions, fewer admissions related to the index hospitalization, and a significant reduction in hospital days per patient. The effects of improved access to primary care physicians was evaluated in a cohort of severely ill patients with heart failure, chronic lung disease, or diabetes in one of nine Veterans Administration Hospitals using an intervention that included patient education, discharge planning, and patient follow-up (65). This intervention resulted in a higher monthly readmission rate (0.19 vs. 0.14, $p = .005$), more hospital days per patient (10.2 vs. 8.8, $p = .041$), and no quality of life improvement.

Cline and associates (66) evaluated a disease management program focused on patient education and self-management techniques that provided access to a nurse-directed heart failure clinic for 1 year after an index admission. Mortality and quality of life did not differ between groups, but fewer readmissions and hospitalizations occurred in the intervention arm. Ekman and colleagues (67) described a nurse-monitored outpatient clinic that focused on early symptom detection, appropriate medical therapy, and education. This intervention did not improve symptoms, reduce readmissions, or alter the mortality (67). Jaarsma et al. (68) demonstrated that an intervention providing heart failure education in the hospital and at home during the week after discharge resulted in better self-care behaviors and a trend toward fewer readmissions. Finally, Serxner and associates (69) provided education to an outpatient population through serial mailings. This resulted in a heightened recognition of the importance of dietary sodium reduction as well as limitations in dietary sodium intake. Intervention patients were more compliant with diet, weight monitoring, and medications and were more confident in their ability to manage their disease. This intervention also resulted in greater improvements in perceived health status.

A meta-analysis of the randomized heart failure disease management trials did not demonstrate a mortality reduction with these strategies (70). Although most trials were unable to demonstrate a statistically significant reduction in hospitalizations, studies that used a multidisciplinary team approach consistently showed fewer hospitalizations, shorter hospital stays, reduced total hospital days, and fewer patients who required multiple readmissions. Only one of five trials demonstrated a positive impact on patientperceived quality of life, but seven of eight trials reported cost reductions in the intervention arm.

PALLIATIVE CARE IN HEART FAILURE

Little has been written about appropriate end-of-life care in heart failure. However, the severity of symptoms and the high morbidity and mortality that are associated with advanced heart failure support the application of palliative care principles to this disease.

Symptom relief is probably the most important palliative issue from the patient's perspective. Because heart failure symptoms vary from patient to patient, an individualized approach to pharmacotherapy is essential. Intra- and extravascular volume overload is a common problem that may manifest as exertional dyspnea, nocturnal dyspnea, abdominal fullness and discomfort, anorexia, and peripheral edema. Nonpharmacological management of volume overload should include daily weight monitoring and careful attention to dietary sodium and fluid intake. Food frequency questionnaires, completed by the patient or the caregivers (or both) provide important insights and facilitate targeted teaching. Patients should be instructed to report weight increases of more than 3–4 lb, as subtle weight increases often antedate worsening symptoms and are useful in directing diuretic therapy. Dietary sodium restriction is a critical component of fluid management. Patients should be counseled on a 2-g sodium diet, recognizing that many individuals are unable to achieve this level of dietary restraint consistently. Fluid restriction (2 liters/day) is valuable for some patients, particularly those with hyponatremia that may result from excess free water intake or the natriuretic effects of diuretics.

Flexible doses of loop diuretics (furosemide, torsemide, bumetanide) are the mainstay of the pharmacological management of excess volume. Patients who remain fluid overloaded despite standard diuretic doses should have the dose doubled, receive additional doses, or have metolazone added to the regimen. Augmented diuresis may be required for several days until the volume status returns to normal, at which time the baseline diuretic regimen can be resumed. Combination diuretic therapy should be used cautiously, as rapid reductions in intravascular volume (overdiuresis) and severe electrolyte abnormalities may occur. Patients who do not respond to an aggressive regimen of oral diuretics due to splanchnic congestion or poor absorption typically respond to intravenous diuretics. Nitrate preparations and morphine can also be used to improve dyspnea. Both agents are venodilators that reduce cardiac preload and pulmonary congestion. Morphine also has anxiolytic properties that are useful in acute or chronic dyspnea from heart failure.

Fatigue is a challenging heart failure symptom for patient and physician. The etiology of fatigue is multifactorial and may include insufficient cardiac output at rest and with activity, lactic acidosis (71), structural and functional changes in skeletal musculature (72,73 and 74), diminished respiratory reserve (75,76 and 77), impaired sleep, and depression (78,79). Fatigue that results from severe impairment of cardiac output may improve with inotropic support (80). Aerobic exercise, performed in formal or informal settings, improves exercise tolerance and decreases the physical limitations that are associated with advanced heart failure (81,82,83 and 84). Altered sleep patterns, including sleep-related breathing disorders and insomnia, are common in patients with heart failure and may contribute to fatigue (85).

Nausea and cachexia are common complaints in the later stages of heart failure. Nausea should prompt a thorough medication review to rule out an iatrogenic etiology. Right heart failure can cause nausea and may respond to enhanced diuresis. In some cases, antiemetics may be required for symptomatic relief. Heart failure–associated anorexia has been attributed to elevated circulating levels of tumor necrosis factor-a (86,87). Pharmacological blockade of tumor necrosis factor-aresults in improved cardiac remodeling and functional status, but there is currently no evidence to suggest that blockade of this pathway reverses anorexia or reduces mortality in humans (88).

ROLE OF THE HOSPICE IN HEART FAILURE CARE

The role of formal hospice programs in providing care to the advanced heart failure population has not been well studied. St. Christopher's Hospice in London reported the management of 19 heart failure patients with a mean age of 73 years (89). Common symptoms included weakness, breathlessness, drowsiness, and anorexia. Nonphysical needs included patient and family adjustments to dying, caregiver exhaustion, family psychological distress, and communication difficulties between the patient and family members or caregivers. The hospice provided psychosocial support, bereavement follow-up, and medication adjustments (principally analgesics and anxiolytics). Two patients required paracentesis for symptom relief. The authors concluded that palliative care specialists can provide an appropriate level of care to this population and that the needs of these patients are not significantly different from those of patients with malignancies. Hope Hospice of Florida has reported the results of managing seven patients with heart failure (90). Inpatient hospital days were reduced from 17.3 per 100 days to 0.66 per 100 days following enrollment into the hospice, and this was associated with a projected annual cost reduction of $45,680. Interestingly, local physicians were concerned that hospice referrals were being made “too soon,” but the 14- and 90-day mortality were 35% and 72%, respectively. A valuable innovation of this hospice was placing a “cardiac comfort care kit” in the home that included intravenous furosemide, nitroglycerin, morphine, anxiolytics, and antiemetics.

The National Hospice and Palliative Care Organization has outlined criteria to be used for patient enrollment to a hospice program (28). In addition to the general criteria that include the presence of a life-limiting illness, the patient's desire for comfort care, and documentation of disease progression and/or impaired nutritional status, cardiacspecific guidelines have been proposed. These guidelines include intractable or frequently recurrent heart failure with or without angina, the use of optimal medical management with diuretics and vasodilators, and the presence of concurrent factors that portend a poor prognosis, including symptomatic arrhythmias, a history of cardiac arrest or syncope, cardiogenic brain embolism, or concomitant human immunodeficiency viral disease.

CONCLUSIONS

Disease management and hospice programs appear to provide a suitable context for implementation of palliative care in advanced heart failure. Each brings unique perspectives, expertise, and management strategies that, if combined, could provide a comprehensive approach to the patient with end-stage heart failure. Disease management and hospice both emphasize education, self-care behaviors, and therapies targeted toward symptomatic improvement, all of which are concordant with the philosophy of palliative care. Disease management is heavily invested in the use of medical therapies that are documented to prolong survival and reduce hospitalization risk. Hospice is more focused on end-of-life issues, including relief of pain and anxiety and the use of community resources. The strengths of these strategies would be complementary and comprehensive. The role of aggressive treatments such as intravenous inotropic therapy in palliative care requires definition. The improvements in exercise performance that allow some patients to perform daily living activities with reductions in fatigue and dyspnea need to be balanced against increased risk of infection risk, which results from long-term intravenous access, high cost, and excess mortality. Other obstacles to the development of comprehensive end-of-life strategies for heart failure include the acceptance of these concepts by physicians who do not frequently use hospice programs, the consideration of new treatments and technologies that improve outcomes, and funding sources. Despite these barriers, the application of palliative care practices to patients with advanced heart failure is a logical extension of a field that is focused on providing quality and compassionate care to patients with terminal illnesses.

MANAGEMENT OF HYPERCOAGULABLE STATES AND COAGULOPATHY

KENNETH D. FRIEDMAN
THOMAS J. RAIFE

Hemostasis is carefully balanced: Hemostatic plugs form at inappropriate openings in the vascular network, but thrombus extension is limited so that the remainder of the vascular highway remains fluid. Many disease processes can undermine this wondrous balance, either by inappropriate plugging of intact blood vessels, or by failure of hemostatic plug formation at sites of vascular wall breakdown. This chapter reviews clinical approaches to both pathological thrombosis and failure of hemostasis, with an eye toward practical measures in a palliative care setting.

THROMBOTIC DISORDERS

Thrombosis can be considered hemostasis that has gone wrong, occurring either at the wrong time or in the wrong place. This review mainly focuses on venous thromboembolic disease (VTE). Risk factors for the development of thrombosis are many, and the prevalence of thrombosis increases with disease severity. A high proportion of hospice patients are on warfarin sodium, reflecting the high rate of thrombotic complications (1). The presenting symptoms of some arterial thrombotic events and most venous events are vague. A high index of suspicion and specific testing for confirmation are required. Therapeutic intervention is undertaken with an understanding of the counterbalancing risks of thrombotic progression on the one hand, and hemorrhagic potential of anticoagulation on the other. Studies of the value of various diagnostic protocols, the efficacy and safety of specific acute interventions, and the risk of bleeding or recurrent thrombosis have led to the development of clinical pathways for diagnosis and have defined “acceptable” rates for complications such as bleeding and recurrent thrombosis. These studies have generally been conducted in patients with expected survival of 3 months or longer, and the principles defined in them may not fully translate to the palliative care setting. The physician must integrate acute care principles with specific end-of-life goals and expectations to arrive at an appropriate palliative care plan.

Mechanism Underlying Thrombotic Risk

Cancer is a well-established risk factor for VTE. The relationship was first reported by Trousseau in 1865 (2). Thrombosis is a major cause for morbidity in patients with neoplastic disease; the reported prevalence varies between 3.8% and 30.7% (3). Mechanisms of cancer-induced activation of the coagulation mechanism have been attributed to expression of tissue factor and cancer procoagulant factors on malignant cells and to inflammatory mechanisms (4,5). Proinflammatory cytokines such as tumor necrosis factor-aand interleukin-1b induce expression of tissue factor on endothelial cells (6). These mechanisms may explain why cancer patients are at increased risk for development of disseminated intravascular coagulation (DIC), which sometimes presents as localized thrombosis. Finally, chemotherapy, hormonal manipulations, and stasis resulting from vascular compression add to thrombotic risk (7).

Many other advanced disease states are also complicated by venous thrombosis. The incidence of stroke and venous thrombosis is as high as 4% in severe heart failure (8). Hepatic dysfunction increases risk of thrombosis, in part through decreased clearance of activated coagulation factors. Inflammatory reactions and acute phase response are common to many disease states; the actions of inflammatory cytokines and elevated levels of coagulation factor VIII, fibrinogen (9,10), and platelets all tip the balance toward thrombosis. Additional circumstantial risk factors include central venous catheters (4) and venous stasis associated with immobilization due to pain and debilitation.

Evaluation of the Patient with Venous Thrombosis

The spectrum of presenting signs and symptoms of VTE are often nonspecific. This problem may be particularly pronounced in the palliative care setting. Alternative explanations for extremity swelling include nonthrombotic vascular obstruction, heart failure, lymphatic obstruction, and neurological factors. Similarly, the sensation of breathlessness may stem from anxiety, cardiac failure, tumor invasion, infection, and obstructive pulmonary disease. Objective investigation is strongly recommended to establish an accurate diagnosis in patients in whom antithrombotic therapy would be considered (11).

Noninvasive studies are the diagnostic tools of choice, because contrast venography and pulmonary angiography (the reference standards) are inconvenient, costly, and associated with substantial morbidity. Quantitation of fibrin D-dimer (the plasmin-derived degradation product of cross-linked fibrin clot) is insufficient for exclusion of VTE in cancer patients. One study reported that the negative predictive value of the SimpliRED bedside D-dimer test was only 79% in cancer patients versus 97% in a more general population of ambulatory patients (12,13).

Clinical approaches that include noninvasive imaging studies are recommended for the evaluation of suspected VTE (14,15). Compression ultrasonography may be the best study for the diagnosis of proximal deep vein thrombosis in the terminal patient. It is simple, highly accurate, and fast when done in experienced facilities. The sensitivity for proximal leg deep vein thrombosis is reported at over 97%, but compression ultrasonography is significantly less useful in the evaluation of thrombosis below the knee (15).

Lung scintography has traditionally been the mainstay for noninvasive diagnosis of pulmonary embolism (PE). A “normal” report effectively excludes the diagnosis of PE, whereas a “high-probability” report is sufficient for diagnosis in a patient with a moderate to high clinical suspicion of PE (16). Unfortunately, approximately two-thirds of patients have a nondiagnostic lung scan (17). Pulmonary disease and tumor in the lung degrade the diagnostic yield of lung scans. Duplex ultrasound of the legs is positive in as many as half such patients, but a negative ultrasound does not exclude VTE in the patient in whom PE is clinically suspected (18). Recently, there has been considerable interest in spiral (helical) computed tomography (CT) for diagnosis. Spiral CT has a high sensitivity for detection of PE in central pulmonary vessels (sensitivity and positive predictive value approach 95%) (17). It may be particularly useful for uncovering alternative sources of pulmonary symptoms in patients with advanced disease, because the images also supply detail of the lung parenchyma, mediastinum, and pleura. The main concern about this promising technique is the lack of evidence for the safety of withholding anticoagulation therapy based on a negative spiral CT study. Other concerns include the low sensitivity for detection of embolism in subsegmental pulmonary arteries, the occasional misinterpretation of studies, the requirement for intravenous injection of a significant iodine-contrast dye load, and the high cost of the study (17,19).

Utilization of these diagnostic techniques in the palliative care setting has not been extensively evaluated. A survey of palliative care physicians in the United Kingdom revealed that only 60–80% of responding physicians would use tests to confirm a clinically suspected venous thrombotic event (20). One palliative care group's protocol for documentation of VTE was to establish the degree of clinical suspicion, and if high, to obtain leg ultrasonography. When PE is suspected and the leg ultrasound is inconclusive, spiral CT is obtained. Pulmonary scintography is reserved for patients in whom dye load is contraindicated (21).

Treatment of the Patient with Venous Thrombosis

The goals of treatment of VTE are to prevent death from progressive PE and to minimize the postphlebitic symptoms of pain, swelling, and dyspnea. The American College of Chest Physicians periodically updates its recommendations for the management of VTE in the nonpalliative care setting (22). Thrombolytic therapy would usually be considered an overly aggressive approach for the patient in such a setting. Anticoagulation is the mainstay of therapy. It is instituted immediately to inhibit new clot formation while the body's fibrinolytic mechanisms lyse clots and rechannelize obstructed blood vessels. Anticoagulation is then continued on a long-term basis to prevent recurrent thrombosis. The duration of anticoagulation therapy is stratified according to the patient's risk for recurrence.

The main complication of anticoagulation therapy is hemorrhage, and assessment of the risks of hemorrhage should be undertaken before instituting anticoagulation (Table 31-1). Absolute contraindications include significant active bleeding or presence of severe bleeding tendency. Relative contraindications include recent bleeding,

recent surgery, a moderate to severe degree of bleeding tendency, thrombocytopenia, active peptic ulcer disease, uncontrolled hypertension, and severe renal or liver disease. Central nervous system hemorrhage is a particular concern in patients with metastatic cancer in the brain, especially from melanoma, choriocarcinoma, or renal cell carcinoma. However, several authors advocate the safety of anticoagulation in the setting of nonhemorrhagic metastatic disease to the central nervous system when close control of anticoagulation is maintained (23,24). When hemorrhagic risk contraindicates anticoagulation therapy, or anticoagulation has proven insufficient to prevent thrombotic progression, inferior vena cava (IVC) filter devices can be deployed to preserve lung function and prevent death from acute PE.

Contraindications
Significant active bleeding (gastrointestinal or elsewhere)
Recent surgery or central nervous system procedure
Severe bleeding tendency
Factors conferring increased bleeding risk
Preexisting abnormality of hemostasis
Thrombocytopenia
Concomitant use of platelet-inhibiting drugs
Coagulopathy
Recent hemorrhagic episode
Recent major surgery
Comorbid disease states
Advanced disease
Active peptic ulcer disease
Uncontrolled hypertension
Severe renal or hepatic disease
Central nervous system metastasis
Heavy ethanol use
Advanced age

TABLE 31-1. CONTRAINDICATIONS AND RELATIVE RISK FACTORS FOR HEMORRHAGIC COMPLICATIONS OF ANTICOAGULANT THERAPY

Heparin drugs have been the mainstay of initial anticoagulation therapy owing to their immediate onset of action (25). Their anticoagulant effect is achieved by accelerating action of the plasma protein antithrombin. Heparin drugs have been subdivided into unfractionated heparin (UFH), and low-molecular-weight heparins (LMWH) derived by depolymerization of UFH. Synthetic pentasaccharide may soon join this group of anticoagulants (26).

Until recently, UFH has been the standard immediateacting anticoagulant used in the management of VTE. Its main advantages are low cost, short half-life, and reversibility by administration of protamine sulfate. The main disadvantages of UFH are its wide dose–response variability and narrow therapeutic window. Other complications include the need for parenteral administration, the rare but serious immunological condition *heparin-induced thrombocytopenia* (27), and the risk of osteoporosis with very-long-term heparin therapy (28). UFH is usually given by continuous infusion (29). The therapeutic dose is determined empirically. Algorithms for prescriptive dose adjustment are recommended based on frequent monitoring of anticoagulant effect (25). The sensitivity of the partial thromboplastin time (PTT) to heparin effect varies widely between labs; one should consult the local laboratory to learn the recommended therapeutic range. The PTT is a less useful yardstick of heparin effect in patients who have “heparin resistance,” which is defined as requirement of over 40,000 units of UFH/day to achieve a therapeutic range PTT (30). Either direct heparin assessment by “anti-factor Xa” assays (therapeutic range 0.35–0.70 U/ml) or a switch to LMWH is recommended in this setting.

LMWH preparations offer several important pharmacological advantages over the UFH precursor (31). LMWH is a parenteral medication, but depolymerization results in a longer half-life, greater bioavailability, and predictable pharmacodynamics. For the average patient with VTE, these pharmacological advantages translate into weight-adjusted dosing once or twice daily without a requirement for laboratory monitoring. These advantages also render LMWH an appropriate agent for outpatient use. Other potential advantages include reduced risk of bleeding (32,33), osteoporosis (28), and heparin-induced thrombocytopenia (34). The main disadvantages are increased cost and a prolonged anticoagulant effect that is less reversible with protamine sulfate. LMWH is cleared by the kidney; monitoring of levels is advisable in patients with renal insufficiency (creatinine greater than 2 mg/dl). Many large clinical trials have demonstrated that LMWH is equivalent in safety and efficacy to UFH in the management of acute VTE (35,36,37,38 and 39), and that it is safe to use in outpatient community-based care (40,41). Among cancer patients, no increased risk for recurrence of thrombosis was detected in LMWH study arms (42), although one study found a trend towards increased recurrence with once daily dosing of enoxaparin sodium compared to twice-daily dosing (43). Somewhat unexpectedly, metaanalysis revealed improved 3-month survival rates in cancer patients treated with LMWH (44,45). Multiple LMWH preparations are licensed. Dosing schedules for each preparation have been largely empirically determined, and they are not known to be interchangeable.

For patients requiring long-term anticoagulation to prevent recurrent thrombosis, warfarin sodium derivates (e.g., Coumadin) are frequently used (22). These oral vitamin K antagonists inhibit hepatic synthesis of multiple coagulation factors. The onset of oral anticoagulant effect is delayed until previously synthesized coagulation factors are cleared; “loading” doses do not overcome the long half-life of clotting factors. Because of this delay, oral anticoagulation is usually initiated concurrently with heparin drugs. Current recommendations suggest that heparin drugs be maintained for at least 5 days and continued for 2 days after laboratory studies confirm that adequate oral anticoagulation has been established.

Management of oral anticoagulation is complex due to the narrow therapeutic window, multiple drug interaction, inter-individual differences in hepatic metabolism, and shifting intensity of anticoagulation due to changes in oral intake (46). The therapeutic intensity of oral anticoagulation requires laboratory monitoring. A prothrombin time (PT)-based international normalized ratio (INR) target of 2.5 is suggested in most settings, but a higher target of 3.0 is suggested for patients with many types of mechanical heart valves (47). The typical initial dose of warfarin sodium is 5 mg/day in acute care patients, but initial doses may need to be lower in chronically ill patients, patients with poor nutrition, patients on medications that are known to increase oral anticoagulant effect, and in the elderly. Initially, INR monitoring and dose adjustment are done daily, with monitoring intervals increased as the chronic dose requirement is empirically established. Weekly evaluation may be prudent for at least the first 6–12 weeks of therapy, the time when the highest rate of hemorrhage occurs (48). In general patient populations, the risk of bleeding with INRs in the therapeutic range is reported between 2% and 3% (49), but cancer patients are at increased risk for bleeding complications. Adverse events might be avoided through more frequent monitoring (24,50). Outcome data are scant in the palliative care literature. One small hospice audit found a very high incidence of warfarin-related hemorrhagic events, and that external bleeding was quite distressing to the patients and their caregivers (1,51). Tight INR control was somewhat helpful, but required INR monitoring once every 2.4 days, adding a considerable burden to dying patients.

Management of a patient with an INR above the target value requires consideration of the degree of INR elevation and patient's risk of hemorrhage (Table 31-2). In patients who are not bleeding, dose adjustments may be sufficient. Low-dose oral vitamin K_1 can be used to shorten the period required for reestablishing the target level. In bleeding patients, the addition of coagulation factor replacement with fresh frozen plasma speeds correction of the INR (29,46). Bleeding patients that are unable to tolerate the volume load of plasma transfusion may be treated with prothrombincomplex concentrates (22) or recombinant factor VIIa; however, the complexity and expense of these measures should be carefully considered in the palliative care setting.

TABLE 31-2. GUIDELINES FOR REVERSAL OF WARFARIN SODIUM ANTICOAGULATION

LMWH has also been evaluated for the long-term anticoagulation of patients. The lack of monitoring requirements and absence of dietary or drug interactions offer significant advantages for the terminally ill patient. The dose chosen is generally similar to that used during initial anticoagulation therapy. Two long-term clinical trials (which included few cancer patients) suggested that prophylactic doses of LMWH may be effective (52,53).

Duration of anticoagulation is determined by risk of recurrence (22). Three to six months of anticoagulation is recommended for a patient with a reversible short-term risk factor, a minimum of 6 months for the patient with idiopathic VTE, and 12 months to indefinitely is recommended for the patient with a significant long-term risk factor. In terminally ill patients with persistent risk factors (such as cancer), the decision to continue anticoagulation should be regularly revisited, as it is unclear at what point the reduction in risk of thrombotic recurrence justifies the logistical burden and the ongoing risk of hemorrhage.

Recurrence of venous thrombosis in the face of anticoagulation appears to be a particular problem in patients with cancer or the antiphospholipid syndrome (14,54). A patient who develops thrombosis in the face of a subtherapeutic INR may be retreated with UFH or LMWH for 5–7 days and then be continued on warfarin sodium with the usual target INR of 2.5. For the patient who is already in the therapeutic INR range at the time of thrombosis, possible courses include aiming for a higher INR of 3 or switching to long-term LMWH. When risk of PE is high, IVC filter placement may be considered.

An IVC filter is not an alternative to anticoagulation, but placement of a filter may prolong life by prevention of acute PE. IVC filters reduce the short-term risk of PE, but

they do so at the expense of increased risk for progressive leg thrombosis and postphlebitic syndrome (55). Placement of an IVC filter should be reserved for patients with active bleeding or a high risk of bleeding, or for patients who develop recurrent thrombosis despite anticoagulant therapy. In the latter setting, concurrent anticoagulation should also be considered; thrombotic complications occurred in one-sixth of cancer patients who had a filter placed (23). Because of the expense and morbidity associated with IVC filters, their use in the palliative care setting should be carefully considered.

Catheter-Related Thromboses

Central catheters are commonly used in cancer and other chronically ill patients for administration of medications, transfusions, and blood monitoring. Thrombus may obstruct a line tip or form a sleeve around the intravascular portion of the catheter or obstruct the veins of the arm, neck, or mediastinum (56).

Low-dose thrombolytic therapy, instilled as a single dose (or occasionally as repeated doses), is usually effective in opening a tip thrombosis. Streptokinase, urokinase, and tissue plasminogen activator have been used for this purpose. Drug shortages have increased the use of tissue plasminogen activator for this purpose (57).

Vein thrombosis is a common complication of central lines. The incidence of symptomatic venous thrombosis is unclear. Symptoms of central vein thrombosis may be nonspecific and objective imaging is necessary to confirm the diagnosis. Anatomical limitations reduce the sensitivity of sonography, but the high specificity of sonography makes a positive study useful (56). Contrast venography may be useful in some patients. Optimal therapy of central vein thrombosis is uncertain. Full-dose anticoagulation or catheter removal may be sufficient, but if one approach is unsuccessful, both measures may be required (58,59). Open-label prospective randomized studies have shown utility of prophylaxis with very-low-dose (1 mg/day) warfarin sodium (60) or daily subcutaneous dalteparin sodium 2500 IU (61).

HEMORRHAGIC DISORDERS

Bleeding, especially if it is massive, can cause considerable anxiety for the patient, family, and health care providers (4). Bleeding may lead to debilitation from anemia and serve as a reminder of the uncontrolled and progressive course of illness. Patients may be unsettled by specific complications associated with bleeding in certain locations, such as chronic cough or dyspnea related to pulmonary bleeding. The clinical approach to these situations requires a balanced consideration of the underlying causes of bleeding (Table 31-3), the available therapeutic modalities, and the patient's palliative care goals.

Loss of vascular integrity
Tumor surface bleeding
Tumor erosion into a major vessel
Mucositis (stress, drug-related, acid-peptic disease, chemotherapy-induced, radiation-therapy induced)
Platelet defects
Thrombocytopenia
Marrow proliferative failure (myelophthisis, drug-induced, radiation therapy-induced, viral, vitamin deficiency)
Accelerated platelet clearance (disseminated intravascular coagulation, sepsis, immunologic, hypersplenism)
Platelet function defect (drug-induced, uremic, paraprotein effect)
Coagulation defects
Vitamin K deficiency (decreased intake or bowel flora production, malabsorption, oral anticoagulant-induced)
Liver disease
Disseminated intravascular coagulation
Accelerated fibrinolysis
Coagulation inhibitors (heparin drugs, autoimmune)
Interventional radiology (vascular embolization)

TABLE 31-3. MECHANISMS OF HEMORRHAGIC RISK

Mechanisms of Hemorrhagic Risk

Vascular Integrity

The loss of vascular wall integrity underlies all bleeding events. Multiple factors conspire in the terminally ill patient to destroy vascular integrity. Local tumor invasion in the gastrointestinal (GI) tract is associated with 12–17% of cases of GI hemorrhage in cancer patients (62). Chest wall breast carcinoma, endobronchial lung cancer, and locally invasive head and neck or cervical cancer can all cause local hemorrhage. Mucositis may be induced by nonsteroidal anti-inflammatory drugs, stress, peptic ulcer disease, local infection, or as a result of chemotherapy or radiation treatment. Finally, primary vascular defects may be involved, as in amyloidosis or vitamin C deficiency.

Platelet Function

Failure of hemostatic mechanisms may allow minor defects of vascular integrity to become manifest. Many factors can result in thrombocytopenia or diminished platelet function. Platelet counts above 50,000/mm^3 are generally well tolerated in the absence of trauma (63), and significant risk of spontaneous hemorrhage is rare until counts fall below 20,000/mm^3 (64). Failure of marrow production is a very common mechanism of thrombocytopenia. Extensive marrow replacement by tumor (myelophthisis) occurs early in leukemia, but is a sign of advanced metastatic disease in solid tumors. Other peripheral blood abnormalities lead to suspicion of myelophthisis, including pancytopenia and the presence of circulating neutrophil precursors, nucleated red blood cells, and “teardrop” red cells. Marrow failure is an anticipated complication of many antineoplastic drugs and may complicate radiation therapy. Other causes of marrow failure include vitamin deficiency (B_{12} or folate), hypothyroidism, viral infections, and adverse medication effects. If required, marrow failure can be confirmed by biopsy. Platelet-selective cytopenias and disorders characterized by shortened platelet survival are characteristic of some druginduced complications. Infection, DIC, hypersplenism, and autoimmune phenomena are all potential underlying mechanisms of thrombocytopenia. The approach to diagnosis and treatment of thrombocytopenia in the palliative care setting requires judgment as to potential benefits in relation to the discomfort, cost, and risk to the patient.

Medication-related inhibition of platelet function should be considered in the bleeding patient, as adjusting medications may be a relatively simple means of treating patients in the palliative care setting (65). Aspirin and most nonsteroidal anti-inflammatory drugs exert antiplatelet-effect due to potent cyclooxygenase inhibition. In addition, these agents increase the risk of gastric erosion. A burgeoning array of antiplatelet agents used in patients with vascular disease should also be questioned in the bleeding patient.

Coagulation Defects

Abnormalities of the coagulation mechanism such as vitamin K deficiency, hepatic disease, and DIC should be considered in a palliative care patient with bleeding (64).

Vitamin K is a fat-soluble factor required for hepatic synthesis of multiple coagulation proteins. Oral anticoagulants achieve their effect through inhibition of vitamin K metabolism. Nutritional deficiency of vitamin K occurs when there is impairment of either dietary intake or bowel flora synthesis of vitamin K. Disruption of both mechanisms is common (65). In addition, malabsorption disorders such as bowel resection/bypass, biliary obstruction, and use of cholestyramine may undermine fatsoluble vitamin absorption. Supportive laboratory evidence includes a prolonged prothrombin time (PT) with a normal or less prolonged activated partial thromboplastin time (aPTT) and normal fibrinogen and platelet levels. The PT should correct after 1:1 mixing with normal plasma, and the abnormalities should improve with vitamin K_1 administration.

Liver dysfunction contributes to bleeding in a variety of ways. The liver produces most coagulation proteins and is a reservoir for vitamin K. In addition to impaired synthetic capacity from parenchymal liver disease, liver dysfunction may cause portal hypertension with resulting thrombocytopenia from hypersplenism, and GI bleeding due to esophageal or rectal varices.

Owing to its short half-life, factor VII levels fall early in the course of liver disease, resulting in prolongation of the PT, which should correct on 1:1 mix with normal plasma. Mildly elevated fibrin degradation products may reflect defective hepatic clearance. The aPTT is typically less prolonged than the PT, and levels of fibrinogen and platelets are variable. Other clinical or biochemical evidence should support the diagnosis of hepatic disease. Clinical improvement in hemostasis with vitamin K_1 administration is generally limited.

DIC is a secondary coagulation disturbance associated with many disorders. There is a frequent association of DIC with cancer. Other causes include trauma, burns, sepsis, and prolonged circulatory insufficiency. DIC is characterized by activation of both procoagulant and fibrinolytic pathways. Activation of these pathways results in

consumption of platelets and coagulation factors, intravascular deposition of fibrin, and simultaneous release of fibrin degradation products and destabilization of hemostatic plugs (66). The thrombotic spectrum of DIC includes macrovascular thrombosis and microvascular obstruction with multiorgan failure. The hemorrhagic spectrum ranges from asymptomatic laboratory abnormalities to increased bruising, reoccurrence of bleeding at sites of prior trauma, or even apparently spontaneous mucosal bleeding. The diagnosis of DIC rests on clinical suspicion supported by laboratory abnormalities including prolonged PT and aPTT, decreased fibrinogen and platelets, and a positive test for fibrin split products or D-dimer.

Clinical Approaches to the Bleeding Patient

The nature and severity of bleeding and underlying cause define the spectrum of interventions available to the bleeding patient. The patient's anticipated life expectancy, quality of life, care setting, and palliative care goals may narrow the spectrum. One must balance the potential benefits of intervention (Table 31-4) with the consequences. In addition to general supportive measures, the care plan may entail avoidance of interventions that increase bleeding risk, local measures to treat bleeding, and systemic interventions to improve hemostasis.

General supportive measures
Identify the patient at risk
Establish open communication of issues for care
Generate care plan and revisit as required
Consider measures for catastrophic bleeding
Use of sedatives (midazolam hydrochloride)
Revisit as required by patient course
Local measures
Packing
Compressive dressings and postures
Topical hemostats (collagen, thrombin, fibrin gel, antifibrinolytics)
Topical astringents or vasoconstrictors (silver nitrate, alum, formaldehyde, cocaine, epinephrine)
Special techniques
Endoscopic interventions (cauterization, sclerosis, ligation)
Interventional radiology (vascular embolization)
Palliative radiotherapy
Palliative surgery (vascular ligation)
Systemic interventions
Discontinue antiplatelet and antithrombotic medications
Vitamin K
Antifibrinolytic medications (tranexamic acid, e-aminocaproic acid)
Transfusion support
Platelets or plasma for hemostasis
Red blood cells to treat anemia
Somatostatin analogs (octreotide acetate)

TABLE 31-4. PALLIATIVE MANAGEMENT OF THE BLEEDING PATIENT

General Supportive Measures

It is helpful to identify patients at particular risk for massive bleeding. Tumors likely to present bleeding problems include fungating tumors of the head and neck, gynecological tumors, and tumors close to major vessels. Patients on antithrombotic therapy and those with severe liver disease or marrow failure are also at increased risk for hemorrhage. Massive bleeding can be extremely distressing to patients and caregivers alike. Panic responses and calls to emergency medical personnel may result in the initiation of inappropriate interventions. Anticipatory conversations between patients and care provision teams empower caregivers to act appropriately if massive bleeding develops (67). Patients with hematemesis should be placed in the left lateral position to reduce respiratory compromise. Use of dark colored towels and basins helps make blood loss less evident, and thus reduces anxiety associated with bleeding. It may be helpful to have prefilled syringes containing sedative medication (e.g., 5 mg of midazolam hydrochloride) available for subcutaneous administration in the event of catastrophic hemorrhage (67,68).

Local Measures

Local interventions to control hemorrhage include compression dressings, application of materials to improve hemostasis, and special procedures to occlude bleeding vessels (64). Packing is useful in areas such as the nose, rectum, or vagina. Pressure through use of balloon catheters or posturing is of additional benefit in areas of small capillary or venous bleeding. Choice of topical agents to further improve hemostasis is generally based on local factors, cost, and individual considerations. Topical cocaine has been used with nasal packing.

Acetone may similarly improve the efficacy of vaginal packing. Purified gelatin, compressed packed foam (Gelfoam), and bovine-derived collagen provide surfaces for formation of a hemostatic clot. Bovine thrombin can be applied topically in powder form to dressings or directly onto oozing surfaces. It can also be used in solution to moisten dressings (69). Fibrin gel can be applied directly to bleeding surfaces (70). Aluminum astringents, such as 1% alum solution or 1 g of sucralfate tablet dispersed in water-soluble gel (e.g., K-Y jelly), can be applied to bleeding sites once or twice daily. Cauterizing and vasoconstrictive agents are alternative approaches to controlling hemorrhage. Formaldehyde solutions have been used to control hematuria (71), and may control bleeding associated with radiation proctitis (72,73). Silver nitrate cauterization is commonly used for nasal bleeding. Epinephrine (either alone in a 0.002% solution, or in combination with lidocaine) may be used to induce vasoconstriction. Lidocaine doses should not exceed 7 mg/kg when used in combination with epinephrine (74,75).

Special Techniques

Specific local interventions include endoscopic or intravascular application of hemostatic measures and use of radiotherapy to induce vascular sclerosis. The spectrum of endoscopic procedures includes cauterization and electrically induced coagulation (76), application of sclerosing agents and ligation of esophageal varices (77,78), and topical application of hemostatic agents. In addition to inconvenience, the risks of endoscopic procedures include worsened bleeding through physical trauma and perforation of organs. Vascular embolization by interventional radiology has been used for a variety of bleeding indications (64,79). Embolic particles include metal coils and gelatin sponge. The technique is restricted to vascular beds in which catheters can be easily guided. Vascular access is usually obtained via an axillary or femoral approach. Embolization therapy is well established in the treatment of head and neck, pelvic, and pulmonary neoplasm-associated bleeding. Complications include the need for mild sedation during the procedure, embolization of vascular beds not affected by tumor, bleeding at the site of vascular access, and a “postembolization” syndrome characterized by discomfort, malaise, and fever after vessel occlusion of a large tumor mass. Palliative radiation therapy may be used to control hemorrhage from head and neck, gynecological, GI, bladder, and other tumors (64,80). The optimal method of treatment remains controversial. Prior therapy in the same radiation field increases the risk of adverse events and limits the utility of this approach in some patients. (For further discussion of this area see Chapter 49.)

Systemic Interventions

Systemic interventions include augmentation of platelet or coagulation mechanisms and inhibition of fibrinolytic mechanisms. Alternatively, some medications may improve vascular or other responses to bleeding. Red blood cell transfusion may palliate the symptoms of anemia.

In the bleeding patient with a platelet count under 50,000/mm^3, platelet transfusion may temporarily help control bleeding. Prophylactic platelet transfusions are used in the care of patients with marrow failure and severe thrombocytopenia under 10,000/mm^3 to 20,000/mm^3 (81). Use of a 10,000/mm^3 threshold for prophylaxis appears to have similar safety to a 20,000/mm^3 threshold (81); however, bleeding may occur with platelet counts over 20,000/mm^3 when associated with vascular and anatomical abnormalities (82). Platelet transfusion therapy is complicated by the short survival of transfused platelets. Although the mean platelet life span is 9.5 days in normal individuals (83), platelet survival may be less than 3 days in patients with stable platelet counts near 20,000/mm^3 due to marrow hypoplasia (84). In the palliative setting marrow failure is often a chronic problem and a single platelet transfusion is unlikely to raise the platelet count for more then a few days. The limited role and complications associated with platelet transfusions should be discussed with the patient and the care providing team to arrive at an appropriate care plan. Palliation with limited platelet transfusions may be considered when symptoms of bleeding are distressing, including mucosal bleeding, painful hematomas, headache, and disturbed vision due to recent hemorrhage (85). (For more extensive comments see Chapter 67.)

The treatment of coagulopathy should be based on the underlying mechanism, the extent of coagulation disturbance, and the urgency of correction of the defect. Vitamin K deficiency and the effect of oral anticoagulation usually respond to vitamin K_1 within 24 hours. Vitamin K_1 is available as 5-mg oral tablets; subcutaneous administration is preferable in patients in whom malabsorption is a factor. Chronic administration (such as 5 mg twice per week) may be required to maintain the effect. Intravenous infusion is discouraged except in emergencies because of rare reports of anaphylactic reaction (86). For rapid correction of the coagulopathy of vitamin K deficiency, and treatment of bleeding patients with liver disease or malignancy-associated DIC, plasma transfusion support is the mainstay of therapy (65). Although fresh frozen plasma contains all necessary coagulation proteins, its use may be considered excessive in the palliative care setting, and supportive care is often limited to comfort measures. In DIC some have recommended use of heparin to control thrombin-generated consumption of platelets and coagulation factors, but its use in this setting remains controversial (64,65).

Antifibrinolytic agents prevent clot lysis by blocking the binding sites of plasmin and its activators in plasma. Among these agents, tranexamic acid is ten times more potent than e-aminocaproic acid and has a longer half-life (87). These drugs are rapidly absorbed from the GI tract and excreted in the urine, and both have dose-related nausea, vomiting, and diarrhea as their main toxicities. A dose of tranexamic acid of 1.5 g, followed by 1 g three times per day, or e-aminocaproic acid

started at 5 g, followed by 1 g four times per day, was used in one palliative care study (88). Fourteen of 16 patients had cessation of tumor-associated bleeding, with most having complete control of hemorrhage within 4 days. Treatment was continued for up to 54 days and bleeding was not reported after cessation of the therapy. Topical administration of these agents was described in this study and in several case reports (64,89). Although antifibrinolytic agents have been used in patients with thrombocytopenic bleeding, results of studies have not been consistent. One placebo-controlled trial did not demonstrate benefit in a population of patients with aplastic anemia or myelodysplasia (90), but two small studies with aminocaproic acid showed some effect on control of hemorrhage (87). Systemic antifibinolytic therapy increases the risk of thrombosis and should be used very cautiously in DIC.

Systemic interventions are occasionally used to alter the physiological response to bleeding. An example is the use of the somatostatin analog octreotide acetate in patients with GI bleeding (64). Although mostly used in the acute treatment of upper GI bleeding, at least one successful use in a palliative care setting is reported (67). It was suggested that octreotide acetate results in decreased splanchnic blood flow, reduced venous pressures, a cytoprotective effect, and suppression of gastric acid secretion. The recommended dose was 50–100 µg administered subcutaneously every 12 hours, increased according to clinical response to a maximum of 600 µg per day. Continuous infusion by either intravenous or subcutaneous route is a possible alternative (64).

UROLOGIC ISSUES OF PALLIATIVE CARE

DANIEL P. ARRISON
STEVEN J. HIRSHBERG
RICHARD E. GREENBERG

The management of patients with a progressive medical disease should allow them to live the remainder of their lives to their fullest potential, maximizing both the quality and quantity of life. The development of complications related to the genitourinary system is not uncommon in these patients. Although some of these problems may merely be considered annoyances, others are quite serious and can potentially undermine the quality of life. The most serious complications can reduce life expectancy.

A common classification of urinary tract problems differentiates the urinary tract into upper and lower systems. The upper urinary tract refers to those organs proximal to the ureterovesical junction. The lower urinary tract pertains to the bladder, prostate, and urethra. This chapter discusses both the diagnosis and management of upper and lower urinary tract pathology.

OUTLET OBSTRUCTION

One of the most common problems originating from the urinary tract in men is bladder outlet obstruction, which can result from either benign or malignant processes. In men, the most common organ to obstruct the bladder is the prostate. Both men and women can develop bladder outlet obstruction from direct tumor extension or from other pathology originating from the rectum or urethra; a lesion of the ovary, cervix, or uterus may be the cause in women. The ultimate consequence to the patient with obstructive uropathy, without intervention, is renal failure secondary to chronic urinary retention. This condition progresses more rapidly if there is also underlying infection, a situation not uncommon in patients who fail to empty their bladder adequately.

A careful history may disclose the lesion responsible for urinary retention. Physiologically, failure to empty the bladder indicates failure to generate a detrusor pressure that is greater than the urethral resistance. This can either be from primary detrusor failure (e.g., associated with diabetes mellitus or sacral plexus injury) or from bladder outlet obstruction at or distal to the bladder neck. A detailed urologic history relating symptoms before the episode of urinary retention may clarify the underlying problem. Patients who complain of urinary frequency, urgency, nocturia, and a slow urinary stream frequently have obstruction as the underlying etiology of their urinary retention. In contrast, patients who report a slow stream, impaired bladder sensation, increasing intervals between voids, and decreased urgency are more likely to have primary detrusor failure (1). Because management of these two disorders differs significantly, it is obviously critical to make this distinction before initiating therapy.

Nonsurgical Treatment

Whereas the initial management of urinary retention secondary to benign prostatic hyperplasia (BPH) may warrant a period of catheter drainage and an empiric trial of selective a_1-blockers (terazosin hydrochloride, doxazosin mesylate, or tamsulosin hydrochloride), bladder outlet obstruction secondary to a malignant disease is unlikely to respond to this approach. Deconditioning and immobility are additional complicating factors in the terminally ill; debility in many terminally ill patients may decrease the likelihood for recovery of adequate bladder detrusor function. Those patients with BPH who fail initial conservative measures (a_1-blockers and bladder rest) after an adequate time period (e.g., 1–2 weeks) may be candidates for alternative measures. These other options, which are all invasive to an extent, include chronic urethral or suprapubic bladder drainage, intermittent catheterization, and surgical procedures, including urethral stenting or surgical resection of the obstructing tissue. In patients with malignant disease, these approaches can be considered earlier.

Hormonal Manipulation

A nonsurgical approach to patients with obstruction caused by prostate cancer involves hormonal manipulation. This approach should be especially considered for those patients not previously treated in this fashion. Up to 72% of patients with advanced prostate cancer may have symptoms of bladder outlet obstruction (2). In a 1989 review, Surya and Provet (3) suggested that androgen deprivation might be preferable to surgery as the initial mode of therapy. Androgen deprivation can either be in the form of surgical bilateral orchiectomy or “medical orchiectomy” with luteinizing hormone releasing hormone (LHRH) analogs (leuprolide or goserelin) or diethylstilbestrol. In those patients who are to be initiated on LHRH analogs, a recent bone scan should be available to rule out significant occult bony disease in the vertebral column. After starting therapy with LHRH analogs, a luteinizing hormone and consequent testosterone surge may occur within the first 2 weeks of therapy, and patients with significant vertebral metastases, whether occult or overt, are at significant risk for spinal cord compression. For similar reasons, patients with bone pain may have increased analgesic needs shortly after beginning treatment with LHRH analogs. To reduce the risk of these adverse events, the authors recommend that all patients should be started on an antiandrogen (flutamide, bicalutamide, nilutamide) before the initiation of LHRH agonist therapy to avoid the testosterone flare phenomenon. At a minimum, patients with documented bony disease in the cervical, thoracic, or lumbar axial skeleton should be started on an antiandrogen 7 days before initiating therapy with LHRH analogs. Two to three weeks after reduction of serum testosterone to castrate levels, patients who fail to void usually require surgical intervention or prolonged catheter drainage.

Clean Intermittent Catheterization

For the medically ill patient who does not wish to undergo a surgical procedure, or who is deemed medically unable to tolerate surgery, clean intermittent catheterization (CIC) and chronic indwelling catheterization represent the two most feasible options for adequate bladder decompression. These options are also best suited for those with retention secondary to detrusor failure as opposed to outlet obstruction. CIC has been the nonsurgical treatment of choice to empty the bladder since Lapides introduced the concept in the late 1960s (4). CIC enables a motivated patient to maintain freedom from a chronic indwelling catheter, thereby decreasing the attendant risks of infection, stricture, epididymitis, and symptoms associated with a defunctionalized bladder. Once a patient is placed on an adequate CIC schedule, bladder residuals must be monitored so that upper tract deterioration from storing urine at high pressures can be avoided. Common findings on routine urinalysis in those patients on CIC include pyuria and bacteriuria. In the absence of systemic evidence of infection (i.e., fever, flank pain, and leukocytosis), the use of broadspectrum antibiotics in an attempt to sterilize the urine should be avoided to forestall the development of resistant bacterial species (5). In patients with recurrent urosepsis, however, chronic antibiotic prophylaxis using low-dose antibiotics or urinary antiseptic drug regimens may be warranted. Sterile intermittent catheterization may also alleviate the problems of recurrent infections in those patients with clinical symptoms. Other issues that must be addressed before initiating CIC, especially in chronically ill patients, are sufficient manual dexterity and an adequate urethral channel to perform catheterization.

Indwelling Catheters

Although the use of indwelling catheters is usually limited to acute urinary retention, the benefits and risks of chronic catheterization in the medically ill patient must be carefully weighed. Frequently, a permanent urethral catheter is the most appropriate method of management in the patient with a very short life expectancy. Because

these catheters can be changed at longer intervals, they may also be the modality of choice for patients who are technically difficult to catheterize or are unable to catheterize themselves due to functional impairments. Urethral catheters are relatively simple devices, but may cause significant discomfort in those patients who experience bladder spasms. These patients may leak urine around the catheter and appear to be incontinent. Other problems with long-term catheterization include obstruction of urine drainage secondary to calcification of the catheter itself, calcification of the balloon, urethral stricture, urethritis, epididymitis, urosepsis, and urethral erosion. Although insertion of a suprapubic catheter avoids urethral trauma and irritation and decreases the risk of urosepsis, significant complications may still occur.

Surgical Treatment

Transurethral Resection of the Prostate

In patients who fail other treatments, transurethral resection of the prostate (TURP) remains the gold standard for the removal of obstructing tissue. Several newer techniques, however, have been developed for resecting, evaporating, or coagulating the obstructing prostatic tissue. These newer techniques include laser prostatectomy, electrosurgical vaporization of the prostate, transurethral needle ablation, and high-frequency radio wave ablation. All claim to have individual benefits to the patient beyond the standard TURP. However, all of these techniques are still evolving, and only several reports have recorded sustained efficacy. Follow-up in these studies is rarely longer than 2–3 years. Overall, these alternative methods have shown adequate subjective improvement in TURP, but objectively have been inferior. One comparison study of TURP and other less invasive therapies showed significantly lower recatheterization and lower readmission rates in TURP (6). It is also worthy of comment that all studies of less invasive therapies were in patients with symptomatic BPH and not obstructing cancer or overt urinary retention.

During a TURP, prostate tissue (benign or malignant) is removed (resected) using an electrocautery loop. Although the procedure itself is usually limited to 1 hour in length, the potential exists for the development of significant complications, especially in patients with underlying cardiac disease. TURP has the potential to create large fluid shifts by the absorption of irrigation fluid through venous channels during the resection. In a patient with underlying cardiac disease, this may place an otherwise compensated patient into congestive heart failure. Other risks associated with the procedure include bleeding, which has the potential to be significant during resection of a large gland; urinary tract infection; urethral stricture; dilutional hyponatremia; bladder perforation; erectile dysfunction; and urinary incontinence. The risk of urinary incontinence is a great concern when resecting malignant obstructing prostatic tissue, which causes alteration of the normal anatomical landmarks and may directly invade the external urethral sphincter.

Channel Transurethral Resection of the Prostate

An alternative to a standard TURP, in which all of the prostatic tissue is removed out to the surgical capsule, is the “channel” TURP. Channel TURP is defined as a TURP performed to alleviate obstructive voiding symptoms in the patient with advanced or previously treated cancer. It may also refer to a TURP performed to remove the obstructing tissue without necessarily removing all of the tissue to the surgical capsule. The advantage of channel TURP over the traditional TURP is that it is a more limited operation with less associated morbidity.

Mazur and Thompson (7) reviewed 41 patients with known prostate cancer who underwent channel TURP. All of these patients were able to void after the procedure, but 11 patients eventually required additional procedures at a minimum of 15 months after the initial resection. The only patients who were totally incontinent were those with invasion of the external sphincter who required intentional resection of this tissue to relieve the obstruction. Although not specifically detailed, the authors stated that there were no complications. Certainly, this duration of response represents a more than adequate period for most of our palliative care patients.

Urethral Stents

Recent advances with novel materials have led to the creation of self-expanding metal stents for placement into multiple organ systems, including the urinary tract. Several reports have suggested that these devices may be promising, especially for a patient with a limited life expectancy who wishes to remain free of catheters and external urine collection devices. Insertion of the stent itself is a relatively simple procedure and usually can be performed with local anesthesia and a minimal amount of sedation. Morgentaler and DeWolf (8) reviewed their experience with self-expanding prostatic stents in 25 patients with symptomatic bladder outlet obstruction. Twenty-one of the 25 patients were in urinary retention and the remaining four had either bladder neck contractures or severe symptoms of BPH. All patients underwent insertion of the Gianturco-Z stent (Cook Inc., Bloomington, IN). Initially, 95% of the patients were able to void. However, at longer follow-up, the success rate had declined to 75% due to stent migration in several patients. The authors theorized that the high rate of stent migration was due to improper selection of stent length. Additional studies (9,10 and 11) have evaluated different stents [UroLume Wallstent (American Medical Systems, Minnetonka, MN) and Titan intraprostatic stent]. The patients enrolled in these studies mainly suffered from BPH and not carcinoma. Overall, there was an almost 100% return of voiding function. Longer follow-up has shown that although these stents often need to be removed or replaced, symptomatic improvements are acceptable (12). The patients who failed to void were found to have detrusor failure secondary to chronic urinary retention. Symptoms after stent insertion were similar to those seen initially after TURP, namely urinary frequency, urgency, and hematuria. Failures in these studies were usually due to either improper stent length or migration of the stent. Complications were minor, and the patients who required stent removal were able to have it performed without extreme difficulty. Other studies, with small numbers of patients, have used stents in prostate cancer patients with similar short-term results (13). Thus, with improvement of stent sizing and insertion technique, intraprostatic stents hold significant promise for treating urinary outflow obstruction in the medically ill patient with bladder outlet obstruction.

IRRITATIVE VOIDING SYMPTOMS

The complex of irritative voiding symptoms refers to the symptoms of urinary frequency, urgency, and dysuria. These symptoms are common in patients seeking urologic evaluation. Rarely, they are the first indication of a severe underlying process. In addition to symptomatic relief, management must be aimed at identifying and treating the underlying disorder. Investigations may be warranted based on clinical presentation and patient prognosis.

Tumor-Related Symptoms

Although significantly less common than urinary tract infection, tumor invasion of the bladder can cause irritative bladder symptoms. Tumor invasion can originate from within the bladder, such as a transitional cell carcinoma, or from within the pelvis. A common genitourinary tumor that presents with irritative voiding symptoms is carcinoma *in situ* of the bladder. Common malignancies originating outside of the bladder include tumors of the ovary, os cervix, uterus, rectum, prostate, and colon.

The distinction between tumor invasion and urinary tract infection can usually be made on the basis of the history and several tests. Although symptoms are often similar, direct tumor invasion is more likely to have an insidious onset and gross hematuria (14). All patients with irritative voiding symptoms should undergo a detailed urinalysis (dipstick and microscopic analysis). If a urinary tract infection is excluded by urinalysis and urine culture (when indicated), other etiologies must be considered. The differential diagnosis for noninfectious causes of bladder irritability includes ureteral stones (secondary to irritation created by a calculus in the intramural tunnel), foreign bodies, and tumors. Like urinary tract infection, some of these diseases produce pyuria on routine urinalysis. However, unless there is a concurrent urinary tract infection, the urine should be sterile, except in the case of the sterile pyuria associated with genitourinary tuberculosis.

Any patient with new onset irritative voiding symptoms and sterile urine should have a voided urinary cytology. Although not necessarily diagnostic of a urothelial tumor, a positive urine cytology is particularly helpful in diagnosing carcinoma *in situ* of the bladder. However, a negative cytology does not exclude malignancy because this test is relatively insensitive for detecting low-grade superficial papillary transitional cell carcinomas of the bladder or upper tracts. These usually insidious tumors rarely cause any change in the normal voiding pattern. Other recent advances in the early diagnosis of carcinoma *in situ* include various urinary markers (e.g., NMP 22, BTA Stat), which are still under investigation as to their clinical usefulness. Although carcinoma *in situ* may be completely asymptomatic, it more commonly presents with irritative voiding symptoms.

Patients who develop irritative voiding symptoms associated with microscopic or gross hematuria and a negative urine also deserve additional evaluation. The gold standard for evaluating these patients includes an intravenous pyelogram and cystoscopy. In patients with an advanced medical illness, in whom diagnosis of a urothelial cancer may not change the overall management, this algorithm may be modified. Renal and bladder ultrasound, which can now be performed with relative ease, can detect solid tumors of the kidney or large tumors in the bladder; it would be unlikely, however, to diagnose a small tumor of the urothelium. Also, newer techniques in computed tomography (CT), with spiral scans and three-dimensional reconstruction, enable detailed evaluation of the entire urinary system with minimal morbidity. With the development of fiber optics and flexible cystoscopes, office or bedside cystoscopy can be performed with minimal discomfort and may be another alternative. If radiologic studies are unrevealing, cystoscopy may be required to rule out an irritative focus (e.g., tumor or stone within the bladder).

The initial treatment of a tumor that directly invades the bladder wall and causes irritative voiding symptoms should be transurethral resection of the bladder tumor (TURBT). Depending on the extent of the tumor, this can be carried out on an outpatient basis, although some form of anesthesia, usually spinal or general, is required. Transurethral resection entails using a special cystoscope (resectoscope) with a cutting “loop.” By application of an electrical current, the loop actually cuts the bladder tissue. This loop is used to resect the abnormal urothelium and the underlying layers (submucosa and muscularis) of the bladder. The diagnostic value of TURBT further supports its acceptance as the procedure of choice for the initial evaluation of all bladder tumors. If a full thickness biopsy is taken, the depth of invasion and the

degree of differentiation can be determined with a single procedure.

Patients who persist with disabling irritative voiding symptoms after TURBT may be treated symptomatically. The anticholinergic drugs oxybutynin chloride, tolterodine tartrate, and hyoscyamine (Ditropan, Detrol, Levsin SL, and Levsinex) are commonly used to treat urinary frequency, urgency, and nocturia. These drugs can be started at low doses and then titrated to effect. Caution must be used in those patients who also have a component of bladder outlet obstruction or bowel obstruction because their anticholinergic action may exacerbate urinary retention and gastrointestinal dysmotility. These patients require careful observation of voiding and bowel elimination patterns during treatment. Fortunately, there are more selective anticholinergic agents (e.g., tolterodine tartrate) now available that have fewer effects on gastrointestinal and parotid tissue and are therefore better tolerated. At times, a fine balance between irritative voiding symptoms and urinary retention can be obtained. In severe cases, anticholinergic therapy can be used to purposely induce retention and then the patient can be effectively managed with CIC as previously described. In addition, there is a relative contraindication to the use of anticholinergic therapy in patients with closed angle glaucoma. However, if patients maintain routine pharmacologic therapy for this condition, there should be little chance of clinical deterioration (15,16).

Urinary analgesic drugs, the most well known of which is phenazopyridine hydrochloride (Pyridium), may offer some symptomatic benefit to patients with irritative voiding symptoms. Phenazopyridine hydrochloride is converted from its inactive to its active form in the urinary tract. At times, a combination of this drug and an anticholinergic drug may be particularly helpful in relieving symptoms.

In rare cases, irritative voiding symptoms can be refractory to conservative therapies. If suffering from unrelieved symptoms is severe, urinary diversion may be contemplated. The standard form of urinary diversion with the lowest risk of short-term morbidity is the ileal conduit (see Radiation Cystitis). This procedure requires general anesthesia, major intraabdominal surgery, and a minimum 5- to 7-day postoperative recovery. Thus, although it is an alternative for those patients who have experienced a marked loss of independence and quality of life, the risks of the procedure itself must be weighed against the possible benefits.

Infection

Urinary tract infection is one of the most common conditions treated by physicians. Typical signs of lower urinary tract infection (simple cystitis) include urinary frequency, urgency, dysuria, foul smelling urine, hematuria, and suprapubic tenderness. Many cases of urinary tract infection in hospitalized or hospice patients are iatrogenic, secondary to urinary tract manipulation (most often by urethral catheters). When evaluating a patient who presents with acute onset of new irritative voiding symptoms, urinary tract infection should be first on the list of differential diagnoses. As previously mentioned, a urinalysis, including both dipstick and microscopic analysis, should be performed before starting empiric antibiotic therapy. Those patients who are either hospitalized, institutionalized, or who have recently been discharged from such a facility should also have a urine culture and sensitivity performed. The potential virulence of the bacterial flora associated with these facilities justifies this early culture. Likewise, a patient with recent urinary tract instrumentation including urethral catheterization who develops signs of urinary tract infection should also have a urine culture obtained at the initial evaluation.

When obtaining urine specimens from patients who appear to have failed appropriate antibiotic therapy, it is particularly important to ensure proper collection of the specimen. This especially holds true for debilitated patients and those with significant functional impairments, who may not be able to properly collect a clean-catch specimen. If the patient is unable to properly collect urine for urinalysis or urine culture, a catheterized specimen may be required before continuing or modifying treatment. Additionally, when specimens are collected from patients with either an indwelling catheter or condom catheter, one must take care in interpreting the results. Urine from these patients is almost always colonized with bacteria, and, consequently, the finding of bacteria on urinalysis does not necessarily indicate active urinary tract infection, although a negative culture under these circumstances is often considered adequate to rule out infection.

Patients who develop recurrent or relapsing symptomatic infections should undergo further evaluation to rule out a structural abnormality as the fundamental problem. Obstruction and stasis of urine flow at any level of the urinary tract predisposes to urinary infection. Obstruction can either be secondary to an anatomical abnormality, an obstructing stone or neoplasm, or bladder outlet obstruction. Factors contributing to urinary tract infection include diabetes mellitus and immunosuppression caused by cancer or its therapies. Other patients at risk include those on chronic steroid therapy and those infected with the human immunodeficiency virus.

Initial evaluation of patients with recurrent urinary tract infections should include a measurement of a “postvoid” residual to rule out the presence of a large residual urine. This can be performed by catheterizing a patient once he has voided to completion. As an alternative, the postvoid residual may be measured by ultrasound, which should include measurements of bladder volume both before and after voiding. Additional studies can include renal or bladder ultrasound to exclude hydronephrosis, noncontrast CT scan for stones, hydronephrosis, or diverticula, or intravenous pyelogram (IVP) to image the entire collecting system. Urine culture and sensitivity are mandatory when infections do not resolve with empiric antibiotic therapy.

Radiation Cystitis

It is not uncommon for patients to develop irritative voiding symptoms after external beam or interstitial radiation therapy to the pelvis. Radiation therapy is commonly used to treat genitourinary, gynecologic, and gastrointestinal tumors. Acute radiation cystitis after external beam radiation is characterized by dysuria, frequency, nocturia, and rarely, hematuria (17). Dean and Lytton (18) evaluated patients after pelvic irradiation and found that 21% reported urologic symptoms. However, in only 2.5% were these truly related to the radiation itself; in most cases, the symptoms were attributable to recurrent or persistent tumor.

Symptoms usually begin to develop after exposure to 3000 cGy, and there is an increased incidence of cystitis in those patients receiving greater than 6000–6500 cGy. Patients who experience persistent symptoms after completion of radiation fall into the category of chronic radiation cystitis. Open bladder surgery, in the subset of patients who receive higher doses of radiation, appears to be an independent risk factor for the development of chronic radiation cystitis.

Measures used to treat acute radiation cystitis are determined by the associated symptom complex. To address symptoms, drugs such as phenazopyridine hydrochloride or anticholinergics, either alone or in combination, are frequently administered. However, those patients who are refractory to these symptomatic treatments can become debilitated and experience a marked decline in quality of life due to severe urinary frequency, urgency, dysuria, nocturia, and at times, urge incontinence. Approaches to treating patients with such intense symptoms are limited to procedures that divert the urine stream. Occasionally, diversion of the urine by a Foley catheter (Bard Medical, Covington, GA) improves symptoms, although frequently the bladder discomfort is actually exacerbated by Foley balloon irritation. Alternatives to catheter drainage, which have been used with limited success, include small suprapubic tubes and bilateral percutaneous nephrostomies.

Invasive approaches aimed at diverting the urine or enlarging the bladder exist, but require major abdominal surgery. A potential contraindication to any surgery involving the bladder in patients with radiation cystitis is the effect of the extensive radiation itself. The risk of complications during or after augmentation cystoplasty or urinary diversion is increased in patients with irradiated bowel or bladder due an underlying vasculitis.

Augmentation cystoplasty involves enlarging the bladder by surgically creating a patch of either small bowel, colon, or stomach and attaching this to the dome of the bladder. Urinary diversion requires constructing either a urostomy with external appliance or continent diversion by creating a pouch that can be catheterized. Again, this procedure requires use of segments of small bowel or large bowel, both of which may have been irradiated. If urinary diversion is entertained, the bladder itself does not necessarily need to be removed. In fact, cystectomy should probably be avoided due to the increased surgical risks after radiation therapy. Although surgical diversion is considered in this discussion for completeness, few patients within the palliative care population are actually candidates for this intervention due to the associated surgical risks and time required for complete recuperation.

Chemical Cystitis

Several agents that are administered intravesically for the treatment of either superficial or multifocal transitional cell carcinoma of the bladder or carcinoma *in situ* can be potentially toxic and irritating. All of these agents have the potential to cause a chemical cystitis to varying degrees.

The most common and most effective medication used for intravesical treatment of bladder carcinoma is bacillus Calmette-Guérin (BCG). A standard course of BCG therapy involves weekly bladder instillations for 6 weeks. Depending on the clinical response and physician preference, maintenance therapy may continue after the initial 6- week regimen. Symptoms of urinary frequency, dysuria, and hematuria usually develop after 2 or 3 instillations and may last for approximately 2 days after each treatment. These symptoms are an expected consequence of the immune stimulation and inflammatory reaction that are thought to be essential components of the mechanism of action of BCG (19). Lamm et al. (20) reviewed the complications of BCG therapy in 1278 patients and found that 91% developed dysuria, 90% had urinary frequency, and 43% had hematuria. These symptoms seemed to increase with both the duration and frequency of treatments. Although BCG is available in several strains, the local irritative symptoms were not limited to any particular strain.

In patients undergoing a 6-week course of therapy, symptoms can usually be well controlled with the combination of phenazopyridine hydrochloride and anticholinergic medications. Although there have not been any randomized or controlled studies of these medications, several investigators with over 2600 patients support their routine use for symptomatic relief (21). For those patients refractory to this regimen, or in those patients who continue with maintenance therapy, treatment with isoniazid, diphenhydramine hydrochloride, acetaminophen, and nonsteroidal antiinflammatory medications can be helpful. Treatment is usually continued for the

duration of symptoms and may be given prophylactically for 3 days starting on the morning of BCG administration. Because all of these agents have a different mechanism of action, they are frequently used in combinations, and doses are titrated until a maximal effect is obtained. A rare complication of treatment with BCG is development of a nonfunctional contracted bladder, which occurs in approximately 0.2% of cases. Because contracted bladders did not develop in patients with severe irritative symptoms who were treated with prophylactic isoniazid, early treatment with antituberculous medication may help prevent this disabling complication.

Local irritative side effects are seen somewhat less frequently with other intravesical chemotherapeutic regimens. Agents used for intravesical treatment of bladder cancer include triethylenethiophosphoramide (Thiotepa), etoglucid (Epodyl), mitomycin C, doxorubicin, and INF-a. Mitomycin C has been associated with chemical cystitis in 10–15% of patients and, in rare cases, can lead to a contracted bladder. Doxorubicin has also been associated with chemical cystitis and defunctionalized bladders. Treatment of cystitis for these agents is similar to that of BCG except that antituberculous medications have no effect on irritative symptoms from these agents.

Systemic administration of some cytotoxic drugs can also lead to irritative symptoms. These symptoms are commonly associated with cyclophosphamide and ifosfamide (oxazaphosphorine alkylating agents), busulfan (1,4-dimethane-sulfonayoxybutane), and methenamine mandelate (22). These symptoms are avoided with these agents through the concomitant administration of mesna during chemotherapy. Mesna is a chelating agent that binds acrolein, a toxic byproduct of phosphamides, thereby decreasing its toxic effects.

HEMATURIA

General Considerations

Gross hematuria refers to blood in the urine that can be seen with the naked eye. It is important to confirm the presence of red blood cells in urine once dark urine is discovered. There are multiple causes of discolored urine other than blood within the specimen. Some of the more common causes of discolored urine include concentrated urine and systemic administration of flutamide, phenazopyridine hydrochloride, sulfasalazine, phenolphthalein (seen with the use of some over-the-counter laxatives), nitrofurantoin, metronidazole, methylene blue, and vitamin B complex.

Two commonly used methods of detecting blood in urine are the microscopic urinalysis and the urine dipstick test (UDT). The UDT works through a peroxidase reaction (i.e., the peroxidaselike activity of hemoglobin causes the oxidation of a chemical indicator impregnated within the dipstick and thereby changes its color). Intact red blood cells are not required for oxidation and false-positive readings may be caused by hemoglobinuria or myoglobinuria. Although the presence of intact red cells usually causes punctate discoloration of the dipstick rather than the uniform discoloration commonly seen with hemoglobinuria, confirmation of red cells is required. Therefore, all patients with a positive UDT require a microscopic urinalysis to confirm the presence of red blood cells. UDTs have been shown to have a sensitivity of greater than 90% when properly used (23,24 and 25). Although some controversy exists as to whether hematuria should be defined as 0–2 or 0–4/5 red blood cells per high power field, clearly more than 5 red blood cells per high power indicates the presence of blood.

Often, the location of urinary tract bleeding can be ascertained by careful history alone. The history should identify the presence or absence of pain, the color of the blood (bright red versus tea color versus light pink), the presence or absence of clots, and the timing of the presence of the hematuria in the urine stream. Also, hematuria must be differentiated from urethral bleeding, which usually presents as either blood at the meatus or spotting on the sheets or undergarments. Bright red blood usually implies that bleeding is from either the prostate or bladder, whereas darker blood more commonly originates from the upper urinary tract. Bleeding only on initiation of the urinary stream (initial hematuria) that is followed by clear urine implies that the bleeding originates distal to the level of the bladder neck or prostate. The presence of blood throughout the urine stream (total hematuria) usually implies that bleeding is from the kidney, ureter, or bladder, whereas terminal hematuria (blood mainly at the end of urination) again implies a disease process near either the bladder neck or prostatic urethra.

The evaluation of confirmed hematuria may include urine culture (in those patients with concurrent pyuria); voided or catheterized urine cytology; an imaging study to evaluate the kidneys, ureters, bladder, and urothelium; and cystoscopy to evaluate the urethra, prostate, and bladder urothelium. In patients with known urinary tract pathology, the assessment of patients with new onset hematuria may be modified, especially if previously performed studies have been negative. Because of the tendency of urothelial malignancies to recur, onset of hematuria within 6 months of initial evaluation should prompt consideration of repeating the above studies.

When considering which imaging study to obtain, the test that yields the most information and is considered the gold standard for imaging the entire urinary system is the IVP, although the IVP does have some limitations. If the ureters are unable to be visualized completely, additional studies may be warranted. Retrograde pyelography, which is used to identify lesions of the collecting system, may be performed at the time of cystoscopic evaluation to better evaluate or possibly localize upper urinary tract pathology.

Ultrasound can be considered as an alternative to IVP in patients at increased risk from exposure to contrast material, including those with azotemia, diabetes mellitus, or history of contrast allergy. Ultrasound is unable to visualize the collecting system unless it is significantly dilated and is not sensitive for detecting abnormalities of the urothelium. Real time ultrasound is relatively sensitive for detecting calcifications within the renal parenchyma and collecting system, but it does not clarify the clinical significance of such calcifications unless there is significant hydronephrosis, which, in turn, may depend in part on the hydrational status of the patient. If ultrasound is used, it should be coupled with a plain abdominal radiograph (a “kidney-ureter-bladder” film) to examine the remainder of the collecting system for calcifications that could lead to obstruction (e.g., ureteral calculus).

CT scans of the abdomen and pelvis have begun to take on a larger role in the screening evaluation for urologic pathology. CT scans are much more sensitive than IVP for detecting certain types of pathology (e.g., renal masses) although they may be less likely to detect subtle obstruction. With the now common use of spiral CT scanners, this technology is becoming more useful for obtaining large amounts of information in a short period of time. Spiral scanning allows not only narrow “cuts” through the kidney for the detection of stones less than 5 mm, but with newer software programs, three-dimensional reconstruction of the entire urinary tract with excellent detail. One benefit of IVP over CT is that it is a functional and dynamic study, which can be tailored to an individual patient when desired. During a CT scan, there is less control over the technique. Despite this drawback, spiral CT scans undoubtedly will hold a greater place in the imaging of the urinary system in the future.

Lower Tract Bleeding

Asymptomatic

Statistically, most microscopic hematuria of a urologic etiology is clinically asymptomatic and arises from the lower urinary tract. The most prevalent cause in males is BPH. Asymptomatic microscopic hematuria rarely, if ever, leads to a significant decrease in the hemoglobin or contributes to iron deficiency anemia. The significance of this microscopic hematuria lies in the fact that it may be a sign of occult urinary tract pathology. Most urologists believe that even a single detection of microscopic hematuria, without the evidence of infection or prior instrumentation, should be evaluated.

If the detection of urinary tract pathology is unlikely to alter the overall management of the patient, the standard algorithm for evaluating hematuria should be individualized. Cystoscopy is an invasive procedure and may be avoided if an obvious cause for the hematuria is detected. For example, if IVP or ultrasound demonstrate a large renal tumor, additional invasive procedures may not be necessary. Although it is possible that a patient could have a second malignancy or other bladder pathology (i.e., transitional cell carcinoma of the bladder), further evaluation may not necessarily be in the best interests of the patient.

If the source of microscopic hematuria is not detected by imaging studies and cystoscopy is contemplated, the benefits and risks of cystoscopy must be assessed. With newer flexible cystoscopes, cystoscopy now approaches both the risk and discomfort associated with urethral catheterization. However, both flexible and rigid cystoscopy can place a patient with well-compensated bladder outlet obstruction into urinary retention. Additionally, patients with BPH who are likely to have delicate dilated veins on the surface of the prostate as the etiology of their hematuria may be at risk for developing significant bleeding after this invasive procedure.

Asymptomatic gross hematuria can be managed similarly to microscopic hematuria. Patients who experience gross hematuria should be advised to increase their fluid intake and avoid strenuous activity. As long as the patient does not experience significant voiding difficulties, the evaluation of this disorder may proceed electively, in a similar fashion to that already described.

Symptomatic

Symptomatic hematuria is less common than asymptomatic hematuria, yet obviously more clinically significant. The spectrum of symptomatology in patients with gross hematuria ranges from no change in the voiding pattern to acute urinary retention caused by obstruction from clots. Most cases of gross hematuria are alarming, but relatively few patients actually require immediate intervention. As noted, patients with new onset gross hematuria should be told to avoid strenuous activities and increase fluid intake. Increased urine production may dilute the blood in the bladder and reduce the risk of forming clots. Patients taking antiplatelet medications should temporarily discontinue use of these agents because this may enhance the clotting process and limit additional bleeding. A patient is unlikely to develop significant voiding difficulties without the formation of blood clots. If clots are passed, significant bleeding should be assumed and the physician should anticipate the need for

intervention. As the concentration of blood increases and larger clots form, a patient eventually develops clot urinary retention.

The first step in treating a patient with clot urinary retention is to place a large catheter into the bladder and evacuate all of the clots. Preferably, a 22F or 24F catheter is used. It is nearly impossible to evacuate blood clots via 16F or 18F Foley catheters, which are commonly available in catheter kits, as it is not uncommon to irrigate 200–300 cc or more of clot from the bladder. It is also wise to insert a three-way Foley catheter, if available, so that continuous bladder irrigation (CBI) can be started if needed. Analogous to increasing the urine flow rate, CBI dilutes the concentration of blood in the urine, thereby helping to prevent new clot formation. After inserting the catheter and irrigating the bladder free of clot, the cause of the hematuria should be assessed, as described in the section General Considerations. In rare cases, when the bladder cannot be cleared of clot via an irrigating catheter, the patient may need operative intervention, with insertion of a resectoscope and manual clot evacuation with syringes or special equipment. In these patients, one should obtain a complete blood count and coagulation studies to exclude an underlying hematological problem. Unlike microscopic hematuria, gross hematuria can frequently lead to anemia and the hemoglobin must be followed. This is especially true of patients debilitated by chronic disease and those recently completing chemotherapy or radiation therapy, who may have decreased bone marrow reserves.

The management of patients who present with gross hematuria can usually be temporized with catheter drainage. Once imaging studies are performed, a differential diagnosis is formulated. When studies of the upper tracts are normal, the pathology is likely to reside either within the prostate or bladder. Cystoscopy should be able to establish the diagnosis and aid in the development of a treatment plan for disorders of either the prostate or bladder. If bleeding is discovered in the prostate during cystoscopy, it may be difficult to control with fulguration (electrocoagulation) alone. More commonly, when bleeding is discovered emanating from the prostate or bladder neck, some prostatic tissue needs to be resected, and the friable area requires coagulation. Bleeding in this area can be diffuse, and hemostasis may be achieved after completion of the procedure by placing a Foley catheter on traction, which causes compression and tamponade of vessels in the prostate and bladder neck. Once the acute situation is resolved, some patients may develop recurrent or chronic hematuria secondary to prostatic bleeding. There have been several reports indicating the efficacy of finasteride in these patients to decrease the extent and number of recurrent episodes of hematuria (26,27). It should be noted that all of these studies were performed on patients with BPH, and not prostate cancer. Despite this, finasteride is a generally well-tolerated medication and is often used empirically in this situation.

Bleeding that originates from within the bladder is termed *hemorrhagic cystitis* and, as already discussed, most commonly occurs from either radiation therapy or chemotherapeutic agents (14). Unlike radiation therapy, hematuria that results from chemotherapy drugs is not necessarily associated with irritative voiding symptoms. The chemotherapeutic agents most commonly associated with hemorrhagic cystitis are cyclophosphamide (Cytoxan) and its analogs. The incidence of hemorrhagic cystitis in early series was reported to be as high as 68%. The compound acrolein is the active metabolite that actually causes the bladder damage produced by cyclophosphamide (28,29). Mesna (2-mercaptoethane sulfonate) was developed specifically to bind to acrolein and thereby reduce the harmful effects of this by-product (30). Mesna is now given routinely when a patient is treated for malignancy with cyclophosphamide.

As described previously, the hematuria caused by radiation is commonly associated with dysuria, frequency, and urgency. Hemorrhagic cystitis can follow external beam or interstitial radiation treatment of primary genitourinary (prostate and bladder) malignancies, cancers of the cervix or rectum, or other pelvic lesions. The spectrum of hematuria secondary to radiation therapy also ranges from microscopic bleeding to bleeding severe enough to require transfusions. The time course of the development of hematuria ranges from months to years after the initiation of radiation therapy.

The damaging effects of radiation therapy on the bladder are similar to those found in other organs. The clinically significant symptoms in all organs are mediated through vascular damage. Radiation therapy induces an obliterative endarteritis, which leads to telangiectasias, submucosal hemorrhage, and fibrosis of smooth muscle and the interstitium. Ischemia of the mucosal surface due to this endarteritis produces areas of hypoxic tissue, which can break down and cause ulceration and bleeding. If chronic, these changes may eventuate in fibrosis (31). These derangements also cause an irradiated bladder to be extremely susceptible to injury and slow to heal when injured. Unlike treatment with cyclophosphamide, there are no prophylactic measures yet available that can be used to prevent bladder damage. Once radiation hemorrhagic cystitis occurs, aggressive symptomatic intervention should be initiated, and all further radiation exposure must be minimized.

As with other types of gross hematuria, initial management of radiation- or chemotherapy-induced cystitis involves insertion of a large Foley catheter. Removal of all clots is paramount for success in eventually clearing the urine. All subsequent therapies will work better in a bladder free of clots because clot evacuation reduces the naturally occurring fibrinolysins, which may act via the clotting cascade to actually perpetuate bleeding. If initial conservative management with catheter drainage and CBI fails, one must turn to alternative therapies to control the bleeding. Several topical agents can be applied intravesically to aid in cessation of bleeding. Before proceeding with these therapies, cystoscopy should be performed to rule out bleeding from the upper tracts and to fulgurate any obvious bleeding sites.

Empiric therapy may be initiated with e-aminocaproic acid (Amicar) given either orally, parenterally (32), or intravesically (33). e-aminocaproic acid reduces fibrinolysis by inhibiting plasminogen activator substances. This drug has been used extensively for idiopathic hematuria (34) and hematuria of unknown etiology associated with sickle cell disease (35,36). Although there have not been any controlled or randomized studies on the use of e-aminocaproic acid for treatment of hematuria, studies and clinical experience substantiate its use for severe hemorrhagic cystitis. Initially given either parenterally or orally, a loading dose of 5 g is followed by hourly doses of 1.00–1.25 g. Maximal response is usually achieved in 8–12 hours. Patients who initially respond to the parenteral route can then be changed to the oral route for maintenance therapy. Maintenance therapy includes taking the total daily dosage (6–8 g) and dividing it into four doses. When given intravesically, 200 mg of e-aminocaproic acid is added to each liter of 0.9% saline, and this mixture is administered as CBI. A side effect of e-aminocaproic acid is the formation of thick, tenacious clots, which can become difficult for the patient to pass spontaneously and extremely difficult to irrigate in patients with catheters. Administering e-aminocaproic acid to patients with bilateral upper tract bleeding is relatively contraindicated because thick clots in the renal pelvis or ureters can lead to upper tract obstruction, clot colic, or even renal failure.

Silver nitrate 0.5–1.0% mixed in sterile water may be administered into the bladder for treatment of acute bleeding. Rather than being run as CBI, this drug is instilled for 10–20 minutes, after which time the bladder is emptied. In certain refractory cases, multiple instillations may be required (37).

One percent alum has also shown some efficacy in treating hemorrhagic cystitis. Unlike silver nitrate, the 1% solution is usually given via CBI (38,39 and 40). Although somewhat effective, the rates of success are variable. The advantage of alum is that, apart from allergy, the substance is safe and requires no anesthesia.

The most efficacious and probably the most toxic treatment for hemorrhagic cystitis is intravesical formalin. Formalin is the aqueous solution of formaldehyde. Formalin acts by fixing the bladder mucosa by cross-linking proteins, thereby preventing necrosis, sloughing, and blood loss. Studies have shown formalin to be up to 80% effective in arresting bladder hemorrhage (41,42 and 43). Formalin is available as 37% or 40% aqueous formaldehyde, which is diluted with sterile water to yield final concentrations of 10% formalin (3.7% formaldehyde) or 1% formalin (0.37% formaldehyde). Formalin administration is painful and requires regional or general anesthesia. It is administered in concentrations ranging from 1.0–10%, starting at the lowest and progressing to the higher concentrations only as clinically indicated. The bladder is usually filled to capacity using gravity drainage and no more than 15 cm/H_2O pressure. Bladder instillation usually lasts 10–14 minutes (44).

Risks of formalin administration include damage to the bladder and upper tracts. Reflux of formalin to the kidneys can lead to fibrosis, obstruction, hydronephrosis, and papillary necrosis. A cystogram should be performed before formalin administration to rule out vesicoureteral reflux. In those patients who are shown to have reflux, ureteral balloon catheters may be inserted to prevent retrograde flow of formalin. Also, the procedure can be performed in the reverse Trendelenburg position to minimize reflux. Through its ability to cross-link proteins within the wall of the bladder, administration of formalin can lead to a decrease in bladder capacity and, in extreme cases, a nonfunctional, contracted bladder. Patients must be advised of these potential risks and formalin therapy must be reserved only for those cases of hemorrhagic cystitis which are truly refractory to all other medical treatments.

Two other nonsurgical therapies for hemorrhagic cystitis deserve mention. There have been several reports (45,46 and 47) on the use of hyperbaric oxygen therapy for radiationinduced hemorrhagic cystitis. More recent studies have now begun to report on some of the long-term success of the treatment (48,49). Hyperbaric oxygen induces hyperoxia, in which increased tissue concentrations of oxygen are attained by the increased dissolved oxygen in the serum. This condition results in neovascularization and secondary growth of healthy granulation tissue. Thus, hyperbaric oxygen tends to reverse the ischemic process caused by radiation therapy. Additionally, hyperoxia itself induces vasoconstriction, which may have a direct effect on bleeding from the bladder mucosa.

Finally, there have been some reports on the use of conjugated estrogens for treatment of hemorrhagic cystitis. Although the mechanism is unknown, there is a suggestion that estrogens may decrease capillary fragility. Liu et al. (50) reported on five consecutive cases in which bleeding from both radiation therapy and cyclophosphamide was successfully treated with conjugated estrogens. A follow-up study by Miller et al. (51) showed that six of seven patients treated with oral estrogens improved sufficiently to avoid further invasive therapy. Although no standard doses or length of therapy have been established, it appears that the usual starting dose of conjugated estrogens is 2.5 mg twice daily. After an adequate response has been achieved, the dose can be tapered. Final doses appear to be in the range of 1.25 mg daily, which can sometimes be weaned to 0.625 mg daily. Conjugated estrogens are well known to induce cardiovascular complications at high doses. Although no thromboembolic or cardiovascular complications occurred in the two studies mentioned, the long-term safety of estrogens at moderate to high doses is unknown. However, in a terminally ill patient, the benefits of estrogen therapy would certainly seem to outweigh the risks if it could control the significant bleeding associated with hemorrhagic cystitis.

For patients who do not respond to intravesical medical therapy, there are more invasive ways of decreasing bleeding from the bladder. Occasionally, selective embolization of branches of the hypogastric arteries is used to control bleeding. This therapy may be preferred in those terminally ill patients who can not undergo a

major surgical procedure because embolization can be performed under local anesthesia. The procedure works best when arteriography demonstrates a particular vessel responsible for the bleeding; unfortunately, this clinical scenario is unusual. If the entire bladder urothelium appears to be involved, the anterior branches of both hypogastric arteries may need to be occluded. Complications of embolization include claudication of the gluteal muscles, temporary lower extremity paralysis, and even necrosis of the bladder (52).

Some patients fail conservative measures and may require surgery to control the bleeding. Unfortunately, many of these patients are poor surgical candidates due to the ongoing hemorrhage and coagulopathy. These patients, who usually undergo urinary diversion, and at times cystectomy, universally do poorly.

Upper Tract Bleeding

Asymptomatic

As with bleeding from the lower urinary tract, asymptomatic bleeding from the upper tract rarely requires therapy and the same algorithm (i.e., urinalysis, imaging study, cystoscopy, and, possibly, culture) should be applied. Unlike asymptomatic bleeding from the lower urinary tract, however, imaging studies may be more useful than cystoscopy to determine the site of bleeding. For most patients with microscopic hematuria originating in the upper tracts, cystoscopy is usually normal. In patients with gross hematuria and no symptoms (gross painless hematuria), cystoscopy may be able to lateralize the bleeding if the study is performed while the patient is actively bleeding. Once the bladder is filled with irrigation fluid, a “jet” of blood may be seen emanating from the ureteral orifice on the side of the pathology.

Although bleeding itself does not necessarily warrant therapy, the pathology causing the bleeding may require treatment. Common etiologies for upper tract bleeding include renal masses, tumors of the renal pelvis and ureter, stones, and papillary necrosis. Once the site of the bleeding is determined either by imaging studies or cystoscopy, further diagnostic techniques, such as retrograde pyelography, selective ureteral catheterization for cytology, or ureteroscopy, can be entertained. The discussion of further therapy for each pathological condition in an asymptomatic patient is beyond the scope of this chapter.

Symptomatic

Symptomatic bleeding from the upper urinary tract is usually manifest by clot colic. *Clot colic* refers to the acute onset of flank pain secondary to acute ureteral obstruction. Clinically, clot colic mimics renal colic secondary to stones. Differentiating the two can sometimes be difficult, especially because clot colic in the presence of complete ureteral obstruction can present without overt hematuria.

The history and selective imaging studies may assist in the diagnosis of acute ureteral obstruction. Acute onset flank pain in an elderly person who has no history of kidney stones is more likely caused by clot or tumor. Likewise, upper urinary tract obstruction without evidence of calcifications on IVP or ultrasound is more likely secondary to clot or tumor.

Unlike bleeding from the lower urinary tract, there are only a few noninvasive measures that may benefit the patient with symptomatic upper tract bleeding. As in lower tract bleeding, forced diuresis by increasing oral and intravenous fluids may help dilute the blood in the urine sufficiently to prevent clot formation. The administration of e-aminocaproic acid can be considered, but as noted previously, upper tract bleeding is a relative contraindication for the use of this drug because small clots that could previously pass through the ureter may become large tenacious clots that can then obstruct the ureter. Thus, e-aminocaproic acid must be used judiciously in upper tract bleeding.

For patients who continue to develop clot colic from persistent upper urinary tract bleeding, most methods to stop the bleeding generally require invasive interventions. If no pathology is seen on imaging studies, including IVP or CT scan, an arteriogram may be warranted to exclude an arteriovenous fistula. This procedure may be able to identify the area of bleeding so that selective embolization can be performed.

If all studies, including the arteriogram, are normal, one may be faced with the difficult question of whether to remove a kidney or ureter. In this situation, cystoscopy may be extremely helpful in lateralizing the pathology. Once lateralized, ureteroscopy can often be employed as a diagnostic and even therapeutic tool. Recent advances in endoscopic equipment have enabled not only visualization of previously unreachable areas, but also biopsy and fulguration of any suspicious lesions. Despite these advances, there remain rare instances of highly symptomatic upper tract bleeding that are elusive to diagnosis. It is a particularly difficult decision to remove a kidney and ureter without a pathological diagnosis. In this situation, a patient must be very symptomatic and have failed all other more conservative means.

Patients with advanced renal cell carcinoma and metastatic disease may also develop bleeding and clot formation. Palliative measures may include radiation therapy or chemotherapy. Because the prognosis in these patients is very poor and surgery to remove the primary tumor does not impact positively on survival, it is again crucially important to document the degree of bleeding and the relative morbidity arising from the bleeding. Only when bleeding and clot colic impact negatively on quality of life should patients be considered for palliative nephrectomy. Statistically, metastatic tumors are much more likely than primary renal cell carcinomas in terminally ill patients.

UPPER TRACT OBSTRUCTION

Perhaps the most difficult problem in patients with advanced medical diseases is bilateral ureteral obstruction. Without treatment, these patients die of uremia. It is the physician's responsibility to help the patient make the appropriate decision concerning aggressive or conservative therapy. In patients with a limited life expectancy and poor quality of life, conservative therapy may allow a patient to die with dignity. Patients who have exhausted all primary treatments and cannot improve their functional status should not be considered for aggressive therapy. Patients who have received an adequate trial of all known useful therapy and who still have rapidly progressive ureteral obstruction despite the administration of optimal therapy will probably receive little benefit from urinary diversion. Also, patients with severe, unrelenting, and unmanageable pain are seldom better off after diversion.

Because the ultimate end point of bilateral ureteral obstruction is renal failure and uremia, both the patient and physician must understand that without treatment the condition is progressive. The progression of renal failure to uremia is marked by fatigue, decreased appetite, nausea, uremic coma, and eventually, death. In a patient who has been suffering with an end-stage malignancy, this may be a welcome situation.

Percutaneous Nephrostomy

Fortunately, with the advent of modern technology, those patients who are acceptable candidates for diversion of the urine stand a better chance of experiencing significant improvement with minimum morbidity. Before the 1970s, urinary diversion required an open surgical procedure to divert the flow of urine from the kidneys to the bladder. These procedures were problematic because most patients with malignant ureteral obstruction were poor surgical candidates due to their underlying nutritional, hematological, and immunologic status. Grabstald and McPhee (53) studied 218 patients who underwent open nephrostomy for malignant ureteral obstruction. They discovered a major life-threatening complication rate of 45%. There was a 3% operative mortality rate, and 43% of these patients did not leave the hospital. A later study by Meyer et al. (54) showed that 30% of patients undergoing an open urinary diversion procedure died within 52 days of surgery, and the overall median survival was only 3.3 months. Thus, open nephrostomy subjects the patient to significant operative and perioperative risks, without durable responses.

As a result of these outcomes, open surgical procedures have been supplanted by newer percutaneous techniques. In those patients who can tolerate anesthesia, cystoscopic insertion of ureteral stents is probably the preferred method of ureteral decompression. Relative contraindications to this procedure include hemodynamic instability and sepsis. When retrograde insertion of ureteral stents is unsuccessful, percutaneous nephrostomy is the technique of choice to relieve ureteral obstruction. As with most procedures, the chances of success and durable response depend mainly on the extent of the underlying disease and whether valid treatment options still exist. Some studies have shown a poor response after percutaneous nephrostomy. Keidan et al. (55) showed that although renal function improved in 85% of patients, the median survival was only 13 weeks, and 55% of the patients required additional hospitalizations for urosepsis and additional procedures. However, a study by Gasparini et al. (56) revealed much better results, albeit in a patient population that included many patients with newly diagnosed disease. They showed that 77% of patients undergoing either percutaneous nephrostomy (68%) or cystoscopic stent insertion (32%) were able to be discharged home. The mean survival time after urinary diversion was 75 weeks, and one patient lived as long as 4.7 years. There appeared to be a survival advantage in those patients who had not previously undergone hormonal therapy or chemotherapy. Also, in contrast to previous studies, there were no perioperative deaths or cardiac, pulmonary, or hemorrhagic complications. Thus, in properly selected patients, endoscopic or percutaneous urinary diversion can be relatively safe and efficacious.

A patient who successfully undergoes percutaneous nephrostomy and returns to a normal lifestyle can be considered for internalization of the nephrostomy tube. This requires placing a ureteral stent into the ureter through an anterograde approach. Hepperlen et al. (57) showed that patients with pigtail ureteral stents, whether inserted initially or after conversion of nephrostomy tube to stent, survived an average of 277 days. More importantly, these patients spent only 8.4% of their remaining time in the hospital. Similarly, Gibbons (58) found no operative mortalities and an 88% satisfaction rate after insertion of a ureteral stent. In contrast, a series by Brin et al. (59), which examined patient outcome after nephrostomy, revealed an average survival of 162 days with 63% of the time spent in the hospital. Thus, there appears

to be a significant survival and quality of life advantage in patients with indwelling stents compared to nephrostomy tubes.

Finally, as with urethral obstruction secondary to malignancy, there have been reports of self-expanding metal stents for treatment of ureteral obstruction. Lugmayr and Pauer (60) studied 23 patients who underwent insertion of the Wallstent device for malignant ureteral obstruction. They were successful in implanting the device in 97% of patients, and 83% of the stented ureters remained patent after 30 weeks. Because 81% of patients survived at least 6 months, the patency rate appeared comparable to survival rates. Thus, ureteral stenting may offer a viable option for treating the obstructed ureter.

PRIAPISM

Although an extremely uncommon oncologic complication, priapism can present severe morbidity for an affected patient. *Priapism* refers to a sustained, painful, penile erection not induced by sexual stimulation. If left untreated, priapism eventually leads to fibrosis and impotence. Although impotence is not generally a concern in the palliative care patient, the severe pain caused by priapism is certainly relevant. Priapism in the oncology patient may have multiple causes including vascular congestion from hematological malignancies, direct invasion of tumor into the corporal bodies, or disruption of venous outflow from a pelvic mass. Regardless of the cause, treatment of malignant priapism is aimed at treating the primary tumor and may include chemotherapy, radiation, or a combination of therapies (61).

CONCLUSION

The ultimate goal with all urologic complications in patients with progressive medical diseases is to maximize the quantity of life without jeopardizing or negatively impacting quality of life. Urologic complications in these patients can arise from benign or malignant disease processes, or as a consequence of treatments for an underlying malignancy. With the armamentarium of imaging studies, medications, and surgical interventions, the physician treating these patients can strive to allow them to live the remainder of their lives to their fullest capacity.

MANAGEMENT OF RENAL FAILURE

SCOTT LONG

This chapter first describes renal failure (RF) in cancer patients at diagnosis and during treatment, mostly acute renal failure (ARF). The second part concerns the care of cancer patients dying of RF and for whom no curative therapy is sought.

RF is characterized by azotemia, metabolic offsets (e.g., hyperkalemia, acidosis), and, in many cases, volume overload. ARF is distinguished by an onset of serious dysfunction over a few days and is often reversible if treated early. Chronic renal failure (CRF) results from parenchymal damage of longer duration, sometimes evolving from undetected or uncorrectable ARF. No clearly defined time limit signals a patient's renal dysfunction passing from ARF to CRF. End-stage renal disease (ESRD) usually implies the need for dialysis to maintain acceptable quality of life in patients with CRF.

Although the perspective in this chapter is primarily medical, care of patients and families entails not only clinical expertise but also education, emotional support, guidance, patience, and responsibility at each step. This undertaking can rarely, if ever, be accomplished by a single clinician. Willing collaboration among caregivers with recognition of individual strengths and limitations furthers cooperation between those giving and those receiving care (1).

INCIDENCE AND CAUSES OF RENAL FAILURE IN CANCER PATIENTS

Epidemiology of RF has changed over recent decades (2,3,4 and 5). Older patients with significant comorbidity, wider use of nephrotoxic agents, increased incidence of sepsis, and multiorgan failure (3,4,6,7) have all complicated RF associated with malignancy. In one large study, one-third of patients with ARF were treated in intensive care units (ICU) in which mortality was 72% compared to mortality of 32% elsewhere in the hospital (8). Mortality rates of 40–60% in patients with ARF of all etiologies have shown little change over the last decades, although two surveys point out improved survival in ARF due to trauma, obstetric, and postoperative cases of severe ARF (3,5). Mortality rates in patients admitted to the hospital for ARF from the community are smaller (15–35%), especially when the kidney is the only organ compromised (9,10 and 11).

During the last two or three decades, ARF and other renal syndromes specifically related to cancer and its therapies have been reviewed (12,13,14,15,16,17,18,19,20,21 and 22). The literature does not set a single defining value of azotemia for ARF. Creatinine levels used to define ARF may vary from 2.0 to 5.7 mg/dl after rehydration, or as increases of 25–100% baseline in creatinine levels (2,5,20,23,24 and 25).

What is the incidence of RF among cancer patients? In a study of renal handling of morphine sulfate, 16 of 109 cancer patients had serum creatinine levels of 3 mg/dl or greater (26); in another study of 36 hospice patients with cancer, 10 had serum creatinine >1.35 mg/dl (27). RF is more common among patients with certain tumors (e.g., multiple myeloma, lymphomas) and treatments (e.g., bone marrow transplantation, radiocontrast dyes, aminoglycoside antibiotics). Among 494 myeloma patients with previously undiagnosed disease, 18% suffered from RF (creatinine >2 mg/dl) (23). In a particularly striking study, 80 of 85 myeloma patients presented with renal insufficiency (serum creatinine >1.5 mg/dl), with an average serum creatinine of 7.9 mg/dl (28). Of 349 patients with hematological neoplasms, 149 (43%) had serum creatinines above 1.7 mg/dl, and 43 (12%) required dialysis (29). Among 272 bone marrow transplant (BMT) patients, 64 (24%) required dialysis; 79 (29%) other patients doubled their baseline creatinines but did not require dialysis (30).

In cancer patients, RF may result from actions of tumors on the kidneys before treatment as well as from diagnostic and therapeutic procedures; nephrotoxicity and ischemia are the major pathways.

The most direct involvement of the kidneys by cancer is renal cell carcinoma (RCC). In one study, ARF occurred in 13% (33/259) of patients undergoing surgery for RCC. ARF was associated with solitary kidney, large tumor size, volume of renal tissue excised, longer times of ischemia, and *ex vivo* surgery (31). Although RF does not usually result from parenchymal infiltration and metastatic deposits, parenchymal infiltration by leukemias and lymphomas is commonly found at autopsy (15); renal metastases were found in 18% of autopsied cancer patients (32).

Acting at greater distance, tumors release antigens that may create pathological changes, most commonly membranous glomerulopathies (especially in stomach, colon, and lung cancer) and minimal change glomerulopathy (especially in Hodgkin's lymphomas). Reviews by Norris and by Mead and Morley are particularly concerned with glomerulopathies associated with cancer (18,33).

Tumor effects on the vascular system can produce RF through disseminated intravascular coagulation, hemolytic uremic syndrome (HUS), and thrombotic thrombocytopenic purpura (TTP); these may arise from distant tumors, from associated conditions like sepsis, and from therapies directed against cancer. Disseminated intravascular coagulation may occur from pancreatic, gastric, prostate, and trophoblastic tumors (33), as well as from acute promyelocytic leukemia (15). HUS and TTP may appear with mucinous gastric adenocarcinoma and carcinomas of pancreas and prostate. Lymphomatous vasculitis can produce glomerulopathy. Large-caliber vessels also may be involved, e.g., in renal vein thrombosis in RCC, in direct invasion by tumor, or in partial venous blockade by adenopathy. Some chemotherapeutic agents promote renal vasculopathy; for example, mitomycin C; bleomycin sulfate plus cisplatin; and high-dose cyclophosphamide plus radiation therapy all promote HUS and TTP.

A single type of tumor may compromise renal function through multiple pathways. Multiple myeloma produces renal damage by toxic effects of light-chain absorption in proximal tubular cells, by obstruction due to intratubular coagulation of myeloma proteins and cellular debris, by parenchymal precipitation of calcium phosphate crystals (nephrocalcinosis), and by deposition of amyloid (23,28).

Conditions blocking renal drainage promote ARF (e.g., retroperitoneal adenopathy of genitourinary tumors or lymphomas compressing ureters; intraureteral blockade by clots, by “sludge” of phosphates, urates, and other products of cell breakdown in tumor lysis syndrome or by renal stones). Retroperitoneal fibrosis producing RF may occur in some cancers after use of methysergide or as a late complication of radiation therapy (34). More distal bilateral ureteral obstruction by genitourinary or other pelvic tumors can produce the same deleterious effects.

Some chemotherapeutic and immunosuppressive agents create dose-related renal damage with such regularity that routine precautions are mandatory. Frequently used for solid tumors, cisplatin at 50–75 mg/m^2 lowers glomerular filtration and is directly toxic to renal cells. Presenting both acutely and chronically, its toxic effects can be mitigated by amifostine (35), in addition to using divided doses of cisplatin and to solute diuresis before, during, and after infusion of the agent. The related compound carboplatin creates less nephrotoxicity but significant marrow suppression; it can be helpful in patients with preexistent risk factors for RF.

Methotrexate (MTX), particularly at high doses (1–7 g/mg/m^2 body surface area), creates damage through intratubular obstruction by precipitated crystals and possibly through direct antimitotic effects on renal cells, as well as by afferent arteriolar constriction. Renal compromise before or after its first use calls for dose-adjustment of MTX; its toxicity includes not only the kidneys but also bone marrow and the gastrointestinal tract. Intravenous hydration with alkaline diuresis, especially if used with high doses requiring leukovorin, helps diminish this compound's nephrotoxicity. RF due to MTX often improves within weeks of its discontinuation (13,19,20 and 21).

Streptozotocin, used in endocrine tumors of the pancreas and in carcinoid tumors, causes both glomerular and proximal tubular damage, including renal insufficiency and, in some cases, severe ARF. RF after exposure to other alkylating agents (e.g., carmustine and lomustine) is less frequent but may present insidiously after

chemotherapy has finished (20,21).

Mitomycin C, used in gastric adenocarcinoma and bladder and anal cancers, produces thrombotic microangiopathy and HUS in patients receiving cumulative doses >30–50 mg/m^2. RF may result 1–2 months after the most recent dose or may be delayed for a much longer period. Although <10% of patients are afflicted with this complication, as many as one-third of these eventually require dialysis. Concurrent use of mitomycin C and tamoxifen citrate in breast cancer patients increases the risk of HUS (20).

The alkylating agent *ifosfamide* is associated with a wide range of renal toxicities. Young age, previous renal damage, and high doses are associated with RF, often delayed in appearance and at times irreversible. Use of divided doses protects the kidney. Mesna, used to prevent cystitis associated with ifosfamide, does not protect the kidney (36).

Among antineoplastic biological agents, *interleukin-2*, used in the treatment of melanoma and RCC, can cause serious renal compromise as part of changes mimicking sepsis, including hypotension and oliguric azotemia. Repeated use increases recurrence and severity of this syndrome. *Interferons* are less frequent causes of ARF (21).

The immunosuppressive agents, *cyclosporin A* and *FK306 (tacrolimus)*, produce both acute and chronic insults to renal function. Acute arteriolar vasoconstriction may be reversed by dose reduction and does not necessarily progress to ARF requiring dialysis. Chronic interstitial fibrosis can occur 6–12 months after exposure to these agents and can progress to ESRD (37,38).

BMT is increasingly used for hematological malignancies and solid tumors. Unfortunately, it is associated with ARF in one-third to one-half of patients. During marrow ablation and reduction of malignant cells, platinum compounds, high-dose MTX, and ifosfamide may precipitate tumor lysis syndrome, as may whole body irradiation. Infection, including sepsis with RF, may occur during this period of immunosuppression. ARF may be further favored by nephrotoxic compounds like aminoglycosides and amphotericin B, which are used to control infection. Infusion of marrow stored in dimethyl sulfoxide can reduce extracellular fluid (ECF) volume through nausea, vomiting, and diarrhea that has been triggered by chemotherapy. Short- and long-term renal injury due to whole body irradiation is reduced by shielding the kidneys (39). The incidence of many of these insults in BMT can be reduced by precautions such as i.v. hydration, alkaline diuresis, allopurinol, and leucopheresis. In the months after transplant, further serious RF can develop related to graft-versus-host disease and its therapies; still later, ARF associated with HUS/TTP may occur (20,38).

Other medications commonly used in cancer patients are also associated with ARF. Aminoglycosides and radiocontrast agents are nephrotoxic. Allergic interstitial nephritis leading to ARF has been identified with beta-lactam and sulfonamide antibiotics, nonsteroidal anti-inflammatory drugs (NSAIDs), thiazide diuretics and furosemide, allopurinol, phenytoin, and cimetidine. Renal perfusion is reduced in some situations by NSAIDs, angiotensin converting enzyme inhibitors, calcineurin inhibitors, amphotericin B, interleukin-2, and radiocontrast dyes (40). Injury from radiocontrast agents is promoted by increased age (>60), diabetes mellitus, preexistent renal disease, decreased ECF volume, and high dose(s) of contrast. The recent use of acetylcysteine in patients with chronic renal insufficiency, as well as careful hydration before dye exposure in all patients, has increased renal protection from injury by radiocontrast dyes (41).

Chronic and acute comorbidities often exacerbate renal insult in cancer patients, many of whom are elderly with decreasing renal reserve and are burdened with other illnesses like diabetes mellitus. Age alone has been identified as an independent risk factor for RF in many studies (3,7,24), but not all (42,43,44 and 45). In the elderly, falling glomerular filtration rate, decreased muscle mass, and reduced ECF volume may produce a falsely “normal” creatinine, which overestimates real creatinine clearance. In this population, creatinine clearance should be measured for a more reliable guide to dosing of potential nephrotoxins (46). In ICUs, the chances of recovering meaningful life, or life at all, decrease rapidly as additional systems fail (5,11).

Anticipating and minimizing effects of disease and therapies on renal function are key steps in protecting one's patients from RF and reducing its complications. Even modest degrees of RF may increase mortality, independent of comorbidity (25). Iatrogenic RF was identified in 40–55% of patients with hospital-acquired renal insufficiency or failure (11,42,45). Many patients have two or more preexistent factors for renal damage, and >50% in one study had two or more acute insults (43,45). Evaluation of baseline renal function identifies patients already at risk, may signal the need for specific preventive measures, and guides treatment of evolving renal compromise if it arises.

DIAGNOSIS OF RENAL FAILURE

Rising azotemia in routine testing of asymptomatic patients is often the first indication of renal insufficiency or failure. Once alerted, the physician begins to search for causes, to measure the rate, and to correct the consequences of evolving failure. Much depends on early detection and effective treatment. ARF can evolve into death or into worsening RF and then CRF with or without dialysis (11,42,47,48). Preexistent renal compromise increases the risks of permanent renal damage (47). Delayed consultation (or no consultation) with nephrologists leads to worse outcomes for patients with RF (9,49).

Physiologically, ARF falls into three general categories: prerenal, renal [also called *parenchymal failure*, *intrinsic failure*, or *acute tubular necrosis* (ATN)], and postrenal. Most studies of ARF report hospital experience. Of 748 hospitalized patients with ARF of all etiologies, approximately 50% had ATN, 25% prerenal, 13% acute-on-chronic, and 10% postrenal causes (8). ATN predominates in the ICU. Community-based studies show greater incidence of prerenal and postrenal failure and lower incidence of ATN in patients hospitalized for community-acquired ARF (9,10 and 11). In each physiological category, RF is further characterized by urine output: anuric <50–100 ml/day, oliguric <400 ml/day, and nonoliguric at higher rates. Patients in nonoliguric RF generally fare better because volume overload is less problematic (11,24,43).

Prerenal failure indicates that one or more precipitating causes of failure are “upstream” from the kidney. A history of ECF depletion, decreases in daily weight and in fluid intake/output, and an examination revealing poor skin turgor, dry oral mucosa, dry axillae, resting tachycardia, orthostatic pulse and pressure, all suggest prerenal failure. Patients with prerenal failure tend to produce small amounts of concentrated urine with low sodium content. Creatinine (urine/plasma) ratios may be ³40, urinary osmolality ³500 mOsm/l, and fractional excretion of sodium £0.01 in patients without renal insufficiency and no recent diuretic use. Plasma blood urea nitrogen/creatinine in prerenal failure is usually ³20. These parameters are less reliable among elderly patients in whom the ability to concentrate urine is reduced (46). Urinary indices can be helpful but not diagnostic. In some patients, increased urine flow after cautious fluid challenge is diagnostic of prerenal failure; for example, small fluid challenges of 200 ml (plus or minus “renal” dopamine) with concomitant central venous or capillary wedge pressure measurement are helpful in assessing ECF status (50,51).

Urinary sediments in prerenal failure are generally free of cellular debris other than clear hyaline tubular casts. In ATN, “active” or “busy” sediments show epithelial cells, cellular debris, and tubular casts, but may contain no casts. Red cell casts suggest glomerulonephritis; tubular casts of leukocytes occur in allergic interstitial nephritis (e.g., due to penicillins, cephalosporins, NSAIDs, and allopurinol) (50,51).

Postrenal failure indicates obstruction “downstream” from the kidney. Ureteral obstruction by tumor, lymphadenopathy, or retroperitoneal fibrosis produces RF through increased back pressure, which compromises renal circulation and glomerular filtration and results in hypoxia. Renal vein thrombosis in renal cell carcinoma causes similar problems. Malignancy is a common cause of postrenal failure and is associated with higher death rates than obstruction of nonmalignant cause (52).

Identified prerenal or postrenal failure does not preclude parenchymal damage because ARF often has more than one cause (8,42,43,45,47). Laboratory testing can identify or consolidate a diagnosis of ATN. Imaging studies with ultrasound, computed tomography, and magnetic resonance imaging, often used early to rule out postobstructive lesions, also describe size and number of kidneys with estimation of cortical thickness to identify preexistent disease (53). Renal biopsy to guide therapy needs consideration if there are no obvious causes for parenchymal damage or if aspects of history, examination, and laboratory data suggest other causes of RF (e.g., glomerular, interstitial, or vascular disease) for which specific treatments exist. In large series of ARF of all etiologies, biopsy rates range from 0–24% (2,6,11,54). Some consider the presence of a terminal illness a contraindication for renal biopsy (55), although biopsy is frequent in workup of myeloma patients, ranging from 33–48% (28,56,57).

TREATMENT OF RENAL FAILURE

Therapies for RF in cancer patients can be divided into two groups, depending on clinical context. The first therapies (“cure plus care”) are based on the judgment that the quantity and quality of life at risk are worth great effort to save or prolong significantly. In this first group, therapy aims to correct underlying pathophysiology and its consequences and to optimize patients' health and comfort. The second group of therapies (“care only”) is brought into play when active curative therapy is no longer sought; these patients often continue some of the palliative measures (e.g., analgesia) started in the “cure plus care” phase. They receive comfort care through palliation of symptoms, understanding that such care will not reverse underlying disease but may make it easier to bear; at this point, hospice may become involved. During evolution of RF or cancer, placement of patients in these groups may change. Advance directives and other earlier consultations between patient/family and caregivers make further discussions easier for all concerned, even if earlier decisions are reversed (58,59).

Active treatment of some problems caused by RF may be required soon after detection to protect the patient's status during further workup and therapy and to prevent evolution of renal damage into long-lasting compromise or death. Treatments chosen depend on the severity of signs and symptoms, comorbidity, desired effects, side effects of each agent or intervention, and overall goals of patient and family.

Nondialytic Therapy

Volume overload most often occurs in patients with oliguric failure unresponsive to cautious fluid challenge. Diuretics (e.g., mannitol, furosemide) and vasodilators (e.g., lowdose dopamine) do not consistently convert oliguric to nonoliguric failure in the early phase of ARF (60,61). Medications to correct other aspects of ARF (e.g., sodium bicarbonate for acidosis or for urinary alkalinization) may promote volume overload and pulmonary edema. Oxygen should be used to counteract hypoxia in pulmonary edema. Increasing venous capacitance with morphine sulfate and some other vasodilators may gain time in the most urgent cases of volume overload. Pulmonary edema requires correction with hemodialysis or hemofiltration unless rapidly resolved by more conservative measures. In less urgent cases, restriction of salt (<2 g/day) and water (<1 l/day) intake, as well as loop diuretics in nonoliguric failure, protects patients from fluid overload. The gut also may be used to excrete fluid through the promotion of diarrhea with poorly reabsorbed carbohydrates like sorbitol or lactulose; as much as 4–5 l/day can be lost by these means.

Metabolic acidosis due to decreased acid excretion in RF and rising acid production in hypercatabolism exerts multiple deleterious effects (e.g., promotion of hyperkalemia and changes in protein structure and function). Neurological and cardiovascular deterioration may result. Acidosis can be controlled by oral or intravenous bicarbonate replacement to bring bicarbonate above 15 mEq/l. Monitoring protects patients from adverse consequences of bicarbonate loads, such as hypocalcemia, hypokalemia, alkalosis, and volume overload. In urgent cases, usually in conjunction with other metabolic offsets, acidosis requires dialysis (e.g., for bicarbonate <10 mEq/l or pH below 7.20). In less severe acidosis, diets low in protein (approximately 0.5 g/kg body weight/day) and high in carbohydrates (approximately 100 g/day) diminish acid production.

Hyperkalemia may accompany RF of all causes, but rapid accumulation of K^+ in ECF is especially threatening with tissue destruction (e.g., tumor lysis syndrome). Hyperkalemia and its treatment are best monitored with plasma levels and electrocardiographic changes. At [K^+] approximately 7 mEq/l, high T-waves and depressed S-T segments occur, followed at [K^+] approximately 8 mEq/l by intraventricular conduction blocks and loss of P-waves, leading to ventricular standstill. Emergent correction of hyperkalemia and follow-up measures to maintain plasma [K^+] at safe levels are described in standard medical texts and manuals.

Hypercalcemia (>14 mg/dl or 3.5 mmol/l, corrected for albumin) is a common metabolic emergency in cancer patients (62). Its incidence is as high as one-third of all myeloma patients with RF (16,56). Myeloma patients with serum [Ca^{2+}] >11.5 mg/dl (corrected for protein binding) had a significantly higher incidence of RF (49%) than those with lower [Ca^{2+}] (10%) (23). Of 50 patients seen for hypercalcemia in hospital setting, cancer was the cause in 41, half of these due to lung cancer (63). Further discussion of hypercalcemia and its treatment in cancer patients is found in Chapter 34.

Hyperuricemia (>15 mg/dl) in cancer patients is primarily the result of tumor lysis syndrome (16). In one series of 43 patients with hematological tumors, 26% were dialyzed for tumor lysis syndrome (29). In addition, tumor lysis syndrome occurs in patients with some solid tumors (64). It can occur spontaneously and should be sought before therapy in patients at risk. Diagnosis of acute uric acid nephropathy in tumor lysis syndrome is suggested by appropriate history and laboratory values. At uric acid levels >20 mg/dl, crystals form in the renal medulla to cause obstruction and inflammation promoting RF. Sludge of uric acid crystals and amorphous material in the renal pelvis and ureters may add a postrenal component. Urinary amorphous or crystalline urates are not diagnostic.

Prevention of hyperuricemia and other metabolic problems in tumor lysis syndrome is preferable to treatment whenever possible. Preventive measures given before, during, and after chemotherapy consist of vigorous intravenous hydration with loop diuretics, allopurinol, and, in patients not already hyperphosphatemic, urinary alkalinization. Alkalinization must be avoided in hyperphosphatemic patients because alkaline urine favors nephrocalcinosis and creates or worsens failure. Thiazide diuretics promote urate reabsorption and are not used. Even without sodium bicarbonate or acetazolamide, hydration may produce fluid overload, especially in oliguric RF. In such cases, hemodialysis is necessary, sometimes on a daily basis to reduce urate quickly.

Hyperphosphatemia (>5 mg/dl or >1.67 mmol/l), like hyperuricemia, is particularly threatening in tumor lysis syndrome. Not only is it associated with nephrocalcinosis, but concomitantly lowered [Ca^{2+}] may present problems in neuromuscular, cardiac, and central nervous system function. In severe cases, usually associated with other metabolic problems, hyperphosphatemia requires dialysis. Mild to moderate elevations of serum phosphate concentrations are commonly found in RF as a result of decreased renal phosphate clearance and increased release of cellular phosphates in acidosis. In these conditions, hyperphosphatemia usually is controlled by phosphate-binding antacids (e.g., aluminum hydroxide), by dietary reduction (including parenteral phosphate), and by avoidance of phosphate-rich enemas (e.g., Fleet enemas). Magnesium-containing antacid should not be used because magnesium accumulates in RF.

Infection in many patients precipitates RF, exacerbates established RF, and threatens renal recovery. Sepsis in patients with ARF is associated with increased mortality (2,3,11,29,54,56). Insults to body integrity are superimposed on the compromised immune system in RF by urinary catheters, intravascular devices, and intubation. During workup of a serious suspicion of infection, one should begin treatment with antibiotics that are chosen to minimize further renal damage and are adjusted for ARF and its concurrent therapies (e.g., dialysis) (65,66).

Some antibiotics can complicate RF. For example, penicillin G promotes seizure activity, whereas K^+ penicillin contributes to hyperkalemia (3 mEq/million units). Trimethoprim, cefoxitin sodium, and cefotetan disodium may cause spuriously high creatinine levels. Tetracyclines may promote uremia through their effects on protein metabolism. Antibiotics dependent on glomerular filtration and tubular secretion (e.g., penicillins, cephalosporins, trimethoprim, and sulfonamides) achieve higher urine concentrations than those dependent on glomerular filtration alone (e.g., aminoglycosides) and are often associated with allergic interstitial nephritis. The aminoglycosides are notoriously nephrotoxic (67).

Nutritional support is provided to patients with RF in partial compensation for protein catabolism and other metabolic dysfunctions, decreased intake, and nutrient loss (e.g., through dialysis). In patients with limited to moderate catabolism, patients should receive supplements to provide energy at 25–30 kcal/kg body weight/day. In those in severe hypercatabolic states (e.g., sepsis or multiple organ dysfunction), the target rates are nearer to 35 kcal/kg body weight/day because rates of oxygen consumption are 20–40% higher than those in normal health. In a prospective study, severe malnutrition was found in 130 of 309 patients with ARF; malnutrition showed a significant correlation with complications (e.g., sepsis), mortality, and length of stay. Of particular relevance to this chapter, 75 of these patients had cancer (68). Nonetheless, despite the many reasons aggressive nutritional supplementation should promote greater well-being and quicker healing in patients with ARF, clinical studies have not consistently shown better return of renal function and longer patient survival when it is provided (61,69).

For complicated patients in ICUs, nutritional supplements should start within 48–72 hours. Patients who are not expected to receive adequate calories by mouth within 5–6 days after onset of ARF should also start nutritional supplements. Enteral routes are preferred for physiological reasons, including the gut's barrier function, immune support, quality of life, and economy. Although dialysis may facilitate nutritional supplementation, it also imposes an additional route for nutrient loss, which will require replacement. Nutritional supplementation entails other risks, such as electrolyte and acid-base imbalances, and may require more intensive dialysis for control of volume and of increased uremia. For optimal nutritional support, the managing physician needs collaboration with a nephrologist, a nutritionist, a pharmacist, and nurses.

Hematological problems in RF include anemia and coagulation problems. *Anemia*, common even in early RF, often has several causes (e.g., bleeding, blood loss through dialysis or surgery, and diminished erythropoietin synthesis in damaged kidneys). Acute repletion occurs through hemostasis and transfusions; erythropoietin supports chronic repletion where appropriate. *Coagulopathies* in uremic patients result primarily from platelet dysfunction but also from anemia, coagulation factor abnormalities (e.g., von Willebrand factor), and thrombocytopenia, as well as other coagulopathies due to comorbid conditions, including cancer. Coagulation is usually measured as bleeding time (normally 6–9 minutes); risk of hemorrhage occurs, especially when the bleeding time exceeds 10 minutes. Temporary or partial correction of coagulopathy in preparation for invasive procedures like renal biopsy can be effected by several means, including infusion of cryoprecipitate, synthetic vasopressin, and infused or oral estrogens (70).

Gastrointestinal bleeding occurs in up to one-third of patients with RF, usually due to stress ulcers. It is most often mild but can be life threatening (11,54). Its role in mortality has decreased with improved prophylaxis and therapy with proton pump inhibitors, H_2 blockers, sucralfate, and antacids. One complication of antacid use is that a more alkaline gastric mucosa favors bacterial growth. Sucralfate suppresses gastric acidity less than the other agents and in one study of ventilated ICU patients was associated with fewer latedeveloping pneumonias than ranitidine or antacid (71).

Uremic encephalopathy, as with many clinical consequences of uremia, shows great variations among patients but is generally worse when azotemia develops rapidly. Anorexia, insomnia, and restlessness characterize the first phase, along with decreased attention and mentation. In untreated encephalopathy, emotional lability, decreased ability to think, vomiting, and lethargy follow. The most severe consequences are agitated confusion, dysarthria, and bizarre behavior, proceeding to stupor, coma, and death (72). Convulsions appear in this phase; in two early studies, the incidence of seizures varied from 5–38% (73,74A). The differential diagnosis of such neurological changes includes paraneoplastic encephalopathies, other metabolic disorders (e.g., liver dysfunction), and medication-induced changes in neurological function (e.g., confusion associated with opiates, benzodiazepines, or NSAIDs). Meperidine hydrochloride metabolites, penicillins, and theophylline have all been

associated with seizures. Quiet surroundings, reassurance, and reorientation by a small number of familiar caregivers help patients in the early stages of uremic encephalopathy. However, medication is often needed; for example, benzodiazepines not only calm the patient but also decrease the likelihood of seizures. A useful review of treating delirium at the end of life has been published, but its recommendation of haloperidol is not advisable in patients in RF (74B). Use of the antipsychotics haloperidol and chlorpromazine for confusion are contraindicated due to their lowering the seizure threshold. Many psychotropic medications (see the section Adjustment of Medication) can be given relatively safely to patients with RF; however, dosing regimens must be monitored and individualized to effect (66,75). Advancing neurological symptoms argue strongly for initiation of dialysis in appropriate patients.

Many drugs and their administration, including antineoplastic medications (76,77), are seriously affected by RF and its therapies. Manuals and reviews exist to guide dose and schedule modification in patients in RF, treated with or without various forms of hemofiltration or dialysis (66,78). Use of analgesics, anticonvulsants, and psychotropics in patients dying of RF is discussed in the section Adjustment of Medication.

In developing ARF, the Cockcroft-Gault equation does not allow adequate estimation of creatinine clearance because serum creatinine levels lag behind renal function; recommended dosage guidelines assume creatinine clearance <10 ml/h in patients with declining renal function. During the recovery phase, underdosing may occur as a result of offset between serum creatinine and renal function in the opposite direction. An additional pitfall in recovery is that rising urine flow rates may incorrectly be assumed to correspond with increasing creatinine clearance, which should continue to be measured (79).

Dialysis

In patients with RF not controlled by conservative measures, dialysis is used to correct signs and symptoms of uremia and of electrolyte and acid-base imbalances; to remove fluid overload; to “make room” for other therapies such as nutrition, blood products, and intravenous medications; and to protect the patient prophylactically from complications before their emergent presentation. ARF develops over a few days or less, and in its initial phase azotemia, abnormal electrolytes, and acid-base values may underestimate renal dysfunction. ARF represents a greater threat to homeostasis than does CRF, as there is a longer period for physiological adaptation in the latter. In the presence of significant comorbidities, as often found in cancer patients, a strong case is made for early initiation of dialysis (50,60,80). Dialysis rates for ARF vary according to clinical setting, usually 13–18% for community-acquired or non-ICU patients and 71% in patients in the ICU (8,9). Rates of dialysis for cancer patients (multiple myeloma, RCC, BMT, hematological malignancies) are reported from 9% to 42% (28,29,30 and 31,56).

Although criteria for urgent dialysis vary among nephrologists, the following are frequently used (24,29,80,81): (a) progressive hyperkalemia, e.g., [K+] 6.0–6.5 mEq/l with electrocardiographic changes if not responding rapidly to conservative therapy; (b) severe acidosis with bicarbonate <10 mEq/l and pH <7.20; (c) volume overload with oliguria, pulmonary edema, congestive heart failure, or hypertension resistant to nondialytic therapy; and (d) azotemia, generally blood urea nitrogen levels of 80–120 mg/dl and creatinine levels of 8–10 mg/dl. Dialysis is begun at lower levels of the cited variables when patients have threatening uremic signs and symptoms like pericarditis, encephalopathy, hemorrhage, or vomiting. Rapid development of uremia favors these signs and symptoms. In tumor lysis syndrome, hyperuricemia, hyperkalemia, and hyperphosphatemia with symptomatic hypocalcemia require prompt dialysis. Hypercalcemia with renal compromise in multiple myeloma is another cause for immediate dialysis.

Techniques for renal replacement in RF include intermittent hemodialysis (IHD), slow continuous renal replacement therapy (CRRT), and peritoneal dialysis (PD) (82,83). Different techniques may be used sequentially in a patient; for example, IHD or PD maintenance therapy after emergent correction by IHD or CRRT.

IHD is an efficient means of altering composition and volume of ECF. In patients with life-threatening volume overload or changes in ECF composition, it is often the method of choice. Associated with rapid shifts in electrolytes, this technique can promote cardiac arrhythmias or hypotension, which in turn may cause further renal injury, as can the use of bioincompatible membranes. IHD is poorly tolerated in patients with cardiovascular instability or multiorgan system failure found in 25–50% of hemodialysis patients (82,83 and 84).

CRRT offers the advantages of hemodynamic stability coupled with control of ECF volume and composition in cancer patients with multiple problems, including cardiovascular instability, hypercatabolism, and the need for large volumes of fluids (e.g., medication and nutrition) (80). However, these therapies require indwelling intravascular catheters, patient immobility, intensive nursing care, and careful control of coagulation for days at a time. The indications for IHD and CRRT in ARF continue to be debated (83,84).

PD produces more gradual changes in volume and composition of ECF than IHD does, is less expensive, and requires no anticoagulation. Its use in emergent ARF is increasingly limited, although it is used more frequently in pediatric cases (83). It is widely used in the treatment of CRF. Recent abdominal surgery or the presence of adhesions argue against use of PD, as do abdominal vascular grafts, which can become infected during bouts of peritonitis.

Outcomes of Dialysis

Most patients with ARF (of all causes) either respond to dialysis or die within a month or two of its initiation (11,23,28,29,48). Among cancer patients undergoing dialysis, survival is poor. Mortality among 588 cancer patients dialysed from 1956 through 1993 averaged 62% (2,3 and 4,28,29,30 and 31,56,81,85,86 and 87). Most survivors of ARF of all causes live without dialysis, although some have persistent renal insufficiency (9,10,47,48), and a few (1–3%) require dialysis for ESRD (11,48).

Dialysis is reported for none to nearly one-third of cancer patients with CRF studied (6,31,42,43,47,85). Among 234,296 patients starting dialysis for ESRD from 1989 through 1992, 1.3% had malignant causes for RF. Nearly one-third of these patients died within the first year of treatment, a rate surpassed at that time only by acquired immunodeficiency syndrome patients with ESRD (88). In another study, 10% of 1766 patients starting dialysis for ESRD had cancer and were more likely to withdraw from dialysis than those without cancer (89). In one study of early death on dialysis (113/822 ESRD patients died in 6 months or less), the odds of death were 5–10 times higher for patient with metastatic malignancy and refractory myeloma than all other univariate predictors (90).

The malignancy in which renal disease has been most closely studied is multiple myeloma, in which ARF and CRF are commonly encountered early. Approximately onehalf of these patients respond to dialysis with reversal of RF, usually within 1–2 months. Recovery of renal function and survival are associated with lower serum creatinine on presentation, although in multivariate analysis, myeloma stage and response to therapy were more significant predictors of survival or remission of myeloma than was renal function (23,28,56). Among 1309 patients referred for dialysis with ESRD due to malignancy, median survival for those with multiple myeloma was approximately 1 year, and for those with RCC or amyloidosis, 15–20 months (91).

Making Decisions About Dialysis

What response can we have when faced with population data on one hand and an individual cancer patient with RF on the other? There is no consensus. For at least one author, a diagnosis of cancer should not automatically exclude dialysis (92), and for some, no diagnosis should rule out a trial of dialysis (93). Others cite concerns for cost, limited resources, and individual clinical circumstances in hesitating to initiate dialysis (6,86,94,95). The possibility of withholding and withdrawing life-sustaining therapies subjects patients, families, and caregivers to great stress and difficult ethical dilemmas. Moss (96) and Brody et al. (97), among others, have discussed these problems with specific reference to RF. Recommendations for working through decisions on starting or withdrawing dialysis in both ARF and ESRD have also been addressed in a document written for the Renal Physicians Association and the American Society of Nephrology and supported by related professional organizations (98).

Withholding or Refusing Dialysis

Many authors emphasize physiological limitations and would not begin dialysis for patients with preexistent poor quality of life or short life expectancy (e.g., those with nonuremic dementia or other irreversible neurological disease; patients with end-stage liver, cardiovascular, or lung disease limiting the activities of daily living; and patients with multisystem failure). Some would specifically not use dialysis for patients with metastatic or nonresectable solid tumor or hematological tumors refractory to treatment (94,99,100 and 101), especially with an expected survival of less than 2 years (102).

Some authors do not feel that diagnosis of neoplasm rules out dialysis, especially early in disease (87,92). In myeloma, RF is often found at diagnosis or soon thereafter, before response to antineoplastic therapy is known, and many would agree that dialysis in most of these patients is reasonable (57,87). Sobel et al. state that palliative intervention (including dialysis) for symptoms associated with uremia is appropriate under any of the following circumstances: (a) the clinician feels symptoms will be controlled or performance status will improve with therapy; (b) the patient strongly wishes the therapy despite recommendation against it; and (c) the patient has a prognosis of >2 months and a Karnofsky score of ³50% (95). In many cases of RF, it seems reasonable to give a trial of dialysis for 1–2 months, sometimes longer, and then reconsider its continuation.

In a cancer patient with RF, concerned physicians must balance factors for and against dialysis, including: (a) desires of patient and family concerning treatment; (b) the patient's “baseline” state before RF and likelihood of tolerating and benefiting from dialysis; and (c) the probable course of underlying malignancy and its response to therapy. This task is difficult. A patient's choice is not fixed or immune to education and experience. Estimation of a patient's baseline state involves not only

evaluation of tumor, its stage, and its predicted response to planned therapy, but also a patient's comorbidities, performance status, and psychosocial issues, all of which are difficult to quantify or predict. The Karnofsky and Eastern Cooperative Oncology Group indices are used for prognostic purposes in cancer patients. In one study, the best prognostic model of survival and recovery of renal function used the Acute Physiological Assessment and Chronic Health Evaluation (APACHE II) score (103). In a second study, APACHE III and the Liano models were the best indicators of those patients in ARF who would die regardless of dialysis (8,104).

Finally, physicians should be clear about their own experience and be able to articulate their reasons and feelings about withholding (or discontinuing) dialysis. A wide variety of opinion and practice exists.

In a state-wide survey of ESRD patients, nephrologists withheld dialysis from ESRD patients less often (7%) than did primary care physicians (22%); nephrologists with some training in law and ethics were more likely (12%) to withhold this procedure than those without (6%). In this survey, the presence of cancer was cited by nearly one-half the primary care physicians as a potential reason for withholding dialysis (101). In turning down 25% of 73 dialysis candidates with ESRD due to nonmalignant disease for poor quality of life or a prognosis limited by comorbidity, the physicians encountered no requests for second opinions from patients, families, or referring physicians, and no legal actions occurred (94). Acquiescence by patient and family to treatment denial in more acute settings is likely to be less uniform (96). Estimates are lacking for the number of cancer patients and families who refused dialysis and for what reasons, although it seems safe to assume that variation among deciding factors is probably as wide as that seen among clinicians.

If a decision to begin dialysis for RF in a cancer patient is made, clearly stated clinical goals, including a timetable for reconsidering dialysis, should be accepted by patient and family. If the situation permits—and it often does not— patient and family may need time to consider options and to ask for further guidance from the physician and other caregivers. In any event, timely decisions must be made. Absence of consensus among patient and family and caregivers presents great problems. Empathy, along with identification of and appropriate responses to crucial differences in styles and content (and, in some cases, legal constraints), may help resolve these difficult problems (96,98,102).

Discontinuation of Dialysis

In general, chronic disease (e.g., dementia, cancer) and advanced age are more likely to lead to withdrawal from dialysis (101,105); the same factors are associated with early death in ESRD patients starting dialysis (90,106). Withdrawal of ESRD patients (all etiologies) from dialysis account for 8–53% of deaths in this population (89,100,106,107).

In three studies of ESRD patients of all etiologies, 30–60% of patients were competent, and 50–60% had advance directives (89,101,106). Clinical deterioration accounted for the majority of decisions, although in the largest study, 26 of 66 (39%) competent patients chose to withdraw from dialysis in the absence of obvious medical complications (89). Over the last decades, the discussion of dialysis withdrawal has increasingly been introduced by patients and families rather than by physicians. This may also account for the fact that among 155 patients stopping dialysis, only one case went to court, and none was reported to the bioethics committee (89).

Many oncologists and nephrologists refer those cancer patients refusing or withdrawing from dialysis to hospice. In recent years, the number and percentages of hospice patients dying of nonmalignant disease have increased; in this group, one can include cancer patients dying “early” of RF. The National Hospice Organization (now the National Hospice and Palliative Care Organization) has drawn up guidelines for hospice admission for patients dying of nonmalignant disease. For renal disease, the criteria include (a) creatinine clearance <10 ml/min or serum creatinine >8 mg/dl; (b) ESRD in patients discontinuing or refusing dialysis, and “therefore with uremia, oliguria, intractable hyperkalemia, uremic pericarditis, hepatorenal syndrome, or intractable fluid overload”; and (c) poor prognosis indicated by “mechanical ventilation, malignancy of other organ systems, chronic lung disease, advanced cardiac disease, advanced liver disease, sepsis, immunosuppression/acquired immunodeficiency syndrome, albumin <35 mg/l, cachexia, platelet count <25 × 10^9; age >75 years, disseminated intravascular coagulation, gastrointestinal bleeding” (108). The emphasis on comorbidity is important because most patients dying of RF have more than one important disease process contributing to their demise, very often cardiovascular disease and/or cancer (5,8,9,47,106).

CARE OF CANCER PATIENTS DYING OF RENAL FAILURE

For cancer patients dying of RF, the decision to forgo further curative treatment shifts the focus from “cure and care” to “care only” for alleviation of suffering and for a death as dignified as possible. Support through the terminal phase often entails realignment of responsibilities among the different caregivers in nursing, medical, social work, pastoral fields, and volunteers (1); in hospice, this collection of caregivers is called the *interdisciplinary team*. Nurses and members of the allied services often play a more dominant role in providing hospice care. Physicians should continue to participate in planning and delivery of care; doctors who disappear at this time can create or intensify a sense of abandonment and despair in patients and families as well as in their fellow caregivers. Support and education continue to be given directly to patients, families and friends, and more directly address concerns about dying, death, and grief.

Major signs and symptoms reported in a careful study of the final day of life in patients stopping dialysis were pain, agitation, myoclonus or twitching, dyspnea or agonal breathing, and fever, present in 20–40%; diarrhea, dysphagia, and nausea occurred less frequently (106). Additional symptoms encountered, with emphasis on patients in CRF, included thirst, hiccough, restless legs, itching, Kussmaul breathing associated with metabolic acidosis, and a bad taste in the mouth (109). Treatments of these problems, which are commonly found in dying cancer patients (110,111), are elucidated in other chapters in this book outside the context of RF. Volume overload is of particular concern to RF patients; most ending dialysis are dialyzed to dry weight to protect them from pulmonary congestion in their final days. Thirst is uncommon, and overload is not usually a threat if caregivers do not confuse a dry mouth with thirst and give fluids rather than mouth care. However, if pulmonary congestion does occur, oxygen, opiates, and vasodilators can often control the problem. In a few cases, it may be expedient and appropriate to use existing access for ultrafiltration.

The remainder of this chapter concerns two issues: (a) the adjustment of analgesic, anticonvulsant, and psychotropic medications, which play major roles in symptom control at the end of life, and (b) discussion of a “good” renal death.

Adjustment of Medication

1. Therapeutic preferences and related issues are best discussed with competent patients before discontinuation of dialysis. However, studies show that only approximately one-third to two-thirds of patients withdrawing from dialysis were competent to make their own decisions; 50–60% had advance directives (89,101,106). Even among dialysis patients with advance directives, withdrawal from dialysis is the least discussed option in advance care planning (112). Patients should be encouraged to consider advance directives long before arriving at this point (58,59; see Chapter 63).
2. Significant inter-individual variations in pharmacological parameters and subjective response occur for many drugs in patients with normal renal function. In patients with ESRD, the situation is further complicated by changes in fluid compartment size, reduction or loss of renal metabolism, effects of uremic toxins on other physiological systems, changes in plasma binding, and other comorbidities, including liver function (66). Medication regimens must be tailored to each patient's responses.
3. Medication regimens should be kept as simple as possible. Dosage adjustments for patients usually become less important at the very end of life. Medications with wide therapeutic ranges are helpful because most terminally ill patients do not want to have blood drawn to check drug levels. For example, phenobarbital is preferable to phenytoin as an anticonvulsant as long as the side effects of greater sedation are acceptable to the patient and family.
4. Other interventions should be as noninvasive as possible to avoid disturbing patients. Nonoral delivery is possible with a wide range of medications relevant to end-of-life care, including opiates, NSAIDs, phenothiazines, benzodiazepines, anticonvulsants, antihistamines, antiemetics, scopolamine, dexamethasone, and proton pump inhibitors (113). Increased use of transdermal, rectal, buccal, and other routes minimizes injections to patients no longer able to take oral medication (110,113). Subcutaneous delivery of medication through a percutaneous button or pump obviates repeated injections and is less painful than intramuscular injections, as well as less likely to produce painful intramuscular hematomas, but it is less effective in patients with anasarca. In patients electing not to continue dialysis, retention of central access, if possible, may be helpful by maintaining an intravenous route for medication.
5. Sedation is considered desirable by and for most patients at the end of their lives but not all; one must ask to know.

Pain is common in patients dying in RF (106). Analgesia is needed for most cancer patients, including those in RF, at some time in their illnesses. In CRF, bone changes are a potential source of pain as well. One study shows that analgesia is not achieved in an important fraction of seriously ill patients, even when additional help is available to physicians (114).

Morphine sulfate is the most frequently used strong opiate, although in many situations other strong opiates may be as effective and offer other advantages. Morphine sulfate is glucuronidated in the liver; of the two resultant glucuronides, morphine-6-glucuronide is analgesic. In animal studies, morphine-3-glucuronide is associated not with analgesia, but with hyperactivity and central excitation. Both glucuronides show high dependence on renal excretion for clearance (115). The question arises whether accumulation of morphine-6-glucuronide and morphine-3-glucuronide place patients in RF at increased risk for significant adverse effects of opiates (e.g., respiratory depression, cognitive deficits, obtundation or hyperexcitability, confusion, myoclonus, nausea), many of which may be present in patients in RF who are not taking opiates. Case reports and small series suggest that the answer is yes (26,27,116,117 and 118). Cancer patients (N = 109) with serum creatinine ranging 0.5–8.0 mg/dl did not show significant association of myoclonus (especially common in patients with RF) or decreased cognitive function with increased

morphine-6-glucuronide/morphine sulfate ratios; however, very high plasma levels of morphine-6-glucuronide in the presence of other metabolic abnormalities (e.g., liver dysfunction as indicated by elevated LDH and bilirubin) were associated with respiratory depression or obtundation in a small number of patients (26). In another study, 19 of 36 cancer patients in hospice were found to have increased nausea and vomiting (N = 10) and delirium (N = 9). As a group, the symptomatic patients had a mean serum creatinine twice that of the 17 patients without these symptoms; however, many of the symptomatic patients had serum creatinine in normal range (27). More studies are needed to refine the relationship of opiates and unwanted side effects in patients with RF.

Information on the effects of metabolite accumulation for other opiates in RF is scanty. Metabolites of hydromorphone (Dilaudid) accumulate in patients with RF. Hydromorphone-3-glucuronide appears to be associated with hyperalgesia, excitatory behavior, and respiratory stimulation (118). Normeperidine, a metabolite of meperidine hydrochloride (Demerol), accumulates in RF and facilitates seizures; for this reason, meperidine hydrochloride should not be used in patients with RF. Both fentanyl (66) and oxycodone hydrochloride (119,120) accumulate in patients with RF. Among weaker opiates, codeine phosphate metabolites show some accumulation in patients in RF and need dose adjustment (66).

Analgesia must be provided to patients in pain as long as they desire it. It is suggested that patients with creatinine clearances of 10–50 ml/min receive a 25% reduction in doses of morphine sulfate or codeine phosphate and that those with creatinine clearances <10 ml/min receive 50% eduction in morphine sulfate and codeine phosphate doses 66). These dose reductions are initial estimates; each patient must be titrated individually for optimal combination of effective analgesia and tolerable side effects. Trials of alternative opiates with adjustment for partial cross tolerance can be helpful.

Analgesia for neuropathic pain may include tricyclic antidepressants, anticonvulsants, and other agents (e.g., clonidine). Nortriptyline hydrochloride and desipramine hydrochloride, tricyclic antidepressants with fewer anticholinergic side effects and a wider therapeutic window than amitriptyline hydrochloride, are used for dull, burning dysesthesias. They can be continued without dose adjustment as long as the patient can take oral medication; parenteral amitriptyline hydrochloride is now available for continued neuropathic coverage. Carbamazepine and phenytoin, anticonvulsants used for lancinating neuropathic pain, can be given without dose adjustment. Gabapentin, an anticonvulsant widely used for burning dysesthesias and lancinating pains, needs dose reduction in patients with RF; for those with creatinine clearances <10 ml/min, 300 mg every other day is sufficient as long as the patient can take medication orally (66).

Some cancer patients with intractable pain, especially neuropathic pain, have received relief from oral, transdermal, or epidural clonidine (121). The medication undergoes significant renal metabolism, can cause sedation and hypotension, and interacts with other medications often used for cancer patients (e.g., tricyclic antidepressants, barbiturates, and other sedatives). However, in transdermal form, it also has been effective in a subpopulation of patients with diabetic neuropathy (122). This route makes it attractive for use in dying patients, although studies of its use in patients dying of ESRD are lacking. In patients with neuropathic pain poorly controlled with other medications, cautious use may be undertaken if patient and family accept the risk.

In addition to opiates and NSAIDs, bisphosphonates (e.g., pamidronate disodium) may be helpful in combating pain due to bony metastases and can be administered by either intravenous or oral routes (123). Data on this use in ESRD patients are lacking, but intravenous bisphosphonates require small fluid loads (250–500 ml) and, of little importance here, may worsen azotemia. Despite their nephrotoxicity, NSAIDs for bony pain may become more relevant in the terminal phase. However, these patients are at greater risk for uremic gastritis and hemorrhage, even with protection of the gastric mucosa. The same risk occurs with the oral or subcutaneous use of corticosteroids for bony pain, although in some orchidectomized patients with prostate carcinoma, small doses (1–2 mg twice a day) of dexamethasone may offer good analgesia with few, if any, risks or side effects. The combination of NSAIDs and corticosteroids should be avoided if possible. For gastroprotection, H_2 blockade is given orally or intravenously in reduced doses for patients with RF, whereas proton pump inhibitors and misoprostol can be given only orally but need no dose adjustment (66).

Phenytoin and phenobarbital are the primary anticonvulsants in terminal patients with ESRD (124). Phenobarbital has a wide therapeutic range and can be given by several routes: oral, subcutaneous, intravenous, or intramuscular. In ESRD, it should be started at 75% of its usual range and adjusted. Less sedating than phenobarbital, phenytoin can be given either orally or intravenously. In ESRD, it has a lower and narrower therapeutic range than in patients with normal renal function, as a result of decreased protein binding. In patients allergic to phenobarbital and phenytoin, carbamazepine is an alternative choice for tonic-clonic seizures as well as for the less frequent partial and complex partial seizures. However, like gabapentin, it can only be given orally.

Benzodiazepines are used to relieve anxiety and to treat myoclonus arising either from accumulation of opiates or intrinsic to uremia, as well as to treat seizures. In general, benzodiazepines with shorter half-lives and no clinically active metabolites (e.g., lorazepam, clonazepam, oxazepam, and temazepam) are preferred to diazepam, with its longer half-life, unless sedation or seizure control are specifically sought. Benzodiazepines can be given initially without dose adjustment and then titrated to effect. Like barbiturates, they may cause respiratory depression.

Midazolam hydrochloride, a benzodiazepine with a short half-life, administered intravenously, subcutaneously, or intramuscularly, is helpful in patients with myoclonus, anxiety, terminal agitation, and, in some cases, seizures (125). In severe RF and in the elderly, 50% of the normal dose is used (66). For patients with multifocal myoclonus, an initial dose of 2–5 mg subcutaneously every hour is recommended until myoclonus is controlled, followed by continuous pump-delivered subcutaneous or intravenous doses. The same approach and initial dose may be used for moribund patients with grand mal seizures (110). Increased infusion rates are often necessary because of midazolam hydrochloride's marked tachyphylaxis.

Agitated confusion is common in cancer patients dying of RF. Sedation is often preferable to patient and family. Benzodiazepines and barbiturates become drugs of choice over antipsychotic medication, especially in the last days of life. In this situation, diazepam may be preferred over shorter-acting benzodiazepines; midazolam hydrochloride is also useful, although tachyphylaxis can complicate its titration. Pentobarbital or phenobarbital can produce a welcome deep sedation. In patients with i.v. access, midazolam hydrochloride 2.5 mg infused over 2 minutes can produce emergency sedation during a catastrophic terminal event.

Among drugs to treat confusion, haloperidol, chlorpromazine, and other high-potency antipsychotics have a greater propensity to promote seizures. These medications undergo extensive hepatic metabolism. Haloperidol is used without dose adjustment to treat nausea and vomiting and is probably safe if used infrequently in low doses. Confusion at this stage of life is more effectively treated with sedating medications like benzodiazepines or barbiturates.

A Good Death in Renal Failure

Many caregivers have clear ideas and strong feelings about what characterizes an acceptable or peaceful death for their patients, and many have focused on these issues in books and articles in the hospice literature. One study (126) reports the attributes of a good death as defined by discussion in focus groups and in-depth interviews with patients, surviving family members, and caregivers (nurses, social workers, chaplain, hospice volunteers, and physicians). Despite the small numbers in each category (total N = 75), the results seem appropriate and probably approximate the thoughts and feelings of many. The six components of a good death were as follows: (a) good pain and symptom management; (b) clear decision-making shared by patients/families and caregivers; (c) preparation for death in both physical and psychosocial dimensions; (d) completion through life reviews, connectedness to others, and resolution of conflicts; (e) contributing to others' well-being; and (f) affirmation of the patient as a whole person, perceived and treated as unique and valuable. The authors point out each attribute “has a biomedical, psychological, social and spiritual component.” Professional roles were evident in discussion. As a group, physicians (N = 6) were more exclusively medical; none spoke of contributing to others as an aspect of a good death and only one mentioned completion. The other caregiver groups recognized all six attributes.

In contrast, explicit definition of criteria of a good death and their application in actual patients dying of RF is rarely published. After a preliminary report (127), an interdisciplinary team reported a mixed retrospective-prospective study of the course of ESRD patients after discontinuation of dialysis. Three-quarters of the fully studied 79 patients had three to seven comorbidities, and 12% had malignancies. Median time to death after dialysis discontinuation was 6 days in 126 patients; the average was 8 days. Some patients lived for 30–46 days, and ten debilitated patients lived less than 2 days (106).

In their original report (127), the authors measured quality of death by quantitating three components: (a) duration of dying after stopping dialysis; (b) presence of physical suffering; and (c) consideration of psychosocial issues (e.g., decision-making process, level of awareness, involvement of family and friends). The category of “good death” included 7 of 11 prospectively studied patients. The remaining four patients' courses after discontinuation of dialysis were compromised by “varying degrees of pain, confusion, agitation, social unrest, and a longer than average survival.” Cohen and his collaborators have published an instrument measuring quality of life in patients with ESRD. It combines relevant physical and psychosocial parameters, the peace and dignity of each death, and the duration of life between stopping dialysis and death in a quantitative index of a “good death” (128).

In the later study (106), caregivers or families felt that treatment was effective in the last 24 hours of life for 93% of patients, a marked improvement over the figures found in the Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments (114). Nonetheless, among 79 prospectively followed patients during this time, pain occurred in 42% (severe in 5%), agitation in 30% (severe in 1%), myoclonus in 28% (severe in 4%), and dyspnea/agonal breathing in 25 (severe in 3%). Pain medication was used at least once after stopping dialysis in 87% of patients. Although none needed ultrafiltration for pulmonary edema, 22% used oxygen. The authors in discussion ask if treatment can be considered acceptable or effective in the presence of these numbers (106). The incidence of pain and dyspnea among patients dying of ESRD is not greatly different from a similar list of disturbances found in 400 hospice patients in the last day of life, although myoclonus is greater among those with ESRD (111).

SUMMARY

RF is a common occurrence in cancer patients. It may be present at diagnosis or arise during therapy and bring about the patient's death. In the specialized world of contemporary medicine, the oncologist's most important functions with regard to RF are prevention, referral, and collaboration—prevention in designing and providing therapy, referral to a nephrologist when renal function is deteriorating, and collaboration with patient, family, and other clinicians throughout the patient's course. Collaboration is often difficult because of the different expertise, experience, and expectations of those involved. Knowledge, patience, practice, and a steady focus on the patient's and family's needs and desires are all-important to effective care.

HYPERCALCEMIA

A. ROSS MORTON
PAUL S. RITCH

Hypercalcemia may occur in as many as 8–10% of patients with malignancy during the course of their disease, making it one of the most common metabolic complications of cancer. Despite this high frequency, the diagnosis of hypercalcemia is often delayed. An awareness of the tumor types most commonly associated with hypercalcemia, the mechanisms giving rise to hypercalcemia, and the symptoms produced permits earlier diagnosis and amelioration of morbidity by the use of effective therapeutic interventions.

Since it was first reported in 1924 (1), hypercalcemia has become well recognized in association with various malignant diseases. The mechanisms responsible for the production of hypercalcemia have been increasingly well defined. Hypercalcemia is most commonly seen in association with squamous cell carcinoma of the lung, carcinoma of the breast, and multiple myeloma. This distribution of tumor types associated with hypercalcemia has remained relatively constant (2,3). Some tumors, including small cell carcinoma of the lung and carcinoma of the prostate (which frequently metastasize to bone), as well as other common tumors such as adenocarcinoma of the colon and stomach, are rarely associated with hypercalcemia, despite biochemical and histomorphometric data indicating enhanced bone resorption (notably in the case of carcinoma of the prostate) (4). The relative frequency of other tumor types associated with hypercalcemia seems to vary with the area of special interest of the investigators reporting the complication. Nevertheless, hypercalcemia is well recognized with squamous tumors of the head and neck and genitourinary neoplasms.

Patients with hypercalcemia and malignant disease are usually in the last weeks of their lives unless effective antitumor therapy is available. Therefore, therapeutic interventions must be as innocuous as they are effective. With modern therapeutic agents, it is possible to restore normocalcemia in most patients without inducing serious side effects.

ETIOLOGY OF HYPERCALCEMIA IN MALIGNANT DISEASE

A brief review of normal bone and calcium metabolism is important in enhancing the understanding of the mechanisms that lead to hypercalcemia and provides a framework for intelligent therapeutic intervention.

Bone is a dynamic structure that undergoes constant remodeling. The remodeling process is a highly integrated interaction between several cell types (5), the two most important of which are the osteoblasts, or bone-forming cells, and the osteoclasts, or bone-resorbing cells. Responding to as yet incompletely understood stimuli, osteoclasts resorb an area of bone that is to be remodeled over a period of approximately 10 days. Osteoclastic resorption involves the enzymatic degradation of bone proteins such as collagen and the release of calcium from the mineral phase of the bone. The resorption phase is followed by a reversal phase, during which the osteoclasts disappear to be replaced by mononuclear cells. Thereafter, a bone-formation phase, lasting several months, occurs in which osteoblasts lay down new bone to repair the defect. To maintain the strength and integrity of the bone, the resorption and formation phases are closely coupled. It is easy to see that any process that could increase osteoclastic bone resorption or decrease osteoblastic bone formation would lead to an increased net calcium flux into the extracellular fluid, which would have to be excreted by the kidneys. If the degree of imbalance is small, a disease process such as osteoporosis would result; however, if the degree of imbalance is quite large, widespread bone lysis and hypercalcemia could be expected.

The adult human body contains approximately 1 kg of calcium, of which all but 10 g is lodged in bone. Minute intracellular concentrations of calcium (10^{-8} to 10^{-7} molar) are vital to normal cellular function, but most of the nonosseous calcium is present in the extracellular fluid. Under normal circumstances, total body calcium represents a steady state between calcium intake and excretion. Somewhere between 25% and 50% of the dietary calcium intake of approximately 1.0–1.5 g per day is absorbed. Although bone represents an enormous reservoir of calcium, little transfer (approximately 500 mg, or 12.5 mmol, per day) occurs between bone and the plasma in the state of good health (6). When net calcium balance is zero, the kidneys are required to excrete approximately 150 mg of calcium daily. Glomerular filtration of non-protein bound calcium is approximately 10 g/day, 65% of which is reabsorbed in the proximal convoluted tubule and 25% in the ascending limb of the loop of Henle, in which resorption is independent of hormonal control. Proximal nephron calcium reabsorption is closely linked to sodium reabsorption. In situations of volume depletion (such as those induced by hypercalcemia), inappropriate calcium retention may occur as the kidney attempts to conserve sodium and hence extracellular fluid volume. A variable amount of the remaining calcium is reabsorbed from the distal convoluted tubule. Calcium reabsorption in this area is increased in the presence of parathyroid hormone (PTH), and it is at this site that the fine-tuning of calcium homeostasis occurs. Renal calcium losses can increase to accommodate an increase in bone turnover of approximately 150% before hypercalcemia occurs.

The routinely measured total plasma calcium concentration is composed of a combination of physiologically active or ionized calcium, accounting for approximately 45% of the total, protein-bound calcium (the bulk of which is bound to albumin and accounts for approximately 45% of the total), and the remainder (10%), which is complexed with ions such as bicarbonate and citrate. In terms of patient management, the ionized calcium concentration carries the greatest significance. Although ion-specific electrode measurement of ionized calcium is available, most centers routinely measure the total serum calcium. The correlation between total serum calcium and ionized calcium is, at best, only fair. The proportion of the total calcium in the unbound or physiologically active state varies with, among other things, the albumin concentration. Numerous algorithms have been designed to attempt to “correct” total serum calcium, particularly in the face of reduced albumin concentrations. The algorithms listed here are clinically useful, and it is imperative that clinical decisions are made not on the basis of a total calcium but at the very least a corrected calcium (7,8).

Ca (corrected) = Ca (measured) + [0.8 × (4–albumin concentration)] *Conventional Units*

Ca (corrected) = Ca (measured) + [0.02 × (40–albumin concentration)] *SI Units*

Under normal circumstances, calcium and bone metabolism are tightly regulated by the action of three main hormones.

PTH is an 84 amino acid polypeptide secreted by the parathyroid glands in response to low ionized serum calcium. It enhances calcium resorption from bone by an indirect action on osteoclasts. In addition, PTH diminishes distal nephron calcium excretion and, by its action on the renal 1-a hydroxylase, increases circulating $1,25\text{-}(OH)_2D_3$ (di-hydroxyvitamin D_3, the main active metabolite of the vitamin D complex of sterols).

Most of the biological activity of PTH is contained within the first 34 amino acid residues (9). This is of clinical significance because this amino acid sequence is shared in part with a tumor product, PTH-related peptide (PTHrP), discussed in the section Parathyroid Hormone-Related Protein.

The vitamin D complex is a group of steroid hormones with important effects on bone metabolism and calcium homeostasis. The main active metabolite is $1,25\text{-}(OH)_2D_3$. Hydroxylation of vitamin D is a two-step process. The 25-hydroxylation takes place in the liver and is substrate dependent. Conversion to the active dihydroxy metabolite is the rate-limiting step, which takes place in the kidney and is stimulated by PTH (vide supra) and inhibited by $1,25\text{-}(OH)_2D_3$. Vitamin D brings about its effects by increasing calcium absorption from the gastrointestinal tract and enhancing calcium reabsorption in the kidney.

Calcitonin, the physiological antagonist to PTH, is a 32 amino acid polypeptide hormone secreted by the C cells of the thyroid gland. Using time-lapse photography, calcitonin can be seen to have a powerful and rapid suppressive action on osteoclast activity. Down-regulation of calcitonin receptors is known to occur, making its clinical effects generally short lived. The true physiological role for calcitonin is unclear because biochemical disturbances are unusual in patients who have had complete thyroidectomies and in patients with extremely high levels in medullar carcinoma of the thyroid gland. It may be that calcitonin is a physiological regulator of postprandial hypercalcemia (10).

Two main mechanisms contribute to the development of hypercalcemia in most patients with malignancy. In local osteolytic hypercalcemia, tumor invasion of bone causes release of large amounts of calcium from destroyed areas of bone. In the humoral hypercalcemia of malignancy, the effects of PTH are mimicked by PTHrP. In this situation, renal tubular reabsorption of filtered calcium is increased in addition to the increased generalized osteoclastic activity throughout the skeleton. These mechanisms are not mutually exclusive because many tumor types that metastasize to bone also manufacture PTHrP. Enhanced gastrointestinal absorption of calcium is a rare mechanism for hypercalcemia of malignancy, limited mainly to hematological disorders.

Local Osteolytic Hypercalcemia

Metastatic tumor cells are capable of resorbing bone directly (11), although the classic studies of Galasko (12) suggest that much of the resorption is carried out by osteoclasts. The tumor types commonly associated with this form of hypercalcemia are carcinoma of the breast, multiple myeloma, and other hematological malignancies. A large bony burden of tumor is usually required to produce the hypercalcemia.

Carcinoma of the Breast

Hypercalcemia is an infrequent finding in patients with carcinoma of the breast in the absence of widespread osseous metastases. Histological evidence demonstrates that bone destruction is mediated by osteoclasts in close proximity to tumor cells. Breast cancer cell growth regulation is thought to occur in part under the influence of a number of closely associated growth factors (13). Epidermal growth factor and transforming growth factor alpha (TGF-a) are produced in a paracrine fashion at the site of bone metastases. These substances, which share a common receptor, are potent stimulators of osteoclastic bone resorption. Both TGF-a and epidermal growth factor can be found by immunohistological techniques in breast cancer cells. The local release (particularly of TGF-a) in bone could be predicted both to increase metastasis growth and to enhance osteoclastic activation and bone resorption, thereby making room for the multiplying tumor cells.

In their classic studies, Galasko and Bennett (14) demonstrated that osteoclast recruitment and bone destruction stimulated by implants of the VX_2 carcinoma in rabbits could be reduced by the oral administration of the cyclooxygenase inhibitor indomethacin. Confirmatory evidence for a role for prostaglandins in the development of metastases came from Powles et al. (15), who showed that cyclooxygenase inhibitors reduced the incidence of bone metastases in rats bearing the Walker tumor. Unfortunately, the use of prostaglandin synthesis inhibitors has not been effective in influencing the course of metastatic bone disease in patients with breast cancer.

Despite the fact that most hypercalcemic breast cancer patients have a significant bony metastatic burden, it is clear that not all cases are due to local factors. An enhanced tubular reabsorption of calcium in breast cancer patients has been demonstrated (16). In this study, the authors concluded that approximately 40% of the observed hypercalcemia was accounted for by a renal mechanism. It is known that breast cancer cells can produce and secrete PTHrP; indeed, one of the original tumor types from which PTHrP was isolated was breast cancer (17). In fact, serum elevation and tumor histochemical localization of PTHrP is common in breast cancer patients, even before the development of hypercalcemia (18). Furthermore, there are increasing data that PTHrP may have a role in the development and maintenance of bone metastases in patients with breast cancer (19).

Multiple Myeloma

In patients with multiple myeloma, there is an intimate association between the malignant plasma cells and the bone marrow. Fracturing, osteopenia, and hypercalcemia are frequent complications in these patients. Histological studies have shown a close association between myeloma cells and activated osteoclasts. Over the last 20 years, significant advances have been made in elucidating the mechanisms of the bone resorption in multiple myeloma. In the mid-1970s, Mundy et al. (20) demonstrated that supernatants from myeloma cells in tissue culture had osteoclastactivating activity that lead to the mobilization of ^{45}Ca from fetal rat long bones. These substances were descriptively named *osteoclast-activating factors*. It has become increasingly clear that more than one substance elaborated by multiple myeloma cells has osteoclast-activating factor activity. Several groups of investigators have identified potent osteoclast-activating properties associated with various multifunctional cytokines, including lymphotoxin (TNF-b) (21), interleukin-1 (IL-1) (22), and interleukin-6 (IL-6) (23). Many of these same factors are also potent inhibitors of osteoblastic bone formation. Furthermore, elevated levels of PTHrP have been found in almost onethird of hypercalcemia multiple myeloma patients in a study by Firkin et al. (24).

The multifunctional cytokine IL-6 is well recognized as a growth promoter for myeloma cells. It potentiates the actions of other bone-resorbing cytokines such as IL-1 and lymphotoxin, although its effect on bone metabolism is not clear. Levels of IL-6 increase in the advanced phases of disease when widespread osteopenia is manifest, although a direct cause and effect phenomenon cannot be inferred.

Patients with multiple myeloma frequently have abnormal renal function. Reductions in glomerular filtration rate caused by myeloma kidney or light-chain nephropathy hamper the ability of the body to excrete the excessive calcium load. Furthermore, the calcium elevation itself is also nephrotoxic and can lead to a vicious cycle of deteriorating renal function and hypercalcemia.

In rare patients with multiple myeloma or monoclonal gammopathy of undetermined significance, the phenomenon of pseudohypercalcemia may occur (25). In this situation, calcium becomes bound to nonalbumin plasma proteins, resulting in a spuriously elevated total serum calcium concentration. The ionized calcium concentration is normal under these circumstances, but correction formulae using albumin will give falsely abnormal results.

Humoral Hypercalcemia of Malignancy

The concept of a humoral factor being responsible for the genesis of hypercalcemia is not a new one. In 1941, Fuller Albright (26) described the case of a patient with a renal cell carcinoma who was significantly hypercalcemic despite a very low bony metastatic burden. This patient also had significant hypophosphatemia, and the clinical features suggestive of primary hyperparathyroidism had been enough to lead the surgeons to perform a neck exploration. Although PTH could not be recovered from biopsy material from the tumor, Albright postulated that a humoral factor secreted by the tumor was responsible for the hypercalcemia. Indeed, the term *pseudohyperparathyroidism* was popularized in the 1960s (27,28).

In their extensive metabolic evaluation of 50 patients with hypercalcemia and malignant disease in 1980, Stewart et al. (29) divided the patients into two groups. One group shared the features of primary hyperparathyroidism, including a tendency to hypophosphatemia, a lowered renal phosphate threshold, and an elevated nephrogenous cyclic adenosine monophosphate (NcAMP) excretion. These patients mostly had squamous carcinomas, renal carcinomas, and urothelial malignancies. The second group, who mostly had metastatic carcinoma of the breast and multiple myeloma, had low levels of NcAMP excretion. The authors concluded that urinary NcAMP was a surrogate marker for a circulating substance that had PTH-like activity. Using assays available at the time, they were unable to detect elevated levels of PTH in the sera of these patients.

Although they continue to be rare, anecdotal reports of ectopic PTH production causing hypercalcemia (30) do occur; however, native PTH is not the substance responsible for most cases of humoral hypercalcemia of malignancy. The strongest evidence came from the fact that using complementary DNA techniques, Simpson et al. (31) failed to demonstrate the production of PTH by tumors commonly associated with hypercalcemia. The development of a sensitive two-site immunoradiometric assay for PTH helped considerably to overcome the problems of measuring this compound, which has a very short plasma half-life but many products of metabolism that interfere with more conventional assays (32).

Parathyroid Hormone–Related Protein

In 1987, three groups independently published descriptions of a novel polypeptide hormone that had been isolated from tumors associated with the hypercalcemia of malignancy (17,33,34). PTH-related protein is a much larger molecule than PTH. Although the predominant circulating form of PTHrP is not yet known with certainty, the original authors describe several isoforms of this hormone, including 139, 141, and 173 amino acid residues that arise by alternative splicing of RNA and differ only in their carboxy termini. The primary structure of these peptides shows considerable N-terminal homology with native PTH, with 8 of the first 13 amino acids being identical; PTHrP interacts with the PTH receptor with equal affinity to the native hormone, accounting for its ability to mimic both the renal and bony effects of PTH. Many normal fetal and adult tissues produce PTHrP. The physiological roles of PTHrP are complex and have been the subject of a recent review by Strewler (35). The hormone appears to have a number of different functions at an autocrine and paracrine level depending on its site of production. Furthermore, PTHrP appears to be a polyhormone (i.e., there are receptors for different regions of the molecule). The amino terminal end shares a common receptor with PTH (and is the part of the molecule responsible for hypercalcemia of malignancy). The midregion of the molecule (amino acids 38–94) may be the main stimulus for the placental calcium pump. The carboxy terminal appears to inhibit bone resorption and may also act within the central nervous system. Data are also appearing to suggest that PTHrP may have a role in regulating renal function and repair after acute renal failure (36). PTHrP has been identified immunohistochemically in divergent areas throughout the kidney including the glomeruli, tubules, and arterial tree. Its exact role in these situations remains uncertain.

Definitive evidence for the biological activity of PTHrP having a causal role in hypercalcemia of malignancy came from studies in nude mice bearing a human tumor responsible for hypercalcemia. By causing an antiserum directed against synthetic human PTHrP, Kukreja et al. (37) were able to reverse the biochemical abnormalities of hypercalcemia, hypophosphatemia, and increased NcAMP excretion in these animals. These experiments provided strong evidence that PTHrP was directly responsible for the hypercalcemia.

The development of assays for PTHrP has been plagued by similar problems as those for PTH. The levels in normal serum are quite low (below 2.5 pmol/l), and the nature and reactivity of metabolic byproducts is not clear. Two-site immunoradiometric assays have been developed and are more sensitive. Using a midregional assay, Blind et al. (38) reported that 81% of hypercalcemic patients who had squamous tumors had an elevated PTHrP level. Studies using two-site assays have detected elevated serum levels of PTHrP in 90–95% of patients with squamous carcinomas and hypercalcemia (39,40).

Whereas PTHrP is commonly considered in the context of humoral hypercalcemia, there are interesting reports of its relationship to bone metastases in patients with breast cancer. Powell et al. reported that 92% of bony metastases from breast cancer stain positive for PTHrP immunohistochemically compared with only 17% of metastases at other sites (41).

Vitamin D

Levels of 1,25-$(OH)_2D_3$ are low in most cases of hypercalcemia of malignancy; however, there are a group of malignant (and some nonmalignant) disorders in which 1,25-$(OH)_2D_3$ is elevated and acts as a humoral mediator of hypercalcemia. It has been known for more than 10 years that granulomatous conditions, such as sarcoidosis (42), are associated with extrarenal synthesis of 1,25-$(OH)_2D_3$. The site of the ectopic 1-a hydroxylation is presumably in the macrophages associated with the granulomata. Davies et al. (43) described a substrate-dependent conversion of 25-hydroxyvitamin D_3 to 1,25-dihydroxyvitamin D_3 in a hypercalcemic patient with Hodgkin's disease exposed to increased levels of sunlight. This response was no longer seen after successful treatment of the malignancy. Although occasional case reports of hypercalcemia and abnormally elevated 1,25-$(OH)_2D_3$ have appeared in the literature (44,45), hypercalcemia remains an uncommon complication of hematological malignancies other than myeloma. In a large series of 217 patients with advanced lymphoma, only four cases of hypercalcemia were reported (46).

A significant exception to the rare finding of hypercalcemia in lymphomas is adult T-cell lymphoma, an uncommon tumor in North America that appears to be associated with infection with the human T-cell lymphotropic virus type 1. More than half of these patients develop hypercalcemia, which is a common cause of death. Although elevated 1,25-$(OH)_2D_3$ levels have been reported in these patients, there is also evidence for elevation in PTHrP levels, suggesting that an interaction of humoral mediators may be responsible (47).

Other Hypercalcemic Factors

Case reports and animal studies have added significantly to the number of mediators that may be responsible for hypercalcemia in malignant disease. Squamous carcinomas have been reported to produce IL-1 either in the presence (48) or absence (49) of hypercalcemia. Furthermore, these tumors also secrete colony-stimulating factors, which may enhance osteoclast precursor generation. Indeed, simultaneous tumor production of IL-1 and PTHrP has been demonstrated (50), and these two hypercalcemic factors may interact synergistically *in vitro* and *in vivo* (51). Cose-cretion of IL-6 and PTHrP also has been described (52). Similarly, tumor production of prostaglandins associated with the development of hypercalcemia is also well recognized (53). Squamous carcinoma cell lines associated with humoral hypercalcemia of malignancy have been shown to secrete an osteoclast differentiation factor (ODF) [also called *tumor necrosis factor-related activation-induced cytokine* (TRANCE)]. This factor is able to induce the differentiation of HL60 promyeloblastic leukemia cells into osteoclasts (54). Formation and secretion of ODF/TRANCE directly by malignant cells may enhance osteoclast number by recruitment and differentiation, in addition to that caused by the effects of PTHrP.

Although PTH is rarely the humoral factor causing hypercalcemia, secreting carcinomas of the parathyroid glands may occur. In the rare group of multiple endocrine neoplasia syndromes, hyperparathyroidism and asymptomatic hypercalcemia due to PTH secretion is common.

EVALUATION OF THE HYPERCALCEMIC PATIENT

Hypercalcemia usually occurs in the face of overt malignancy, and so the diagnosis as to the cause of the hypercalcemia is rarely in doubt. In spite of this fact, it is worth considering other causes of hypercalcemia (Table 34-1), which may be readily amenable to therapeutic intervention. Additionally, aggravating factors such as immobilization should be sought and attempts made to rectify these factors.

Endocrine	Hyperparathyroidism
	Hyperthyroidism
	Addison disease
Iatrogenic	Immobilization
	Vitamins A and D
	Thiazide diuretics
	Lithium carbonate
Other	Paget disease of bone
	Granulomatous disease

TABLE 34-1. NONMALIGNANT CAUSES OF HYPERCALCEMIA

Clinical Findings

The symptoms of hypercalcemia are often vague and nonspecific. Furthermore, there is an imperfect correlation between calcium level and degree of symptomatology. Indeed, severe hypercalcemia may be an incidental finding on a biochemical screen of a patient with malignant disease. The rate of development of hypercalcemia may influence the occurrence of symptoms.

Gastrointestinal upset occurs in most symptomatic individuals. Nausea, anorexia, and vomiting are common, but they may be ascribed to the side effects of chemotherapy or to symptoms produced by the tumor itself. By inducing dehydration and hence aggravating the hypercalcemia, these complications set up a vicious cycle. Constipation is common, and complete ileus may occur at severely raised calcium levels. Cramping abdominal pains such as those seen in primary hyperparathyroidism are encountered occasionally, but acute pancreatitis or peptic ulceration complicating the hypercalcemia of malignancy is extremely rare. It is

likely that the relative acuteness of the disease as compared with, for example, primary hyperparathyroidism, accounts for the low incidence of these latter adverse effects.

Hypercalcemia *per se* is toxic to the renal tubules. It causes a reversible impairment in renal concentrating ability, resulting in the production of large volumes of dilute urine. This polyuria serves to aggravate the volume depletion produced by the gastrointestinal effects and results in a fall in the glomerular filtration rate, which in turn causes further impairment of the kidney's ability to handle the abnormal calcium load, and the vicious cycle continues.

Although the major disturbance in tubular function is related to changes in urinary concentrating ability, another important renal effect is that of an inappropriate natriuresis. The extracellular fluid volume contraction results in attempts by the proximal tubule to conserve sodium, and because of a linkage between renal sodium and calcium handling, calcium is also retained. Despite the fact that the thirst mechanism is intact and polydypsia occurs, the gastrointestinal upset is often so great that severe volume depletion occurs. Impaired mental status may further compromise fluid intake. Solute washout of potassium and magnesium can occur as a result of the polyuria, and some of the neuromuscular effects of hypercalcemia can be aggravated by relative deficiencies of these ions.

Hypercalcemia frequently is overlooked as a cause of neuropsychiatric symptoms in patients with advanced malignant disease. Rather, these are often ascribed to the underlying neoplasm or to medications the patient may be taking, such as narcotic analgesics, antiemetics, or sedatives. Muscle weakness may be profound, confining the patient to bed and aggravating the hypercalcemia because of immobility. As hypercalcemia worsens, confusion and finally coma supervene. Reversible focal neurological symptoms with hypercalcemia have been reported but are rare.

Cardiac muscle appears relatively immune to the effects of hypercalcemia, which has a digitalis-like effect on cardiac contractility. Reduction of the QT_c may be observed occasionally on ECG, but unless the patient is given cardiac glycosides, the cardiac effects are of little clinical significance. Arrhythmias are more likely to occur because of associated hypokalemia or hypomagnesemia during the treatment phase, in which rapid intravascular volume expansion is occurring.

Bone pain is a frequent symptom of both malignant disease and hypercalcemia. Although this pain may be due in part to the presence of bony metastases, the symptom is also present in the absence of demonstrable metastatic disease. Calcium may act as a neurosensitizer, decreasing the pain threshold, but the precise mechanism of pain generation in hypercalcemia is unclear.

The syndrome of hypercalcemia of malignancy, therefore, presents itself with anorexia, fatigue, apathy, and polyuria but may rapidly progress to obtundation and death.

Laboratory Investigations

The diagnosis and management of hypercalcemia in a patient with malignant disease require little in the way of investigations. A complete blood count with estimation of the platelet count should be performed, and measurement of serum electrolytes, blood urea nitrogen, and creatinine is mandatory. The ionized calcium level is the best clinically relevant measurement to perform; however, it is less readily available and more expensive than a total calcium level. The total serum calcium level is a poor indicator of the biologically active component and should not be used alone to direct initial management without the use of a correction algorithm to take into account the effect of altered albumin concentrations. In asymptomatic patients with hypercalcemia and multiple myeloma, a serum ionized calcium should be obtained to exclude pseudohypercalcemia.

Renal function and the response of the calcium to therapy should be monitored daily until the calcium concentration normalizes. Close attention should be paid to changes in potassium and magnesium levels, which may drop dramatically during the early treatment phase because of volume expansion and increased glomerular filtration rate as the hypercalcemia is corrected. An underlying potassium deficiency caused by poor dietary intake is frequently unmasked at this time. Serum phosphate levels may fall precipitously in some patients, particularly when potent antiresorptive therapy is used.

Once the calcium level returns to normal, weekly estimation can act as a guide to the need for further antihypercalcemia therapy. Of course, investigations should be individualized depending on the patient's clinical condition and response to therapy.

From the academic viewpoint, greater insight into the mechanism behind the hypercalcemia can be gained from more complex investigations. These have few practical implications given the current therapeutic options but may become more relevant if, for example, effective blockade of the PTH receptor becomes possible or monoclonal antibodies to PTHrP are developed for clinical use. In the absence of a readily available assay for PTHrP, biochemical clues to its presence include hypophosphatemia, hyperchloremia, and a mild metabolic acidosis, although these could not be considered diagnostic. Urinary excretion of calcium is high in all cases of hypercalcemia (despite inappropriate calcium resorption stimulated by PTHrP). The renal phosphate threshold is low in the presence of PTHrP, indicating a renal phosphate leak, and significant hypophosphatemia may result after the treatment of hypercalcemia.

The serum immunoreactive PTH is low or undetectable unless the primary site of malignancy is the parathyroid gland itself. Vitamin D metabolites are also frequently low in most cases of hypercalcemia, despite the fact that PTHrP is capable of stimulating the renal 1-a hydroxylase in animal models. The reason for this paradox is not clear, although it has been suggested that tumors may secrete an independent inhibitor of 1-a hydroxylase (55). Measures of osteoblastic function, such as alkaline phosphatase and bone gla-protein (osteocalcin), have little to offer in the diagnosis of hypercalcemia. Although plain radiography and isotope bone scans may help with other aspects of management, they are of little use in the diagnosis and management of hypercalcemia in the face of established disease.

Grading Hypercalcemia in Malignant Disease

The appearance of hypercalcemia in patients with malignant disease is a poor prognostic indicator in most clinical situations. The major exception is in patients recently initiated on tamoxifen citrate therapy for breast cancer. The mechanism by which tamoxifen citrate causes hypercalcemia is unclear. It is likely, however, that prostaglandins play a central role in this phenomenon of tamoxifen citrateinduced “flare,” which is frequently associated with bone pain and subsequently a response of the tumor to therapy.

From a practical point of view, it is important to note that the development and severity of symptoms do not correlate well with the serum calcium level. Indeed, patients with symptoms readily relatable to hypercalcemia should be classified and treated as severe, independent of the absolute calcium level. An observation that is frequently made but poorly understood is that patients with tumor-induced hypercalcemia often have greater symptomatology for any given rise in calcium level compared with patients with primary hyperthyroidism.

Patients with a corrected serum calcium level below 3.0 mmol/l (<12 mg/dl) who are asymptomatic can be considered as having mild hypercalcemia. This condition may have been detected as part of the routine biochemical work up in patients with tumor types known to predispose to hypercalcemia. Often these patients are being monitored in the outpatient clinic. With the new development of hypercalcemia, it is important to reevaluate the current antineoplastic therapy because this complication may be an early indication of a diminishing response. Immediate treatment of the hypercalcemia may not be indicated, but it is important to remember that the natural history is for the hypercalcemia to worsen unless a tumor response can be obtained or some intercurrent illness that has precipitated the hypercalcemia can be reversed.

In asymptomatic patients with a serum calcium of 3.0–3.5 mmol/l (12–14 mg/dl), the situation is more serious. Any event that induces volume depletion or reduces the glomerular filtration rate, including the institution of medication such as nonsteroidal anti-inflammatory agents, may be enough to lead to severe hypercalcemia. Patients with a corrected serum calcium concentration of greater than 3.5 mmol/l (>14 mg/dl) require urgent treatment, as do patients with symptomatic hypercalcemia.

TREATMENT OF HYPERCALCEMIA

General Considerations

It is possible to lower the serum calcium concentration in nearly all patients with tumor-induced hypercalcemia. The basic principles to be used are relatively simple. Most patients with hypercalcemia are sodium- and waterdepleted and require aggressive rehydration. The best therapeutic strategy is one directed at removing the cause of the hypercalcemia, including the judicious use of surgery, radiotherapy, and chemotherapy. Hypercalcemia is maintained by two main pathways. Enhanced osteoclastic bone resorption is present in virtually all cases of hypercalcemia. Specific antiresorptive therapy is available and should be used early in the management of the complication. Increased renal reabsorption of calcium is present in cases in which PTHrP is acting on the kidneys. In an attempt to offset this problem, high urine volume should be maintained, but direct antagonism of the effects of PTHrP on the kidney is not readily available.

Dietary restriction of calcium-containing products seems intuitively appropriate; however, it is important to remember that, except where the mechanism of the hypercalcemia is thought to be vitamin D–dependent, gastrointestinal absorption of calcium is very low. Every effort should be made to maintain the mobility of the

patient, and medications predisposing to hypercalcemia, such as thiazide diuretics and vitamin D and A supplements, should be avoided. Table 34-2 summarizes potential options for the management of hypercalcemia in malignant disease.

Treatment	Dose	Response[b]	Comments
Saline diuresis	3 l/d i.v. (or more)	Rarely complete	Important component of therapy for severe hypercalcemia due to accompanying dehydration (see text).
Furosemide	40–80 mg/d p.o. or i.v.	See comment	Useful for maintaining diuresis in patients receiving aggressive hydration (especially enteral) to avoid fluid overload.
Zoledronic acid	4 mg i.v. over ≥15 min	Approximately 80%	Potential for longer duration of response. Short infusion times facilitate outpatient use. Renal dysfunction with dose escalation or rapid infusion times.
Pamidronate disodium	60–90 mg i.v. over 4 h	60–90%	Highly effective, well tolerated, convenient for outpatient administration.
Etidronate disodium Gallium nitrate Mithramycin (Mithracymin)	7.5 mg/kg/d i.v. over 2 h for 3–5 d 200 mg/m² for 5 d i.v. 25 μg/kg i.v. (approximately 1.5–2.0 mg)	25–45% 75–80% Approximately 80%	Widely infused only. Inconvenient schedule, potentially nephrotoxic. Teratogenic, anticant. Increased response with repeated daily dosing but with increased myelosuppression, hepatic and renal toxicity.
Calcitonin	4 MRC U/kg s.c. q2–2h to 8 MRC U/kg s.c. q8h (approximately 300–400 U)	See comment	Rapid effect but seldom complete normalization of serum calcium. Tachyphylaxis.
Glucocorticoids	Prednisone, 40–100 mg/d or equivalent.	See comment	Effective in hematological malignancies with cytokine or $1,25-(OH)_2D_3$-mediated hypercalcemia and hormone-induced skeletal flare response.
Antiprostaglandins	Indomethacin, 75–100 mg/d or equivalent	Rare	Little value.
Inorganic phosphorus	1 g/d in divided doses titrated to 2–3 g/d	Maintenance range	Dose-limiting diarrhea.

MRC, Medical Research Council.
[a]Currently approved in the United States.
[b]Normalization of albumin-adjusted serum calcium.

TABLE 34-2. THERAPEUTIC OPTIONS FOR HYPERCALCEMIA[a]

Establishing Treatment Goals

When embarking on the treatment of hypercalcemia in malignant disease, it is important to have clear goals in mind. If no therapeutic intervention directed at the underlying malignancy is available or planned, patient survival is short-lived. Ralston et al. (56) reported a median survival time of 30 days for 100 hypercalcemic patients in whom no antitumor therapy was available; indeed, all patients in this group had died by 120 days. These data are similar to those presented by Nussbaum et al. (3), who reported a median survival of 1.4 months. If such a patient is relatively asymptomatic or already obtunded, it may be that aggressive attempts to normalize calcium levels are unwarranted. In most patients with symptomatic hypercalcemia, however, the mental status abnormalities and confusion, as well as the chronic nausea and constipation, are so troublesome as to make palliative antihypercalcemic therapy worthwhile. Indeed, even in cases in which symptoms may be severe, normalization of serum calcium and resolution of symptoms can be achieved with appropriate therapy, which may allow a terminally ill patient another chance to see and speak with family members and clergy, attend to legal matters, and complete unfinished business. We find that early consultation with the palliative care team is extremely useful in these circumstances, as long-term antihypercalcemia therapy can be given on an outpatient basis or even in the patient's home.

Extracellular Fluid Volume Expansion

The combined effects of anorexia, vomiting, compromised mental status, and nephrogenic diabetes insipidus render most patients with hypercalcemia significantly volumedepleted, as much as 5–10 liters. Under these circumstances, the glomerular filtration rate is reduced and inappropriate calcium retention occurs as the kidneys attempt to conserve sodium. Normal saline solution should be infused, initially as rapidly as the patient's cardiac status will tolerate. Thereafter a saline infusion should be continued until normocalcemia is restored by other means. If a state of mild volume overload can be induced, the fractional excretion of calcium can be increased significantly. Hosking et al. (57) demonstrated that it was possible to produce a mean drop in calcium concentration of 0.6 mmol/l (2.4 mg/dl) in their study of 16 hypercalcemic patients. The authors concluded that most of the calciumlowering effect was based on improving the glomerular filtration rate and increasing the fractional excretion of sodium, permitting appropriate off-loading of calcium by the kidneys. They noted three patients in whom the tubular resorption rate of calcium appeared fixed. Presumably, those patients were reabsorbing calcium under the influence of PTHrP. Although restoration of fluid volume rarely restores the calcium level to the normal range—the mean postrehydration value in Hosking's study was 3.24 mmol/l (12.8 mg/dl)—a failure to rehydrate the patients certainly compromises the efficiency of other therapeutic maneuvers.

Antiresorptive Therapy

Enhanced osteoclastic bone resorption, either driven hormonally by the effects of PTHrP or in a paracrine fashion by factors released from tumor deposits within bone, is the final common pathway in the genesis of hypercalcemia in malignant disease. It is of little surprise, therefore, that osteoclast inhibitors are effective in the treatment of hypercalcemia. In the last decade, the introduction of newer, more effective, and less toxic antiresponsive medications have replaced more conventional methods for the management of the hypercalcemia of malignancy.

Bisphosphonates

The bisphosphonates are structural analogs of pyrophosphate in which the P-O-P bond is replaced by a P-C-P bond that is resistant to enzymatic cleavage by endogenous pyrophosphatases. The commonly available bisphosphonates are etidronate disodium, clodronate, and the aminobisphosphonates, pamidronate disodium and alendronate.

Several newer bisphosphonates have undergone clinical trials in patients with hypercalcemia including risedronate sodium, ibandronate, and zoledronic acid.

Bisphosphonates share poor and unpredictable oral bioavailability. Furthermore, the bioavailability is reduced almost to zero if they are ingested with food. In the setting of symptomatic hypercalcemia of malignancy, the intravenous route is preferred because nausea and vomiting are such frequent occurrences. Once absorbed, approximately half of the ingested dose is excreted unchanged in the urine. Bone mineral has a high affinity for bisphosphonates, which are rapidly adsorbed onto the bone surface (58). Although the bulk of any absorbed bisphosphonate is rapidly relocated to the bone, this is nonhomogeneous, with most of the bisphosphonate located in areas of highest bone turnover.

The method by which bisphosphonates inhibit osteoclast function is unclear, and it is likely that several mechanisms are involved. The high-affinity adsorption of bisphosphonates to hydroxyapatite crystals suggests that an important physicochemical process may operate. Bisphosphonates affect the ionic composition of the hydration layer that normally surrounds bone crystals (59). The altered concentrations of calcium and phosphate in this microenvironment may be responsible for the relative stability induced by the bisphosphonates.

Osteoclast attachment to bone may be reduced in the presence of bisphosphonates. Carano et al. (60) demonstrated a 30% reduction in bone binding by osteoclasts in tissue culture in the presence of etidronate disodium, clodronate, and pamidronate disodium. An inhibition of osteoclast acid hydrolases also has been described (61). Given that these enzymes are so important in bone resorption, this may account in part for some of the effects of the bisphosphonates. Other effects suggested for bisphosphonates include a reduction in osteoclast progenitor maturation, interference with energy-producing enzymes, and a direct cytotoxic effect on osteoclasts.

Aminobisphosphonates

Pamidronate disodium was the first aminobisphosphonate licensed for clinical use. It is effective in restoring normocalcemia (Fig. 34-1), with expected response rates of the order of 90% (62). Although an early dose–response study suggested little advantage to increasing the dose beyond 0.25 mg/kg, a large multicenter trial in the United States has shown that a single starting dose of 90 mg may be optimal (3). In initial studies, pamidronate disodium was given in divided doses over a period of several days; however, the normocalcemic effect can be achieved with single-dose therapy (63). Dodwell et al. (64) studied more rapid infusion rates and found that the drug can be given safely and efficaciously over a 2-hour period.

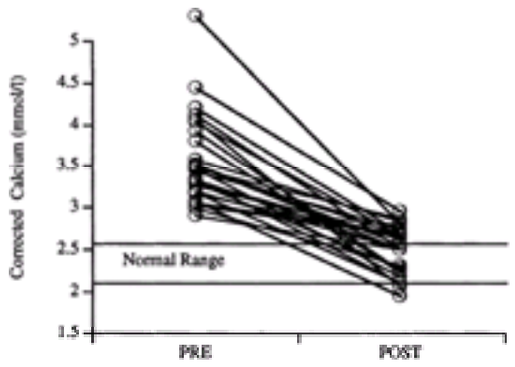

FIGURE 34-1. Effect of pamidronate disodium therapy on 30 hypercalcemic patients. [From Morton AR, Cantrill JA, Craig AE, et al. Single dose versus daily intravenous aminohydroxypropylidene bisphosphonate (APD) for the hypercalcaemia of malignancy. *BMJ* 1988;296:811, with permission.]

Pamidronate disodium was shown to be the most effective of the bisphosphonates available in 1989 (65). Another study has confirmed the superiority of pamidronate disodium to clodronate using higher doses of each drug. Not only was the complete response rate greater for pamidronate disodium as compared to clodronate, but the duration of the response was significantly longer (66). In a comparative randomized, crossover study, Thürlimann et al. (67) demonstrated that a single intravenous dose of 60 mg pamidronate disodium was more effective than a dose of 20 µg/kg of plicamycin. No primary failures occurred in the pamidronate disodium–treated group, and those primary failures in the plicamycin-treated group became normocalcemic when treated with pamidronate disodium. Although one randomized study comparing 30 mg with 90 mg pamidronate disodium failed to show a significant difference in therapeutic efficacy (68), other prospective and retrospective evaluations identified a clear dose–response relationship over this dose range (3,69). This may have important clinical implications, particularly for patients with severely elevated serum calcium levels in whom higher doses may be necessary to achieve normocalcemia. For most patients, 60 mg pamidronate disodium appears adequate to restore the serum calcium to normal. In the United States, initial approval restricted pamidronate disodium administration to a 24-hour intravenous infusion. Subsequently, the approval was liberalized to allow shorter duration infusions over 4 hours, thus facilitating outpatient or home administration.

Alendronate disodium is an aminobisphosphonate that is routinely used in the management of osteoporosis. Like other bisphosphonates, it is a powerful antihypercalcemic agent (70). A dose–response and duration of response study demonstrated that normalization of corrected calcium can be expected in approximately 90% of patients given 10 mg of this agent intravenously over 2 or 24 hours (71). As with pamidronate disodium, the efficacy and safety of a rapid infusion rate lend itself to outpatient management.

Ibandronate is an amino-substituted bisphosphonate that is approximately 50 times more potent than pamidronate disodium in animal models of stimulated osteoclast activity. Two dose–response studies of ibandronate have confirmed its efficacy in the treatment of hypercalcemia in malignant disease (72,73). Ralston et al. found a 77.4% complete response rate to a dose of 6 mg infused over 2 hours (73). This response rate is similar to that found in the studies of pamidronate disodium, but the two agents have not yet been compared in a randomized trial.

Other Bisphosphonates

The first commercially available bisphosphonate, etidronate disodium, has a relatively weak antihypercalcemic effect. Randomized studies proved it to be less effective than pamidronate disodium, clodronate, or gallium nitrate (65,74).

Clodronate is a highly efficacious bisphosphonate. The appearance of three cases of acute leukemia in 664 patients in a multicenter study involving its use in the United States led to the temporary withdrawal of this agent (75). Despite this concern, clodronate has continued to be used both intravenously and orally for the management of hypercalcemia and other neoplastic effects on bone in Europe and Canada. It is an effective agent in restoring normocalcemia, with a reported response rate of 89% (24 of 27 patients) in one study of patients receiving 100–300 mg/day for 3–10 days (76). Oral clodronate also appears able to induce a normocalcemic response (77). In the clinical situation of the acute management of hypercalcemia, the intravenous route is preferred; however, long-term treatment with oral clodronate may be a useful therapy to maintain normocalcemia. In direct comparative studies (65,66), clodronate was less effective than pamidronate disodium both in frequency and duration of patient response.

Zoledronic acid is a new nitrogen-containing heterocyclic imidazole bisphosphonate that is estimated to be approximately 100 times more powerful than pamidronate disodium. An early dose-finding study indicated that the effective dose was approximately 0.02–0.04 mg/kg (78). An analysis of randomized, controlled clinical trials has demonstrated the superiority of 4 and 8 mg of zoledronic acid over 90 mg pamidronate disodium both in terms of complete response rate for normalization of corrected calcium levels and duration of antihypercalcemia response (79).

Effect of Tumor Type on Response to Bisphosphonates

Evidence suggests that cases of hypercalcemia that are mediated mainly by PTHrP may be more resistant to antiresorptive therapy (80,81). Decreased responsiveness to pamidronate disodium was observed when the hypercalcemia was associated with elevated levels of PTHrP (82). In a study of the efficacy of ibandronate (73), tumor type was clearly identified as a predictor of response to therapy. Patients with breast cancer or hematological malignancies were statistically more likely to respond to ibandronate than those with other tumor types. In a study with zoledronic acid, the complete response rate to 4 and 8 mg was lower in patients with elevated PTHrP levels, although this did not reach statistical significance (79). The implications are that patients with hypercalcemia due to tumor types that are associated with PTHrP production are likely to be less responsive to lower doses of bisphosphonate therapy.

Duration of Response to Bisphosphonate Therapy

The true duration of response to bisphosphonates is difficult to determine. The mortality rate in this group is high, and many patients die without becoming hypercalcemic again. Furthermore, effective antitumor therapy is introduced whenever possible, confounding the issue of time to recurrence of hypercalcemia. For pamidronate disodium the median duration of normocalcemia was found by Thiébaud et al. to be 35 days (83), significantly longer than the 9–13 days reported by Nussbaum et al. (3) and the 18 days found in the large comparative study with zoledronic acid (79). The median response duration for ibandronate was approximately 12 days regardless of 2-, 4-, or 6-mg dose (73). For zoledronic acid, the response duration was 32 days for the 4 mg dose and 43 days for 8 mg dose (79).

Side Effects of Bisphosphonates

Bisphosphonates have a wide therapeutic index, making them a good choice of agent for patients with advanced malignancy. Oral formulations tend to be associated with gastrointestinal intolerance, which may be dose limiting. This is not usually a problem in the acute setting, in which intravenous therapy is indicated, but may limit their role for chronic administration. Rapid intravenous infusions of etidronate disodium and clodronate have been associated with the deterioration of kidney function in patients with myeloma and preexisting renal compromise (84). Renal adverse events, including significant elevations in serum creatinine, were noted infrequently in all groups of patients in the zoledronic acid comparison study with pamidronate disodium (79). Low-grade pyrexia is noted in 10–15% of patients. Hyperphosphatemia is noted with etidronate disodium therapy, but hypophosphatemia is also seen with clodronate, pamidronate disodium, ibandronate, and zoledronic acid treatment. The mechanisms of phosphate imbalance are unclear and are rarely of clinical significance. Ocular adverse reactions occasionally may be observed, including anterior uveitis, scleritis or episcleritis, and nonspecific conjunctivitis (85).

Calcitonin

The hypocalcemic effects of calcitonin are due in part to a direct inhibition of osteoclast function. Normocalcemia is rarely restored with this agent; however, its actions are rapid, and it can be combined effectively with one of the powerful bisphosphonates (86,87). This may be particularly useful in patients in whom neurological symptoms due to the hypercalcemia are troublesome.

An additional advantage for calcitonin is that it induces a mild degree of renal calcium wasting that begins promptly after administration (88). Unfortunately, tachyphylaxis develops within 2–3 days due to down-regulation of calcitonin receptors, and although this effect may be reduced by the simultaneous administration of corticosteroids (89), the effects of calcitonin are not long lasting. The suggested dose is 4 Medical Research Council U/kg every 12 hours by injection, although doses as high as 8 MRC U/kg every 6 hours may be used. A test dose of 1 MRC U intradermally has been recommended to identify allergic individuals. An alternative route of

administration is by rectal suppository (90).

Gallium Nitrate and Plicamycin (Mithramycin)

Gallium nitrate is an effective antihypercalcemic agent, the mechanism of action of which is unclear (91). Its utility is limited by the fact that the most effective dose is a continuous infusion of 200 mg/m^2 given daily for 5 days.

Plicamycin, formerly mithramycin, is an antitumor antibiotic that has antiosteoclastic activity. Its mechanism of osteoclast inhibition is incompletely understood, but it appears to interfere with mRNA synthesis within the cells (92). Although effective in restoring normocalcemia, much concern has been raised over the potential side effects of marrow, hepatic, and renal toxicity. In fact, an infusion of 25 µg/kg over 4–6 hours is approximately one-tenth the dose at which those side effects are commonly seen, but restores normocalcemia in approximately 40% of patients (93). The onset of the hypocalcemic effect is rapid with plicamycin, being evident within the first 24 hours. As with other agents, the individual duration of response is unpredictable, and close monitoring is necessary to avoid serious rebound hypercalcemia. Plicamycin has been used with success in patients with recalcitrant hypercalcemia.

Prostaglandin Synthesis Inhibitors

Given the fact that some tumor types could cause hypercalcemia in association with the high renal excretion of prostaglandin synthetase inhibitors, it was hoped that these agents would be a powerful addition to the oncologist's armamentarium. Unfortunately, responses to these agents are relatively rare.

Other Therapy

Furosemide

The loop diuretic furosemide continues to be used frequently in the management of hypercalcemia. Evidence for its effectiveness comes from a study in 1970 by Suki et al. (94), who used high doses of furosemide, approximately 80–100 mg every 2–4 hours, to achieve their effect. Generally speaking, this regimen is impractical because intensive fluid and electrolyte monitoring with appropriate replacement is required. The use of diuretics before establishing mild hypervolemia may even be counterproductive by enhancing the renal resorption of calcium linked to sodium from the proximal convoluted tubules.

Furosemide should be limited to patients in whom aggressive fluid replacement can potentially induce congestive cardiac failure. It has no place in the chronic management of hypercalcemia.

Corticosteroids

Glucocorticoids are another group of agents that are frequently used in the management of hypercalcemia of malignancy despite evidence that their role is very limited (Fig. 34-2) (95,96). Certain tumor types are inherently responsive to glucocorticoid therapy, including multiple myeloma and lymphoma. Osteolytic cytokines mediating the hypercalcemia may be inhibited by corticosteroids, and these agents also may be useful in managing the flare response occasionally seen after initiating hormonal therapy for breast cancer. In cases in which hypercalcemia is mediated by excessive 1,25-$(OH)_2D_3$, glucocorticoids may have an antagonistic effect on calcium absorption from the gut.

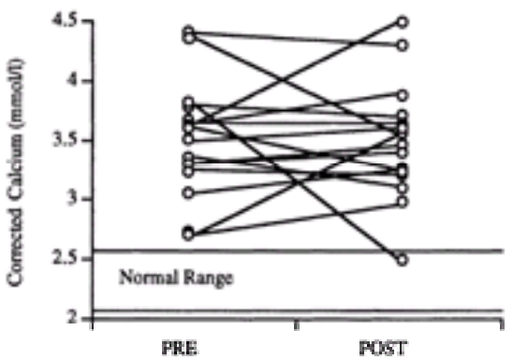

FIGURE 34-2. Effect of varying doses of corticosteroids on ten hypercalcemic patients with solid tumors. (From Thalassinos NC, Joplin GF. Failure of corticosteroid therapy to correct the hypercalcemia of malignant disease. *Lancet* 1970;2:537, with permission.)

Phosphate

Oral phosphate, with its chelating action on intestinal calcium, may be useful as an adjunct for the long-term management of hypercalcemia. The dose-limiting side effect is diarrhea.

Experimental Agents

Established antitumor agents such as cisplatinum have been used in an attempt to control hypercalcemia. The total dose used by Lad et al. (97) in their study of 13 patients with hypercalcemia was 100 mg/m^2. Aside from its antineoplastic effects, the mechanism of hypopcalcemia with cisplatinum is unclear. It is recognized that this agent is toxic to the loop of Henle in the kidney, and this may represent the source of calcium wasting.

Ethiofos (WR-2721) is a myeloprotective agent that appears able to suppress PTH secretion and bone resorption. Although its effects on PTHrP release are currently unknown, ethiofos could have great potential if able to suppress the release of this tumor product. It is associated with mild nausea and vomiting as well as potentially troublesome hypotension. Clinical experience in the management of hypercalcemia with this agent remains limited.

Osteoprotegrin is an autocrine substance secreted in the bony milieu that appears to act by binding ODF, thus preventing the differentiation of osteoclasts (98). Early animal studies suggest that it is a potent antihypercalcemic agent, even in tumors expressing PTHrP (99).

SUMMARY

Hypercalcemia of malignancy is a common problem. If promptly recognized, useful palliation may be made available. Strategies aimed at removing or reducing the underlying tumor burden should be sought. Where no effective therapy for the tumor is available, patients are normally in the last few weeks to months of their lives. A thoughtful decision should be made before embarking on antihypercalcemic therapy in terminally ill patients who may be relatively asymptomatic. Volume repletion is the mainstay of therapy, followed by the use of antiresponsive medications. The aminobisphosphonates are effective, safe agents in this regard. They may be given over short infusion times, which can allow therapy to take place in the outpatient or home setting. Individualization of therapy is required because the duration of response to any of the hypercalcemic agents is relatively unpredictable.

METABOLIC DISORDERS IN THE CANCER PATIENT

ALBERT L. JOCHEN
IRENE M. O'SHAUGHNESSY

Endocrine disorders occur in persons with advanced malignancy under various circumstances. Cancer may produce effects through the excess production of hormones, cytokines, and growth factors, the so-called “paraneoplastic syndromes” (Table 35-1). Conversely, the cancer or its metastases may interfere with the normal function of endocrine organs, resulting in hormone-deficiency states. Most commonly, patients have a metabolic disorder such as diabetes, thyroid dysfunction, or hyperparathyroidism that predates the diagnosis of their malignancy or is diagnosed incidentally during the course of their malignancy. This chapter discusses the most common paraneoplastic syndromes and hormone-deficiency states associated with malignancy, as well as the management of diabetes and thyroid disease in the cancer patient.

Syndrome	Tumor type
Inappropriate antidiuresis (hormone vasopressin)	Lung cancer, all types
Cushing's syndrome (adrenocorticotropic hormone, corticotropic hormone)	Lung cancer, all types
Hypocalcemia	Bone metastases
Hypophosphatemia ("phosphatonin")	Mesenchymal tumors
Hyperthyroidism (human chorionic gonadotropin)	Lung cancer, all types
Gynecomastia (estrogens, follicle-stimulating hormone, lutenizing hormone)	Lung cancer, all types
Calcitoninemia (calcitonin)	Medullary carcinoma of the thyroid, lung cancer, breast cancer
Acromegaly (growth hormone, growth hormone releasing hormone)	Carcinoids, pheochromocytoma, pancreatic cancer

TABLE 35-1. COMMON PARANEOPLASTIC SYNDROMES

ENDOCRINE PARANEOPLASTIC SYNDROMES

Inappropriate Antidiuresis

The differential diagnosis of hyponatremia in the cancer patient is similar to that in the general population and includes hepatic and cardiac failure, renal disease, overdiuresis, factitious hyponatremia associated with hyperglycemia, and other conditions. In the syndrome of inappropriate antidiuretic hormone (SIADH), hyponatremia results from the overproduction of vasopressin (AVP) by the posterior pituitary gland in response to a stimulus by tumor cells, by the actual production of AVP or AVP-like peptides by tumor cells, or as a side effect of medications able to stimulate AVP production.

Epidemiology

The most common malignancies causing SIADH are small cell lung cancer and carcinoid tumors; SIADH also is seen with cancers of the esophagus, pancreas, duodenum, colon, adrenal cortex, prostate, thymomas, and lymphomas. In one series, the incidence of clinically significant SIADH was 9% among 523 small cell lung cancer patients. A larger fraction of patients had milder abnormalities in AVP metabolism without hyponatremia. Thus, approximately one-half of patients had abnormal renal handling of water loads that were subclinical (1,2). Another study found that 41% of patients with all types of lung cancers and 43% of colon cancer patients had significantly elevated levels of AVP without evidence of clinically significant SIADH (3).

Clinical Features

The clinical features of hyponatremia depend on the degree of hyponatremia and the rate of its development. Most patients with chronic hyponatremia are asymptomatic. Generally, symptoms do not occur until the serum sodium falls below 115–120 mEq/l (4). When they occur, the signs and symptoms of SIADH are caused by water intoxication (i.e., hypoosmolality and hyponatremia) and are manifested by confusion, lethargy, seizures, or coma. Occasionally, patients may present with focal neurological deficits.

Diagnosis

Because most cases of SIADH are asymptomatic, the diagnosis is usually first suspected by noting a low serum sodium on routine chemistries. Other causes of hyponatremia, such as hypovolemia, hypervolemia (occurring in renal or hepatic disease or cardiac failure), hypothyroidism, and adrenal insufficiency, must be excluded before the diagnosis of SIADH can be considered. Urine chemistries show urinary osmolality greater than serum osmolality and a high urinary sodium concentration (Table 35-2). Medications commonly used by cancer patients associated with SIADH include morphine sulfate, vincristine sulfate, cyclophosphamide, phenothiazines, and tricyclic antidepressants. Most drugs cause SIADH by stimulating posterior pituitary secretion of AVP.

Plasma sodium level below 135 mEq/l
Urine osmolality greater than serum osmolality
Elevated urine sodium (>20 mEq/l)
Normal extracellular fluid volume
Rule out other causes of euvolemic hyponatremia

TABLE 35-2. DIAGNOSIS OF SYNDROME OF INAPPROPRIATE ANTIDIURESIS

Treatment

The treatment of SIADH is determined by the rate of development of hyponatremia and by the presence of neurological sequelae. If the patient is symptomatic and has a serum sodium level below 130 mEq/L, fluid restriction to 800–1000 ml per 24 hours is effective in slowly raising serum osmolality over a period of 3–10 days. Acute hyponatremia with neurological symptoms has a mortality rate of 5–8% and warrants more aggressive treatment. For patients with more severe hyponatremia, the intravenous administration of hypertonic saline (3% saline at a rate of 0.1 mg/kg per minute) and furosemide may be necessary (5). Careful monitoring of vital signs and urinary losses of sodium and potassium is indicated. Rapid correction of severe hyponatremia has been associated with central pontine myelinosis, which presents with quadriparesis and bulbar palsy 1–2 days after correcting hyponatremia. A safe rate of correction in severe hyponatremia is 0.5–1.0 mEq/l per hour until the sodium concentration reaches 125 mEq/l (6,7).

Fluid restriction is not feasible in some patients who require long-term treatment of SIADH. In these patients, medications, including demeclocycline hydrochloride, lithium carbonate, and urea, have been tried. Demeclocyline is the drug of choice and causes partial nephrogenic diabetes insipidus by inhibiting the formation of AVP-induced cyclic adenosine monophosphate in distal tubules. It is initially administered orally in divided doses of 900–1200 mg/day and then reduced to maintenance doses of 600–900 mg/day. Side effects are mainly gastrointestinal, although hypersensitivity and nephrotoxicity can occur. Similar to demeclocycline hydrochloride, lithium carbonate also causes a reversible, partial form of nephrogenic diabetes insipidus but is less effective. Urea acts as an osmotic diuretic and allows the patient to maintain a normal fluid intake. Urea can be administered intravenously or orally. When given by mouth, the usual dosing is 30 g of urea dissolved in 100 ml of orange juice or water once daily (8).

Cushing's Syndrome

Endogenous Cushing's syndrome is due to one of three causes: overproduction of glucocorticoid by a primary adrenal neoplasm, excessive production of adrenocorticotropic hormone (ACTH) by a pituitary adenoma, or a paraneoplastic syndrome in which either ACTH or corticotropic hormone (CRH) are produced ectopically by the tumor. A number of tumors are capable of producing ACTH, its prohormone “big ACTH,” or pro-opiomelanocortin (POMC) (Table 35-3). The POMC gene is located at *p23* on the short arm of chromosome 2 near N-*myc* oncogene at *p24*. The expression of the POMC gene normally is influenced by glucocorticoids, which suppress transcription, and CRH, which stimulates transcription via cyclic adenosine monophosphate. The activation of alternative steroidinsensitive promoters may result in ectopic ACTH production that is insensitive to glucocorticoid suppression. Pituitary cells and some tumors produce the normal 1200-base mRNA transcript; however, some nonpituitary tissues produce either a larger or smaller POMC mRNA transcript. Alternative posttranscription processing of POMC gives rise to a large number of biologically active peptides in addition to ACTH. These include pro-ACTH and a number of different peptides containing melanocyte-stimulating hormone (MSH) (a-MSH, ACTH, pro-ACTH, b-MSH, t-lipotropin, b-lipotropin, t-MSH, N-POMC, pro-t- MSH), all of which can lead to generalized hyperpigmentation (9,10). Radioimmunoassays differ in their abilities to detect aberrant ACTH. The immunoradiometric assay for ACTH is able to distinguish between ACTH and its larger precursors, pro-ACTH, and POMC (11).

Small cell lung carcinoma
Thymoma
Pancreatic islet-cell tumor
Carcinoid tumors (lung, gut, pancreas, ovary)
Medullary carcinomas of the thyroid
Pheochromocytomas

TABLE 35-3. TUMORS ASSOCIATED WITH ECTOPIC ADRENOCORTICOTROPIC HORMONE/CORTICOTROPIC HORMONE SYNDROME

Epidemiology

Ectopic ACTH is most frequently secreted by lung carcinomas. A number of other tumor types are also capable of producing this syndrome (Table 35-3). In the general population, approximately 65% of patients with Cushing's syndrome have pituitary adenomas producing ACTH (Cushing's disease), 20% have primary adrenal tumors, and 14% have ectopic ACTH. Therefore, ectopic ACTH production is the least common of the three major causes in the general population.

Clinical Features of Ectopic Adrenocorticotropic Hormone Syndrome

Manifestations of the ectopic ACTH syndrome include hypokalemia, hyperglycemia, edema, muscle weakness (especially proximal) and atrophy, hypertension, and weight loss. Features typically seen in long-standing pituitary or adrenal Cushing's syndrome (e.g., central obesity, plethoric facies, cutaneous striae, “buffalo hump,” and hyperpigmentation) are less common in highly malignant tumors such as small cell lung carcinoma but occur more frequently in more indolent tumors such as carcinoids, thymomas, and pheochromocytomas.

Diagnosis

The biochemical diagnosis of Cushing's syndrome is suggested by an elevated 24-hour urinary-free cortisol (>100 µg/24 hours). The other principal screening test is the overnight low-dose dexamethasone suppression test. The test is positive when 1 mg of dexamethasone given at midnight is unable to suppress the following 8:00 a.m. cortisol to less than 5 µg/dl. Failure of cortisol to suppress after high-dose dexamethasone (8 mg at midnight) suggests either ectopic ACTH or a primary adrenal tumor (12). These two are differentiated by measuring plasma ACTH. In primary adrenal tumors, ACTH levels are below 20 pg/ml, whereas in ectopic ACTH levels are generally greater than 100 to 200 pg/ml and frequently are elevated above 1000 pg/ml. Inferior petrosal sinus sampling of ACTH is useful in confirming the diagnosis of pituitary Cushing's syndrome (13), but it is rarely indicated in the patient with advanced malignancy secreting ectopic ACTH.

Difficulties arise in differentiating those rare tumors producing ectopic CRH from the more common ectopic ACTH production; CRH stimulates release of pituitary ACTH. The clinical presentation and biochemical results are identical for ectopic CRH and ACTH. The prognosis and therapy are identical for the two disorders.

Treatment of Ectopic Adrenocorticotropic Hormone Syndromes

Where possible, the treatment of ectopic ACTH syndrome should be directed primarily at the tumor. Palliative treatment of Cushing's syndrome involves inhibition of steroid synthesis. Drugs successfully used include aminoglutethamide, metyrapone, mitotane, ketoconazole, and octreotide acetate (14). Rarely, bilateral adrenalectomy is considered.

Aminoglutethamide blocks the first step in cortisol biosynthesis. At higher doses, it inhibits production of glucocorticoids, mineralocorticoids, and androgens, whereas at lower doses it primarily inhibits the conversion of androgens to estrogens, contributing to its efficacy in the treatment of postmenopausal breast cancer. At the higher doses required to treat ectopic ACTH syndrome, many patients experience sedation, ataxia, and skin rashes. Metyrapone inhibits 11 b-hydroxylase and 18-hydroxylase, resulting in adrenal atrophy and necrosis. It is a toxic drug with significant gastrointestinal side effects, including anorexia, nausea, vomiting, and diarrhea, and central nervous system toxicity, including lethargy and somnolence. For these reasons, it is used as second-line therapy.

Ketoconazole acts mainly on the first step of cortisol biosynthesis but also inhibits the conversion of 11-deoxycortisol to cortisol. It can cause rare but significant

reversible hepatotoxicity and is associated with nausea and vomiting.

Octreotide acetate, a long-acting analog of somatostatin, can reduce ectopic ACTH secretion. It must be injected, is expensive, and is only partially effective in most patients. The efficacy of these treatments can be monitored by 24-hour urine cortisol measurements. As levels return to normal and then fall below normal, replacement with glucocorticoids and mineralocorticoids in physiological doses similar to patients with Addison's disease is frequently necessary. In cases of stress, these patients require stress doses of glucocorticoids (e.g., hydrocortisone 100 mg intravenously every 8 hours).

Hypocalcemia

Hypocalcemia is an uncommon paraneoplastic syndrome occurring primarily in patients with bony metastases. It occurs most commonly in association with osteoblastic metastases of the breast, prostate, and lung; its incidence is approximately 16% (15). Tetany is a rare complication of tumor-associated hypocalcemia. The etiology of the hypocalcemia is not understood. Ectopic calcitonin secretion from the underlying tumor has been rarely implicated.

Oncogenic Hypophosphatemic Osteomalacia

Oncogenic hypophosphatemic osteomalacia, an acquired form of adult-onset, vitamin D-resistant rickets, is associated with mesenchymal tumors, often benign, that occur in soft tissues or bone (16). These tumors are also referred to as *ossifying mesenchymal tumors*, *giant cell tumors of bone, sclerosing hemangioma*, or *cavernous hemangioma*. This syndrome has been rarely reported with other cancers, such as lung and prostate. The clinical syndrome can precede the discovery of the tumor by several years. Clinical and laboratory features include osteomalacia, severe phosphaturia, renal glycosuria, hypophosphatemia, normocalcemia (normal parathyroid hormone levels), and increased alkaline phosphatase. The proposed mechanisms for this syndrome include inhibition of the conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D and a substance produced by the tumor with a phosphaturic effect “phosphatonin.” A candidate gene for “phosphatonin” has recently been described— fibroblastic growth factor 23 (17). Treatment is directed at surgical resection of the underlying tumor. When this is not possible, treatment with high doses of vitamin D and phosphate is often required.

Hyperthyroidism

Human chorionic gonadotropin (hCG) most commonly is secreted by trophoblastic or germ cell tumors (18). Because of its evolutionary homology with thyroid stimulating hormone (TSH), hCG has intrinsic thyrotropic action. Overt hyperthyroidism usually occurs with large tumors secreting large quantities of hCG, such as gestational trophoblastic disease (e.g., choriocarcinoma, hydatidiform mole) and testicular tumors. The hyperthyroidism resolves with surgical resection of the underlying tumor. When necessary, treatment of the hyperthyroidism is achieved by using antithyroid drugs such as propylthiouracil or methimazole.

Gynecomastia

Gynecomastia is defined as palpable breast tissue in men (19) and may be caused by drugs that lower testosterone levels (20), including alkylating agents, vinca alkaloids, and nitroureas. Antiemetics, such as metoclopramide and phenothiazines, may produce gynecomastia by stimulating prolactin production. Alternatively, tumor production of gonadotropins or estrogens may result in gynecomastia; these include adrenal and testicular tumors and hepatomas. Tumors that produce hCG can stimulate estrogen production by interstitial and Sertoli cells of the testes, resulting in gynecomastia. The approach to the treatment of gynecomastia includes treatment of the underlying tumor and, if implicated, cessation of drugs known to cause gynecomastia.

Treatment of gynecomastia with antiestrogens and androgens such as tamoxifen citrate, clomiphene citrate, topical dishydrotestosterone, and danazol is generally unsuccessful. For more severe cases, long-term management with liposuction and subcutaneous mastectomy may be necessary. Low-dose radiation therapy has been used with some success for the treatment of painful gynecomastia.

Calcitoninemia

Calcitonin is a polypeptide hormone produced by the C cells of the thyroid. It diminishes the release of calcium from bone and increases the excretion of urine calcium, sodium, and phosphate. Interestingly, no clinical syndromes are associated with tumor production of calcitonin except for one reported case of a small cell carcinoma patient with hypercalcitoninemia and hypocalcemia (21). Calcitonin plays an important role as a tumor marker in monitoring patients with medullary carcinoma of the thyroid and in the diagnosis of multiple endocrine neoplasia type 2, a familial disorder characterized by medullary carcinoma of the thyroid, parathyroid adenomas, and pheochromocytoma. In addition to medullary thyroid carcinoma, a number of other cancers have been associated with elevations in calcitonin, including small cell (48–64%) and other lung cancers, carcinoid, breast cancer, colon cancer (24%), and gastric cancer (38%). With the exception of medullary thyroid carcinoma, the clinical usefulness of serum calcitonin levels as a tumor marker remains undetermined (22).

Acromegaly

Most cases of acromegaly result from growth hormone overproduction by pituitary tumors. Growth hormone elevations also may result from production of growth hormone releasing hormone by tumors, particularly pancreatic islet-cell tumors and bronchial carcinoids. Treatment of this paraneoplastic syndrome is directed at treatment of the underlying tumor. Occasionally, growth hormone releasing hormone secretion responds to administration of longacting somatostatin analogs (23).

Carcinoid Syndrome

The classic carcinoid syndrome is characterized by flushing, diarrhea, and bronchospasm. Less frequent signs and symptoms include coronary artery spasm leading to angina pectoris, pellagra, endocardial fibrosis, arthropathy, glucose intolerance, and hypotension. The symptoms are due primarily to the production of 5-hydroxytrytophan (serotonin), although secretion of other hormones, such as bradykinin, hydroxytryptophan, and prostaglandins, also may play a role. Carcinoid tumors are found throughout the gastrointestinal tract, including the esophagus, stomach, duodenum, jejunum, ileum, the Meckel diverticulum, appendix, colon, rectum, bile ducts, pancreas, and liver. They also have been found in the larynx, thymus, lung, breast, ovary, urethra, and testis.

The medical treatment of the carcinoid syndrome is directed at inhibiting serotonin synthesis and at blocking its effects peripherally. Different drugs can be used to accomplish these goals (24,25). Antiserotonin agents such as cyproheptadine hydrochloride and methysergide can ameliorate the diarrhea. For long-term treatment, cyproheptadine hydrochloride is the preferred medication because of the risk of retroperitoneal, cardiac, and pulmonary fibrosis associated with methysergide. Antidiarrheal agents such as loperamide hydrochloride and diphenoxylate hydrochloride also can be quite helpful in controlling the diarrhea.

Flushing appears to be due to the secretion of histamine. The administration of a combination of H_1 and H_2 histamine receptor antagonists often can control this symptom. Somatostatin analogs such as octreotide acetate are effective in controlling the symptoms of flushing and diarrhea in up to 75% of patients. Octreotide acetate is administered subcutaneously every 8 hours. Side effects include hypoglycemia, steatorrhea, and cholelithiasis. Carcinoid syndrome associated with bronchial carcinoid tumors has distinctive features and is treated differently. Many patients experience improvement in symptoms with glucocorticoids or phenothiazines.

Extrapancreatic Tumor Hypoglycemia

Tumors most likely to cause hypoglycemia are of mesodermal origin, such as fibrosarcomas and mesotheliomas, or of epithelial origin, such as hepatomas, adrenal cortical carcinomas, and gastrointestinal adenocarcinomas. Hypoglycemia usually occurs in the late stages of malignancy. The mechanism by which hypoglycemia occurs involves a combination of impaired hepatic glucose production and increased peripheral glucose utilization. Many patients have poor nutritional status, with depleted stores of the glycogen and protein needed to sustain hepatic glycogenolysis and gluconeogenesis. Hepatic damage from metastases further limits the ability to sustain gluconeogenesis. In most patients, however, hypoglycemia results predominantly from increased peripheral glucose utilization, raising the possibility of production of hormones with insulin-like properties. Insulin levels, as well as levels of insulin-like growth factor I and growth hormone, are low, whereas insulin-like growth factor II (IGF-II) levels are usually normal. Recent work has focused on tumor production of an abnormally processed variant of IGF-II, “big IGF-II.” This variant is not measured in usual radioimmunoassays for IGF-II but possesses normal biological activity. It is likely that “big IGF-II” accounts for many or most cases of tumor hypoglycemia (26,27).

Symptoms of hypoglycemia result from neuroglycopenia (confusion, seizures, and coma) or from activation of the adrenergic nervous system (sweating, palpitations, hunger, and tremors). The presence of tumor-associated hypoglycemia is established by demonstrating a low serum glucose level (less than 40–50 mg%) in a patient with symptoms of hypoglycemia who responds to oral or intravenous glucose. No further diagnostic workup is necessary. The primary treatment is nutritional support, either oral or intravenous. For immediate relief of symptomatic hypoglycemia, glucose is given as an intravenous bolus of 50% dextrose and then continued as a drip of

10% glucose. Refractory hypoglycemia can be treated with the counterregulatory hormones glucagon or cortisone.

ENDOCRINE DISEASES IN CANCER PATIENTS

Malignancies often occur in patients with preexisting medical conditions such as diabetes mellitus and thyroid disease. Treatment of these conditions must continue during and after treatment of the malignancy and during palliative care. In each condition, goals of treatment must be reevaluated with prognosis of the underlying malignancy in mind.

Diabetes Mellitus

Standard guidelines for the treatment of both type I and type II diabetes mellitus generally can be followed in the cancer patient; however, the appropriateness of “tight control” needs to be addressed in these patients. Based on results of the Diabetes Control and Complications Trial (28), it is accepted that intensive insulin treatment of type I diabetes results in a decrease in microvascular complications. These results have been extrapolated to type II diabetes mellitus (29); however, in the cancer patient with a limited life expectancy, intensive insulin therapy to prevent long-term complications is not a reasonable goal. The major complication of intensive insulin therapy is an increased risk of hypoglycemia. In patients with malignancies and poor nutrition, the risk of hypoglycemia is increased further. Additionally, intensive insulin treatment requires frequent blood sugar monitoring, which may place a further burden on the patient and his or her caregivers. Sulfonylurea agents frequently are included in treatment regimens for type II diabetes. In the cancer population with suboptimal nutrition, recent weight loss, or impaired kidney or liver function, these agents should be used with extreme caution. Severe prolonged hypoglycemia can result from using sulfonylurea drugs. Many type II diabetics previously treated with these agents can have their diabetic medication discontinued because of normalization of blood sugars secondary to weight loss and poor calorie intake.

Diets should be tailored to meet the needs of the individual patient. Patients with poor appetite and decreased oral intake should be allowed to liberalize their diets from the traditional “diabetic diet.” Patients may experience early satiety and mechanical problems with chewing and swallowing; nutritional supplementation with commercial products may be necessary. Consultation with a registered dietitian is helpful when devising an appropriate diet for the cancer patient with diabetics.

In summary, when choosing an appropriate treatment for diabetes mellitus in the cancer population, reasonable goals should be chosen. An attempt should be made to avoid symptomatic hyperglycemia, to decrease the risk of hypoglycemia, and to provide the patient with as many dietary choices as possible.

Euthyroid Sick Syndrome

Severe illness, whether acute or chronic, can cause changes in thyroid physiology, leading to what has been referred to as the *euthyroid sick syndrome* (30). Changes can occur in levels of total thyroxine (T_4) and, to a lesser extent, free thyroxine and TSH levels. T_4 is decreased due to its decreased binding to its serum transport proteins. The decrease in triiodothyronine (T_3) results from inhibition of 5'-deiodinase, the enzyme that converts T_4 to T_3. Low T_4 levels are associated with a higher mortality rate; TSH levels are generally helpful in distinguishing euthyroid sick syndrome from pituitary hypothyroidism. In addition, free thyroxine levels are usually normal.

Adrenal Insufficiency

Because of the vascular nature of the adrenal cortex, the adrenal glands are common sites of metastatic disease. Typically, adrenal metastases are found incidentally during abdominal computed tomography and magnetic resonance imaging scans and are usually of no functional significance. In a minority of cases, bilateral adrenal cortical destruction is sufficiently advanced to impair normal functioning and result in deficient production of cortisol (31). Symptoms of adrenocortical deficiency overlap with typical symptoms of advanced malignancy and include weight loss, fatigue, nausea, anorexia, and hypotension. The presence of hyponatremia or hyperkalemia further suggests the diagnosis.

The ACTH stimulation test is the most direct diagnostic study used to exclude adrenocortical insufficiency. A normal test contains the following three elements: a morning basal cortisol of at least 7–9 µg/dl, an increase greater than 7 µg/dl 30 minutes after administration of 0.25 mg intravenous ACTH, and a maximum response to intravenous ACTH of 18–20 µg/dl or greater.

Severely symptomatic adrenal insufficiency *(adrenal crisis*) is treated with intravenous saline and stress doses of hydrocortisone, 100 mg intravenously every 8 hours, tapered to a chronic oral maintenance dose of 20 mg every morning and 10 mg every evening. Patients with concomitant aldosterone deficiency resulting in hyperkalemia also may require the addition of the oral aldosterone analog fludrocortisone acetate (0.05–0.20 mg daily).

HEADACHE AND OTHER NEUROLOGIC COMPLICATIONS

WENDY C. ZIAI
NEIL A. HAGEN

Intracranial pathology can result in a variety of distressing symptoms. Fortunately, the underlying cause often can be identified and treated, and the accompanying symptoms commonly respond to supportive measures.

This chapter is divided into two sections. The first deals with headache and other symptoms of intracranial pathology and reviews their pathogenesis and management strategies. Although nausea and vomiting are common in patients with intracranial pathology, this topic is covered elsewhere in this volume. The second section reviews cancer-related neurologic syndromes, such as brain metastasis, base of skull metastasis, and cerebrovascular disease; oncologic interventions and supportive care strategies are outlined for each.

SYMPTOMS OF INTRACRANIAL PATHOLOGY

Headache

Assessment

Principles of headache assessment used for the general medical population (1) can be useful for patients with a cancer history, with one important exception: Headache in a cancer patient often heralds serious disease. The potential for headache to be the presenting symptom of a serious complication of the disease or its treatment compels an early and thorough assessment for structural disease. This assessment begins by confirming the onset, duration, progression, and focality of the headache. Pain characteristics include qualitative descriptors, severity, exacerbating and relieving features, associated symptoms, and the outcome of analgesic drugs or other therapies. Although prior headache history is important, the burden of proof is to rule out a new and serious cause of headache; brain metastasis can present with a headache similar to a previously experienced benign headache (2).

Cancer or its treatment can cause headache in a variety of ways. Some processes are considerably more likely to occur at particular points along the course of the disease. For example, approximately 90% of patients who die of melanoma have central nervous system metastases at autopsy; disseminated metastases are less likely to occur until regional metastases have developed. Therefore, the cancer history, extent of known disease, and prior treatments should be determined for all cancer patients with a headache.

The physical examination of the cancer patient with headache begins with a general physical examination and screening neurologic examination, including examination of the ocular fundi, range of motion of the cervical spine, and assessment for meningismus. Provocation of the pain by the examiner can be informative: An underlying pathological process is usually not far from the area of tenderness. Sites of pain indicated by the patient should be inspected and palpated. The examiner should palpate over facial sinuses, bony skull prominences, the occipitonuccal junction, and neck arteries. The orbits should be gently palpated and examined for proptosis. If the patient's pain is provoked by any of these maneuvers, the pain referral pattern should be noted.

Although comprehensive investigations can help document the cause of headaches caused by cancer, the extent of investigation should be guided according to the clinical situation. Bone scintigram, computed tomography (CT) of the head with fine bone windows, magnetic resonance imaging (MRI), and spinal fluid examinations are all commonly used in headache assessment. Blood tests can include serum hemoglobin, blood gas levels, and sedimentation rate.

Head pain usually originates from intracranial or extracranial pain sensitive structures. Nociceptive input from these sites arises by displacement, distention, or inflammation of vascular structures, by sustained contraction of muscles, or by direct pressure on nerves. Alternatively, head pain may arise from nonnociceptive mechanisms arising from damage to peripheral or central pain pathways that subserve the head.

Anatomy of Head Pain

Pain-sensitive structures in the head include the fifth, ninth, and tenth cranial nerves; the upper three cervical nerves; and the great venous sinuses and their tributaries from the surface of the brain. In addition, all the tissues covering the cranium, especially the arteries, are pain sensitive. The cranial bones, diploic and emissary veins, brain parenchyma, parts of the dura, most of the pia mater and arachnoid, and the ependymal lining of the ventricles and choroid plexus, are insensitive to pain.

Nociceptive input from supratentorial structures, including the superior surface of the tentorium cerebelli, causes pain to be felt anterior to a line drawn from the ears across the top of the head. Damage to these structures activates branches of the trigeminal nerve. Nociceptive input from infratentorial structures, including the inferior surface of the tentorium cerebelli, causes pain to be experienced posterior to this line and is conveyed by sensory fibers in the fifth, seventh, ninth, and tenth cranial nerves and the upper three cervical nerves (3).

Primary and Secondary Headaches

Primary headaches, migraines, tension-type headaches, cluster headaches, and others are the most frequent headache types in Western society. They are functional disorders that, by definition, are characterized by the absence of a structural lesion. In contrast, secondary headaches are symptomatic of an underlying disease, either an intracranial lesion or systemic process. The International Headache Society has provided a comprehensive classification of headache that identifies eight groups of secondary headaches (4) (Table 36-1). Although a temporal relationship between the headache and the underlying disorder is usually apparent, the diagnosis can be challenging because of the high prevalence and similar features of primary headaches.

Head trauma
Vascular disorders
Nonvascular intracranial disorder
Substances or their withdrawal
Noncephalic infection
Metabolic disorder
Disorder of cranium, neck, eyes, ears, nose, sinuses, teeth, mouth or other facial structures, cranial neuralgias, nerve trunk pain, and deafferentation pain
Headache not classifiable

Modified after Olesen J. Headache classification committee of the International Headache Society: classification and diagnostic criteria for headache disorders, cranial neuralgias, and facial pain. Cephalalgia 1988;7[Suppl 8]:1, with permission.

TABLE 36-1. SECONDARY CAUSES OF HEADACHE

The incidence of headache in patients with primary or metastatic brain tumors is approximately 50% (5). Headache is a presenting symptom in 30–60% of adult brain tumor patients, and 60–70% of patients develop headache during the course of this illness (6,7). Primary and metastatic brain tumors have a similar incidence of headache in a New York– based study (8), although other studies report higher headache occurrence in primary than metastatic tumors (7,9). The median duration of headache at diagnosis, ranging from 3.5 weeks in the New York study (8) to 15.7 months in a study from Bangkok (7), may depend on socioeconomic factors, such as access to neurosurgical expertise and neuroimaging.

Factors reported to influence the incidence of headache in patients with brain tumors include tumor location, rate of growth, increased intracranial pressure (ICP), size of the enhancing lesion, amount of midline shift, and a history of previous headache (2). Headache occurs more commonly in infratentorial (64–84%) than supratentorial (34–60%) tumors (5,6 and 7,10,11) and is especially common with midline and basal tumors (95% and 70%, respectively). Slowly growing tumors such as low-grade supratentorial astrocytomas and neuroepithelial tumors (including gangliogliomas, dysembryoplastic neuroepithelial tumors, and pleomorphic xanthoastrocytomas) have a low headache incidence but frequently are associated with seizures (12,13,14 and 15). Faster growing tumors, particularly high-grade gliomas, have been reported to cause headache in approximately one-half of patients but have a lower incidence of seizures.

The classic brain tumor headache is characterized by its progressively increasing severity, frequency, and duration; early morning awakening; disappearance after rising; association with nausea and vomiting; and aggravation by the Valsalva maneuver. This syndrome is actually uncommon, occurring in only 17–28% of patients (5,16). In reality, no single headache pattern is typical of a brain tumor. The most common headache profile is bifrontal, often worse ipsilaterally, dull, nonthrobbing, and aching in nature. These characteristics are similar to a tension-type headache. The pain is usually mild to moderate, intermittent, and relieved by simple analgesics in approximately one-half of patients. Severe headaches are reported by approximately 40% of patients, and 45% indicate that headache is the worst symptom. Also, 30–70% of patients experience nocturnal headache, and only 18–36% report early morning headache. Positional changes, either supine to standing or standing to supine, induce or aggravate headache in 20–32%; in 18–23% of patients, the headache worsens with Valsalva maneuvers. Nausea and vomiting are associated with headache in 36–48% of patients (5,6 and 7,17).

Brain tumor headaches may mimic primary headaches. Forsyth and Posner (2) found that tumor headaches were similar to tension-type headaches in 77% of patients; 9% had migrainelike headaches, and 14% had other types. In one study of cancer patients with a significant history of prior headache, 78% experienced new headaches associated with their brain tumor (5). The brain-tumor headache may be similar to the patient's prior headache but is generally more severe, frequent, or associated with new symptoms or abnormal signs.

The location of the headache in relation to tumor site, the presence of raised ICP, and the localizing value of focal headache depend on the mechanism by which headache is produced. Two mechanisms commonly account for headache in brain tumor patients: (a) direct traction or distortion of painsensitive structures by the tumor mass, and (b) distant traction through extensive displacement of brain tissue, either directly by the mass (e.g., herniation syndromes) or by hydrocephalus caused by obstruction of cerebrospinal fluid (CSF) pathways (17). Direct traction accounts for the localizing value of headaches in patients without raised ICP. Supratentorial tumors not associated with raised ICP often produce bilateral headache in the frontal region (85%). Unilateral headache is present in 28–53% (5,7), and the headache usually lateralizes to the side of the tumor. With the exception of cerebellopontine-angle tumors, which are more likely to produce symptoms by compression of adjacent cranial nerves, posterior fossa tumors often present with posterior head pain as the first symptom.

The headache of increased ICP tends to be severe, aching, and constant; is unrelieved by simple analgesics; is worse in the morning and with Valsalva maneuvers; and is associated with nausea or vomiting. It is most commonly located in the frontal region, either bifrontal or vertex, or in the neck alone. Occasionally, increased ICP accounts for the surprising occurrence of occipital headaches in association with a supratentorial tumor or frontal headache in association with a posterior fossa tumor.

Increased ICP is not necessary for the occurrence of headache, nor is it always associated with headache. Headache is commonly associated with “plateau waves,” however, which may occur when increased ICP is severe. Plateau waves are transient elevations in ICP, which range from 25–60 mm Hg and last 1–10 minutes (18). They may be either spontaneous or induced by Valsalva maneuvers or changes in body position. In addition to headache, these episodes may be associated with impaired hearing or vision, nausea, vomiting, photophobia, lethargy, and transient neurologic deficits. Severely increased ICP ultimately can result in life-threatening cerebral herniation syndromes and sudden death.

Intracranial Pathology: Analgesic Strategies

Management strategies for patients with pain from intracranial pathology derive from the general principles of supportive care and focus on both oncologic interventions and analgesic interventions (Table 36-2). The use of surgery to manage symptoms from intracranial pathology is limited to highly selected patients who may be offered procedures to relieve specific syndromes that are refractory to more conservative treatment. For example, rare patients undergo resection of a large cerebellar metastasis to reduce severe headache, despite the presence of other, less symptomatic metastatic lesions. Others are offered percutaneous aspiration of a tumor cyst through an Ommaya reservoir, if relief of mass effect on initial aspiration results in significant relief of symptoms (19).

Oncologic interventions
Radiation therapy
Surgery
Chemotherapy
Analgesic interventions
Pharmacotherapy
Physical measures
Psychological measures
Neurolytic or anesthetic procedures
Neurostimulatory procedures

TABLE 36-2. MANAGEMENT STRATEGIES FOR PAIN FROM INTRACRANIAL PATHOLOGY

Radiotherapy is frequently effective to relieve pain or other symptoms from metastatic disease, even if the primary tumor is relatively radiation resistant (20,21 and 22). If the goal of treatment is limited to symptom control alone, patients are generally candidates for radiotherapy if life expectancy is greater than 2 months and symptoms are not easily managed with more conservative means.

Chemotherapy can be palliative for metastatic intracranial disease from specific tumor primaries, including breast (23), small cell carcinoma of the lung (24), testes (25), and others. Hormonal therapy can be well tolerated and can be effective to shrink metastatic disease in patients with breast or prostate cancer who have not previously been exposed to such treatment.

The role of corticosteroids to manage symptoms from intracranial pathology requires particular emphasis. An empiric course over a few days can be used to establish efficacy (26). Although dexamethasone is usually preferred, prednisone (27), prednisolone (28), and adrenocorticotropic hormone (29) also have been reported to relieve symptoms from intracranial pathology. Dexamethasone is available in both oral and parenteral formulations, and generally lacks mineralocorticoid effect. Nonfluorinated corticosteroids such as prednisone may have less risk of causing myopathy (27,28). Controlled trials comparing the efficacy and side effect profile of different steroids are needed. The dose–effect relationship of dexamethasone is also a controversial subject, and the optimum dose for tumor-related cerebral edema has not been established. Comparison of 4-, 8- and 16-mg/day dexamethasone (Decadron) therapy in 89 patients with CT-proven brain metastasis, no signs of impending herniation, and Karnofsky scores of 80 or less showed the same degree of improvement in Karnofsky score over 1 week, and more frequent toxicity in the 16-mg/day group over 4 weeks (30). Another study of 12 patients with brain metastasis treated with high-dose dexamethasone for 48 hours reported complete responses in only three patients, partial response in one, and no response in eight (31). Other reports support using steroid doses much higher than the conventional 4 mg every 6 hours, up to 96 mg over 24 hours, suggesting that the ideal dexamethasone dose should be established for each individual patient (32,33).

In brain tumor patients, cushingoid facies predict the presence of steroid myopathy (27). Other side effects of steroids include hyperglycemia, cataracts, osteoporosis, and neuropsychiatric effects. Side effects can become disabling over time. To reduce the risk of side effects, the lowest effective dose of steroid should be identified by methodical titration upward or downward.

Neuropathic Pain Due to Central Nervous System Disease

Central pain is defined as pain associated with a lesion of the central nervous system, particularly of the spinothalamic tract or thalamus (34). Central pain must be differentiated from other types of neuropathic pain associated with lesions of the peripheral nervous system and from nociceptive pain associated with ongoing stimulation of nociceptors by a tissue-damaging lesion. Current theories of central pain postulate selective deafferentation of the spinothalamic tract over prior concepts of thalamic pain as the more likely underlying mechanism (35).

Many types of structural lesions in the brain and spinal cord can cause central pain. Although the type, duration, and size of the lesion can influence the tendency to produce central pain, similar lesions may or may not be painful, or they may produce different types of pain (36). Only a minority of patients with susceptible lesions actually develop central pain. The locations of most painful lesions are in the spinal cord, lower brainstem, and ventral posterior part of the thalamus (37,38 and 39). The most common causes of these lesions are spinal cord trauma and cerebrovascular accidents. The prevalence of central pain is highest in syringomyelia; most patients with this lesion develop central pain during the course of the disease. Central pain is less common in traumatic spinal cord injuries (30%) and multiple sclerosis (23%). Interestingly, intracranial and spinal tumors have a low prevalence of central pain. Several patients with central pain due to meningioma have been reported (40). In a series of 49 patients with thalamic tumors, only one had central pain (41).

The diagnosis of central pain depends on a detailed neurologic history and examination along with laboratory investigations, including CT or MRI scans, CSF analysis, neurophysiologic testing, and other tests as appropriate. Symptoms characteristic of central pain are rarely psychogenic in origin (36).

The onset of central pain may be immediate or delayed, first appearing years after the original problem. Although the pain typically has a burning, tingling, or “pins and needles” quality, it may be superficial, deep, or both. It is not always dysesthetic, and can have a variety of descriptors in the same or different regions. The sensation is often unlike any prior experience and is typically difficult to describe (35). The pain may be triggered by physical activity, stress, loud noise, vibrations, weather changes, altered muscle or visceral function, or seizures (37). It is usually constant, varies in severity from mild tingling to unbearable, and may have more than one element; commonly, a severe intermittent component is superimposed on constant pain. Central pain is usually permanent, although transient pain in spinal cord injury patients and complete cessation of pain either spontaneously or after the occurrence of new lesions have been reported (36,42,43). Although not necessary for its development, central pain usually is associated with a sensory deficit in the same area as the pain. Hypesthesia to temperature is the most common finding. Sensory deficits are consistent with the site of the known lesion; for example, ventral posterior thalamic lesions may be associated with a hemibody sensory loss, and low brainstem infarcts may produce a crossed, dissociated sensory loss.

The management of central pain is based largely on clinical experience. Treatment modalities include pharmacotherapy, sensory stimulation, neurosurgical procedures, and sympathetic blockade (37,44). The first-line drugs are antidepressants with noradrenergic properties, specifically amitriptyline hydrochloride, which appears to be the most effective but also has the most side effects. Other medications have been found to be effective in randomized, controlled trials for central pain, including intravenous lidocaine (45) and oral lamotrigine (46). Second-line drugs include antiepileptics (AEDs) and membrane-stabilizing drugs, the most effective being carbamazepine. Other newer AEDs of potential benefit, such as gabapentin, have not yet been subjected to double-blind clinical trials (35). The best central pain response to antidepressants is seen in poststroke patients, whereas AEDs seem to be most effective for paroxysmal central pain, especially in multiple sclerosis (36). Nonsteroidal anti-inflammatory drugs and opioids generally have a weak or no effect. A range of other therapies are used, including g-aminobutyric acid (A) agonists (e.g., diazepam [Valium]), intrathecal baclofen, clonidine, neuroleptics, systemically administered local anesthetics, and naloxone hydrochloride (47). Stimulation techniques include low- and high-frequency transcutaneous electrical nerve stimulation, spinal cord stimulation, and deep brain stimulation. Motor-cortex stimulation, a relatively new technique, is reported to benefit certain forms of intractable pain (48).

Cranial Neuralgias

Cranial neuralgias are of particular significance to the cancer patient, as they frequently lead to a diagnosis of base of skull or neck metastases. Also, the frequent response of these pain syndromes to a regimen containing selected adjuvant analgesics (e.g., anticonvulsants) highlights the value of prompt diagnosis. Trigeminal neuralgia and glossopharyngeal neuralgia are characterized by paroxysmal lancinating pain in the face or throat and neck, respectively. Pain lasts from a few seconds to a minute or two, with frequent recurrence. The pain is often spontaneous in onset, but it may be initiated by sensory stimuli such as touch or tickle applied to certain trigger areas; movements such as chewing or talking also can precipitate pains. Other features, such as continuous dull aching, burning, or pressure pain, are often reported (49). The differential diagnosis includes disorders of the jaw, teeth, sinuses, base of skull, and neck. Although these neuralgias are most commonly idiopathic, the onset of cranial neuralgia in a patient with a cancer history mandates a search for metastatic disease. Numb chin syndrome, involving facial and oral numbness in the distribution of the mental nerve, has been associated with a metastatic etiology in 89% of patients (50). Radiological studies include CT or MRI with views of the base of skull and sinuses. Plain radiographs or tomograms of the skull base may show abnormalities. CSF analysis may be abnormal in patients with associated leptomeningeal metastases.

Seizures

A seizure may be defined as an episode of uncontrolled motor, sensory, or psychological activity caused by the sudden excessive discharge of cerebral cortical neurons (51,52), followed by a postictal phase of metabolic cerebral depression lasting a variable period. There are two broad types: primary generalized seizures and partial (also called focal or secondary) seizures. A partial seizure is caused by an epileptogenic lesion. Clinically, a seizure discharge is most effectively identified by electroencephalography, whereas an epileptogenic lesion may be demonstrated by CT or MRI scanning. The first appearance of any seizure during adulthood, with or without a localizing aura, is sufficiently suspicious to warrant an investigation for neoplasm.

Generalized or focal seizures occur in 20–50% of patients with brain tumors (52). The occurrence of a seizure depends on tumor site, type, and infiltration or expansive properties. In patients with supratentorial tumors, seizures are a presenting symptom in up to half of patients (53,54). The highest seizure incidences occur with oligodenrogliomas (92%), astrocytomas (70%), meningiomas (67%), and glioblastomas (37%) (56). In patients with slow-growing chronic tumors, the seizure incidence is as high as 75% and may predate other symptoms for years (56). The time interval from first seizure to tumor diagnosis was 16 months in one European study (61). Focal seizures are associated with tumors involving motor cortex, sensory cortex, or the temporal lobe. Temporal lobe gliomas typically produce psychomotor seizures, with or without olfactory hallucinations (uncinate fits); abnormal visual or auditory perception; déjá vu phenomenon; or automatic behavior (57). Parietal lobe tumors may cause generalized or focal sensory seizures, and occipital lobe neoplasms have been associated with an aura of flashing lights, but not formed images. Infratentorial tumors and neoplasms involving the white matter only are not commonly associated with seizures.

In patients with intracerebral metastases, the incidence of seizures as a presenting symptom ranges from 15% to 21% (16,58,59). Thirty percent to 40% of patients experience at least one seizure (60). In one study, late seizures developed in 10% of patients from 1 to 59 weeks after diagnosis of intracerebral metastases (60). With the exception of malignant melanoma and choriocarcinoma, metastatic brain neoplasms are less likely to cause seizures than primary brain tumors. The presence of multiple metastases or combined brain and leptomeningeal metastases are the conditions most frequently associated with seizures (62). Seizures associated with cerebral metastases are usually of the simple or complex partial type (62).

Seizures can be an indication of tumor progression or recurrence, often occurring late after initial oncologic therapy. Other etiologies, such as electrolyte disturbances (e.g., hyponatremia), drug interactions, and noncompliance with anticonvulsants may predispose to the late development of seizures. *Status epilepticus*, defined as a persistent seizure (usually considered to last longer than 5 minutes) or repeated seizures without interictal return of consciousness, is an important neurooncological emergency. All clinicians should be familiar with the treatment of this condition. Acute management begins with assurance of the airway, ventilation, and perfusion. Blood should be sampled for urgent electrolyte screen and other appropriate tests, and a dose of glucose should be given (usually 50 ml of a 50% solution) before any results are known. The typical treatment protocol involves the intravenous administration of a benzodiazepine, such as lorazepam or diazepam, followed by intravenous loading with phenytoin or valproate sodium. Persistent seizure activity beyond 7–10 minutes is an indication for continuous electroencephalography monitoring and to start general anesthetic procedures, with intubation followed by a short-acting barbiturate (pentobarbital sodium or thiopental sodium), midazolam hydrochloride, or propofol (63). The minimal dose of anesthetic agents required to stop electrographic seizures is generally recommended. Although focal continuous epilepsy (epilepsy partialis continua) is also treated promptly, this syndrome is less injurious to the patient and usually is treated without the high-dose intravenous drugs administered for generalized status (64).

The routine use of prophylactic anticonvulsants in brain tumor patients is recommended in patients who present with seizures and in patients undergoing craniotomy. There are, however, no published data showing efficacy of anticonvulsants in preventing further seizures (65). The most commonly prescribed drug is phenytoin, in doses of 300–400 mg/day. Carbamazepine, phenobarbital, and valproate sodium also are used. Patients with benign brain tumors and no history of seizures do not require prophylaxis.

There is currently conflicting advice regarding the use of prophylactic anticonvulsants in patients with malignant primary or metastatic brain tumors who have never had a seizure. In one study, a 10% incidence of late seizures in patients with brain metastases was noted regardless of whether prophylactic phenytoin was given (60); however, serum anticonvulsant levels were subtherapeutic in twothirds of the patients who developed seizures, which may explain the therapeutic failure. Two randomized prospective studies with over 130 patients have found no significant benefit of prophylactic anticonvulsants in preventing late seizures over placebo or no treatment in brain tumor patients who had no prior history of seizures (66,67). Therefore, routine use of prophylactic anticonvulsants is not currently supported by the literature although it continues to be practiced. Patients with cerebral metastases from melanoma should probably receive prophylactic anticonvulsants due to the higher risk of seizures (up to 50%) in this patient group (68).

Therapeutic anticonvulsant levels can be difficult to achieve in brain tumor patients, especially with concomitant use of dexamethasone, which increases the required dose of phenytoin (69). Interaction between phenytoin and dexamethasone also reduces the bioavailability of the dexamethasone (70). Toxic phenytoin levels may occur with frequent dosage adjustments and can produce side effects of nystagmus and ataxia, which can suggest tumor recurrence. Other potential complications from phenytoin include erythema multiforme and Stevens-Johnson syndrome, which have been associated with the combined administration of whole brain radiation therapy (WBRT) and phenytoin (71); myopathy (72); immunosuppressive effects specifically targeted against cell-mediated immunity (73,74); hepatoxicity; hyperkinetic movement disorder; and osteomalacia (75).

Discontinuation of seizure prophylaxis in patients with a benign tumor and preoperative seizures has been recommended only for patients with complete excision of a benign tumor who remain seizure free after 12 months. The risk of relapse remains at least 35% if the patient has had previous seizures (76).

Singultus (Hiccups)

Singultus (hiccups) is a forceful involuntary inspiration caused by spasmodic contraction of the diaphragm that terminates with sudden closure of the glottis. Closure of the glottis results in the characteristic hiccup sound. Hiccups serve no known physiological function (77) and are usually a transient benign disorder that resolves without medical therapy. Chronic hiccups may reflect underlying pathology, including a lesion that irritates the peripheral vagus or phrenic nerves, drug toxicity, metabolic abnormalities, infection, and intracranial disease. Rarely, chronic hiccups are psychogenic.

The mechanism of hiccup may involve dysfunction of peripheral components or central connections of the reflex arc. The afferent neural pathway is composed of sensory branches of the phrenic and vagus nerves as well as dorsal sympathetic afferents from T6 through T12. The principal efferent limb, which produces the diaphragmatic contraction, includes motor fibers of the phrenic nerve and efferent branches to the glottis and external intercostal muscles (inspiratory). There is reciprocal inhibition of the expiratory intercostal muscles. The separate innervation of right and left hemidiaphragms and the long course of the two phrenic nerves, each of which contacts various organs, account for the large variety of reported mechanisms for hiccup. Hiccups may be bilateral or unilateral; most occur in the left diaphragm. The central control of hiccups, although not yet fully defined, is believed to include a supraspinal center that is integrated with the respiratory center output to respiratory motor neurons in the spinal cord (78). Experimental electrical stimulation of the medulla in cats has demonstrated generation of hiccup-like responses in the medullary reticular formation lateral to the nucleus ambiguus, just rostral to the obex (79,80). Cells in the nucleus raphe magnus containing the inhibitory neurotransmitter g-aminobutyric acid may be the source of inhibitory inputs to the hiccups reflex arc. The reported rate of repetitive hiccups is between 4 and 60 per minute; the most common rate is 17–20 per minute— not surprisingly, similar to the respiratory rate (81).

Central nervous system causes of hiccups include parenchymal lesions within the medulla and local pathology causing medullary compression. Both of these lesions can produce dysfunction at the level of the vagal nucleus and the nucleus tractus solitarius (82). It also has been suggested that central nervous system conditions causing hiccups may release the normal inhibitory tone on the hiccup reflex arc (77). Specific lesions of the medulla include neoplasms, syringomyelia, infarction (often the territory of the posterior inferior cerebellar artery), and infections, including meningitis, encephalitis, neurosyphilis, and human immunodeficiency virus encephalopathy. Compressive lesions causing hiccups include neoplasms, hematomas, cavernomas, and bleeding into the fourth ventricle (83). Most lesions develop slowly, are located near the dorsolateral aspect of the medulla, and extend towards the obex (84).

Identification of serious underlying causes of hiccups depends on their duration, severity, and associated conditions. Benign hiccup bouts may last up to 48 hours and usually are related to gastric distension, alcohol ingestion, or emotional factors. Persistent hiccups are defined as a hiccup episode lasting longer than 48 hours but less than 1 month, and intractable hiccups are defined as a hiccup episode persisting longer than a month. Both are assumed to have an organic etiology until proven otherwise by extensive medical and laboratory investigations (85).

Neurogenic hiccups may require urgent management. Some patients experience severe fatigue as a result of sleep deprivation. Others develop respiratory irregularity or even respiratory arrest, probably related to a lesion at the medullary respiratory control centers (86). When respiratory difficulties occur, associated brainstem symptoms or signs are usually present. It should be noted that, with the exception of intubated patients or those with a tracheotomy, hiccups alone do not produce any significant ventilatory effect because the glottis closes almost immediately after the onset of diaphragmatic contraction (78).

The management of hiccups includes physical, pharmacological, and surgical interventions. Initial therapy should focus on elimination or treatment of the underlying cause. Physical stimulation of afferent nerve endings or certain end-organs may interrupt the hiccup reflex arc (87) and are the basis of anecdotal folk remedies, such as swallowing granulated sugar, breathing into a bag, and breath-holding. Physiologically, the hiccup reflex is inhibited by high arterial carbon dioxide tension (88).

Pharmacological measures for hiccups are supported by anecdotal experience. Numerous classes of drugs have been used, including antipsychotics, tricyclic antidepressants, anticonvulsants, antiarrhythmics, central nervous system stimulants, muscle relaxants, inhalation agents, local anesthetics, and gastric motility agents. The most commonly used and most consistently effective agent is chlorpromazine, a centrally acting major tranquilizer and dopamine antagonist. It is especially effective given as an intravenous bolus (89). The second drug of choice is metoclopramide, a gastric motility agent and dopamine antagonist (91,92 and 93). Other valuable agents include the anticonvulsants carbamazepine, phenytoin, and valproic acid and the antispasmodic baclofen. Surgical interventions are reserved for intractable hiccups that fail to respond to physical or pharmacological therapy. Phrenic nerve transection, crushing, or anesthetic blockade may be complicated by severe respiratory impairment, especially if both phrenic nerves are disrupted. In addition, such a procedure may fail to relieve hiccups (89). Phrenic nerve surgery is therefore a last resort and should be preceded by a local anesthetic block to assess efficacy and the potential respiratory compromise from diaphragmatic paralysis (93).

Neurologic Impairments Caused by Intracranial Pathology

Focal neurologic symptoms such as weakness, numbness, incoordination, and visual impairment can interfere significantly with function. If correctly diagnosed, treatment of the underlying cause may be possible. In all cases, measures to accommodate the deficit can be helpful. Although the spectrum of manifestations resulting from intracranial disease are protean, two complex neurologic syndromes and specific neuropsychiatric conditions deserve emphasis because of the high degree of impairment and the clinical difficulty in making a correct diagnosis.

Patients with bifrontal disease may appear to the family as lacking initiative and sparkle. Speech is sparse or nonexistent (*mutism*), and yet the patient is fully aware of the conversation around him or her. There may be urinary urgency or incontinence (“unwitting wetting”); a shuffling, wide-based gait; and an apparent slowness of thought processes. Damage to both frontal lobes can be a sequela of radiation therapy or can result from multiple bilateral metastases, hydrocephalus, leptomeningeal tumor, cerebrovascular disease, or other causes. Findings on examination that support the diagnosis include bilateral grasp reflexes, a snout reflex, a positive glabellar tap, presence of bilateral palmomental reflexes, and an apraxic gait. Families need to be aware that the patient may be cognitively intact and able to later recall details of events that occurred while he or she was sick. Understanding that the lack of motivation is neurologic, rather than psychological, may help the family cope with the patient's condition.

In the nondominant parietal syndrome, there is denial of illness and the patient may believe he or she should be able to manage alone at home despite severe impairment. Brain metastases and cerebrovascular disease are the most common causes. The diagnosis of a nondominant parietal syndrome is confirmed by identifying focal sensory or motor deficits (usually affecting the left side of the body), hemianopsia, dressing and constructional apraxia, agnosia, and denial of body parts (neglect). The overall management and rehabilitation strategies are similar to those used for other neuropsychological impairments. The prognosis for improvement is poor as a result of the patient's lack of insight.

Intracranial pathology also can cause delirium and specific disorders of mood or perception. Delirium is an acute organic disorder of attention and cognition. Thinking, perception, memory, and psychomotor status all may be disturbed in the delirious patient (94). In contrast to dementia, delirium is acute and potentially reversible. Delirium involves a wide differential diagnosis in which toxic and metabolic disorders are prominent. In addition to neoplasm, many other structural disorders may be responsible, including hydrocephalus, stroke, subdural hematoma, cranial arteritis, and trauma (95). Delirium also may be caused by seizures. New onset of delirium requires prompt assessment for treatable causes.

Personality changes, including depression, euphoria, loss of inhibition, and impulsive behavior, also may reflect intracranial disease, including raised ICP secondary to a space-occupying lesion. Temporal lobe lesions have been noted to produce bizarre thinking and immature emotional behavior (57). The diagnosis of these

conditions, particularly the organic mood disorders, may be challenging given the high prevalence of primary psychiatric disorders in the cancer population.

CANCER-RELATED NEUROLOGIC SYNDROMES

Brain Metastases

Clinically evident brain metastases occur in 20–30% of patients with systemic cancer and are found at autopsy in up to 50% (20,96,97,98,99 and 100). Metastases are the most common malignant tumor of the brain (97) and have an annual incidence three times that of primary brain tumors (98,99). The three most common cancers that metastasize to the brain are lung, breast, and melanoma (97).

Brain metastases tend to be a late finding; evidence of other metastatic disease is usually present. Only 19% of 201 patients with brain metastases studied at the Memorial Sloan-Kettering Cancer Center lacked evidence of systemic metastases on initial evaluation (20). The interval between diagnosis of the primary malignancy and the discovery of brain metastases depends on the tumor type. Small cell lung cancer, for example, metastasizes early; there is an 11% incidence of silent metastases at diagnosis (101). Other tumors, such as breast carcinoma, typically develop brain metastases late, once disseminated disease is present (102,103 and 104). In addition to the primary cancer, factors that influence brain metastases include age and gender (105). Some tumors, such as breast or renal cancers, tend to cause single lesions, whereas others, such as melanoma, lung cancer, and tumors of unknown origin, are more likely to cause multiple metastases (106). In lung cancer and melanoma patients, men have a greater predilection to develop brain metastases than women, perhaps reflecting the more common site of melanoma in men on the head, neck, and trunk; for lung cancer, explanations for this observation are lacking (105). Certain metastatic brain tumors are prone to hemorrhage, melanoma, choriocarcinoma, renal cell carcinoma, and bronchogenic carcinoma (107). Skull metastases occur with cancers of the breast and prostate (106).

The distribution of brain metastases is proportional to cerebral blood flow as well as brain weight (110). The cerebral hemispheres receive 85% of cerebral blood flow and are the site of approximately 80% of brain metastases. The posterior fossa, the recipient of 15% of cerebral flow, is the site in 20% of metastases (16% are in the cerebellum and 3% are in the brainstem) (105,111). The observation that there is a predilection of gastrointestinal and pelvic malignancies to metastasize to the posterior fossa suggests a route of dissemination via Batson's plexus, which may receive venous drainage from the pelvic organs, but the evidence for this is not conclusive (103,108,112).

The location of brain metastases is frequently at the gray–white matter interface, or at vascular borders called “watershed zones”; the latter account for one-third of the total brain volume, but two-thirds of brain metastases (113). In these regions, the blood vessels rapidly branch into end capillaries and may act as a trap for metastatic cell emboli (114).

The most common presenting symptoms are headache, weakness, and behavioral changes (116). Patients usually have focal findings, which typically exhibit an onset over days to weeks and have a progressive course. Although focal signs often suggest the site of metastases, false localizing signs may occur as a result of compression of distant structures by shifts caused by increased ICP. These signs may cause a perplexing constellation of symptoms and signs. Generalized neurologic dysfunction caused by raised ICP may present in an acute or gradual manner.

Headache is the most common initial complaint. It occurs in half of patients with a single brain metastasis, and almost all these patients manifest other signs or symptoms. Patients with multiple or cerebellar metastases have a higher incidence of headache (105,106). Papilledema occurs in less than one-fourth of patients with brain metastases (109,112). Focal weakness, the second most common presenting symptom, is reported in approximately 40% of patients, although examination reveals weakness in up to two-thirds of patients (111,120). Mental or behavioral changes, an initial finding in 30% of patients, may reflect multiple brain metastases or focal lesions causing raised ICP or hydrocephalus. One study reported that three-fourths of brain metastasis patients failed to score normally on standard mental status tests (121). Seizures, either focal or generalized, are the first sign in 15–20% of patients. Occasionally, transient neurologic events occur with complete resolution; excluding seizures, an acute onset of symptoms has been reported in less than 10% of patients. The complaint of gait ataxia can result from posterior fossa, a large frontal lobe lesion, or hydrocephalus. These patients may lack significant unsteadiness on examination. Other presenting symptoms include sensory disturbance and vision loss, typically hemianopsia. The onset of neurologic dysfunction may be insidious, over weeks or months. Intratumoral hemorrhage may cause an acute worsening of preexisting, slowly evolving symptoms.

The most sensitive diagnostic test for brain metastases is MRI. This test should be considered for any cancer patient with an unexplained neurologic disturbance. It also is indicated for neurologically asymptomatic patients undergoing attempted curative treatment of a primary tumor with high metastatic potential to brain, such as lung cancer or metastatic melanoma (117). Gadolinium-enhanced MRI reveals multiple metastases in approximately 70% of patients, compared to 50% with CT (118). Features that suggest a metastatic lesion include round appearance with “ring” enhancement, location at the gray–white matter junction, and vasogenic edema (119).

Evaluation of the status of the systemic cancer is important in determining appropriate therapy for an intracranial metastasis. Factors that affect the choice of treatment modality for brain metastases include patient age, size and location of the metastasis, neurologic status, patient performance status, extent of the primary tumor, other sites of metastatic disease, and response to prior therapy (105,115). Therapeutic options range from no treatment, which may be appropriate in patients near death with disseminated disease, to emergency surgery for potentially reversible but otherwise imminently fatal lesions. Most commonly, various combinations of medical, radiation, and surgical therapy are employed.

Without treatment, patients with brain metastases have a median survival of approximately 1 month (122,123). Corticosteroids double the median survival to 2 months (124,125). Approximately 70% of patients show significant improvement by day 2 of treatment (126). To reduce the risk of side effects, steroid dose is tapered downward from the starting dose, as tolerated.

WBRT is reported to increase median survival to 3–6 months (121,128,129). For patients irradiated, the death rate from neurologic progression of metastases is similar to that of systemic disease (127). Two-thirds of patients with serious neurologic dysfunction and one-third of patients with moderate dysfunction obtain relief or improvement of symptoms (105,130). The standard dose is 3000 cGy in 10 fractions (300 cGy per treatment), although regimens vary depending on the center. Protracted radiation therapy regimens (2000 cGy in 20 fractions) are advised when anticipated survival is greater than 1 year due to a lesser rate of later neurologic complications associated with this regimen (131). Accelerated radiation therapy may be used to achieve rapid palliation in patients whose condition is deteriorating quickly. Prophylactic cranial irradiation is advocated for newly diagnosed cancer patients with a high risk of developing brain metastases (e.g., small cell lung cancer) (114). This approach remains controversial despite significant reduction in cranial metastatic disease, as no consistent survival benefit has been shown (132). Other irradiation modalities include interstitial brachytherapy and radiosurgery (133).

Radiosurgery, which delivers a very high dose of radiation to a small target, has undergone an exponential growth in use and may eventually replace surgery as the primary treatment modality for small brain metastases not producing life-threatening mass effect. One series reported approximately 88% local control with a single fraction of 1600–3500 cGy (almost double the local control rate achieved with standard whole brain radiation) (133). Several reviews of this modality demonstrate comparable survival and local control to combined surgical resection and whole brain irradiation (114). It should be mentioned that whole brain irradiation is often given with radiosurgery to prevent more distant recurrence. One multicenter analysis by Auchter et al. (134) demonstrated a survival and functional independence advantage over surgical resection plus WBRT with a decrease in deaths from central nervous system progression. A prospective randomized trial is currently under way to compare whole brain irradiation with and without stereotactic radiosurgery. Factors influencing the efficacy of radiosurgery include size and shape of the lesion, number of tumors, and nature of the primary tumor. In general, welldemarcated, spherical tumors of small volume (<4 cm), without invasion deep into brain tissue, respond best to radiosurgery. The risk for distant recurrences increases significantly when more than three metastases are treated in one patient. Radiosurgery treatment for metastases secondary to melanoma and renal cell carcinoma has been associated with high quality of life even in the presence of multiple metastases, compared with lung cancer patients, who have a significantly shorter life expectancy. Relative contraindications to stereotactic radiosurgery include large tumors, hemorrhagic tumors, and tumors producing significant mass effect. Conventional treatment with surgery followed by WBRT is then recommended.

Of patients who exhibit an initial clinical response to radiotherapy, approximately 80% maintain clinical improvement at 3 months and 60% are stable at 6 months (104). Two-thirds of patients who show a major response to radiotherapy die of systemic disease, and only 15% die solely as a result of neurologic deterioration (117). Extent of systemic cancer is, therefore, a strong prognostic indicator in patients with brain metastases. The presence of liver or lung metastases predicts poor survival in patients who develop brain metastases.

Surgical interventions in patients with brain metastases encompass procedures to relieve ICP, biopsy to establish diagnosis (principally in patients with an unknown primary), and resection of metastatic lesions. Surgical resection of brain metastases is most likely to benefit those with a solitary lesion in a surgically accessible location, with either no evidence of systemic disease or controlled systemic disease, and with a life expectancy greater than 2 months (104,135,139,140). Unfortunately, only approximately 25% of patients with brain metastases fulfill these indications, as only half of brain metastases are single, and half of single metastases are excluded based on inaccessibility of the tumor, extensive systemic disease, or other factors. In patients who are surgical candidates, resection followed by WBRT has been shown in prospective, randomized studies to improve survival and local control compared with WBRT without surgery. Patchell et al. (135) reported a median survival of 40 weeks in the surgery plus radiotherapy group compared with 15 weeks in the radiation group; recurrence at the original site was 20% and 52% in the surgical and radiation groups, respectively (135). Patients treated with surgery remained functionally independent for a median of 38 weeks versus 8 weeks in the radiated group. An additional benefit of surgical intervention is the tissue diagnosis; in one study, 11% of patients did not have metastatic tumors despite

radiographic findings (135). Surgery alone for a single brain metastasis has a better survival rate than radiotherapy alone, although metastases recur in 70–85% of patients without addition of cranial irradiation (114,136). The combination of surgical resection followed by whole brain irradiation has a median survival of nearly 1 year with improved disease-free survival and functional independence, and decreased rate of death from brain metastases (136,137 and 138).

For most patients, treatment of multiple brain metastases remains WBRT with corticosteroids. Rarely, surgical resection may be considered for easily accessible metastases if other criteria for surgery are met. The contribution of chemotherapy to the management of brain metastases remains uncertain for most types of cancer. Regression of brain metastases has occurred after effective systemically administered cytotoxic chemotherapy (23,24 and 25).

Leptomeningeal Metastases

The syndrome of leptomeningeal metastases (also known as *meningeal carcinomatosis* or *lymphomatous/leukemic meningitis*) refers to diffuse or multifocal seeding of the leptomeninges by systemic cancer (141). Leptomeningeal metastases are identified at autopsy in up to 8% of patients with systemic cancer. The most frequent cancers to metastasize to the leptomeninges are solid tumors, notably breast, lung, melanoma, and gastrointestinal cancers, as well as lymphomas and acute leukemias (142). Primary brain tumors account for 10–32% of cases in some series (142). Acquired immunodeficiency virus–associated lymphomatous meningitis accounted for nearly one-third of cases at one center (143). Some cancers have a high affinity for the nervous system, however, and leptomeningeal disease may be clinically evident in almost half of patients (144). The duration from discovery of the primary malignancy to the diagnosis of leptomeningeal involvement is very broad, from 3 months to 6 years in some series (145).

Two characteristic features suggest a diagnosis of leptomeningeal cancer. First, neurologic dysfunction appears at multiple levels of the neuraxis in the absence of brain or spinal epidural metastases on radiographic examination. The patient may present with a variety of complaints and tends to accumulate new symptoms over weeks as the disease progresses. Second, neurologic signs tend to be much more prominent than symptoms. Although most patients initially complain of symptoms in one anatomical area, examination reveals signs of neurologic abnormality in two or more areas in more than 80% of patients (156).

Symptoms referable to the brain are the initial complaint in approximately half of patients, with headache the single most frequent initial symptom; headache is reported by one-third of patients at presentation (141). The headache can occur in a variety of locations, including bifrontal, diffuse, or radiating from the occipital region into the neck. Nausea or vomiting, light-headedness, and cognitive disturbances are associated features. Changes in mental status alone are a common finding and eventually occur in 80% of patients; these changes are characterized by lethargy, confusion, and memory deficit. Other common cranial symptoms and signs include lateralized weakness, seizures, cranial nerve palsies (most commonly diplopia, hearing loss, and facial weakness) and papilledema. Spinal symptoms due to involvement of the spinal cord or exiting nerve roots and meninges include weakness (lower or upper motor neuron), sensory loss (dermatomal or segmental), pain, ataxia, fecal incontinence, and urinary retention. Occasionally, asymptomatic urinary retention occurs.

The diagnosis of leptomeningeal metastases is based on clinical findings and CSF analysis. The finding of malignant cells in the CSF is the diagnostic gold standard; positive cytology is eventually found in 90% of patients, although three or more examinations of large volumes of CSF may be required (141,145,146). Associated CSF findings include elevated protein, decreased glucose, and lymphocytosis. The CSF levels of these components can vary if sampled at different levels of the neuraxis, with some patients only showing positive cytology if sampled from the ventricular system (147). After two negative lumbar punctures for CSF cytology, it has been recommended to proceed to ventricular or lateral cervical CSF analysis (142). Other biochemical markers of leptomeningeal metastases are used as adjunctive tests, or for serial evaluation of response to treatment (142). Other investigations include flow cytometry of CSF content for evaluation of DNA abnormalities, myelography, a CSF flow study by lumbar or ventricular radioisotope administration, CT of the head, and the most sensitive radiologic examination, MRI of the head and spine with gadolinium (144,145 and 146,148,149,150,151,152 and 153). A pathological diagnosis of cancer with the clinical syndrome of leptomeningeal metastases can also make this diagnosis (142).

Treatment of leptomeningeal metastases is aimed at prolonging survival and improving or stabilizing neurologic disability. Untreated, leptomeningeal metastases from a variety of tumor types have a median survival of 4–6 weeks (154,155). With standard treatment, which is always palliative, survival ranges from 4 to 10 months (156). Meningeal lymphoma and breast cancer have a more favorable prognosis, and may respond to systemic chemotherapy without the addition of intrathecal chemotherapy. Management of leptomeningeal metastases may include radiation therapy to symptomatic sites of the neuroaxis, and intrathecal or intraventricular chemotherapy. Involved-field radiotherapy is recommended if there is associated bulky metastatic disease, regardless of symptoms (145). Craniospinal radiation, used for treatment of leukemic meningitis, is associated with significant systemic toxicity. In general, systemic chemotherapy fails due to poor CSF penetration (142). Intra-CSF chemotherapy, delivered by an Ommaya reservoir, or via lumbar puncture, results in high CSF drug levels without systemic dose-limiting toxicity.

Base of Skull Metastases

The base of the skull includes the temporal, sphenoid, and occipital bones (including the clivus) as well as the bony orbit. Base of skull metastases are most commonly secondary to tumors of the breast, lung, and prostate. Other tumors that may metastasize to the skull base include head and neck tumors, lymphoma, and other tumors that metastasize to bone. The median interval from primary tumor diagnosis to onset of neurologic signs was 23 months in one study; twothirds of patients had metastatic disease elsewhere when the base of skull metastases were diagnosed (157). Several discrete neurologic syndromes have been described, characterized by dysfunction of cranial nerves as they pass through bony foramen. Common areas include the bony orbit, parasellar region, middle cranial fossa, jugular foramen, occipital condyle, clivus, and sphenoid sinus. Base of skull metastases may present with head pain, cranial nerve palsies, or both. Treatment is usually effective and includes pharmacological analgesic interventions (usually nonsteroidal anti-inflammatories with opioids) and focal radiation therapy. Recovery of cranial nerve function tends to be slow.

Cerebrovascular Disease in Cancer Patients

After metastases, cerebrovascular lesions are the next most common neurologic finding at autopsy in cancer patients. In one autopsy series, 14.6% of patients had cerebrovascular lesions (158); of these, approximately half had clinical symptoms of cerebrovascular disease during life. The usual risk factors in the general population for stroke, including age, hypertension, coronary artery disease, and diabetes, are less important in this population than the pathophysiological effects of neoplastic disease and its treatment (159).

Hemorrhagic cerebrovascular events are more common than ischemic events in the cancer population (158). Cerebral metastases and coagulation disturbances, including thrombocytopenia and leukostasis, are the usual causes of intracerebral hemorrhage (ICH) in cancer patients. The reported overall incidence of hemorrhage from an intracranial tumor is 1–15% (160). One neurosurgical series demonstrated an overall tumor hemorrhage rate of 14.6%, of which 5.4% were classified as macroscopic and 9.2% as microscopic (161). As a cause of spontaneous ICH, however, tumor-induced ICH is not a common etiology (only 2% of 461 autopsy cases in one study) (162).

Among all tumor types, those with the highest incidence of bleeding are metastatic melanoma, renal cell carcinoma, germ cell tumors (particularly choriocarcinoma), and bronchogenic carcinoma. The latter is the most common cause because lung cancer is responsible for the majority of brain metastasis (163). Simultaneous hemorrhage into multiple brain metastases occurs frequently (164). The usual presentation mimics an acute vascular event, such as a hypertensive hemorrhage or ruptured berry aneurysm (165). Headache, progressive obtundation, seizures, and focal neurologic signs are reported in two-thirds of cancer patients with intracranial hemorrhage. Hypertensive hemorrhages may be distinguished from intratumoral bleeding by the presence of a history of high blood pressure and location of the hemorrhage in the basal ganglia in 90% of cases. Hypertensive hemorrhage is a relatively rare cause of ICH in the cancer patient (158). Neoplastic aneurysms, although uncommon, are another cause of intracranial hemorrhage in cancer patients.

Coagulopathy may be an indirect effect of the tumor or result from iatrogenic causes, including chemotherapyrelated thrombocytopenia and treatment with warfarin sodium. Disease-related coagulopathy may be consumptive, such as disseminated intravascular coagulation (DIC). Neurologic complications from the latter disorder may be either ischemic or hemorrhagic, including intracerebral bleed and subdural hematoma. Coagulopathy-induced intraparenchymal hemorrhage is most commonly associated with hematological malignancies, especially acute leukemia. Eighteen percent of acute myelocytic leukemia (AML) and 8% of acute lymphocytic leukemia (ALL) patients have ICH found at autopsy (166). The hemorrhage is often large and fatal in AML, yet small and may be asymptomatic in ALL (164). Patients with solid tumors and thrombocytopenia have a low incidence of ICH except when the platelet count falls below 10,000/µl; coagulopathy-related ICH in this population, which may be due to DIC, liver dysfunction, or cancer therapy, usually occurs as a terminal event (160). DIC with ICH is a common cause of death in acute promyelocytic leukemia (167). Anticoagulant-induced intracranial hemorrhage is not common.

Clinically, patients with either spontaneous cerebral hemorrhage from a coagulopathy or hemorrhage into a brain tumor present with a combination of headache, vomiting, seizures, progressive decline in level of consciousness, and focal neurologic deficits. DIC can present with encephalopathy, even in the absence of abnormalities in blood clotting parameters or low platelets. Onset of symptoms may be gradual from coagulopathy-induced ICH, compared to an acute presentation from hemorrhage into a metastatic tumor. Suspected intratumoral hemorrhage should be investigated with CT scan or MRI. Management is primarily medical, and includes ensuring airway control, treatment of severe hypertension, management of elevated ICP, corticosteroids (for tumor edema only), reversal of hemostatic abnormalities (if possible), and antitumor therapy (if appropriate). Surgical evacuation of the hematoma should be considered in selected patients depending on hematoma location and size, patient status, and correctable hematological abnormalities. An intraventricular catheter may be placed for management of hydrocephalus

or increased ICP. Spontaneous ICH in acute promyelocytic leukemia has been reduced significantly with prophylactic heparin, chemotherapy, and transretinoic acid (168,169 and 170).

In patients with leukemia, another cause of ICH is hyperleukocytosis (elevation of the peripheral blast count to greater than 100,000/mm^3 in AML, or 140,000/mm^3 in ALL), which causes early death secondary to ICH in a reported 15% of patients (171,172). Clinically, such patients develop multiple intraparenchymal hemorrhages, occasionally associated with intraventricular or subarachnoid hemorrhage. Chemotherapy and leukophoresis to lower the peripheral blast count can reduce, but not eliminate, the risk of ICH (158,171). Leukostasis can also be treated with radiation therapy (1200–2400 cGy) (155). Blood hyperviscosity can be treated with plasmapheresis or phlebotomy for polycythemia vera (164).

Causes of cerebral infarction in cancer patients include atherosclerosis, nonbacterial thrombotic endocarditis (NBTE), cerebral DIC, venous sinus thrombosis, infection, tumor embolism, and treatment complications. Atherosclerosis and NBTE are the two most frequent causes of cerebral infarction in cancer patients. NBTE causes cerebral infarction by either intravascular microthrombosis or embolism from fibrin and platelet deposition on heart valves (158). NBTE is most commonly associated with adenocarcinoma, especially mucin-producing carcinomas of the lung or gastrointestinal tract. The clinical presentation is usually an acute onset of focal neurologic signs, most frequently aphasia, which either stabilize or progressively worsen. A diffuse encephalopathy also commonly accompanies focal signs. Systemic bleeding, venous thrombosis, and pulmonary embolism are part of the spectrum of coagulopathy that may accompany NBTE. Cerebral infarction from NBTE is suggested by CT or MRI findings of infarction (159). In the absence of associated systemic findings, diagnosis can be difficult. Treatment focuses on the underlying cause of the syndrome; heparin has been shown to improve symptoms from cerebral ischemia but carries the risk of intracerebral and systemic bleeding (159).

Radiation of the head and neck for treatment of Hodgkin's disease, head and neck carcinomas, breast cancer, and primary brain tumors can produce accelerated carotid atherosclerosis, causing symptomatic carotid occlusive disease from 6 months to decades after radiation therapy. The total dose is usually greater than 50 Gy and accelerated atherosclerotic disease is limited to vessels within the irradiated area. There is no association with generalized atherosclerosis beyond concurrent patient-related factors, such as cigarette smoking. The process is accelerated with concurrent hypercholesterolemia (173). The presentation mimics non–radiation-related atherosclerosis and may include transient ischemic attacks, infarction, amaurosis fugax, or seizures. Cerebral angiography shows occlusion or extensive stenosis disproportionately affecting the common carotid artery (174). Although carotid endarterectomy (with or without a patch) remains the standard treatment for this complication, carotid stenting appears to be a safe and efficient treatment for even severe radiation-induced stenosis (175,176,177,178 and 179). Another complication of neck radiation is acute rupture of the carotid artery (which usually occurs after resection of head and neck malignancies), in which necrosis of the skin flap and surgical wound infection have occurred. Although low-dose heparin may reduce the risk of infarction, the prognosis is poor because of potential exanguination or infarction if the carotid artery is ligated (180,181 and 182).

Thrombosis of cerebral venous sinuses or large cortical veins in patients with cancer may be either a metastatic or nonmetastatic complication. In both cases, the superior sagittal sinus is most frequently involved. Metastatic tumor directly causes sagittal sinus thrombosis by either external compression or infiltration of the sinus, which results in stasis or a nidus around which a thrombus may form (183). Nonmetastatic sagittal sinus occlusion may be caused by local injury to the sinus, but is more likely related to a hypercoagulable state of malignancy. Metastatic involvement of the sagittal sinus is seen in lymphoma and some solid tumors, such as neuroblastoma and lung cancer. Nonmetastatic venous thrombosis is less common and occurs in patients with hematological malignancies; it usually is associated with advanced disease. Clinically, nonmetastatic sagittal sinus thrombosis usually presents as an acute onset of seizures, which may be accompanied by encephalopathy and focal signs if infarction has occurred (159). Metastatic sagittal sinus thrombosis presents with subacute signs of increased ICP, such as headache and vomiting; cerebral infarction can also occur. Diagnosis is best made by MRI, magnetic resonance venography, or coronal views during enhanced CT scan. When patients present early in their disease, prognosis is usually good, often with spontaneous recovery. Patients with advanced disease have a poor prognosis. The benefit of heparin in the cancer population is not certain, given the risk of major hemorrhage. Cranial irradiation is indicated for metastatic sagittal sinus thrombosis.

Cerebral hemorrhage or infarction also can occur as complications of treatment of neoplastic disease. Chemotherapy such as asparaginase (superior sagittal sinus thrombosis), mitomycin, and others have been associated with a variety of cerebral complications, either hemorrhagic or ischemic (159,184).

CONCLUSION

Symptoms from neurologic complications of malignancy are common and serious and can be difficult to diagnose. Because of their prevalence and potential for effective palliation, intracranial manifestations of malignancy and their management deserve the attention of all cancer health care providers.

MANAGEMENT OF SPINAL CORD AND CAUDA EQUINA COMPRESSION

SHARON M. WEINSTEIN

EPIDEMIOLOGY

The spine is the most frequent site of bony involvement in patients with malignant metastases (1). The major complications of spinal neoplasm are pain and neurological injury. Compression of neural structures may be caused directly by tumor mass or by displacement of bony fragments into the spinal canal. Tumor of the vertebral bodies has been demonstrated in 25–70% of patients with metastatic cancer (2), and spinal metastases are present in 40% of patients who die from cancer (3). Metastatic lesions are three to four times as common as primary bony tumors of the spine (4).

Each year in the United States, approximately 20,000 cancer patients are treated for malignant epidural spinal cord or cauda equina compression (SCCEC). SCCEC affects 5–10% of adult solid tumor patients and 5% of pediatric solid tumor patients (5,6). This is corroborated by autopsy series (7,8).

Half of patients presenting with SCCEC are not known to have cancer at the time that pain or neurological deficits begin (9).

The distribution of spinal tumors reflects the prevalence of primary malignancies and the physiology of metastasis. Multiple myeloma is the most common primary bone tumor, representing 10–15% of malignant epidural spinal disease. Osteogenic sarcoma is the second most common primary spinal tumor, usually affecting children and adolescents. Fifty percent of chordomas affect the sacrococcygeal bones and 35% affect the base of the skull. Chondrosarcoma and Ewing's sarcoma are other bone tumors that are rarely primary in the vertebrae.

Primary tumors of the breast, lung, and prostate commonly spread to the spinal column. The spine is a frequent site of metastasis of a nonspinal primary osteogenic sarcoma. Spinal metastases are less common in renal carcinoma, melanoma, soft tissue sarcoma, Ewing's sarcoma, germ cell tumors, neuroblastoma, and carcinomas of the head and neck, thyroid, and bladder. Rarely, malignant neoplasms of the brain, pancreas, liver, or ovary affect the bony spinal column. Ten percent of symptomatic spinal metastases originate from unknown primary tumors (3). Some malignancies spread to the intraspinal space without directly affecting bone. Lymphoma and neuroblastoma often invade the spinal canal through the intervertebral foramina. Ewing's sarcoma may be primary in the epidural space, as may osteosarcoma. Primary epidural tumors are rare.

By location, thoracic metastases are estimated to occur twice as frequently as lumbar, and four times as frequently as cervical metastases (10). Almost two-thirds of metastatic spinal lesions present clinically in the thoracic region (11), although in some autopsy series, lesions of the lumbar spine have been most prevalent (3). The level of spinal involvement varies with tumor type. Breast and lung tumor metastases are equally distributed throughout the spine. Prostate, renal, and gastrointestinal metastases are more often found in the lower thoracic, lumbar, and sacral levels. Tumors of the uterus and uterine cervix most commonly spread to the lower lumbar and sacral spine. Pancoast tumors of the apex of the lung extend directly into the cervicothoracic spine in 25% of cases (11), often by intraforaminal extension. Multiple noncontiguous levels of spinal tumor are present in 10–38% of cases (12); this pattern is relatively less common in patients with lung cancer (9).

SCCEC is caused by direct extension of tumor from the vertebral body in 85–90% of cases (11). In pediatric patients, SCCEC due to tumor of the posterior elements is more likely, and intraforaminal spread of tumor from paraspinal sites also occurs more frequently than in adults (12). Tumor metastases to the epidural space seldom breach the dura (3,13).

The prevalence of SCCEC varies according to tumor type. In one series of 103 patients with lung cancer, 26% with squamous histology, 9% with adenocarcinoma, and 14% with small cell tumors had spinal cord compression (14). The prevalence of all neurological complications in this series was approximately 40%.

Breast cancer accounts for almost one-fourth of SCCEC diagnosed in cancer hospitals. Vertebral metastases are identified in 60% of breast cancer patients, and multiple levels of epidural compression are common. SCCEC is rarely the initial presentation or an early finding in breast cancer (15).

Approximately 7% of prostate cancer patients develop SCCEC. SCCEC was noted in 12.2% of patients with poorly differentiated tumors, and 2.9% of those with welldifferentiated tumors (16). The average time from initial prostate cancer diagnosis to SCCEC is 2 years, although it is shorter in stage D2. In approximately 30% of prostate cancer patients with SCCEC, it is the initial manifestation of the cancer (17).

Renal cell carcinomas may also cause SCCEC secondary to bony metastasis. Testicular cancer rarely metastasizes to bone, but may grow into the spinal canal from the retroperitoneal space. Malignant melanoma may produce SCCEC from vertebral disease, but intradural and leptomeningeal involvement are probably more common. Head and neck cancers rarely metastasize beyond the cervical lymph nodes; approximately 80% of distant metastases are detected within 2 years of initial diagnosis. Therefore, a head and neck cancer patient presenting with SCCEC after 2 years should be evaluated for a second primary malignancy. SCCEC occurred at all levels of the spine in one small series of patients with head and neck cancers (18).

Esophageal cancers may rarely cause SCCEC by direct invasion to the thoracic spinal column (19). Carcinoid tumors are associated with neurological complications in less than 20% of cases; the most frequent is SCCEC due to spinal metastases, generally a late complication.

In plasmacytoma and multiple myeloma, SCCEC is usually due to bony collapse, occurring in more than 10% of patients. Hodgkin's disease and non-Hodgkin's lymphomas are associated with a 5% incidence of SCCEC, usually in the presence of extranodal or extensive nodal disease. The thoracic spine is most often involved, in many cases by intraforaminal spread of tumor (20). Patients with SCCEC due to lymphoma are at high risk for meningeal disease. Cerebrospinal fluid (CSF) examination should be considered along with spinal imaging, as concurrent meningeal lymphoma is common and affects the antineoplastic treatment regimen. Vertebral compression fracture with radicular pain is a rare presenting sign of acute leukemia (21).

SCCEC is the presenting sign of cancer in up to 30% of pediatric cases. The time interval to presentation with SCCEC may be twice as long in children without a known cancer, compared to those already diagnosed with malignancy (22). Children without a cancer history presenting with SCCEC are often initially misdiagnosed (23). SCCEC is the most frequent neurological complication of Ewing's sarcoma (24).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of back pain and neurological dysfunction secondary to SCCEC includes benign tumors; meningiomas occur frequently in patients with breast cancer (25). Coexisting nonmalignant disease of the spine may affect as many as 30% of patients with SCCEC (26). Degenerative, inflammatory, and infectious processes affect the spinal structures (27). Soft tissue injuries causing back pain are very common. Trauma is the most common cause of back pain in children; other nonmalignant conditions such as Scheuermann's disease and scoliosis (28) also present in this age group. Back pain in cancer patients may also be caused by

vertebral osteoporosis due to radiation therapy or corticosteroids.

Spinal cord or cauda equina dysfunction may be related to direct tumor or treatment effects, without SCCEC. Leptomeningeal disease, intradural extramedullary or intramedullary spinal cord disease, paraneoplastic necrotizing myelopathy, and myelopathy induced by radiation or intrathecal chemotherapy should be considered if no epidural compressive lesion is found. Myelopathy is a late complication of radiation; epidural lipomatosis may be caused by corticosteroid therapy. Vascular events of the spinal cord may occur in association with tumor masses.

PATHOGENESIS OF NEUROLOGICAL DYSFUNCTION AND PAIN

The high incidence of metastasis to the vertebrae, despite their poor blood supply, is explained by specific physiological features. The vertebrae have a large capillary capacity, promoting local stasis of blood. The walls of the vascular sinusoids are discontinuous and intersinusoidal cords form cul-de-sacs for tumor. Tumor products and the products of bone resorption act to stimulate tumor growth (29). Monocytes producing interleukin-1 may promote resorption of normal bone (30). Metastases may occur more commonly in previously damaged bone (31). Batson's plexus is a valveless system of epidural veins in which blood may flow rostrally or caudally. On Valsalva maneuver, this system drains the viscera and may be a route of metastatic spread. Tumor also reaches bone via the arteries, lymphatics, and by direct extension.

Epidural tumor produces dysfunction of neural structures by direct compression, and by secondary demyelination, ischemia, and tissue edema. Inflammation may change vascular permeability and disrupt the blood–spinal barrier at the tumor site. The release of excitatory amino acids by injured neurons may further promote ischemia and injury.

In the initial stage of epidural cord compression there may be white matter edema and axonal swelling with normal blood flow. These changes are due to direct compression or venous congestion. Over time, progressive compression decreases blood flow and disturbs vascular autoregulation, leading to the development of vasogenic edema. Spinal cord infarction may result from interruption of venous outflow or occlusion of small arteries, or from interruption of the major arterial supply to the spinal cord (including the artery of Adamkiewicz) or radicular arteries in the intervertebral foramina.

A necrotic cavity, usually located in the ventral portion of the posterior columns or dorsal horn, has been visualized on magnetic resonance imaging (MRI) (12). The effects of cord compression may also be due to coup or contrecoup injury, which is not easily predicted on the basis of tumor location in relation to spinal cord. Demyelination as a mechanism of neural dysfunction (5) is supported by pathological examination, which demonstrates greater demyelination of white matter than gray matter, a pattern that does not conform to arterial supply. Animal experiments indicate that more rapid ischemic change produces a greater degree of irreversible neurological injury (32,33). Similar observations have been made in the human spinal cord.

Pain due to malignancy of the spine may result from activation of afferent nociceptive neurons by mechanical distortion and inflammatory mediators (nociceptive pain) or from neural dysfunction (neuropathic pain). Nociceptors innervate the periosteum, soft tissues (ligaments and muscles), facet articular cartilage, dura mater, nerve root sheaths, and blood vessels. Vertebral collapse and structural instability can give rise to mechanical pain through injury to these structures, which worsens during spine loading and weight shifting. There may be secondary myofascial pain as well. Neuropathic pain results from altered peripheral and central neural activity that may be induced by injury of the nerve roots, axonal injury, or other processes such as deafferentation.

PATIENT EVALUATION

Although it is widely recognized that pain is often the first symptom of spinal neoplasm, accurate assessment of back and neck pain in the cancer patient may be challenging to even the experienced clinician. A complete history and physical examination, including thorough neurological examination, are essential to localize the underlying pathology. Proper clinical localization is necessary to choose diagnostic and therapeutic interventions correctly (Table 37-1). Inadequate evaluation increases the likelihood of otherwise preventable neurological compromise. In a retrospective survey of cancer patients presenting with back pain, misdiagnosis was attributed to poor history, inadequate examination, and insufficient diagnostic evaluation (34). In a review of cancer pain consultations performed by a neurology-based pain service, the comprehensive evaluation of pain led to an identification of new malignant involvement in 65% of cases (35).

TABLE 37-1. PATTERNS OF SPINAL TUMOR INVOLVEMENT

History

Up to 95% of adult and 80% of pediatric patients with SCCEC present with pain (12,36). The difference in pain prevalence between adults and children may reflect greater difficulty in pain assessment and underreporting of pain in children. Pain may precede other symptoms and signs by 1 year (12). This interval may vary by tumor type; it is generally shorter for lung cancer than breast cancer (37). Overall, patients experience pain for an average of 4–5 months before presentation (3).

Pain may be local at the site of pathology or referred in a nonradicular distribution, a radicular (dermatomal) distribution, or have combined features. Radicular or root pain is reported in 90% of lumbosacral SCCEC, 79% of cervical, and 55% of thoracic cord compression (37). Radicular pain may be bilateral in thoracic lesions, and is often described as a tight band around the chest or abdomen. It is important to note that radicular pain may be experienced in only one part of a dermatome. When a nerve root lesion produces chest or abdominal pain, the complaint may be mistakenly identified as referred pain of visceral origin. Radicular lesions are usually associated with segmental findings on examination. Nonradicular referred pain may be associated with vague paresthesias and tenderness at the painful site. Pain may be continuous at rest and markedly aggravated by body movements (incident pain). Although local pain from a vertebral lesion is worsened with loading due to upright posture, pain due to SCCEC is often greatly increased by lying supine. A lesion confined to the vertebral body may also produce nonradicular referred pain. Disease at C7 may refer pain to the interscapular region, and pain due to disease at L1 may be referred to the iliac crests, hips, or sacroiliac region. Sacral disease often causes midline pain radiating to the buttocks, which is made worse with sitting. Radicular pain in particular may be paroxysmal, spontaneous, or provoked by movement or sensory stimulation. Valsalva maneuver may produce or aggravate both local and radicular pain. Pain on neck flexion or straight leg raising implies dural traction. Lhermitte's sign (electric shock-like pain) indicates a spinal cord lesion. Compression of the cervical spinal cord rarely produces funicular pain, which is pain referred to the lower extremities, thorax, or abdomen as a band of paresthesias. “Pseudoclaudication” of legs may be an isolated lumbar root symptom (38).

The neurological findings associated with SCCEC also vary. There can be extensive epidural tumor with no neurological findings on examination. Upper motor neuron weakness may occur with lesions of the spinal cord (above the L1 vertebral body). This finding is present in 75% of patients with SCCEC at diagnosis (11). Sensory changes occur in approximately half of patients at presentation, including paresthesias and sensory loss, which can be segmental or below the level of injury. Sensory complaint without pain is exceedingly rare. Bladder and bowel dysfunction are evident in more than half of patients on presentation with SCCEC; constipation usually precedes urinary retention or incontinence (39).

Examination

The physical examination begins with observation of posture, spinal curvature, symmetry of paraspinal muscles, extremities, and skin. The practitioner may appreciate tenderness of the spinous processes on palpation or percussion, although this may not correlate with the level of spinal disease. Gibbus deformity and vertebral misalignments are frequently palpable; actual crepitus of the spine is unusual. Tenderness or spasm of the paraspinal muscles may also be noted. Urinary retention may be demonstrated by bladder percussion. Laxity of the anal sphincter may be apparent on digital rectal examination. Specific areas of sacral or coccygeal

tenderness may be identified by external palpation, rectal, or pelvic examination.

Spinal maneuvers to elicit pain should be performed carefully. Thoracic and abdominal radicular pain may be provoked on lateral flexion and rotation of the trunk. Increased pain on neck flexion and straight leg raise sign may be “pseudomeningeal” signs of dural traction due to epidural tumor. If neck rigidity is present, the examiner should use extreme caution with range-of-motion maneuvers. Muscle spasm may be triggered by bony instability of the cervical spine, and forced movements may dislodge bony fragments, causing acute spinal cord or brainstem injury.

The neurological examination reveals positive findings in the majority of patients with SCCEC. The examination should include assessment of mental status, cranial nerves, motor function, reflexes, sensation, coordination, and gait. Proximal lower extremity weakness may be initially evident only as difficulty rising from a chair. Although weakness due to upper motor neuron dysfunction is usually associated with increased tone and hyperreflexia, acute “spinal shock” can cause a flaccid areflexic paralysis. In the subacute phase of recovery from spinal shock, “mass reflexes” appear consisting of flexor spasms, hyperhydrosis, and piloerection due to autonomic dysfunction. Lower motor neuron weakness may be accompanied by flaccidity, atrophy, muscle fasciculations, and hyporeflexia. A cervical lesion can produce segmental hyporeflexia in the arm or arms and increased reflexes below. Lesions above the pyramidal decussation of the corticospinal tracts in the lower brainstem may be associated with loss of contralateral abdominal reflexes; lesions below the decussation produce loss of ipsilateral abdominal reflexes. Segmental motor dysfunction due to thoracic nerve root disease may produce asymmetric abdominal muscle contraction and loss of abdominal reflexes. Beevor's sign (upward movement of the umbilicus on attempted flexion of the trunk) indicates a lesion at or near the T10 level. Lesions of the roots of the upper lumbar plexus produce hip flexion weakness and a dropped knee jerk reflex; lesions of the roots to the lower lumbar plexus may produce foot drop and diminished ankle jerk reflex. Loss of bulbocavernosus and anal reflexes may accompany conus and cauda equina lesions (39).

Although the sensory examination may help in determining the level of epidural disease, SCCEC results in a broad variation of sensory dysfunction, with incomplete lesions the rule. The level of reduced sensation may be determined to be up to five segmental levels below, or one to two segments above, the level of cord compression. A sensory level on the trunk sparing the sacral dermatomes may occur in up to 20% of patients with thoracic or high lumbar compression (40). Suspended partial sensory levels, or unilateral bands of sensory loss may be seen with spinal cord lesions up to the brainstem. Compression of the conus of the spinal cord may produce sensory loss in the saddle area (buttocks and perineum). Facial numbness may be due to upper cervical lesions. Lesions of the upper thoracic nerve roots may result in Horner's syndrome, with autonomic dysfunction of the face and upper extremity.

Gait ataxia is an uncommon isolated sign of spinal cord compression. Other unusual features are signs of raised intracranial pressure; facial paresis, lower extremity fasciculations or sciatica with cervical tumor; nystagmus with thoracic tumor; spinal myoclonus; an inverted knee jerk reflex; and “painful legs and moving toes” (12).

Diagnostic Evaluation

The selection of specific imaging tests is guided by the clinical presentation. Several imaging methods are available to confirm SCCEC. Because the correct interpretation of symptomatic and asymptomatic lesions on diagnostic imaging studies requires thorough knowledge of the patient's clinical presentation, it is strongly recommended that clinicoradiographic correlation be made by the examining physician. In each individual case, the “neurological urgency” for further diagnostic tests must be modified according to the potential for treatment, the patient's condition, and overall prognosis (Fig. 37-1).

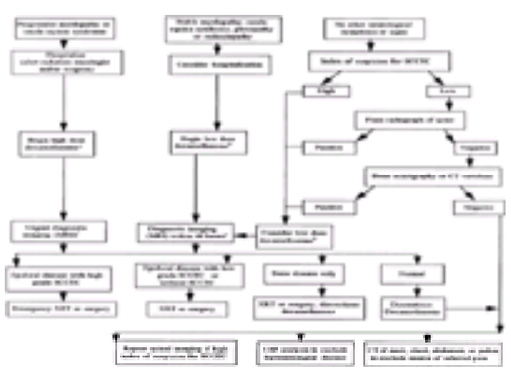

FIGURE 37-1. Cancer patient with back or neck pain—candidate for radiotherapy or surgery. CSF, cerebrospinal fluid; CT, computed tomography; MRI, magnetic resonance imaging; SCCEC, spinal cord or cauda equina compression; XRT, external beam radiotherapy. [a]High-dose dexamethasone, 100 mg followed by 24 mg q 6h with taper over weeks. [b]Low-dose dexamethasone, 20 mg followed by 4 mg q 6h with taper over weeks. [c]MRI, suggest sagittal screen of vertebral column with expanded imaging of affected areas or CT myelography (see text). (Data from Foley KM. Pain syndromes in patients with cancer. In: Portenoy RK, Kanner RM, eds. Pain management: theory and practice. Philadelphia: FA Davis Co, 1995:195; and Posner, JB. Neurological complications of cancer, contemporary neurology series vol 45. Philadelphia: FA Davis Co, 1995:112, with permission.)

Plain radiographs confirm tumor and assess structural stability of the spinal elements. In the cancer patient at risk for spinal metastases with neck, shoulder, or upper extremity pain, flexion and extension views of the cervical spine should not be forced. Although plain radiographs are over 90% sensitive and 86% specific for demonstrating abnormalities in the patient with symptomatic spinal metastases, autopsy series suggest that up to 25% of spinal lesions are invisible on radiography (41). False-negatives occur due to mild degree of pathology, poor visualization (e.g., the first thoracic vertebra), or because the abnormality is missed on interpretation. The false-positive rate for interpreting collapsed vertebrae as malignant may be as high as 20% (42).

It is estimated that a 30–50% change in bone mass is needed before plain films become abnormal (36). On anterior/posterior view, spinal radiographs may show pedicle erosion (the “winking owl” sign), increased interpeduncular distance, paraspinal widening, or paraspinal soft tissue shadow. On lateral view, vertebral collapse (wedging of the body), scalloped bodies, disc space destruction, a narrow spinal canal, hypertrophied facets, and disc calcification may be seen. Oblique views are needed to discriminate spondylolytic osteophytic encroachment from tumor causing foraminal abnormality (5). Greater than 50% vertebral collapse and pedicle erosion are especially predictive of SCCEC. On plain radiography, multiple vertebral involvement is noted in up to 86% of patients with spinal tumor (5), and in greater than 30% of patients with SCCEC.

Computed tomography (CT) may be useful to better delineate pathology using restricted fields of view (41). CT is superior to other imaging techniques for demonstrating cortical bone architecture (43). Before the availability of MRI, CT in combination with myelography was considered the gold standard for demonstrating the level and extent of epidural disease. CT-myelography may be considered if the index of suspicion for epidural disease is high and other imaging studies are normal, or if MRI cannot be interpreted or performed. Lumbar puncture should precede cervical puncture in most cases. Injection of air to supplement contrast medium may better image CSF block. If the upper and lower extent of the block cover a long spinal segment, myelography may be repeated after treatment to determine if multiple discrete lesions are present and to better define radiotherapy portals. If repeated imaging is anticipated, oil-based contrast medium may be used to allow for follow-up radiographic imaging without repeated punctures. Another advantage of myelography over other diagnostic imaging tests is the collection of CSF for analysis. However, there is a risk of worsening neurological function after dural puncture in the patient with partial CSF block, due to “coning” of the spinal cord as pressure below the block is relieved. This risk may be as high as 15% (12,44). It is therefore recommended that under these conditions, corticosteroids be administered before dural puncture.

Radionuclide bone scintigrams reveal a 5–10% change in bone tissue (36). Bone scintigrams are more sensitive than radiographs except in multiple myeloma (12). They are not as specific as radiographs in identifying the level of SCCEC. False-positives may be due to nonmalignant skeletal conditions, and false-negatives may be due to lytic lesions, e.g., myeloma or solid tumors such as lung and melanoma, and prior radiation therapy. If the entire skeleton is involved by tumor, no contrast in the radionuclide uptake can be appreciated. New technology of immunoscintigraphy may prove to be more sensitive (41).

MRI is now considered by many experts to be the imaging procedure of choice for SCCEC. MRI without contrast enhancement may eliminate the need for other imaging studies. MRI sensitivity and specificity rival that of CT-myelography and are better with contrast. In the patient with back pain and radicular symptoms but no bony tumor on plain radiograph, gadolinium-enhanced MRI is indicated to identify intraforaminal disease such as occurs in lymphoma and some solid tumors (36). Double-dose gadolinium-enhanced MRI may increase accuracy. MRI with and without contrast excludes vertebral metastases, paravertebral lesions, SCCEC, intramedullary tumor, and many leptomeningeal processes. Fat-suppression and T-2 weighting, not supplemented by addition of contrast, may improve detection of myeloma lesions (45). In previously irradiated bone, MRI signal intensity is increased and gadolinium contrast enhancement is decreased.

In the cancer patient with back pain and suspected SCCEC, complete spine MRI is indicated when there is high risk of noncontiguous or skip lesions. A full spine sagittal “screening” image to identify targets for more detailed imaging is suggested (5). Often the cervical spine is not imaged because it adds significantly to

sequencing time. Failure to identify multiple levels of SCCEC may compromise radiotherapy if untreated lesions become symptomatic and are detected at a later time. The cost-effectiveness of sagittal screening studies for identifying treatable lesions has not yet been determined. In patients with claustrophobia or severe pain in the supine position, conscious sedation or general anesthesia may be required to complete the MRI. The risk of sedation or anesthesia for MRI must be weighed against the risks of alternative imaging procedures, such as CT-myelography, for each individual patient.

CSF examination is not required for the diagnosis of epidural tumor, and as noted above, dural puncture may pose some risk to the patient with SCCEC. CSF analysis may show elevated protein with normal glucose, and rarely, pleiocytosis.

The patient presenting with MESCC and an unknown primary tumor generally undergoes a battery of tests to identify the primary neoplasm. At times, biopsy of a vertebral, epidural, or paraspinal lesion is needed to determine the tumor histology.

MANAGEMENT OF ACUTE SPINAL CORD OR CAUDA EQUINA COMPRESSION

Pharmacological Interventions

Corticosteroids are the mainstay of pharmacological therapy for acute SCCEC. The administration of these agents prevents lipid peroxidation of neuronal cell membranes, ischemia, and increased intracellular calcium (46). Vasogenic edema in SCCEC has been demonstrated to be responsive to corticosteroids. Cytotoxic edema may also play a role. Alternative steroids and other agents to treat edema, such as mannitol, may be used.

The timing of administration and dosage of corticosteroids may affect neurological outcome, and there is some evidence for a therapeutic window (38,46). Better analgesic effect of higher-dose regimens has been demonstrated in one study (47). Many authors favor a prolonged course of high-dose corticosteroids, e.g., the equivalent of a bolus of 100 mg dexamethasone followed by 96 mg per day in divided doses, tapered over a few weeks for high-grade SCCEC, and a lower dosage, e.g., 20 mg dexamethasone followed by 16 mg per day in divided doses with a taper, for low-grade SCCEC (5,47,48).

High-dose therapy may be more analgesic, but increases the risk of side effects. Side effects depend on duration of drug administration, cumulative dose, and regimen. In one prospective study of SCCEC patients treated with highdose corticosteroids, it was noted that depressive symptoms and disorders were more common than in similar patients not receiving such treatment (49). Suppression of the hypothalamic-pituitary-adrenal axis occurs with sustained dosing; it is suggested that dosing be readministered after withdrawal in situations of severe physiological stress. Steroid-induced osteoporosis may be reversible in the young (50). Other withdrawal symptoms, including *Pneumocystis* infection, have been reported. Corticosteroids are metabolized by the cytochrome P450 system, which has implications for drug interactions with anticonvulsants and other medications; this potential interaction with anticonvulsants may be least with valproate sodium (46). Clinicians should be aware that rapid administration of steroids causes severe burning pain in the perineum; therefore, it is preferable that doses not be given as intravenous push. Except in emergency situations, corticosteroids should be held before making the cancer diagnosis if lymphoma is suspected due to the immediate oncolytic effect, which would impede diagnosis.

Virtually all patients presenting with SCCEC have severe pain requiring opioid analgesics. Practitioners should be prepared to titrate opioid to effect; this may require high doses, especially in patients with neurological involvement (51).

Nonpharmacological Interventions

Radiation Therapy

Radiation therapy for SCCEC is chosen to inhibit tumor growth, restore and preserve neurological function, treat pain, and improve quality of life. The course of external beam radiotherapy (XRT) for spinal metastases and SCCEC depends on the radiosensitivity of the tumor and its extent. Currently, XRT is considered by many clinicians to be the primary treatment for SCCEC. The course may be accelerated for patients in severe pain. The spinal section routinely treated includes two vertebral segments above and below a single site of neurological compression. Anterior/posterior portals are set to include the vertebral body, especially in low thoracic and lumbar lesions. Fields are also designed to accommodate paravertebral tumor. A single port field can be used in very cachectic patients. As there are no known predictive factors for epidural progression with multiple sites of spinal disease, the decision to treat asymptomatic noncontiguous sites depends on clinical judgment. In addition to clinical condition of the patient, factors to be considered include the type of tumor, presence of vertebral collapse, and anticipated future difficulty in matching radiation portals. Special techniques are required to reirradiate. XRT alone is more than 85% effective for SCCEC in radiosensitive tumors (3). Motor improvement is seen in 49% and stabilization of function in another 31% of patients. However, less than 50% of patients regain lost function (3). The possibility of progression to SCCEC may be reduced by irradiating bony lesions. It is uncertain if radiation is treating micrometastases or preventing them. The response to XRT may be delayed in some cases; the factors accounting for this observation are not well understood (52). Brachytherapy can be used for adjacent paraspinal masses and may prevent SCCEC (53).

Surgery

Surgical intervention for SCCEC may be performed to (a) establish the cancer diagnosis when it is in doubt and tissue is required for histological examination, (b) achieve surgical cure for a primary neoplasm, (c) treat prior irradiated radioresistant tumor with symptomatic progression of SCCEC, (d) decompress neural structures and stabilize the spine, or (e) halt a rapid clinical deterioration (3,54,55 and 56). The specific goals of surgery are to resect pathology, restore load-bearing capacity, decompress neural structures, achieve stability, treat pain, and improve quality of life.

Many factors affect choice of surgical technique, including tumor location, tumor extent, integrity of adjacent segments, and general debility. In vascular tumors such as renal and thyroid, operative intervention may be preceded by vascular embolization. Tumor decompression and stabilization may be achieved through either an anterior vertebrectomy or laminectomy. Posterior decompression through wide laminectomy is generally followed by stabilization to prevent kyphosis (57,58,59 and 60). New posterolateral techniques are being developed for specific SCCEC syndromes in advanced cancer patients.

In one thorough retrospective study (61) of 110 patients after aggressive surgical intervention for spinal metastases, 82% of patients showed improvement in pain relief and ambulatory status. The goals of treatment were identified as gross total resection of tumor and spine reconstruction. Half of the patients had prior treatment and were deteriorating clinically. The “traditional” criteria for surgery, such as relapse after radiation therapy and for determination of histology, were expanded to include gross tumor resection for radioresistant or solitary lesions and for spinal stabilization. In this series, more complex surgical instrumentation was used than previously reported. Most patients received ongoing systemic therapy, partly confounding the analysis of long-term outcomes. The complication rate of 48% correlated with age older than 65, prior spinal treatment, and the presence of paraparesis. These factors also correlated with greater morbidity and poorer survival. However, in this series, nearly half of the patients were alive at 2 years, an improvement over prior studies that had compared the posterior surgical laminectomy and radiation therapy to radiation therapy alone. This improvement in survival was noted in patients with more advanced cancer and prior treatment. These authors concluded based on prior reports (62,63) and the data from this series that the anterior surgical approach with stabilization may improve outcomes, and suggested further definition of the subset of patients that might benefit from early anterior resection and spinal stabilization.

Early reviews of surgical outcomes have confirmed higher morbidity and mortality in patients with prior spine irradiation, age older than 70 years, and those with poor performance status at the time of surgery (64). In a recently reported series, the factors predictive of shorter survival were poorer preoperative neurological status (leg strength grade 3/5 or weaker), anatomical site of the primary carcinoma (lung or colon cancer), and multiple vertebral body involvement. These authors consider surgical intervention contraindicated if two or more of those factors are present (63). Several authors have suggested that a limited posterolateral approach to tumor resection be reserved for patients with expected survival less than 6 months (61,65). Few data are available regarding surgical intervention for lateral epidural or intraforaminal disease. In a recent experience, a small group of patients, not considered candidates for major surgical procedures, benefited from limited resection of lateral epidural tumor. Surgery was preceded by careful correlation of symptoms with tumor mass, and good outcomes were recorded in all eight patients (65). This experience supports careful consideration in each case until criteria for primary surgical intervention are more fully delineated. Further refinement of surgical approaches also depends on precise neuroanatomic localization of neoplastic involvement (Table 37-1).

The complication rate for spinal surgery may be as high as 30% in patients who have undergone prior XRT (3). Coagulopathy and exogenous anticoagulants increase the risk of hematoma at the operative site. Difficult wound healing, infection, bony instability, nonfusion, displacement of implants, and other complications may occur.

There has been a steady evolution in the concepts and execution of surgical management for SCCEC. In choosing primary surgical versus radiotherapeutic intervention, the prognosis for neurological improvement and expected impact on functional status must be considered. In some series, radiation therapy has been shown to be equally effective to laminectomy and radiation, but with less than 50% neurological improvement overall (11). De novo anterior-posterior resection with spine stabilization may result in better outcomes than laminectomy and radiation or radiation alone, as surgical complications are generally manageable, survival is improved (although the 2-year survival for lung cancer may be 10% and for colorectal cancer only 17%), and patients may remain ambulatory longer (61). The data are as yet insufficient to draw final conclusions regarding pain and quality of life outcomes. The decision to recommend initial radiation therapy versus surgical intervention

must be individualized. It has been suggested that without bony instability, the speed of progression of neurological deficit and radiosensitivity of the tumor are the main factors to consider. Severe deficits hold a poor prognosis independent of treatment.

Nonsurgical stabilization of the bony spine can be accomplished with a cervical collar or body bracing. The cancer patient with neck pain and suspected cervical spine disease should be placed in a collar while diagnostic evaluation is being conducted.

ONGOING CARE

Pain Management

Extended corticosteroid administration (i.e., for the duration of life in patients with SCCEC and short prognosis) has not been well studied but is common in clinical practice. This practice should be discouraged unless there is evidence of ongoing steroid-reversible neurological deficits, due to the high risk of steroid toxicities discussed in the section Pharmacological Interventions (66).

Guidelines for the use of nonsteroidal anti-inflammatories, opioids, and adjuvant analgesics for neuropathic pain have been published in recent years (67,68,69,70 and 71). Chronic opioid therapy is often required for persistent pain after treatment of SCCEC. Cases have been reported in which patients with SCCEC required prolonged high-dose intrathecal infusion of opioid and local anesthetic to obtain adequate analgesia (72,73). Radionuclides are discussed in other chapters.

Neuroablative procedures are considered when the benefit to risk ratio favors analgesia over the potential for further neurological compromise. Destruction of nervous tissue may be accomplished by anesthetic or surgical means. Chemical epidural neurolysis may be chosen to effect single or multiple nerve root interruption. Intrathecal neurolysis would be anticipated to achieve analgesia over a wider territory, and may be selected when the epidural space is compromised. Both approaches entail risk of acute neurological deterioration, which may be irreversible (74). Neurosurgical ablation of nerve roots (rhizotomy) involves major surgery, and is less often indicated in very sick patients. Midline myelotomy may be indicated for patients with severe midline sacral pain and bladder or bowel compromise due to tumor of the sacrum. Spinothalamic tractotomy or cordotomy, although more easily performed as a percutaneous procedure, is not generally useful for pain in association with spine disease or SCCEC. Hypophysectomy for diffuse painful metastatic bone disease may yield success rates as high as 90% in some endocrine responsive tumors (75).

Integration of pharmacological and nonpharmacological analgesic therapies is needed for the vast majority of patients with SCCEC. A multidisciplinary approach to pain management and rehabilitation of patients with resected sacral chordoma has been reported (76).

Rehabilitation

Each patient's rehabilitation program must be individually tailored and continually reassessed and modified. For some patients, comprehensive care may be best accomplished in a formal rehabilitation setting (77). Specific rehabilitation goals are to improve ambulation, achieve weight bearing and transfers, restore bladder and bowel function, and protect the skin.

Spinal orthotics stabilize the spine and may decrease spinal pain by limiting motion. Physical therapy techniques for pain include massage, ultrasound, and transcutaneous electrical nerve stimulation.

Approximately 50% of patients require urinary catheterization before and after XRT for SCCEC (3). Sexual dysfunction may be treatable with specific physical interventions.

A number of medical problems common to the cancer population may limit aggressive rehabilitation efforts. Organ failure due to the disease or its treatment, poor nutrition, and multiple physical and psychological symptoms may complicate rehabilitation. An active exercise program may have to be modified. Weakness due to spinal cord or nerve root compression may be complicated by peripheral neuropathy or myopathy, which are common complications of antineoplastic treatment. The skin of many cancer patients is relatively more prone to breakdown and infection. Skin care and protection are essential, especially in the bedridden patient.

Chronic musculoskeletal problems may occur in children after spine irradiation during growth, due to the development of secondary spinal deformities. The risk of fracture in osteoporotic or tumor-laden bones should be carefully evaluated before initiating a mobility program. In paraparetic or paraplegic patients, prophylactic fixation of upper extremity lesions may be considered to aid mobility and weight bearing. In bedridden patients with multiple impending fractures, positioning and transfers must be undertaken with great caution.

The goals of physical medicine and rehabilitation in the patient with SCCEC range from active programs to supportive care (78). Preventive rehabilitation therapy is directed toward achieving maximal functional restoration in patients cured or in stable remission from their cancer. Continued encouragement for the effort required in aggressive rehabilitation is needed for a progressive decline in function due to advancing disease. For patients with limited prognosis, usually considered as less than 6 months life expectancy, family participation receives more emphasis. The needs of the patient trend toward more dependent care as cancer progresses. Palliative rehabilitation interventions are intended to provide comfort in the terminal stages of cancer.

Psychological Interventions

Ongoing psychological support of the patient with metastatic spine disease is essential. Issues of loss of independence and loss of function require careful attention. Families often benefit from emotional support for anticipatory grieving. Professional assistance is indicated as the burden of care increases with a patient's progressing disease.

CLINICAL OUTCOMES

The potential for recovery of function in patients with tumor involvement of the spine and associated neurological structures varies by tumor type (primary or metastatic), the number of vertebrae involved, the nature and degree of neurological involvement, the oncologic status, and general medical condition. In most series, approximately 50% of patients with metastatic spine tumors are ambulatory at presentation, 35% are paretic, and 15% are plegic (38). Up to 30% of patients with weakness become plegic within the first week of presentation (5). The prognosis for regaining ambulatory status in SCCEC patients who begin therapy while ambulatory is 75%; prognosis declines to 30–50% for patients who begin therapy paretic, and to 10% for those who begin therapy plegic (36). The duration of neurological symptoms before treatment also affects prognosis for neurological recovery. If paraplegia has been present for days, or urinary retention present for more than 30 hours, the likelihood of recovery is decreased (79). Rapidly progressing symptoms confer a worse prognosis.

Patients who remain unable to ambulate after irradiation for SCCEC have a particularly poor prognosis for survival, due to complications of paresis and more advanced disease. Survival rates for patients with SCCEC are 40% at 1 year if ambulatory before and after radiation treatment, whereas patients who are nonambulatory before and ambulatory after treatment have a survival rate of 30% at 1 year and 20% at 3 years. Prognosis falls to 7% at 1 year for patients who are nonambulatory after treatment (3).

Response to treatment for SCCEC and survival vary with the nature of the malignancy. In patients with prostate cancer, the response to treatment of neurological complications depends on whether the patient has received prior hormonal therapy. Better response to hormonal manipulation correlates with longer survival. The median survival of prostate cancer patients after diagnosis with SCCEC is 6 months; only 34% survive at least 1 year (80). Renal cancer is poorly radioresponsive, and median survival time after diagnosis with SCCEC is less than 4 months (81). Hemorrhagic complications of spinal surgery for metastatic renal tumor may be avoided by preoperative embolization (82). In testicular cancer, chemotherapy is effective for untreated lesions or for responsive tumors (83), but radiation and surgery may be considered if the disease is not chemoresponsive (81). Up to 75% of melanoma patients with SCCEC respond to radiation therapy (84,85 and 86.) Patients with carcinoid tumor and SCCEC have a median survival of 6 months. Ambulatory status may be preserved with radiation in up to 90% of patients with carcinoid tumors (19). In myeloma, long-term survival is common. In a series of patients with multiple myeloma, the 1-year survival was 100% and median survival 37 months after SCCEC was diagnosed (87). Solitary plasmacytomas are generally irradiated and surgically removed. Multiple myeloma patients often receive radiation therapy to maximum spinal cord tolerance before surgical intervention is considered. Most lymphomas respond to chemotherapy and radiation. In pediatric patients, surgery may be preferred for radioresistant sarcomas and small cell tumors (Ewing's sarcoma, neuroblastoma, lymphoma, and germ cell tumors) presenting with rapid neurological deterioration. A trend toward extended survival has been shown after surgical decompression in Ewing's sarcoma. Many small cell tumors respond to chemotherapy or radiation. Younger age may confer greater risk of radiation complications (88). Complete resection of primary spinal extraosseous epidural Ewing's sarcoma may be difficult. The 18-month survival was less than 40% in a small series of patients with this unusual malignancy (89).

The survival prognosis for all patients treated for SCCEC is less than 50% at 2 months (11). Definitive intervention for SCCEC must therefore be considered in the context of the patient's overall disease status. Systemic antineoplastic therapy may at times precede or entirely supplant intervention targeted at SCCEC. For patients

with very advanced cancer, the burden of intervention to reverse SCCEC often outweighs minimal potential gains in function. Although few studies of quality of life have been conducted in this population, pain control should remain a high priority regardless of prognosis. Given limited available data, the clinician caring for patients with spinal neoplasm must carefully select medical interventions to achieve therapeutic goals for each individual patient and family.

NEUROMUSCULAR DYSFUNCTION AND PALLIATIVE CARE

DIANNA QUAN
JAMES W. TEENER
JOHN T. FARRAR

The neuromuscular disorders experienced by cancer patients may cause weakness, fatigue, sensory loss, and pain, including cramps and dysesthesias. To determine the etiology of these symptoms accurately and formulate a treatment strategy, physicians need a logical approach to assessment. First, a careful history and neurological examination are needed to identify potential neuromuscular dysfunction, presenting as part of the complex set of symptoms that occur with cancer. Second, a specific diagnosis is established through laboratory testing or appropriate consultation. Finally, appropriate therapy is prescribed. In this chapter, such an approach is explored with reference to common cancer-associated neuromuscular diseases.

DEFINITIONS

The term *neuromuscular* refers to both the muscle and the peripheral nervous system, which includes the anterior horn cell, the dorsal root ganglion, the sensory and motor nerve roots, the plexi, the peripheral nerves, and the neuromuscular junction. Patients with cancer can develop neuromuscular dysfunction through direct compression or invasion of these structures by neoplasm, toxic effects of antineoplastic therapies, or paraneoplastic effects.

HISTORY AND EXAMINATION

A careful history and examination of the patient complaining of fatigue, weakness, sensory abnormalities, or pain help the practitioner differentiate a neuromuscular problem from disturbances caused by central nervous system (CNS) or nonneurological dysfunction. The tempo of symptom onset is important. Weakness or sensory dysfunction that develops abruptly may indicate a vascular injury in the central or peripheral nervous system, tumor impingement on neural structures, or a fulminant autoimmune or inflammatory process. Patients with recent onset, rapidly progressive neuromuscular symptoms require immediate attention. Regardless of tempo of onset, symptoms should be assessed in the context of the location and nature of the underlying malignancy, and previous or current treatments and medications.

The nature and distribution of symptoms offer further diagnostic clues. For example, both positive (e.g., tingling or pain) and negative (e.g., numbness) sensory complaints are common with peripheral nerve injury. Motor weakness of one side of the body suggests a CNS lesion, whereas weakness of distal leg and hand muscles often is caused by a neuropathy. Proximal weakness is more typical of myopathies or defects of neuromuscular transmission. Distal weakness is more typical of a neuropathy. Similarly, a sensory level over the trunk is typical of spinal cord compression, whereas foot and hand numbness in a stocking/glove pattern is more typical of a neuropathy. Reflexes are usually brisk when weakness is caused by a CNS lesion and reduced in cases of neuropathy. Reflexes are often normal in myopathy but may be reduced if the myopathy is severe.

The physical examination is generally not definitive, and other diagnostic procedures should be used to confirm the diagnosis. Electrodiagnostic studies frequently can help to localize the dysfunction. Additional laboratory studies, such as hemoglobin A1C, thyroid function tests, vitamin B_{12}, Lyme antibody titers, cryoglobulins, and serum protein electrophoresis, may allow a specific diagnosis to be made. Even when the primary diagnosis is clear, testing for treatable contributing factors should be performed. If found, these other potential causes of neuromuscular dysfunction should be treated to prevent further deterioration.

Table 38-1 presents the symptoms that may be caused by neuromuscular dysfunction and the most typical neuromuscular disorders causing those symptoms. Some of the symptoms, such as fatigue and diffuse weakness, do not help localize the defect. Others, such as muscle tenderness or focal pain, may lead to an anatomical localization.

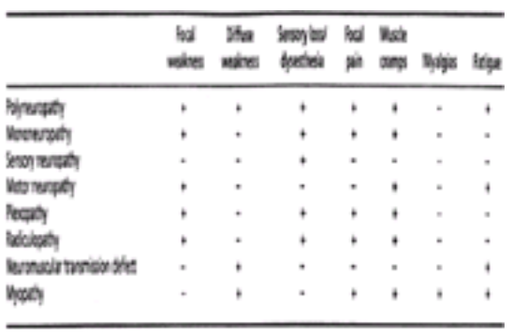

TABLE 38-1. CARDINAL SYMPTOMS OF NEUROMUSCULAR DYSFUNCTION (MOST SYMPTOMS ALSO HAVE A LARGE NUMBER OF NONNEUROMUSCULAR CAUSES)

TREATMENT

Treatment strategies for neuromuscular disorders fall into two categories: etiological and symptomatic. With our current state of knowledge, reversal of disease with effective etiological therapy is rare. When available, etiological treatments are presented with the description of the specific disease entity. Symptomatic therapy, which is becoming more effective, is presented as a separate section. One important general point is that damaged tissues may require substantially higher levels of nutrients and cofactors to support the maximum degree of recovery. Although there are no specific data, appropriate nutrition and supplementation of vitamins and trace minerals are likely to be important components in the treatment of all oncology-related neuromuscular disorders.

We do not specifically discuss any alternative or complementary therapeutic approaches because there is inadequate evidence to support the use of any of these particular treatments in this set of disorders. However, the use of these treatments continues to increase and must be included when reviewing the care of all patients with oncologyrelated neuromuscular disease (1).

SPECIFIC NEUROMUSCULAR DISORDERS

Neuropathy

Neuropathy is the most frequently encountered neuromuscular complication of cancer. Although neurotoxic chemotherapy is most commonly implicated, neuropathy also may be caused by direct or metastatic tumor infiltration of nerve or by remote (paraneoplastic) effects of the cancer. Nerve involvement may be focal or widespread, and, consequently, symptoms and signs may be focal or diffuse. Reflexes are generally reduced or absent in the affected areas. Dysesthetic pain and burning are frequent complaints. Fatigue and muscle cramps also may be troublesome.

It is useful to categorize neuropathies according to the primary neurological modalities affected: sensory, motor, or sensorimotor. The neuropathy may be further classified according to the predominant pathology: axonal loss, demyelination, or neuron cell body death. Disorders that affect sensation or strength exclusively most often are caused by lesions of the dorsal root ganglion cells or anterior horn cells, respectively, and thus are described most accurately as neuronopathies. Although one deficit may predominate, sensation and strength are usually both involved to some degree in most neuropathies.

The evaluation of a neuropathy usually involves an electromyogram (EMG) and nerve conduction studies. These tests confirm the extent and distribution of nerve involvement and help differentiate primary neuronal or axonal injury from injury to the myelin sheathe. Nerve biopsy is rarely indicated but can be helpful in differentiating direct tumor invasion (possibly amenable to chemotherapy or radiation) from a toxic or paraneoplastic process. Advances in magnetic resonance imaging (MRI) make it useful for diagnosing carcinomatous meningitis. This diagnosis cannot be excluded without a lumbar puncture. Cerebrospinal fluid (CSF) surrounds nerve roots, and examination of this fluid may clarify pathology at this level. It may also be important to evaluate potential nonneoplastic causes of neuropathy. A useful scheme for evaluation of neuropathy has been presented by Brown (2).

The primary treatment of a neuropathy, if any, is generally directed at the specific, underlying cause. The treatment of neuropathy-related symptoms depends primarily on the predominant symptom (e.g., weakness, sensory loss, pain) and is discussed in the section Symptomatic Treatments.

Chemotherapy Toxicity

Chemotherapeutic agents are among the most frequently encountered causes of neuropathy in cancer patients. A wide variety of chemotherapeutic agents has been associated with the development of neuropathy; vinca alkaloids, platinumbased agents, and taxanes are most frequently involved. Other neurotoxic drugs include misonidazole, procarbazine hydrochloride, suramin, cytozine arabinoside (ARA-C), etoposide, ifosfamide, dolostatin-10, and thalidomide (3,4,5,6,7,8,9,10 and 11).

Vinca alkaloids, such as vincristine sulfate, vinblastine sulfate, and vinorelbine tartrate, are a frequent cause of chemotherapy-induced neurotoxicity. Vincristine sulfate uniformly causes a peripheral neuropathy when used at the usual weekly doses of 1.4 mg/m^{2}or greater (12). The first clinical sign is usually the loss of ankle reflexes. Paresthesias may first become noticeable in the fingers. Although mild sensory loss does not warrant a reduction in dosage, weakness may develop rapidly, and is a dose-limiting side effect when severe. Signs of impending motor involvement include cramps and mild clumsiness. Weakness typically reverses when the dose is reduced or the drug is stopped; parasthesias take longer to disappear, and mild sensory deficits may persist. Occasionally, patients develop prolonged or permanent dysfunction. Electrodiagnostic studies demonstrate a sensorimotor polyneuropathy with predominant axonal involvement. Peripheral neuropathy may occur less frequently with vinorelbine tartrate than with other vinca alkaloids (13,14).

Cisplatin may begin to cause neurotoxicity or ototoxicity at a cumulative dose of approximately 300 mg/m^2, and more than 50% of patients who receive 600 mg/m^{2}develop symptoms (15,16). The neuropathy is predominantly sensory; decreases in vibratory, light touch, and pinprick sensation are accompanied by progressive loss of deep tendon reflexes. The loss of proprioception may result in a sensory ataxia. Despite discontinuation of the drug, neuropathic symptoms may continue to increase for weeks before stabilizing, in a phenomenon known as “coasting.” Recovery occurs over months, but is often incomplete (17). Weakness is rare in all but the most severely affected patients. Other platinum-based agents cause similar symptoms, although newer derivatives, such as oxaliplatin, may have fewer neurotoxic effects (18).

Paclitaxel and the other taxanes cause a predominantly large fiber sensory polyneuropathy. Pain, tingling, and numbness may begin within 1–3 days after a single highdose treatment (19). Weakness occasionally develops but invariably improves when the drug is discontinued. Neurotoxicity is generally not dose limiting. Risk factors for the development of neuropathy include a prior neuropathy, high doses (>250 mg/m^2), length of treatment, and possibly older age (20).

Patients who may have chemotherapy-related neuropathy should undergo a standard neuropathy evaluation to ensure that there is no other contributing cause. It is occasionally useful to follow electrodiagnostic markers of nerve dysfunction prospectively to identify impending nerve dysfunction early in the course of chemotherapy. Somatosensory-evoked responses are generally affected first, followed by a reduction in sensory amplitudes on nerve conduction studies (21).

Treatment consists mainly of limiting the patient's exposure to the offending medication. Chemoprotective agents are under investigation and ultimately may allow prophylactic therapy for neurotoxicity. Amifostine (WR-2721), for example, has demonstrated protective effects against the development of neuropathy in patients treated with cisplatin. The dephosphorylated metabolite of this compound, WR-1065, is thought to protect cells from injury by binding platinum and alkylating agents, scavenging oxygen free radicals, and repairing cell damage through hydrogen donation (22). The antioxidant glutathione also has been observed to have a slight effect in reducing neuropathy from cisplatin (23).

Cancer-Related Neuropathies

A large number of acute and chronic sensorimotor neuropathies has been associated with cancer itself. In most cases, the pathological mechanism or mechanisms are not known. The syndromes are grouped according to the predominant pathological process.

Axonal Sensorimotor Neuropathy

Polyneuropathy

Patients with advanced malignancy often develop a mild sensorimotor neuropathy, which is of little clinical importance. Much less frequently, a clinically significant axonal sensorimotor neuropathy accompanies or even precedes the diagnosis of cancer. This neuropathy typically presents with numbness and tingling in the feet. The lesion may progress to cause more widespread sensory disturbances as well as distal leg and hand weakness. Nerve conduction studies confirm an axonal neuropathy; CSF protein may be normal or, rarely, slightly elevated. The pathogenesis of this neuropathy is unknown in most cases. In some patients with non-Hodgkin's lymphoma, a lymphomatous infiltration of nerve roots and nerves has been detected on nerve biopsy; these patients may respond to antineoplastic treatment (24,25,26 and 27).

Focal Neuropathy

Isolated mononeuropathies also may develop in patients with cancer. Peroneal neuropathies at the fibular head typically develop in bedbound patients with weight loss. Loss of the usual fatty cushion predisposes the peroneal nerve to compression at this site. Nutritional, metabolic, and microcirculatory factors also may contribute to this neuropathy. Focal compression neuropathies generally improve with simple measures, such as careful positioning to avoid further compression and padding of vulnerable areas such as the elbow and fibular head (28).

Other focal neuropathies arise when malignant cells invade the nerves and cause axonal degeneration. Widespread metastatic infiltration of nerves by lymphoma or melanoma may result in a multifocal neuropathy that is indistinguishable from a sensorimotor polyneuropathy (29). If no other cause is found, contrast-enhanced MRI of the affected area maybe positive. A nerve biopsy should be considered if further antineoplastic therapy is a possibility.

Vasculitic Neuropathy

Peripheral nerves may be damaged by a cancer-associated vasculitis, which typically causes either an acute or chronic sensorimotor neuropathy, usually beginning as a painful asymmetric neuropathy or pattern consistent with a mononeuritis multiplex. Nerve conduction studies demonstrate evidence of axonal damage. The diagnosis is confirmed by the demonstration of lymphocytic infiltration and necrosis of blood vessels on nerve or muscle biopsy. Treatment with corticosteroids or other immunosuppressants may result in symptomatic improvement (30,31).

Demyelinating Neuropathy

Acute Inflammatory Demyelinating Polyneuropathy (Guillain-Barré Syndrome)

Guillain-Barré syndrome has a higher incidence in patients with Hodgkin's lymphoma and solid tumors, particularly those involving the lung. Patients suspected of having this disorder require immediate hospitalization for monitoring of their respiratory vital capacity and cardiac function. The rate of progression of this disease is highly variable; patients can deteriorate acutely in the first few days. Cancer patients appear to respond to the same therapies used for noncancer-related Guillain-Barré syndrome, such as plasmapheresis or intravenous immunoglobulin (32,33).

Chronic Inflammatory Demyelinating Neuropathy

Chronic inflammatory demyelinating disease is rarely associated with cancer (34). The pattern of weakness and sensory loss may be quite asymmetric, and nerve conduction studies reveal classic demyelinating physiology; CSF protein is frequently elevated. Remissions are reported after removal of the tumor; the neuropathy may respond to treatment with corticosteroids or intravenous immunoglobulin (26,35).

Paraproteinemic Neuropathy

A variety of neuropathies may be associated with paraproteinemia secondary to multiple myeloma, osteosclerotic myeloma, Waldenstrom macroglobulinemia, primary systemic amyloidosis, or monoclonal gammopathy of undetermined significance. Subacute or chronic axonal or demyelinating neuropathies occur in up to 13% of patients with multiple myeloma (36). In some patients with Waldenstrom macroglobulinemia or monoclonal gammopathy of undetermined significance, an IgM antibody directed against myelin-associated glycoprotein can be detected in serum and in the myelin sheath. These patients have a predominantly sensory demyelinating neuropathy (37). In most other cases, the pathogenesis of the neuropathy is uncertain, and the paraprotein may not be involved directly in the pathogenesis. A predominantly motor demyelinating neuropathy can be identified in up to 50% of patients with osteosclerotic myeloma. The neuropathy may occur as part of a syndrome consisting of polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes. These neuropathies may markedly improve with treatment of the tumor (38).

Patients with systemic amyloidosis due to plasma cell dyscrasia may develop a neuropathy that is predominantly sensory and typically involves small unmyelinated or thinly myelinated fibers; autonomic dysfunction is a prominent feature. The diagnosis is made by demonstration of the amyloid material on nerve biopsy. Unfortunately, this disorder has a grim prognosis; there is no effective primary treatment (39).

Neuronopathy

Paraneoplastic processes preferentially attack nerve cell bodies. The cell bodies of motor and sensory neurons are found in the anterior horn of the spinal cord and the dorsal root ganglion, respectively. Damage to the cell bodies of these neurons produces a lesion that is most accurately called a *neuronopathy*. Patients presenting with exclusively sensory or motor dysfunction should be evaluated for the presence of neuronopathy. Symptomatic therapy again depends on the predominant symptoms and is discussed in the section Symptomatic Treatments.

Motor Neuronopathy

Three separate conditions are currently best understood as motor syndromes due to a remote effect of cancer. Treatment of the tumor is of uncertain benefit; there is no effective primary therapy. Physical and occupational therapy can maximize patients' functional capabilities.

Subacute Motor Neuronopathy

Subacute motor neuropathy, which presents with slowly progressive, painless weakness (predominantly in the legs), is a well-established remote effect of non-Hodgkin's and Hodgkin's lymphomas (40,41 and 42). Bulbar involvement and upper motor neuron signs are not seen. The symptoms often develop after radiation, or when the lymphoma is in remission. After a period of progression, symptoms may improve slowly over months to years. Electrodiagnostic studies demonstrate widespread denervation. The cause of the subacute motor neuronopathy is uncertain.

Paraneoplastic Encephalomyelitis

Motor neuron involvement is also seen as a feature of paraneoplastic encephalomyelitis, which typically is associated with a sensory neuronopathy, but neurons at any level of the nervous system, including the motor neurons of the anterior horn, may be affected. When paraneoplastic encephalomyelitis is caused by small cell lung cancer, an antineuronal antibody associated with cancer, known as *anti-Hu*, is typically present.

Amyotrophic Lateral Sclerosis

Rarely is amyotrophic lateral sclerosis (ALS) related to a neoplasm. Although large, epidemiological studies generally conclude that the incidence of cancer is not increased in patients with ALS, case reports have described cancer patients with typical ALS who improved after removal of the tumor (43,44). Most patients with typical ALS do not need an evaluation for malignancy. Only patients who do not fit the typical age profile or patients with sensory complaints or other evidence of more widespread nervous system involvement should be considered for a search for an underlying occult malignancy.

Sensory Neuronopathy

So-called *subacute sensory neuronopathy*, often referred to as a *sensory neuropathy*, is the most widely recognized neuromuscular paraneoplastic syndrome (45,46). Patients typically present with numbness, dysesthesias, parasthesias, and occasionally, aching pain. The findings can be asymmetric. A sensory ataxia due to loss of proprioception is typical and can be severe. Electrodiagnostic studies show markedly decreased or absent sensory nerve action potentials, findings consistent with damage to dorsal root ganglia. Motor nerve conduction studies should be normal.

Patients who develop sensory neuronopathy without a known cancer require a detailed and perhaps repeated search for an underlying malignancy. Small cell lung cancer is by far the most commonly associated cancer; breast, ovarian, uterine, and gastrointestinal carcinomas also must be considered. The presence of anti-Hu antibodies is highly suggestive of the presence of a small cell lung cancer. In approximately 70% of patients with an anti-Hu antibody, there is evidence of CNS or lower motor neuron involvement as well (47). In these patients, an immune mechanism has been supported by the identification of a complement-binding IgG antibody that binds to an antigen found in the tumor and a 35–38-kD brain nuclear protein (48,49). Treatment of the underlying tumor may result in stabilization of the sensory neuronopathy or, in rare cases, improvement. Some patients can learn to adapt to the sensory ataxia by using visual cues, but in severe cases, function is permanently lost and patients become wheelchair bound. Intravenous immunoglobulin and plasmapheresis have not been demonstrated to be efficacious in the few reported clinical trials.

Radiculopathies

Radiculopathy implies dysfunction of the nerve roots. New onset of radicular symptoms in a cancer patient should prompt an urgent evaluation of the spinal column. Perispinal tumor masses can cause acute and rapid spinal cord compression leading to paraplegia. Tumors originating from the spinal column commonly compress nerve roots as well as the spinal cord. Pain is usually the first symptom of compressive radiculopathy. Symptoms and signs of sensory or motor dysfunction may follow, depending on the nerve roots involved and the progression of the lesion.

Radiculopathy also may be caused by leptomeningeal tumor; meningeal carcinomatosis or lymphoma can cause radicular pain, sensory loss, weakness, and areflexia. Signs of meningeal irritation, such as meningismus and, occasionally, headache, may be present. Leptomeningeal spread is most common with cancers of the breast, lung, and gastrointestinal tract, melanoma, and lymphoma, but it is possible with any tumor. Tumor-invading multiple roots can produce a polyradiculopathy that closely resembles a severe sensorimotor polyneuropathy. Cranial polyneuropathies, resulting from invasion of the cranial nerves as they traverse the subarachnoid space, are common.

Advances in MRI technology are making it the initial step in the evaluation of a patient with suspected meningeal carcinomatosis or lymphomatosis. Contrast-enhanced MRI may demonstrate enhancement of thickened nerve roots, particularly when the cauda equina is affected. If an MRI is contraindicated, myelography sometimes

demonstrates multiple nodular defects on nerve roots. Unless the MRI is unequivocally positive, the next step should be a spinal fluid examination. In nearly all cases of meningeal carcinomatosis or lymphomatosis, the spinal fluid proves to be abnormal. Spinal fluid cytology may provide a specific diagnosis, but repeated sampling may be required. In one study, 50% of patients had false-negative CSF cytology at the initial lumbar puncture, but the CSF almost always had some abnormality (50). Most experts suggest performing at least three lumbar punctures separated by several days, if initial cytologies are negative (51). Electrodiagnostic studies can confirm a radiculopathy and are also helpful in identifying a confounding or coexisting peripheral neuropathy. Rarely, a meningeal or nerve root biopsy is needed if a high degree of suspicion remains despite an unrevealing noninvasive evaluation. Meningeal tumors can sometimes be controlled for a time with radiation and intrathecal or intracerebroventricular chemotherapy; however, long-term prognosis is grim (52).

Plexopathies

The diagnosis of plexopathy in the cancer patient is perhaps the most challenging neuromuscular complication. Because of the proximity of the brachial and lumbar plexus to frequently used radiation ports, plexopathy may be a complication of radiation therapy. Differentiating between recurrent cancer and radiation-induced plexopathy can be difficult, and has obvious implications for therapy. As with all peripheral nerve injury, plexopathies usually present with both positive (e.g., tingling) and negative (e.g., numb ness) sensory complaints and weakness of the involved limb. In general, malignant plexopathy is more painful than radiation-induced plexopathy. A severely painful plexopathy is likely to be tumor-related, but radiographic or tissue diagnosis is strongly recommended before proceeding with additional antitumor therapy.

Other causes of plexopathy are rare. Idiopathic brachial plexopathy has been reported in patients with Hodgkin's disease (53). Brachial plexopathy can complicate a lymphedematous shoulder, and lumbosacral plexopathy can occur after psoas muscle hemorrhage or abscess (54,55). Regional intraarterial infusion of chemotherapeutic agents has produced local neurotoxicity manifesting as brachial or lumbosacral plexopathies (56).

Diagnostic studies are required to confirm the diagnosis. Electromyographic data can help localize the lesion and, in some cases, suggest an etiology. Radiation-induced plexopathy tends to be associated with a more diffuse injury on EMG, and with myokymia (rhythmic, repetitive spontaneous discharges). Myokymia occurs frequently in patients with radiation-induced plexopathy but has not been reported in those with malignant plexopathy (57,58). MRI may reveal a mass in the region of the plexus or enhancement along the nerve trunks. Occasionally, the etiology of a plexopathy cannot be established noninvasively, and exploration of the plexus with biopsy is required (59,60).

The treatment of a plexopathy is difficult. In patients with malignant plexopathy, radiotherapy may provide pain relief. Neurological signs may not improve, however, and pain can persist and become a difficult management problem. Radiation-induced plexopathy is generally less painful but is slowly progressive and eventually causes significant disability. There is no specific primary treatment.

Brachial Plexopathies

Brachial plexopathies are typically unilateral. The most common causes are local extension or metastatic spread of breast or lung cancer (61,62). Lymphoma, sarcoma, melanoma, and other types of cancer less commonly invade the brachial plexus. Patients with malignant brachial plexopathy typically experience pain that radiates from the shoulder girdle into the medial arm and hand (61,63). The lower nerve trunk of the brachial plexus is usually most involved, producing hand weakness, atrophy, and sensory disturbances that may mimic an ulnar neuropathy. Horner syndrome is seen in up to 50% of patients. Exacerbation of lymphedema of the arm is seen occasionally.

Radiation may induce a brachial plexopathy when given at a dose greater than 6000 cGy. Brachial plexopathy is a late manifestation of radiation therapy, and onset has been reported from 3 months to 26 years after treatment. Unlike neoplastic plexopathies, parasthesias and swelling of the arm predominate over pain. Also, the upper nerve trunk or entire brachial plexus is more likely to be involved.

For brachial plexopathy, clinical features that can help distinguish malignant from radiation-induced plexopathy are pain severity (worse with neoplasm), presence of Horner's syndrome (with neoplasm), lymphedema (uncommon after radiation), and the distribution of the arm weakness (proximal with radiation injury, and more distal from neoplastic invasion). A painful lower nerve trunk lesion with Horner's syndrome suggests a metastatic plexopathy, whereas a painless upper nerve trunk lesion with a swollen arm is more typically a sign of a radiation plexopathy (61).

Lumbosacral Plexopathies

Lumbosacral plexopathies are most commonly caused by direct extension of intraabdominal neoplasms, such as colorectal or cervical cancer, or by radiation (64,65). Pain is a frequent early feature, and the upper, lower, or entire nerve plexus can be affected. The plexopathy is frequently slowly progressive, and bilateral symptoms may be seen. Computed tomography or MRI scanning of the region of the lumbosacral plexus typically demonstrates the responsible mass. A biopsy is required only if there is no previous tissue diagnosis.

Radiation-induced lumbosacral plexopathy generally presents as slowly progressive weakness; pain occurs in 50% of patients. Like radiation-induced brachial plexopathy, the plexopathy may follow radiation by months to years. Myokymia is seen on electrodiagnostic studies in 50% of patients.

Neuromuscular Junction Disorders

Myasthenia gravis and the Lambert-Eaton myasthenic syndrome (LEMS) are the two most frequently encountered disorders of neuromuscular transmission. Myasthenia gravis may be associated with thymoma but probably is not associated with extrathymic tumors.

Although LEMS is rare, it is associated with cancer in 50–70% of patients. Among these patients with cancerassociated LEMS, 80% have a small cell lung cancer. There have been case reports of associations between LEMS and many other types of cancer, but these associations may be incidental. In patients younger than 40 years of age, the syndrome is more likely to be autoimmune than paraneoplastic; LEMS occurs more frequently in men than in women (approximately a 2:1 ratio), and cancer is the cause more often in men (70%) than women (25%) (66).

The cause of LEMS is IgG antibodies directed against the voltage-sensitive calcium channels of the motor and autonomic nerve terminals. The antibodies interfere with the voltage-dependent release of neurotransmittter at the neuromuscular junction and in autonomic nerves. Calcium channel antibody titers can be measured in the serum of LEMS patients. The immunologic stimulus is likely the voltage sensitive calcium channel of the carcinoma cells.

Proximal muscle weakness in patients with LEMS is typical, and there may be mild myalgias and tenderness of the muscles. Given these findings, LEMS can be misdiagnosed as polymyositis. Bulbar and ocular muscles are rarely affected and never to the degree seen in myasthenia gravis. Patients may complain of severe fatigue and weakness, but on examination often have only mild demonstrable weakness. Occasionally, strength may improve after exercise but then decline further with sustained activity. Deep tendon reflexes tend to be reduced or absent at rest but may increase if tested immediately after a brief, strong contraction of the appropriate muscle. Most patients complain of dry mouth, and some patients have other autonomic manifestations, including impotence, hypotension, and constipation.

The diagnosis of LEMS can be confirmed through electrodiagnostic studies. Routine nerve conduction studies often show reduced motor amplitudes due to impaired release of acetylcholine. A small decrement is seen with repetitive stimulation at low rates; however, with high rates of stimulation or immediately after a brief contraction of the muscle, the motor amplitudes markedly increase to at least double their resting size (most likely because of an increase in the concentration of calcium in the nerve terminals leading to increased acetylcholine release). In questionable situations, the diagnosis can be confirmed with single-fiber EMG (67).

Therapy for LEMS should be tailored to the individual patient and based on clinical severity, the presence of underlying disease, and life expectancy. If the diagnosis of LEMS has been confirmed in a patient without a known malignancy, an extensive search for malignancy must be carried out. Computed tomography scanning of the chest and sometimes bronchoscopy are recommended. If small cell lung cancer is identified, initial therapy should aim at treating the cancer. Weakness associated with LEMS frequently improves with effective cancer therapy, and often, no further treatment is needed (68,69). Cholinesterase inhibitors, such as pyridostigmine, usually do not produce significant improvement, but in rare patients there is some benefit. Pyridostigmine bromide can be tried at a dose of 30–120 mg every 4–6 hours if required. Immunotherapy with plasma exchange, intravenous immunoglobulin, corticosteroids, or azathioprine may be used if the weakness is severe and unresponsive to less aggressive therapy. The orphan drug 3-4 diaminopyridine improves strength and lessens autonomic symptoms in most patients with LEMS (70).

As with myasthenia gravis, drugs that adversely affect neuromuscular transmission should be avoided. These include the aminoglycosides, beta-blockers, calcium channel blockers, and antiarrhythmics such as quinine sulfate, quinidine sulfate, or procainamide hydrochloride. Neuromuscular blocking agents typically used during intubation have an exaggerated and prolonged effect in patients with LEMS.

Myopathy

Except for the local invasion of myofascial structures, primary muscle dysfunction associated with cancer most often arises as a remote effect, thought to be due to autoimmune or toxic metabolites. The best known example is dermatomyositis. Some cancer therapies, particularly corticosteroids, also can cause a myopathy. Myopathy should be suspected in the patient with progressive weakness, especially if proximal, and no sensory symptoms. Most myopathies are associated with an elevated creatinine phosphokinase. Myopathy often can be confirmed by EMG, and a muscle biopsy may help to define the syndrome fully. Treatment usually involves therapy directed towards the specific underlying disorder. There are few symptomatic therapies.

Inflammatory Myopathies

Historically, there has been considerable confusion regarding the relationship between cancer and the inflammatory myopathies. Whereas some studies have demonstrated an increased incidence of neoplasm in patients with both polymyositis and dermatomyositis, others found no such relationship. Currently, little evidence suggests that either inclusion-body myositis or polymyositis is associated with cancer; however, there does appear to be an increased incidence of malignancy in patients with dermatomyositis, particularly among older patients. In a recent series, approximately 25% of patients with dermatomyositis had a known malignancy at presentation, or a malignancy was detected soon after the diagnosis of dermatomyositis (71).

The distinction between polymyositis and dermatomyositis is based on the presence or absence of the characteristic skin manifestations of dermatomyositis. These include a purplish (heliotrope) periorbital rash and a more widespread erythematous pruritic scaly rash over extensor surfaces and sun-exposed areas.

Dermatomyositis associated with malignancy usually responds to immunosuppressive therapy with oral corticosteroids, such as prednisone at 40–60 mg per day for at least 1–2 months, followed by a slow taper. The daily dose can be reduced by 5 mg every week until 30 mg per day, with further tapering at only 2.5 mg per week. Relapse frequently occurs after early or rapid reduction in steroid doses. Other immunosuppressive agents, including methotrexate, cyclophosphamide, chlorambucil, and azathiaprine, have been used, most typically in patients who do not respond to corticosteroids or cannot tolerate their side effects. Intravenous immunoglobulin at a total dose of 2 g/ kg divided over several days also was recently demonstrated to be effective (72). Treatment of the underlying tumor also may result in improvement of the myositis (73).

Cancer-Related Muscle Necrosis

Cancer-related muscle necrosis, a rare, rapidly progressive, fatal muscle degeneration, has been linked to small cell lung cancer and to gastrointestinal, breast, and bladder cancers (74). This disorder presents with a rapidly progressive weakness that spreads from the limbs to involve bulbar and respiratory muscles. Electrodiagnostic studies demonstrate changes typical of myopathy. On muscle biopsy, there is profound muscle-fiber necrosis with little or no inflammation. In general, no treatment has proved helpful.

Carcinoid Tumor–Associated Myopathy

Carcinoid tumors may cause muscle damage and progressive proximal weakness, perhaps related to secretion of serotonin or other substances by the tumor (75). Most histopathologic changes are nonspecific, with preponderance of type I fibers and type II fiber atrophy. The symptoms sometimes improve with a serotonin antagonist such as cyproheptadine hydrochloride or methysergide.

Steroid-Induced Myopathy

Corticosteroids often produce myopathy, which can be progressive. The weakness typically has an insidious onset, but may occasionally be sudden. Despite profound weakness, the serum creatinine phosphokinase is typically normal or only mildly elevated, and EMG may or may not reveal myopathic changes. Muscle biopsy may demonstrate the nonspecific finding of type II muscle fiber atrophy. Necrosis and regenerating fibers are rarely seen. Susceptibility to steroid myopathy varies widely. Patients who develop significant cushingoid body habitus seem to be more at risk (76). The fluorinated corticosteroids, such as dexamethasone, betamethasone, or triamcinolone, more often are implicated in the development of steroid myopathy.

Patients often improve with a reduction in the steroid dose. Strength in some patients who are receiving a fluorinated drug improves if therapy is changed to a nonfluorinated steroid, such as prednisone or hydrocortisone. Physical exercise also can help prevent muscle weakness and atrophy.

SYMPTOMATIC TREATMENTS

Primary treatment of the oncologic or neuromuscular lesion should be provided if feasible and appropriate for the patient's medical condition and goals. In some cases, this strategy may halt or reverse neurological deficits and possibly provide some degree of symptom control. Purely symptomatic therapies are often needed as well, and become the major interventions for those who cannot benefit from primary therapy.

Pharmacological

Aside from muscular cramps, symptoms involving the peripheral nervous system are predominantly neuropathic in origin, specifically sensory loss, paresthesias, dysesthesias, or nondysesthetic pain. Pain is usually the most compelling symptom, and management can be challenging. Opioid drugs, combined with nonopioid analgesics and adjuvant analgesic drugs, are commonly administered. The adjuvant analgesics are particularly important in the treatment of neuropathic pain, which overall is less responsive to the opioids than other types of pain.

Occasional patients with medically refractory pain may be candidates for an anesthetic, neurostimulatory, or neurosurgical intervention. The decision to undertake an invasive therapy must carefully consider potential risks and benefits and relies on a comprehensive assessment of the patient.

Muscle cramps can be particularly troublesome in patients with cancer. Although cramps are often thought of as nonspecific, in reality they typically point to underlying neuromuscular or metabolic dysfunction. In a recent study of 50 cancer patients who complained of muscle cramps, examination and evaluation of the patient led to a specific etiology in 82% (77). Peripheral neuropathy was identified in 22 of the patients, nerve root or plexus lesions in 17 patients, and polymyositis in two patients. Hypomagnesemia was thought to account for muscle cramps in one patient. Thus, muscle cramps typically mark the presence of an identifiable and often previously unsuspected neurological disorder.

Cramps are most effectively eliminated by treating the underlying cause. Unfortunately, this is rarely possible in patients with cancer, except when cramps are due to calcium abnormalities. Cramps occasionally may be successfully treated using agents thought to stabilize muscle membrane, such as quinine sulfate, or a number of antiepileptic medications. Quinine sulfate appears to be most effective in treating nocturnal cramps, whereas antiepileptic medication should be tried for daytime cramping. Strict attention to adequate hydration and electrolyte balance are also critical. Other agents, such as benzodiazepines, antispasticity drugs (e.g., baclofen, tizanidine hydrochloride), antiinflammatory agents, or narcotics, have not been shown to be effective, but their sedating properties may help patients sleep more readily.

The mainstays of pharmacological treatment for positive neuropathic symptoms (e.g., dysesthesias, paresthesias, radiating pain) are anticonvulsants and tricyclic antidepressants (78,79). Less well studied are baclofen, the benzodiazepines, oral anesthetic agents, and a-adrenergic blockers. Numbness or sensory loss does not respond to medication and can only be reduced by addressing the primary neurotoxic process and allowing injured nerves to recover.

The following important principles are generally applicable. Choose each medication carefully, considering both the intended effects and potential side effects. If potential side effects are significant, start with a very low dose, increasing slowly every few days to allow patients to become tolerant to the side effects. Increase the dose of each medication until the desired effect is achieved, until side effects become unmanageable, or until high therapeutic drug levels are obtained. Give each medication an adequate trial before considering it a failure or success, as some drugs may require several weeks to reach their maximum efficacy. Even when treating the same symptoms in different patients, it is important to remember that each patient's response to neuroactive agents is different, and a number of different agents should be tried sequentially until an effective one is found.

Six new anticonvulsants have been introduced in the last 5 years, several of which have better safety profiles than those of existing medications. The introduction of these new drugs has resulted in increased treatment options for neuropathic pain. Currently, gabapentin has become the drug of first choice because of its low side-effect profile and relative lack of interaction with other medications. Two excellent, doubleblind, randomized, placebo-controlled clinical trials have been conducted

showing efficacy and safety (80,81). Based on the information currently available, a number of the newer agents also show similar promise (82,83 and 84).

Rehabilitation

Rehabilitation should play an important role in the treatment of any neuromuscular complication of cancer. There is increasing evidence that monitored exercise can improve muscle strength and endurance while reducing the complications of joint contractures, disuse atrophy, joint stiffness, osteoporosis, and pain. In a study of 301 terminal cancer patients, an increase in the Barthel mobility index from 12 to 19 was achieved with a supervised program of rehabilitation in the hospice setting. The rehabilitation program was thought to be effective by most patients and their families. In another study, a supervised program of active resistance and endurance exercise was shown to maintain and even increase muscular strength in patients with neuromuscular disease (85). Although the special features of neuromuscular disease in cancer patients were not addressed specifically in these studies, it is reasonable to conclude that supervised rehabilitation efforts, particularly physical therapy, can be effective in maximizing the function of patients suffering from neuromuscular complications of cancer.

Over time, weakness can lead to contractures of the affected joint. Regular stretching exercises may prevent this complication. For patients with severe weakness from any cause, splinting in a neutral position also may be needed to prevent contractures. In addition to exercise, appropriate devices can increase patient function. Orthotic braces may allow a weak joint to function more normally. For example, molded ankle-foot orthotics, which stabilize the ankle in a neutral position and eliminate foot drop, can help a patient maintain ambulation.

Significant loss of proprioception often results in gait instability. A cane or walker can provide additional stability, which often helps patients feel more secure. Walking should be encouraged, because gait tends to improve as the brain adapts to a reduced level of proprioceptive input. Use of a cane, walker, or even wheelchair should be encouraged to allow continued independence. Reduced sensation in the hands produces difficulty with fine manipulation, such as buttoning a shirt. Special devices can be created to improve hand and finger function. A trained occupational therapist is best qualified to evaluate and fit patients for such assistive devices.

Other techniques that may be of use for pain or other neuromuscular symptoms include heat, cold, massage, transcutaneous electrical nerve stimulation, and acupuncture (86,87,88,89 and 90). The available literature is generally inconclusive about the efficacy of these therapies; trials were recommended by a recent expert panel (91).

Psychological

Cognitive interventions, such as relaxation, imagery distraction, reframing, hypnosis, and biofeedback, can be helpful in managing pain and improving function (92,93,94,95 and 96). Because the success of these techniques is highly dependent on the patient's ongoing commitment to use them, the clinician must try to identify techniques that are best suited for a patient's specific needs and personality.

SUMMARY

Through a logical approach guided by the physical examination and selected additional studies, the etiology of most neuromuscular complications of cancer can be determined. In many cases, therapy aimed at the specific etiology is effective. Symptomatic therapies should always be considered to enhance function and reduce discomfort. Although many of the neuromuscular manifestations of cancer lack effective primary therapy, significant palliation should be possible in most patients.

DELIRIUM

JANE M. INGHAM
AUGUSTO CARACENI

Delirium has been defined as a transient organic brain syndrome characterized by the acute onset of disordered attention and cognition and accompanied by disturbances of psychomotor behavior and perception (1). It is highly prevalent in the medically ill and has been associated with a wide range of etiological factors. Given data from studies in other medical populations (2,3), it is likely that delirium is under-recognized by medical and nursing staff in the oncology setting. Unless promptly reversed, this condition can increase family distress and precipitate conflict between staff and families (4). The presence of delirium has been shown to prolong hospital stay and increase mortality (5,6). Those caring for oncology patients must be cognizant of the prevalence and phenomenology of delirium and be able to initiate and monitor appropriate treatment interventions.

TERMINOLOGY

The study of mental status changes in patients with cancer and other illnesses has been hampered by a lack of consistency in terminology. A plethora of terms have been used to describe the clinical syndrome consistent with delirium. The *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV*) of the American Psychiatric Association (7) provides the current gold standard for syndrome definition in psychiatry. This document provides the definition that is used throughout this chapter. Delirium is considered to be a single nosologic entity (8), and the *DSM-IV* proposes specific diagnostic criteria for its diagnosis (Table 39-1) (7). Although the earlier *DSM-III-R* criteria classified delirium as one of the organic brain syndromes (9), this classification was seen to imply that other psychiatric illnesses had no biological correlates. To correct this apparent anomaly, the term “organic brain syndromes” was revised in the *DSM-IV*, which classifies delirium in the category titled “Delirium, Dementia and Amnestic and Other Cognitive Disorders” (7).

A. Disturbance of consciousness with reduced ability to focus, sustain and shift attention.
B. Change in cognition (e.g., memory deficit, disorientation, language disturbances) or perception disturbances not better explained by a preexisting stabilized or evolving dementia.
C. The disturbance develops over a short period of time and tends to fluctuate during the course of the day.
D. There is evidence from the history, physical examination, or laboratory findings that the disturbance is caused by the direct physiological consequences of a general medical condition.

TABLE 39-1. CRITERIA FOR DIAGNOSING DELIRIUM DUE TO A GENERAL MEDICAL CONDITION: *DIAGNOSTIC AND STATISTICAL MANUAL OF MENTAL DISORDERS, FOURTH EDITION*

The diagnostic criteria for delirium have evolved over time, yet the term *delirium* is frequently used without adherence to these criteria. In the past, for example, delirium has been used to describe conditions linked to febrile states characterized by agitation and associated with perceptual abnormalities, clouding of consciousness, and disorientation (10). In addition, other terms, particularly “confusion” and “encephalopathy,” have been widely used in the clinical setting to describe the mental status changes that would fulfill the criteria for delirium. The French literature described the phenomena found in these states as “oneirism” or “oneiric consciousness,” with the most striking case of a confused oneiric state being delirium tremens (DT) due to alcohol withdrawal.

The terms “encephalopathy” and “acute confusional state” have been used by neurologists to describe acute changes in mental status (11,12). These terms are applied in lieu of the psychiatric classification based on the *DSM* criteria. As a consequence, a dichotomous tendency exists between the psychiatric and neurological literature. This dualism is usually only semantic. The *DSM* classification criteria are preferred because they have the advantage of defining the essential features of the syndrome (see the section Mental Status Changes and Clinical Applications of Diagnostic Criteria) while leaving open the door to further classifying clinical and patho-physiological subtypes. In the clinical setting, the imprecise terminology has been compounded by a lack of understanding of the important distinction between symptoms and pathological processes or diagnoses. Symptoms are subjective “physical or mental phenomena . . . accompanying a disorder and constituting evidence for it” (13). When used to describe a subjective experience, “confusion” is a symptom. When used by medical and nursing staff to describe a patient's mental state, however, the term is a broad descriptor that is neither a symptom nor a diagnosis. It should never be used synonymously with the diagnosis of delirium. “Confusion” has no diagnostic specificity and may characterize numerous disease states, including both delirium and dementia. Given evidence of confusion, a clinician should consider a detailed clinical examination to facilitate a diagnosis for the mental status change and to seek out etiological factors.

The problems with inconsistent terminology that have characterized both the study of delirium and its diagnosis in the clinical setting may be minimized by the use of *DSM* criteria. Instruments have been developed based on these criteria that facilitate the diagnosis and allow the monitoring of the syndrome (see the section Evaluation Instruments for the Assessment of Delirium). As further research efforts are directed to delirium, it may be that the diagnostic criteria will be further refined. Although the *DSM* criteria for delirium are now considered the gold standard for diagnosis, these criteria and the *DSM-IV*–classified disorders are reflections of a consensus of the formulations of current knowledge in psychiatry. This is an evolving field, and the classification is likely to evolve further and indeed may, as it exists now, not encompass all conditions that may be legitimate targets for treatment or research.

PATHOPHYSIOLOGY OF DELIRIUM

Delirium is an altered mental state characterized by altered alertness and impaired cognition that has been described by Engels and Romano as a syndrome of cerebral insufficiency (14). It is considered to be a stereotyped response of the brain to a spectrum of differing insults and has been viewed as a state on the continuum between normal wakefulness and stupor and coma. The number of possible etiologies, including head trauma, metabolic abnormalities, and innumerable drugs, suggests the existence of a final common pathway with diverse inciting pathophysiologies. An alternative interpretation is that each of the clinical subtypes of delirium is a final common pathway for a set of etiologies or pathophysiologies that share characteristics. The current state of knowledge regarding the pathogenesis of delirium has been most comprehensively reviewed by Trzepacz (15,16).

Anatomically, it is known that both subcortical and cortical structures are important in the development of the syndrome (15,16). Any pathological process that, either structurally or functionally, affects most or all of the cortical mantle may modify the level of consciousness (12). This mechanism of diffuse damage or dysfunction is

likely to play a part in the pathophysiology of many cases, particularly in delirium triggered by metabolic dysfunction.

Some specific brain structures have also been implicated in the pathogenesis of delirium (15,16). These include the brainstem nuclei and tracts that subserve normal wakefulness and the regulation of the sleep-wake cycle (17), as well as hypothalamic-cortical pathways (18). Mesulam et al. observed that right-sided cerebral infarcts are more often associated with delirium (19). The prefrontal, orbital, and nondominant parietal regions and the thalamic and hippocampal structures are also likely to be important structures (15,16).

Abnormalities in cerebral blood flow have been described in delirium, although the etiological implications of these observations are uncertain (15,16). A reduction in cortical flow has been demonstrated in subclinical hepatic encephalopathy (20) and in posttraumatic delirium (21). Cerebral blood flow has been reported to be globally increased in DT (22).

Many neurotransmitters have been implicated in the pathogenesis of delirium (15,16). For example, abnormalities in cholinergic neurotransmission have been implicated in the pathophysiology of many different forms of delirium. It has been postulated that a reduction of acetylcholine synthesis and release may unify many clinical observations in etiologically diverse forms of delirium (15,16). Other neurotransmitters have also been tentatively implicated in specific types of delirium (15,16). For example, overstimulation of the gamma-aminobutyric acid system has been linked to hepatic failure encephalopathy and benzodiazepine intoxication; gamma-aminobutyric acid system understimulation may relate to benzodiazepine and alcohol withdrawal; *N*-methyl-D-aspartate receptor blockade could be involved in phencyclidine delirium; serotonin antagonism could be a causal factor in D-lysergic acid diethylamide hallucinations and delirium; and dopaminergic overactivity has been considered a cause of hyperactive deliria (15,16).

These diverse associations further suggest the existence of a final common metabolic and cellular pathway for delirium (23). Hypoglycemia, hypoxia, ischemia, and other insults may affect oxidative metabolism and induce profound changes in the cholinergic system. Such insults potentially also impact on the function of other neurotransmitters, including dopamine and glutamate. These changes may occur in association with conditions that predispose to delirium, including nutritional cofactor deficiencies (e.g., thiamine), aging processes, and disease states such as Alzheimer's disease. The link between neurotransmitter deficiency, altered brain metabolism, and the clinical manifestations of delirium is postulated to be based on abnormalities of the second messenger systems including calcium, cyclic guanosine monophosphate, and the phosphatidylinositol cascade (23).

It is clear that there is a need for a greater understanding of the pathophysiology of delirium. As such an understanding evolves, it may in time allow the development of treatment strategies aimed at specific abnormalities in second messenger systems, neurotransmitters, or other abnormalities.

ELECTROPHYSIOLOGY OF DELIRIUM

The electroencephalogram (EEG) of patients with delirium, regardless of the etiology of the delirium, demonstrates a generalized symmetric slowing of the EEG with reduction of the alpha rhythm and an increase in delta and theta frequencies (14). These changes are not dissimilar to those found in stages of the sleep pattern. In general, the degree of EEG slowing correlates with decrease in arousal. In some conditions, EEG fast wave activity, beta activity, is also present (24). This activity is more prevalent in delirium characterized by hyperactive phenomena, such as DT.

Recent studies have suggested that EEG techniques may be useful in the study of delirium, clarifying the differential diagnosis and severity and providing a better method for serial monitoring (25,26,27 and 28). EEG findings, specifically decreased alpha and increased delta and theta frequencies, have been demonstrated to correlate with low Mini-Mental State Examination scores in delirious patients (26,27). In these investigations, the reduction of alpha rhythm, demonstrated using quantitative spectral analysis techniques, was particularly useful in diagnosing delirium, whereas the pattern of theta and delta waves was more useful in differentiating dementia from delirium. The utility of EEG in the differential diagnosis of delirium has also been demonstrated in the differentiation of nonconvulsive status epilepticus from delirium and several specific diagnostic entities. For example, the EEG associated with delirium produced by high-dose ifosfamide shows rhythmic complexes typical of seizurelike activity, in contrast to generalized symmetric slowing of the EEG considered to be typical of other types of delirium (29).

Evoked potential techniques have seldom been applied to the study of delirium (15,16). Abnormalities of brainstem acoustic responses and visual evoked potentials have been observed in hepatic encephalopathy (30). Long latency evoked potentials, which are influenced by cognitive processes, can be an interesting tool for exploring the early manifestations of delirium, pattern of recovery, and therapeutic interventions. These potentials have been used in identifying subclinical encephalopathy in liver transplant candidates (30), in interleukin administration (31), and in recovery from head trauma (32).

PREVALENCE AND INCIDENCE OF DELIRIUM

In hospitalized medical and surgical patients, the prevalence of delirium is approximately 10% (10,33,34). In hospitalized cancer patients, the prevalence ranges from 8% to 40% (35,36 and 37). A higher prevalence, reaching as high as 50% in some studies, has been demonstrated in specific subpopulations, including the elderly, patients in the postoperative period, patients presenting to the emergency room, and patients in the terminal phase of illness (10,33,37,38,39,40 and 41). Although recently there have been an increasing number of studies undertaken that focus on the terminally ill population (suggesting prevalence figures of 20–88%, depending on how close to death the survey is undertaken) (37,38,42,43 and 44), studies specifically exploring the prevalence of delirium remain rare in the population with malignant disease (35).

Although small numbers of patients have been studied in the setting of terminal illness related to cancer, the incidence of delirium has been even less widely investigated than its prevalence, particularly in the oncology setting (37,38,42,45). In a review of 26 relevant and valid studies on postoperative delirium, Bitondo Dyer et al. concluded that the overall incidence was almost 36.8%, with wide variation (0.0–73.5%) (39). Similar variability in the incidence of delirium (14–56%) has been reported in hospitalized, medically ill, elderly patients (5,33,34,46). In a study by Gagnon et al., 18 (20%) of 89 cancer patients consecutively hospitalized for terminal care were positive on screening at admission, and among the 71 who were free of delirium at admission, the incidence of confirmed delirium was 32.8% (42). In a similar population, 104 patients in an acute palliative care unit in a university-affiliated teaching hospital, Lawlor et al. diagnosed delirium in 44 patients (42%), and of the remaining 60, delirium developed in 27 (45%) (43). Reversal of delirium occurred in 46 (49%) of 94 episodes in 71 patients, and terminal delirium occurred in 46 (88%) of the 52 deaths (43).

Clinical experience suggests that the risk of delirium varies during the course of a disease, including cancer. The incidence of delirium is likely to be relatively high during episodes of sepsis; postoperatively; when multiple drugs are administered, including chemotherapeutic agents, opioids, and anticholinergics; and in the terminal phases of illness. In the oncology setting, several studies have now reported on delirium and/or cognitive failure and demonstrated, with the exception of one study suggesting a lower incidence (42), that these entities developed in >80% of cancer patients nearing death (38,43,45). One study, which did not use strict criteria for diagnosis of delirium, suggested that the incidence of delirium in patients after surgery for head and neck cancer was 9–25% (47).

The reported variation in the prevalence and incidence of delirium reflects differences in the diagnostic criteria and variation in the populations studied. Although the studies cited previously specifically sought to define cases of delirium, delirium may appear to be less prevalent in the clinical setting than the reports would suggest. The most likely factor contributing to this perception is underdiagnosis. It is well documented that the symptoms of delirium are frequently attributed to other disorders or, alternatively, not observed at all (2,3,48,49). In the emergency room setting, for example, one study demonstrated that only 6% of delirium diagnoses were detected by the emergency room physician (49). In a series of elderly medical patients, the physicians' diagnoses correctly identified only eight of 47 patients as being delirious or acutely confused (3).

PREDISPOSING, PREDICTIVE, AND ETIOLOGICAL FACTORS IN DELIRIUM

The sociodemographic and disease-related factors that may predispose to delirium or predict its occurrence have not been documented in cancer patients. The studies that have investigated delirium in the oncology setting have generally sought to address the spectrum and prevalence of a range of psychiatric diagnoses rather than to address factors involved in specific diagnoses, such as delirium (35,36 and 37,44). As a consequence, the number of delirious cancer patients that has been studied has not been large enough to allow investigators to draw conclusions that relate to predictive factors.

Although there is a paucity of studies in the cancer population and further research is needed in this area, studies that have explored delirium in the hospitalized elderly and in patients before surgery may have some application in the cancer population. This is particularly so given that a high proportion of cancer patients is elderly and many undergo surgery. Unfortunately, many of the studies of delirium predictors have significant methodological limitations. In some studies, for example, standardized validated instruments were not used for delirium diagnosis. Other studies failed to distinguish baseline vulnerability and precipitating factors. Inouye and Charpentier proposed a multifactorial model for delirium in the hospitalized elderly that may be relevant in the cancer population (34,41,50). The model involves the interaction between “baseline vulnerability” and “precipitating factors or insults” (41). In this model, baseline vulnerability is defined by the predisposing factors present at the time of admission to hospital, and the precipitating factors are the noxious insults that occurred during hospitalization. Patients who have high baseline vulnerability may develop delirium with any precipitating factor, whereas those with low baseline vulnerability will be more resistant to the development of delirium, even with noxious insults. The factors that Inouye et al. specifically demonstrated to be contributory to baseline vulnerability in the elderly include visual impairment, severe illness,

cognitive impairment, and an elevated serum urea nitrogencreatinine ratio of ³18 (dehydration) (46,50). Other studies have implicated risk factors including each of the aforementioned factors; age; dementia; depression; alcohol abuse; the preoperative use of anticholinergic drugs; poor functional status; and markedly abnormal preoperative serum sodium, potassium, or glucose levels (5,39,51,52,53,54 and 55). Certain medications have also been implicated as risk factors for delirium, including neuroleptics, opioids, and anticholinergic drugs (5,52,56).

Several authors have suggested predictive models for the stratification of patients at risk for delirium (41,46,47,50,53,54). The Inouye et al. predictive model for elderly hospitalized patients is based on the four baseline vulnerability factors (discussed above) and five precipitating factors (the use of physical restraints, malnutrition, more than three medications added, use of a bladder catheter, and any iatrogenic event) (41,46,50). Although the precipitating factors may not in themselves represent the "cause" of delirium, each may reflect an array of risk factors. Such "risk" may be a consequence of the factor's direct effect on cerebral function or it may relate to the fact that the presence of the factor increases the likelihood of other delirium precipitants or risks also being present, including immobility or infection. Precipitating factors occurred during hospitalization, whereas baseline factors were present at admission to hospital. The precipitating and baseline vulnerability factors were shown to be highly interrelated and contributory to delirium development in independent, substantive, and cumulative ways (41). More recently, Inouye et al. proposed a multicomponent prevention strategy that systematically targeted any of six risk factors for delirium: cognitive impairment, sleep deprivation, immobility, visual impairments, hearing impairments, and dehydration (50,57). In a prospective trial involving 852 elderly patients with intervention and "usual care" arms, this group of investigators used standardized protocols to ameliorate each of these risk factors when present (50,57). The number of episodes of delirium and the total days with delirium were significantly lower in the intervention group. Once delirium developed, however, the severity and the rate of recurrence were the same in both groups of patients. This latter point serves to emphasize the importance of primary prevention in the treatment of delirium. No studies of this nature have been conducted, to date, specifically in an oncology population.

Other authors have attempted to define predictive models in the elderly and in surgical populations based, for the most part, on the admission characteristics of patients rather than on in-hospital events (41,46,47,53,54). In a study of advanced cancer patients in palliative care settings, Caraceni et al. found that the diagnosis of delirium was independently associated with male gender, central nervous system metastases, lower performance status, worse clinical prediction of survival, and progestational treatment (58). In another of the few studies undertaken in oncology patients, Weed et al. sought to define a method of preoperative identification of patients at risk for delirium after major head and neck cancer surgery (47). In this study, the defined criteria included factors related to age, alcohol abuse, cognitive impairment, biochemical abnormalities, and function. Although these may indeed be valid predictive factors, the latter study methodology did not use strict criteria for the definition of delirium.

In cancer patients, the potential etiologies of delirium, as distinct from "risk factors," may be divided into direct effects related to tumor involvement and indirect effects (Table 39-2) (59). The latter category includes drugs, electrolyte imbalance, cranial irradiation, organ failure, nutritional deficiencies, vascular complications, paraneoplastic syndromes, and many other factors (43,59,60,61,62 and 63). Two studies have looked at these factors. The first, a survey of 140 confused cancer patients referred initially for a neurology consultation demonstrated a multifactorial etiology in most cases (64,65). A single cause of the altered mental status was found in 31% of patients, whereas 69% had multiple causes; the median number of probable contributing factors in each patient was three (64). Drugs, especially opioids, were associated with altered mental status in 64% of patients, metabolic abnormalities in 53%, infection in 46%, and recent surgery in 32%. A structural brain lesion was the sole cause of encephalopathy in 15% of patients. Lateralizing neurological signs were found in 41% of patients, and of those 42% had cerebral metastases. Importantly, however, it was noted that 25% of patients without lateralizing signs who had neuroimaging had a focal cerebral lesion defined as a cause or a contributory factor to the delirium. Two-thirds of the patients in this survey recovered cognitive function when the cause of the delirium was treated. In a second study addressing this problem, Lawlor et al. studied a population of 104 patients with advanced cancer admitted to a palliative care unit (43). In this population, as in Tuma's population, the median number of precipitating factors was three, and 49% of patients had delirium that was reversible. Psychoactive medications, predominantly opioids were precipitating factors that were independently associated with reversibility of the delirium, but the authors concluded that oftentimes more than one factor (e.g., opioid medication and dehydration) requires attention if the delirium is to be reversed (43).

Primary tumors of the nervous system
Metastases to the central nervous system
Cerebral tumor
Leptomeningeal tumor
Nonmetastatic complications of cancer
Metabolic encephalopathy due to organ failure
Other metabolic disturbances
Electrolyte imbalance, including disturbances of sodium, calcium, and others
Hypoglycemia or hyperglycemia
Infection
Hematological abnormalities
Nutritional deficiencies
Paraneoplastic syndromes
Vasculitic processes
Treatment side effects from
Chemotherapeutic agents
Steroids
Radiation
Opioids
Anticholinergics
Antiemetics
Other medications

Data from Patchell RA, Posner JB. Cancer and the nervous system. and Plotkman SB, Lesko LM. Delirium and dementia. In: Holland J, Rowland J, eds. Handbook of psychooncology: psychological care of the cancer patient. New York, Oxford University Press, 1989, with permission.

TABLE 39-2. CAUSES OF DELIRIUM IN CANCER PATIENTS

Other studies have demonstrated that drug interactions and metabolic failure (especially renal impairment) can produce unexpected toxicities, especially in the patient with advanced disease (66,67 and 68). Other etiologies (Table 39-2) are also possible in cancer patients. For example, one report established delirium as a possible complication of leptomeningeal disease (69) and paraneoplastic encephalitis, including that associated with Anti-Hu and other antineuronal antibodies, has also been reported as a cause of delirium (70,71 and 72). Nonconvulsive epileptic status, which can occur in association with complex metabolic problems and also with ifosfamide encephalopathy, is a condition that can also result in altered consciousness and can lead to a clinical state of delirium (29). EEG can be used to confirm this diagnosis.

Finally, it is important to recognize that many factors contributing to delirium are potentially reversible; these are often underestimated in this population, including, among others, dehydration (73), borderline renal function, infections, metabolic causes, drug withdrawal, psychoactive medications, and the accumulation of opioid metabolites (43,64,74,75).

MENTAL STATUS CHANGES AND CLINICAL APPLICATIONS OF DIAGNOSTIC CRITERIA

Investigators have proposed two theoretical models of mental status change to explain the clinical manifesta tions of delirium. One model suggests a homogeneous deterioration of cognitive functions (10), and the other, based on the studies by Chedru and Geschwind, suggests that the cognitive deficits are secondary to attention failure (70,71 and 72,76,77 and 78). The latter theory suggests that common clinical features—distortion and disorganization of memories, orientation, thinking, and language—occur because of an abnormal attention matrix and that the cognitive performances with the highest attentional demand, including language and writing abilities, are likely to be the most affected. Although in the clinical setting disturbed attention failure is a prominent feature of the syndrome and is considered to be among the essential criteria for diagnosing delirium (Table 39-1) (7), the variety and intensity of symptoms suggest that regional areas of the brain are likely to be functioning abnormally and contributing to the clinical picture (15,16). The common clinical features of delirium are listed in Table 39-3.

Insomnia and daytime somnolence
Nightmares
Restlessness, agitation
Irritability
Distractibility
Hypersensitivity to light and sound
Anxiety
Difficulty in marshaling thoughts
Fleeting illusions, hallucinations, and delusions
Emotional lability
Attention deficits
Memory disturbances

TABLE 39-3. DELIRIUM SYMPTOMS

Several of the characteristic clinical features of delirium contribute to the tendency to underdiagnose the condition. For example, the symptoms and signs fluctuate and the diagnosis may be overlooked if careful attention is not given to the changes in mental status examination over time. Additionally, subtle changes frequently precede the onset of delirium. These minor symptoms and behavioral changes may go unnoticed, only to be recalled later in family or staff interviews. Even when the symptoms of delirium are most apparent, the fact that these symptoms are highly prevalent in advanced cancer (79,80 and 81) contributes to diagnostic confusion. A patient with cancer may, for example, be restless, anxious, depressed, irritable, angry, or emotionally labile. Clinicians must be cognizant of the fact that these symptoms are not specific for a diagnosis. The spectrum of symptoms must be assessed because in isolation each may be a manifestation of an adjustment disorder, may represent a symptom of delirium, or may be a consequence of any of a large number of conditions, including dementia (Table 39-3 and Table 39-4) (35,44,82). Finally, although most patients have disturbances in multiple aspects of cognition and behavior, the highly variable clinical manifestations of the syndrome result in significant interpatient variability.

TABLE 39-4. DIFFERENTIAL FEATURES OF DELIRIUM, DEMENTIA, AND PSYCHOSIS

In the early stages of delirium, some patients experience an isolated disturbance that may be related to an organic cause that alone may not fulfill the criteria for a diagnosis of delirium. Findings frequently include daytime somnolence with nighttime insomnia and subtle mood and personality changes (Table 39-3). For example, a patient may experience hallucinations or a mood disturbance in the absence of any other evidence of cognitive dysfunction. Such problems must be fully assessed and monitored over time. If other disturbances occur later, the criteria for a diagnosis of delirium may then be met.

Although the clinical presentation of delirium is often extremely varied, the diagnosis can be established on the basis of new-onset disturbances involving cognition, affective state, perception, or arousal and responsiveness. Table 39-1 outlines the specific *DSM-IV* criteria for diagnosis of delirium and each of these criteria must be met for diagnosis.

The first of the *DSM* diagnostic criteria for delirium relates to disturbance of consciousness and impaired attention. This disturbance can be highly variable, characterized by increased or decreased arousal or merely by distractibility and reduced responsiveness. Three clinical variants of delirium have been described based on the type of arousal disturbance: hypoalerthypoactive, hyperalert-hyperactive, and mixed type (with fluctuations from hypoalert to hyperalert) (82,83). The hypoactive form is characterized by lethargy and appears to be associated with less “positive” clinical phenomena than the hyperactive form, which is often accompanied by hallucinations, delusions, and illusions. In one study, 15% of cases presented hyperactive delirium, 19% had the hypoactive form, 52% had mixed forms, and 14% had neither (83).

Although few studies have explored the variation in arousal, it has been suggested that this aspect of delirium phenomenology may be related to specific etiological factors (84,85). For example, a small study of patients with hepatic encephalopathy found that those patients were more likely to be hypoalert or somnolent than those in whom fever was the main etiological factor. In the latter group, patients were equally likely to have a somnolent (hypoalert) or a hyperactive (hyperalert) delirium (84). This study demonstrated a trend toward a hyperactive delirium in patients with alcohol withdrawal, an observation that is consistent with clinical experience. In another recent investigation, Meagher et al. reported that, in comparison with cases with an anticholinergic etiology, drugrelated cases of delirium had higher total scores on the Delirium Rating Scale and higher scores for perceptual changes, delusions, psychomotor disturbance, and mood lability (85). Drug-related cases also had higher scores than both the anticholinergic and infectious/electrolyte groups for changes in sleep-wake cycle and fluctuation of symptoms. More patients from the anticholinergic etiological group were likely to fit the hypoactive subtype. Except in cases of alcohol-related delirium, a definite relationship between etiology and clinical subtypes has not been consistently supported by neurodiagnostic studies (15,16). To date, no study has specifically described the phenomenology of delirium in cancer patients. Nonetheless, the diagnosis of delirium may be overlooked if the existence of differing phenomenologic subtypes, particularly the less apparent hypoactive delirium, is not recognized.

Specific attention disturbances are manifest not only by the level of arousal but also by changes in the patient's ability to concentrate, which can be subtle. Attention disturbances may be evidenced by an inability to maintain a conversation or to attend to its flow. Concentration may be assessed using a variety of assessment instruments for delirium (see the section Evaluation Instruments for the Assessment of Delirium). The Mini-Mental State Examination (86), for example, contains a specific question that seeks to define the patient's ability to concentrate by assessing the ability to subtract serial sevens or to spell the word “world” backward. Although specific assessment of concentration is an invaluable tool in the clinical evaluation of mental status, it is important to recognize apparent abnormalities of attention that may be influenced by language skills, hearing deficits, and other abilities or impairments (87,88).

The second *DSM* criterion for delirium relates to the presence of changed cognition—for example, disorientation; memory deficits; and disturbances of language, reasoning, and perception. It is important to recognize that a diagnosis of delirium may be established in the presence of any one of these cognitive abnormalities. For example, a patient who is not disoriented may still fulfill the criteria for a diagnosis of delirium if he or she is experiencing memory, language, or perceptual disturbances.

Orientation to time, place, and persons is one of the features most commonly associated with the syndrome. Although other features are also common, the perception that the prevalence of disorientation is high may, in part, be a consequence of the ease with which it is assessed. Clinical experience suggests that orientation in time is the first to be affected (10). Patients who are disoriented frequently locate themselves in a known space—for example, in a familiar hospital or house. Recognition of family and self is usually preserved, whereas the ability to recognize less well-known people, such as housestaff, is often lost. This hierarchical organization of person, space, and time orientation has also been observed in other conditions, such as the progressive recovery from electroshock (89).

Memory is another aspect of cognition that is often affected. Impairments in short-term memory are most probably due to the presence of attention failure. Remote memory can also be affected and more familiar memories appear to be retained more commonly than others—for example, patients frequently lose the ability to recall presidents' names before the name of their hometown (76). In addition to memory loss, memories may be disrupted and disorganized, with paramnesias and duplications (90).

Language abnormalities are frequently present in delirium and are often compounded by the presence of incoherent reasoning. Language may lack fluency and spontaneity, and conversation may be prolonged and interrupted by long pauses or repetitions. The language may reflect an inability to find the correct word or to name objects (anomia) and may be characterized by “passe-partout” words (nonspecific phrases that substitute for specific language, e.g., “you know what I mean”), stereotypes, and clichés. The general meaning of speech may be lost due to incoherence or the patient's inability to sustain attention. Chedru and Geschwind provided a series of unique observations on the neuropsychology of delirium and demonstrated that writing abilities are affected early and more severely than other language-related skills (91). More recently, in addition to dysgraphia, Baranowski et al. demonstrated that constructional apraxia was a useful clinical sign of delirium in the psychiatric inpatient population (92). This aspect of the neurological dysfunction can be useful in both the diagnosis and study of delirium. Assessment of these aspects of neurological function can be easily incorporated into bedside mental status examinations, but for this abnormality to be fully appreciated, it is optimal to have skilled interpretation of a substantial number of written words rather than simply a short written phrase.

Delirium may affect reasoning in complex ways. As the ability to reason and to think in the abstract requires intact attention, this aspect of cognition may be most difficult to evaluate. Nonetheless, patients frequently demonstrate irrelevant or rambling thinking, abnormal conceptualization, and altered insight with anosognosia (93).

Perceptual abnormalities may be more prevalent in particular delirium subtypes, such as DT. In some cases, these perceptions may be frightening and associated with agitated behavior. In one series of delirious medical and surgical patients, 24% experienced hallucinations, 18% delusions, and 9% illusions (84). Illusions and hallucinations usually involve visual phenomena, although auditory and tactile features may also be present. In another recent retrospective study of 227 delirious hospitalized patients evaluated by a psychiatry service, the prevalence of psychotic symptoms was 42.7%, with 27% of patients having visual hallucinations, 12.4% having auditory hallucinations, and 2.7% having tactile hallucinations (94). In this population, the presence of visual hallucinations, but not delusions or auditory hallucinations, was significantly associated with more active medical diagnoses and multiple etiologies causing the delirium.

Delusions may be associated with hallucinations. These delusions are frequently poorly organized and characterized by paranoid features, which may incorporate themes that relate, for example, to homicide, imprisonment, or jealousy. Occupational delusions are among the most common with the patient locating himself or herself in a familiar time and space and attending to usual activities. Lipowski describes “the law of the unfamiliar mistaken for the familiar” (10) and suggests that perceptions are influenced by the emotional color of the situation and the patient's personality characteristics. For example, doctors around the bed may be perceived to be ghosts announcing death. It has been observed that some patients may manifest similar delusional themes in more than one episode of delirium and in episodes

triggered by different etiological factors (10,95). In the study discussed above, Webster and Holroyd found that 25.6% of 227 delirious in-patients experienced delusions (94).

Although they are not among the diagnostic criteria, affective disturbances may characterize delirium. Such disturbances range from dysphoria to hypomania. The prevailing emotion of patients with delirium is probably anxiety (95). When insight is lost, mood often appears to be depressed and apathetic. The patient may suffer from his or her own confusion and may painfully try to keep focused and to understand the disease process and the surrounding world. There may be emotional lability, with fluctuating restlessness, irritability, anger, sadness, and anxiety. In the few available reports from patients recovering from delirium, the experience is usually described as a frightening, twilight dreamy state (10). Little is known about the associations that may exist between lack of insight, symptoms, and level of distress during episodes. A small study of 14 patients with cancer pain and severe cognitive failure found that during episodes of agitated cognitive failure, pain intensity as assessed by a nurse was significantly higher than the patient's assessment had been before and after the episode (4). On complete recovery, none of these patients recalled having had any discomfort during the episode. Although interpretation of these data is difficult, the authors suggest that patients who recover from a severe episode of delirium may have no memory of the experience, including the pain, and that medical and nursing staff are likely to overestimate the discomfort of patients with this condition. Another interpretation could be that patients with delirium are acutely sensitive to many irritating factors, including pain, noise, and other factors, and therefore risk becoming more distressed in the setting of delirium and such irritants [if, however, the latter interpretation were correct it would seem logical to consider careful titration of treatments directed toward both delirium *and* the irritant (e.g., pain) as a means of diminishing distress].

The third criterion for diagnosis of delirium relates to the time course of the disturbance. For diagnosis, there must be evidence confirming that the disturbance has developed over a short period of time and tends to fluctuate during the course of the day. This pattern of disturbance is characteristic of delirium, but as with the other diagnostic criteria, this pattern is not specific for delirium. The development of mental status changes over a short period may occur in other conditions, including certain types of dementia.

Fluctuation in the clinical manifestations of delirium is usually apparent in disturbance of the sleep-wake cycle. Patients usually experience insomnia and may be agitated at night and somnolent during the day. As noted previously, this change in sleep pattern is often found to be among the prodromal symptoms of the syndrome. The phenomenon known as “sundowning” refers to the worsening of symptoms toward evening and probably has more to do with sleep-wake abnormalities than with environmental factors (10).

In addition to mental status changes, described above, the neurological examination may identify findings associated with diffuse brain dysfunction, such as multifocal myoclonus and asterixis. Some findings may be relatively specific for one or more etiologies. For example, tremulousness is typical of alcohol withdrawal states; miosis and mydriasis suggest opioid toxicity and anticholinergic toxicity, respectively; and tachypnea may be a manifestation of a central process or of sepsis or hypoxemia.

The final *DSM* criterion for diagnosis requires evidence of a general medical condition judged to be etiologically related to the disturbance. The criteria do not state that proof of etiology is necessary. The implication of this criterion is that a medical condition that could feasibly have resulted in delirium must be present. As outlined in Table 39-2, numerous conditions can fulfill this criterion, including electrolyte disturbances, infection, fever, multisystem failure, and treatment with centrally acting drugs. A detailed history and physical examination may reveal findings that point to the etiology of the delirium and are therefore essential for establishing the diagnosis of delirium in addition to being essential for the assessment of treatment options (see the section Approach to Assessment).

In summary, a comprehensive history, combined with both careful observation and a mental status examination, will frequently provide evidence for the criteria necessary for a *DSM-IV* diagnosis (Table 39-1). A physical examination and review of laboratory data will frequently assist in defining the etiology of the syndrome.

CLINICAL FEATURES OF DELIRIUM IN SPECIFIC SUBPOPULATIONS

It is useful to distinguish several subpopulations in which the prevalence of delirium is high. Syndromes characterized by delirium may complicate withdrawal from alcohol and sedative-hypnotic drugs (96,97,98,99,100 and 101). Given that the lifetime prevalence of alcohol disorders in the United States is considered to be approximately 13% (102), alcohol is likely to be an important risk factor for delirium. In the oncology setting, the risk that alcohol withdrawal could be an etiological factor in delirium is increased in those populations who have tumors associated with alcohol consumption, such as those undergoing surgery for head and neck cancer (99).

The severity of alcohol withdrawal varies from minor symptoms of tremulousness through to the most severe form, DT (97,101). DT is usually seen in patients with a long history of alcoholism who are admitted to hospital for an intervening medical problem. Characteristically, these patients become delirious after 2 or 3 days, but symptoms may occur as late as 14 days after alcohol consumption has decreased or stopped (96,97,100). The onset is usually sudden, although the delirium may be preceded by tremulousness. It is characterized by agitation, tremors, vivid hallucinations, sleeplessness, and signs of autonomic hyperactivity. When hallucinations are related to withdrawal and DT, visual hallucinations tend to predominate, and auditory and tactile perceptual hallucinations are less common (103). Of note, alcoholic hallucinations may occur in the presence of a clear sensorium, as separate, isolated phenomena unrelated to delirium (98,101). These hallucinations are frequently auditory. Seizures may also occur in DT. In most cases, the withdrawal syndrome continues for <72 hours and is associated with spontaneous recovery, frequently followed by a period of deep sleep (101,104). DT can be associated with severe autonomic instability. This disturbance and intercurrent illness account for a mortality for DT between 5% and 15%.

Delirium is common in the postoperative setting. Numerous factors may contribute to a higher likelihood of delirium in this setting, including pain medications, anaesthetic agents, medical illness, and other factors (39). Although this group of patients has been extensively investigated, there have been no studies to suggest that the clinical picture in postoperative delirium is significantly different than delirium from metabolic disturbances or other causes. Those who experience delirium in the postoperative setting have a higher mortality, lesser functional recovery, and longer hospital stays than those who do not develop this complication (6,33,53,105).

Delirium is highly prevalent in patients with advanced terminal illness who are approaching the end of life (37,38,42,43,45,54,58). Accordingly, the assessment and treatment of mental status changes are a very important aspect of palliative care. “Terminal restlessness” is a term that is frequently used to describe the clinical appearance of some patients as they approach death. This condition could, most often, be more accurately described as “agitated delirium in a dying patient” (106). Unfortunately, this particular subgroup of patients has rarely been studied using strict diagnostic criteria for delirium. Although surveys of the last few weeks of life frequently cite “confusion” as a problem, this term does not provide diagnostic specificity. Clinical experience and some recently studies suggest that terminal delirium is prevalent in the hospice and palliative care setting (37,38,42,43,45,54,58) and may be associated with multifocal myoclonus and convulsions. The etiology of the delirium is likely to be multifactorial, with metabolic and drug-related factors in the setting of multisystem failure being contributory. Lawlor et al. found that psychoactive medications, predominantly opioids, dehydration, hypoxic encephalopathy, metabolic factors, and nonrespiratory infection were common associations with delirium in this setting (43).

APPROACH TO ASSESSMENT

Assessment of the patient with a change in mental status should seek to both clarify the diagnosis and define the etiology of the change. Assessment should also aim to provide the clinician with a view of the patient in the context of the overall medical condition. This view should include an understanding of both the impact of the symptoms and disease and the goals of treatment. The latter is imperative, as the patient's and family's goals of care, particularly in case of advanced illness, will influence decisions regarding the extent of the diagnostic workup and the options for interventions.

A thorough evaluation should be considered when any change in mental status is observed (see the section Mental Status Changes and Clinical Applications of Diagnostic Criteria). This applies not only to the presence of “confusion” and prominent psychiatric symptoms, such as hallucinations and paranoia, but also to other psychological symptoms, including anxiety, fear, sleep disturbance, somnolence, and others (Table 39-3). Each of these symptoms may be components of delirium. In assessment, it is important to consider symptoms as multidimensional experiences that may be evaluated in terms of their specific characteristics and their impact (79,107,108,109 and 110). The symptoms associated with delirium should be assessed in terms of their frequency, severity, and distress. Psychiatric symptoms must be assessed also in relation to their perceptual characteristics and the patient's interpretation of their meaning (111). The impact of symptoms and the mental status changes associated with the overall syndrome should be explored in relation to the patient's level of distress; family or caregiver distress; behavior patterns, including behavior that may predispose to injury; and spheres of functioning.

A full medical history is a vital component of the workup of delirium. The degree to which the patient can respond cogently is an important part of the evaluation (111). Even when the patient is capable of giving the history, insight may be lacking as a direct consequence of the evolution of the delirium. An interview with those caring for the patient, perhaps family or nursing staff, may be necessary. For example, nighttime symptoms or subtle evidence of cognitive impairment may have been noticed by the caregivers and not by the patient. The interview must also explore the patient's medical and psychiatric history, systems review, social and family history, medications, previous drug reactions, and allergies. Some symptoms, such as fever, may assist in establishing the etiological factors. All drugs consumed by the patient in the days preceding the episode should be carefully reviewed, with attention to the pattern of administration and dosing in relation to the delirium. Although the extent of the disease may in some cases be known, in others this may need to be defined.

As discussed above in relation to the *DSM* criteria, physical examination, including a mental status and neurological examination, should seek to define the

neurological and psychiatric syndrome (112,113) and should assess for evidence of potential contributory factors, including sepsis, dehydration, or major organ failure. Given the importance of the detection of subtle changes in mental status for detection and diagnosis of delirium, assessment of baseline mental status should be routine in the assessment of patients with acute illness or before the administration of therapies that may precipitate delirium. The use of an evaluation instrument may be useful for both baseline and ongoing assessment (see the section Evaluation Instruments for the Assessment of Delirium).

Assessment of laboratory parameters will allow assessment of the possible role of metabolic abnormalities, such as hypercalcemia, and other problems such as hypoxia or disseminated intravascular coagulation (Table 39-5). Bedside assessments, such as oxygen saturation and blood glucose, may also provide important information. The choice of investigations should be guided by the clinical situation and the goals of care. EEG may supplement the clinical assessment and assist in the clarifying the diagnosis, particularly if there is concern that the differential diagnosis includes epileptiform activity or central nervous system pathology characterized by specific EEG findings. Similarly, brain imaging studies and assessment of the cerebrospinal fluid may be useful when considering the evaluation of etiological factors.

Blood glucose
Electrolytes (sodium, potassium, chlorine, calcium)
Urea and creatinine
Oxygen partial pressure, carbon dioxide partial pressure, bicarbonate, pH (arterial blood)
Full blood count
Osmolality
Other blood tests may be indicated, including, among others, VDRL; heavy metal screen; tests for vitamin B_{12} and folate levels; tests for lupus erythematosus, antinuclear antibody, urinary porphyrins, ammonia, human immunodeficiency virus, antineuronal antibodies
Electrocardiogram
Cerebrospinal fluid examination: Blood, glucose, protein, cells, culture
Screen for disseminated intravascular coagulation
Liver function tests
Infection screens: Blood, urine, and other cultures
Thyroid and adrenal function tests
Head computed tomography scan or magnetic resonance imaging
Electroencephalography

TABLE 39-5. DIAGNOSTIC TESTS TO CONSIDER IN A PATIENT WITH DELIRIUM

Studies in patients with advanced cancer have demonstrated the usefulness of this thorough diagnostic assessment (38,64,65,114). One study found that 67% of delirious cancer patients improved with treatment (64). This improvement was achievable even in a population in whom delirium was a poor prognostic factor for overall outcome—the 30-day mortality was 25%, and 44% of patients died within 6 months (usually from progression of the underlying cancer). Another study found that one-third of the episodes of cognitive failure improved after an evaluation that yielded a cause for these episodes in 43% (38). Lawlor et al. also found that reversal of delirium occurred in 49% of 94 episodes in 71 patients with far advanced cancer (43). Each of these studies confirms the usefulness and importance of a vigilant and active approach to the diagnosis and treatment of delirium—even in the setting of far advanced disease.

DIFFERENTIAL DIAGNOSES OF DELIRIUM

Although the most important diagnoses to be differentiated from delirium are dementia and other psychiatric conditions, the differential diagnosis of delirium encompasses almost the whole spectrum of psychiatric disease as well as an array of neurological disorders (12,115). As discussed previously, it is most important for clinicians to be cognizant of the spectrum of symptoms that may be features of delirium and aware that almost any psychiatric symptom may be a manifestation of delirium. As a consequence, the mental status examination is an important aspect of the assessment of all psychiatric symptoms in the cancer patient, including anxiety, tearfulness, nervousness, depression, irritability, and others. Although these symptoms may be within the normal spectrum of response to serious illness or represent a primary psychiatric disorder, they could indicate a subtle delirium.

When the mental status examination reveals impaired cognition, the potential diagnoses include delirium, dementia of various types, amnestic disorders, and druginduced disorders. The *DSM-IV* categorizes this group as “cognitive impairment disorders” (7). Table 39-4 reports some of the features that facilitate the differentiation of these conditions (82).

The dementias are characterized by progressive cognitive impairment. A history of a chronic decline without alteration in level of arousal assists in distinguishing these syndromes from delirium. Nonetheless, the assessment can be challenging. Dementia increases the risk of delirium and the two conditions may occur concurrently, particularly in the elderly. Demented patients are particularly sensitive to drug toxicities, especially to drugs with anticholinergic activity, and to metabolic and physical stress, including surgery (51). A history of the patient's baseline mental status, level of cognitive impairment, and behavioral pattern is important in the assessment of the demented patient who may be experiencing delirium.

The acute psychoses also can be difficult to differentiate from delirium. The term *pseudodeliria* has been introduced to describe these episodes, which usually occur in patients with a psychiatric history (82). Vigilance is usually preserved and the EEG is normal. Delusions tend to be more systematized and bizarre in cases of psychosis. A patient with a known history of psychiatric disease who develops an episode of confusion requires careful screening of possible organic causes.

Mood disorders are also common, both in the elderly and in the cancer population, and may contribute to diagnostic uncertainty in the evaluation of cognitive impairment (35,36,44,48,116,117,118,119 and 120). Although mood disorders, in particular depression, are common, depressive symptoms are also a common manifestation of delirium. A study of elderly patients found that 42% of the patients who were referred for evaluation of depressive symptoms had a diagnosis of delirium (48). This diagnosis had been considered by the referring health care provider in only 3% of cases. The high prevalence of both mood disorders and delirium in the ill population serves to emphasize the need for a comprehensive assessment that incorporates neurological, psychiatric, and cognitive evaluation.

It is well known that cognitive functions may be affected by brain lesions. When metastases or other structural disease is possible, a full assessment of cognitive impairment must include a comprehensive neurological examination, including aspects of speech and other higher cortical functions (12). An apparent case of delirium manifest by language disturbance may be found, on further examination, to relate to a dysphasic syndrome secondary to a focal cerebral lesion.

Finally, the diagnosis of delirium can be challenging when isolated aspects of the disorder occur without fulfilling the criteria for delirium. Just as depressive symptoms may occur in a patient who does not meet the criteria for a formal psychiatric diagnosis (119,120 and 121), drug-induced hallucinations may occur in isolation without cognitive impairment (122). As alluded to above, the presence of isolated symptoms should prompt comprehensive assessment, monitoring, and, if necessary, treatment to minimize distress.

EVALUATION INSTRUMENTS FOR THE ASSESSMENT OF DELIRIUM

Instruments useful in delirium assessment include those developed for the assessment of cognitive impairment and those specifically developed for the assessment of delirium (Table 39-6) (123,124 and 125). These instruments can be used to identify and quantify cognitive impairment and to determine the likelihood that the impairment can be ascribed to the diagnosis of delirium. As the *DSM-IV* criteria define cognitive impairment as a component of delirium, the abnormalities found on screening tests for cognitive impairment, although not diagnostic of delirium, can be useful in alerting the clinician to the presence of cognitive impairment. Smith et al. comprehensively reviewed the evaluation tools for delirium assessment (124).

Diagnostic classification systems
DSM-III (132), *DSM-III-R* (9), *DSM-IV* (7), *ICD-9* (211), *ICD-10* (212)
Instruments for assessment and screening for cognitive impairment
Mini-Mental State Examination (86)
Short Portable Mental Status Questionnaire (213)
Cognitive Capacity Screening Examination (214)
Blessed Orientation Memory Concentration Test (126)
Other screening instruments, checklists, and algorithm methods
Confusion Rating Scale (215)
Saskatoon Delirium Checklist (216)
Confusion assessment method (128)
Diagnostic interviews
Delirium symptom interview (129)
Delirium rating scales
Delirium Rating Scale (DRS and DRS-R-98) (130,131)
The Memorial Delirium Assessment Scale (133)
Laboratory examinations
Electroencephalogram, brain imaging
Serum anticholinergic activity

TABLE 39-6. EVALUATION METHODS AND INSTRUMENTS FOR DELIRIUM ASSESSMENT AND RESEARCH IN CANCER PATIENTS

Instruments for assessment of cognitive impairment include the Mini-Mental State Examination (86) and the Blessed Orientation-Memory-Concentration Test (126). Although these tools are sensitive indicators of cognitive impairment (37,38,127), the diagnosis of delirium requires further assessment with either a clinical interview or the administration of another validated instrument.

The clinical psychiatric interview using the *DSM* criteria remains the gold standard for the evaluation and diagnosis of delirium (7,111). Instruments that are available to facilitate the diagnosis (124) include the confusion assessment method (128), the delirium symptom interview (129), and the Delirium Rating Scale (130,131). These instruments were initially developed based on the earlier criteria outlined in the *DSM-III* (132) or *DSM-III-R* (9) and use an interview format to characterize the features of the cognitive impairment. Many of these instruments use either a score above a cutoff point or an algorithm to document the presence or absence of delirium but do not address severity. With the exception of the one instrument discussed below, none of the currently available instruments has been adequately validated as a measure of delirium severity. Trzepacz et al. further validated the Delirium Rating Scale (Delirium Rating Scale-revised-98) (131). This 16-item clinicianrated scale has 13 severity items and three diagnostic items, and this recent validation study found it to be a valid measure of delirium severity over a broad range of symptoms, thus suggesting that it may have diagnostic and assessment use and be useful in longitudinal studies. The Memorial Delirium Assessment Scale is a rating scale that has undergone early validation studies in patients with cancer and human immunodeficiency virus and may prove a useful clinical and research tool, especially in these populations, if further studies confirm its usefulness (133). Instruments may have a useful role in providing a method for the monitoring of patients predisposed to delirium or receiving treatment for this condition. Although this potential exists, many of the instruments used to date in screening have lacked adequate validation for this purpose (123,124). With the availability of the recent validation information about the Delirium Rating Scale-revised-98, this instrument may prove to be useful in this regard (131).

The instruments for delirium diagnosis have an important role in research, but none has been widely used in routine clinical practice. Their use in this manner could focus staff attention on assessment and be used to review the quality of patient care and situation-specific barriers to symptom control (37,134,135 and 136). In considering routine use, simplicity and brevity are important features. For this reason, some clinicians have selected the Mini-Mental State Examination (86) for routine monitoring (37,134,135,136 and 137). If using the instrument for this purpose, clinicians should be aware that it has population-specific limits relating to age, language, and education (87,138). In addition, as mentioned previously, the instrument does not fully assess the criteria necessary for a diagnosis of delirium.

TREATMENT

The management of delirium comprises interventions directed at symptom control and interventions directed at underlying causes (64,114,115,127,139,140 and 141). The degree to which these treatments are pursued is determined by the goals of care. It is important, especially when discussing treatment, to consider issues of competency and consent. Patients with delirium are frequently medically ill, and, oftentimes, complex treatment decisions must be made during or around an episode of delirium. Such decisions may involve the treatment of the underlying disease, the establishment (or reestablishment) of goals of care, and specific treatments for delirium. Unfortunately, the nature of delirium itself and its impact on concentration, insight, and cognition in general may interfere with the ability of a patient to make such decisions. Although delirium does not always equate with lack of capacity to give informed consent, this issue must be considered, monitored over time, and formally assessed when decisions are to be made. Respect for the patient's previously defined wishes must be considered in settings in which the patient is not competent, and involvement of the health care proxy is crucial in these settings (139).

Etiological Interventions

As discussed previously, the etiology may be related to one factor or many factors (Table 39-2). Although in advanced disease the goals of care may dictate a limited workup, the identification and correction of the underlying cause(s) should be pursued, to whatever degree is appropriate and feasible, concurrently with the implementation of symptomatic therapies. In complex cases, it may be possible to address at least one, if not several, of the etiological factors. For example, a drug-induced delirium may be ameliorated by dose reduction, if feasible, or by switching to an alternative drug. Even those patients in whom the etiology of delirium is multifactorial may be observed to benefit after reversal of one or more factors (37,43,64,75,142,143). In addition, certain problems can be difficult to diagnose but suspected clinically, and such problems may warrant empirical treatment. For example, in patients with delirium who have a reason to be deficient in vitamin B (e.g., those who have problems with alcoholism or malnutrition) multivitamin replacement should generally be given (139).

In many patients, drugs are contributory factors in delirium (43,64). All nonessential drugs should be stopped (or tapered if that is the appropriate method of cessation for the particular medication). When opioid-induced delirium is the most likely diagnosis, it may be useful to institute a switch from one opioid to another (144,145 and 146). Although no opioid has been shown to have a more favorable central nervous system side effect profile than any other, this practice may identify a drug with a more favorable balance between analgesia and side effects in an individual patient. Bruera et al. suggested that in terminal cancer patients careful monitoring of cognitive function, attention to dehydration, and opioid rotation can reduce the incidence of agitated delirium and the need for neuroleptic medication (145).

Behavioral and Environmental Management

Treatment measures for delirium, regardless of cause, include the manipulation of the environment to provide a safe, quiet, and reorienting milieu and support and reassurance through communication with the patient and family. Where possible, measures should be implemented that increase structure and familiarity and reduce anxiety and disorientation. These measures may include encouraging the family to sit with the patient and placing the patient in a quiet, well-lit room with familiar personnel. The use of orienting devices, such as clocks, calendars, and familiar objects from the patient's home, may be useful. In a randomized prospective trial, discussed above, Inouye et al. used both behavioral and environmental interventions aimed at reducing delirium risk factors and with these effectively reduced the incidence of delirium in hospitalized elderly patients (57). In this population, the significant findings were that delirium developed in 9.9% of the intervention group, as compared with 15% of the usual-care group, and the total number of days with delirium and the total number of episodes were significantly lower in the intervention group. However, the severity of delirium and recurrence rates were not significantly different (57).

The safety of the patient with delirium must be ensured. One-to-one nursing observation may be necessary. Occasionally, physical restraint may be needed for a brief time to prevent harm to the patient and others. The use of physical restraints must be minimized, implemented strictly according to national and institutional policies and regulations, and relinquished as soon as behavioral control is attained with drugs.

Patient and family counseling is an important part of delirium treatment. At any time, but especially when the condition is associated with terminal disease, the communication difficulties associated with the condition may cause distress in family members (147). Table 39-7 highlights some of the issues that should be addressed in family counseling. Although psychological expertise may be helpful in complex cases, a discussion between the physician and family will usually suffice to allay family concerns, guide the family's approach to the patient, and assist them in decision making. Importantly, a family member is frequently the proxy for health care decision making for the cognitively impaired patient, and for this reason as well as many others, family members should be kept apprised of the patient's medical condition.

Communication barrier
Patient's awareness of physical and psychological suffering
Reversibility
Short-term prognosis
Fluctuations of cognitive functions
Role of opioid and other therapies in etiology
Role and goal of sedation
Goals of care

TABLE 39-7. CRITICAL ISSUES IN COUNSELING FOR THE FAMILY OF DELIRIOUS PATIENTS

During an episode of delirium, the patient may experience fear related to an awareness of the impairment. In such circumstances, the patient may require repeated reassurance. The importance of patient counseling before the potential onset of postoperative delirium and of systematic reorientation during the episode has been demonstrated in two studies (148,149). These studies confirm the often cited importance of environmental approaches directed to maximizing safety and providing psychosocial support (150,151).

Pharmacological Therapy

Symptomatic treatment of delirium is often, but not always, necessary. It is appropriate, while treatment is being instituted for etiological factors, to alleviate distress in severe cases, to reduce the risk of mortality in DT, and to manage cases with unknown or untreatable etiologies. Except in the case of DT, for which a benzodiazepine is the first-line drug, a neuroleptic is generally the most appropriate drug for the initial management of delirium (Table 39-8). Although for some time this has been the accepted approach, a recent study of symptoms of delirium in medically hospitalized acquired immunodeficiency syndrome patients provided evidence of the efficacy of this approach (152). Breitbart et al. demonstrated that delirium can be treated efficaciously and with few side effects by using lowdose neuroleptics (haloperidol or chlorpromazine) and that the use of benzodiazepines alone, specifically in this case lorazepam, appeared to be ineffective and associated with treatment-limiting adverse effects (152). Of note, the benefits of treating mild delirium without distress have not been established. In addition, the value of neuroleptic therapy has not been confirmed in hypoactive delirium although psychostimulants have been suggested for the treatment of the this condition (135,153,154).

Drug	Commonly used routes
Neuroleptics	
Haloperidol	Oral, intramuscular, intravenous, subcutaneous
Droperidol	Intravenous, intramuscular
Thioridazine	Oral
Chlorpromazine	Oral, intramuscular, intravenous
Methotrimeprazine	Oral, subcutaneous
Benzodiazepines	
Lorazepam	Oral, intramuscular, intravenous
Midazolam	Intravenous, subcutaneous

TABLE 39-8. COMMON MEDICATIONS USED FOR THE MANAGEMENT OF DELIRIUM IN ADULT CANCER PATIENTS

To date, haloperidol has generally been considered the drug of choice for hallucinations and agitation related to delirium in the medically ill (10,37,134,139,151,152,155,156,157,158,159,160,161,162,163 and 164). Comparative trials are lacking in this area but the clinical preference tends to be for haloperidol, with this preference based on both clinical experience and anecdotal evidence (10,127,139,162). Haloperidol is a potent dopamine blocker with useful sedating effects and a relatively low incidence of cardiovascular and anticholinergic effects. Other neuroleptic drugs may also be efficacious— for example, thioridazine, droperidol, and chlorpromazine. The recent American Psychiatric Association's Practice guidelines cite droperidol, a butyrophenone with a rapid onset of action and relatively short half-life, as having some use for agitation in the hospital setting; these guidelines suggest that this medication, which is more sedating than haloperidol, may have its main use in hospitalized patients with agitation, as there is some evidence to suggest a more rapid response may be obtained with droperidol than with haloperidol (165,166). The role of the newer antipsychotic drugs with fewer extrapyramidal side effects and with activity on dopamine, serotonin, and histamine receptors (e.g., risperidone, olanzapine, and clozapine) has not to date been clarified (167,168,169,170,171 and 172). A few case reports have been published reporting the use of these atypical neuroleptics (139,172,173,174 and 175). To date, these medications have not been widely used for delirium, but it will be important for their role to be explored in future studies.

Haloperidol has been used via the oral, intramuscular, intravenous, or subcutaneous route. The oral route may be appropriate in mild delirium cases; agitation and uncooperative behavior necessitate parenteral administration. Although the intravenous route has not been approved by the U.S. Food and Drug Administration, this route has been reported to be safe and effective (176,177 and 178) and is widely used for treatment of delirium in the severely ill (139,162,177). The subcutaneous route has been frequently used in the palliative care setting (66,127,179). Parenteral doses of haloperidol are roughly twice as potent as oral doses, and clinical effects are usually observed within 30 minutes after intravenous administration and may last for 4–8 hours (162). The half-life of haloperidol is between 14 and 20 hours and the drug is widely distributed and may remain in the body for long periods (180,181).

Empirical guidelines have been proposed for the treatment of delirium (139,162,164,177). There have been few studies to determine the optimal doses of antipsychotic medications in the treatment of delirium. On the basis of doses used in several studies, for very agitated delirium, starting haloperidol in the range of 1–2 mg parenterally every 2–4 hours as needed has been suggested with appropriate monitoring (see below), and low doses, for example, as low as 0.25–0.50 mg of haloperidol every 4 hours as needed, have been suggested for elderly patients (139). Some guidelines mention the use of either droperidol or haloperidol for very agitated cases. The dose can be repeated after 20–30 minutes—and if this is needed it is usually recommended only with a limit of 5 mg of haloperidol every 15 minutes, again with appropriate monitoring (see below). Generally, unless agitation is very severe, dosing should be titrated against symptoms at intervals of 45–60 minutes (182). Typical doses are likely to range between 0.5 and 20 mg of haloperidol administered in the first hour. When the patient is calm, haloperidol is continued by either the oral or parenteral route. The usual dose is 0.5–3.0 mg of haloperidol one to three times daily, which can be given on an as-needed basis or on a fixed schedule. When delirium is mild, treatment can be initiated with haloperidol, 1–2 mg orally or 0.5–1.0 mg parenterally.

Although most guidelines recommend initial treatment with small doses (139), published series have actually reported varying dose regimens. For example, one study of less severe cases, which included hypoactive delirium, noted that low doses (3 mg) of haloperidol appeared to improve symptoms (183). A survey of the management strategies used for intoxicated or head trauma patients observed that average cumulative doses of 8.2 mg were helpful in reducing aggressive behavior (156). A study of acquired immunodeficiency syndrome delirium reported symptomatic improvement with combination therapy of haloperidol (average daily dose of 42 mg) and lorazepam (average daily dose of 7.5 mg) (158), and surveys in intensive care units have reported the use of high doses of intermittently administered or continuously infused haloperidol (48–1155 mg/day) (182,184,185). Despite the high doses administered in the latter studies, clinical experience would suggest that most patients respond to doses of <20 mg of haloperidol in a 24-hour period.

A drawback to the use of haloperidol and other neuroleptic drugs is the potential for extrapyramidal side effects and movement disorders (37,186). Acute dystonias and other extrapyramidal side effects generally respond to antiparkinsonian medications, including diphenhydramine, benztropine, and trihexyphenidyl. Akathisia may respond to low doses of either propranolol (5 mg two to three times per day) or lorazepam (0.5–1.0 mg two to three times per day) (187). A trial of benztropine (1–2 mg once or twice per day) may prove to be useful; however, this medication is not generally used as a first-line treatment for akathisia (187). It is important to be vigilant for this latter side effect, which may go unnoticed in a patient with restlessness associated with the delirium itself.

A rare and serious complication of neuroleptic medications is the neuroleptic malignant syndrome, which may occur as an isolated event or may be triggered by a concurrent illness or fever (186,188). This syndrome may be fatal and must be treated as a potential medical emergency. Although neuroleptic malignant syndrome usually occurs after prolonged, high-dose administration of neuroleptics, it may occur spontaneously in patients on lower doses. It is characterized by hyperthermia, increased confusion, leukocytosis, muscular rigidity, myoglobinuria, and high serum creatine phosphokinase. Treatment measures should include discontinuation of the neuroleptic, general supportive measures, treatment of precipitating factors, and the use of dantrolene sodium and bromocriptine mesylate (186,188).

In addition to its neurological side effects, haloperidol may be associated with cardiac arrhythmias (e.g., torsade de pointes, ventricular fibrillation, and sudden death) through prolongation of the QT interval on the electrocardiogram (189,190,191 and 192). The American Psychiatric Association has made specific recommendations in its practice guidelines, as have others about this problem (139,189,190,191 and 192). In summary, the guidelines recommend that medication management include a baseline electrocardiogram, with special attention paid to the length of the QTc interval. If the baseline QTc interval is ³440 msec, or >25% over that in previous electrocardiograms, the patient may warrant telemetry, a cardiology consultation, dose reduction, or discontinuation of the antipsychotics. The same approach is recommended for patients receiving other drugs that may prolong the QTc interval or those that have electrolyte disturbances. It has also been recommended that serum levels of magnesium and potassium be monitored, and attention should also be given to widening of the QT interval that may occur during administration of these medications in critically ill patients. Special attention should be given to those receiving doses of >50 mg/24 hours, as these patients appear to be at greatest risk for development of conduction disturbances. It is important to note that goals of care may also influence the degree to which monitoring is appropriate. It may, for example, be acceptable to treat a dying patient who has clearly defined goals of care that are focused on comfort alone with less intense electrocardiographic and electrolyte monitoring. The common occurrence of delirium at the end of life speaks to the need and importance of establishing and maintaining clarity with respect to goals of care with the patient or their health care proxy throughout the course of advanced illness.

Haloperidol alone may fail to control the symptoms of delirium. In such cases, either a benzodiazepine or another sedative, or a neuroleptic other than haloperidol, can be added. Anecdotal experience is greatest with lorazepam and midazolam. Clinical experience, along with one case series in the cancer population, confirms the need for the use of more than one drug for delirium management in patients with advanced cancer (37). Of the 39 cancer patients reported in the one reported series, 20% were controlled with haloperidol alone, 13% with lorazepam alone, 26% with a combination of lorazepam and haloperidol, and 40% needed another neuroleptic medication (chlorpromazine or methotrimeprazine). Overall, 26% of the patients needed sedation, usually achieved with midazolam, to control delirium.

The choice of a second drug in the management of delirium should be guided by the drug pharmacokinetics and side effects profile and by the goals of care. For example, propofol, midazolam, or lorazepam has been recommended in the critical care setting because the pharmacokinetics of these drugs favor rapid dose titration in the initial phases of treatment (162). Chlorpromazine is not recommended in these circumstances because of the likelihood of hypotension and other anticholinergic effects. When sedation would be an acceptable or even favorable outcome, for example, in the terminal setting where the patient has lost the ability to interact, chlorpromazine or a benzodiazepine may be a valuable drug. Other factors may also be considered in some patients: The patient with hypotension should be treated with the medication with the least effect on blood pressure, and the delirious postoperative patient who has an ileus or urinary retention should receive the antipsychotic medication with the fewest anticholinergic effects.

In contrast to neuroleptic drugs such as haloperidol, benzodiazepines do not serve to clear a delirious patient's sensorium or improve cognition. As discussed above, in a double-blind randomized trial comparing haloperidol, chlorpromazine, and lorazepam, Breitbart et al. demonstrated that lorazepam alone, in doses up to 8 mg in a 12-hour period, was ineffective in the treatment of delirium and contributed to worsening cognitive impairment (152). Both of the neuroleptic drugs, in low doses (approximately 2 mg of haloperidol equivalent/24 hours), were highly effective in controlling the symptoms of delirium and in improving cognitive function. Benzodiazepines should not, therefore, be considered as first-line treatments for delirium but rather as sedatives that may be useful to reduce agitation. In some cases, particularly in the last days of life, clearing the sensorium and improving cognition may not always be attainable goals. The processes causing delirium may, as death nears, be ongoing and irreversible. Ventafridda, Fainsinger, and their respective colleagues have reported that a group (10–50%) of terminally ill patients experience delirium that can be controlled only by sedation to the point of a significantly decreased level of consciousness (134,136,193). In such cases, and occasionally in the course of management of reversible delirium, a common strategy in the management of agitated delirium is to supplement the regimen of haloperidol with parenteral benzodiazepine (158,182).

Lorazepam is generally considered to be the drug of first choice when a benzodiazepine is necessary. This drug undergoes glucuronidation and has an intermediate half-life. These characteristics and the observation that lorazepam, unlike other benzodiazepines, has no active metabolites have suggested the superiority of this drug when treating elderly patients or patients with liver disease (194). It can be safely administered even in the critically ill (162,195,196 and 197). Dosing usually begins at doses of 1–2 mg orally in mild cases or 0.5–2.0 mg (0.044 mg/kg) administered intravenously or intramuscularly in severe cases (162,197). This medication can be administered by the oral, intramuscular, or intravenous route.

Some authors have expressed a preference for the use of midazolam for the management of delirium. It has been reported to be of use in cases of agitated delirium attributed to the excitatory effects of high-dose opioids and for the management of terminal delirium (106,198). Although theoretically any benzodiazepine may be useful for the latter indication, midazolam can be administered via the subcutaneous route, which can be viewed as a significant advantage in the palliative care setting (106,198).

During acute dosing, midazolam is short-acting and has a rapid onset of effect (within minutes) (162). Reported dose ranges have been between 20 and 60 mg/day although higher doses (up to 200 mg/day) have been administered without untoward incidents (106,198). The drug is rapidly redistributed and is likely to require continuous infusion to maintain its effects. Long-term administration results in prolongation of the clinical effects of the drug. Active metabolites can accumulate in liver failure. These factors contribute to the observation that midazolam is associated with a less rapid awakening than lorazepam. Consequently, midazolam is considered to be less suitable for use when prolonged treatment is likely to be needed and recovery is expected (162). Aside from its pharmacokinetic profile, the comparative cost of this drug has also been cited as a reason for a preference for lorazepam when prolonged treatment is required (162).

Methotrimeprazine is also commonly used to control confusion and agitation in the setting of terminal disease (199). Dosages range from 12.5 mg to 50.0 mg every 4–8 hours, up to 300 mg/24 hours. Hypotension and sedation may limit the use of this drug. However, often the goal of treatment with this medication, as with midazolam, may be to achieve quiet sedation at the end of life.

Alcohol withdrawal and sedative hypnotic withdrawal are special cases of delirium in that their treatment relies on the use of benzodiazepines (97,99,100,103,194,200,201,202,203 and 204). In alcohol withdrawal, benzodiazepines are recommended both to prevent the severe manifestations of DT in patients with minor symptoms of withdrawal and for first-line treatment. This “prophylactic” role in high-risk patients with mild withdrawal has not been explored for delirium related to other etiological factors and currently is unique to the management of the alcohol withdrawal syndrome. The risk of seizures and the high mortality of this condition are factors that contribute to need for early treatment. Diazepam, chlordiazepoxide, and lorazepam are the most commonly used benzodiazepines but, to date, controlled trials have not settled the ongoing debate as to which of these medications is the drug of first choice (194). Haloperidol may be useful, however, in the management of alcohol-related hallucinations.

PROGNOSTIC ISSUES

The resolution of delirium is likely to depend on many factors and the course may be complicated. Although frequently the clinical perception is that the condition is transient and brief, in a study of elderly delirious patients, the average duration of an episode was found to be >2 weeks (19.5 ± 15.4 days) (6). In this group, the most common etiologies for delirium were stroke, infections, and metabolic disorders; coexistent structural brain disease was present in many (81%). Levkoff et al. evaluated a group of acutely hospitalized elderly patients and demonstrated that among those with delirium resolution of symptoms was often incomplete, with only 4% experiencing resolution of all new symptoms before hospital discharge, and 20.8% and 17.7% had symptom resolution by 3 and 6 months, respectively (33). To complicate this issue further, many patients experience delirium in the terminal phases of illness, and although it is common that this condition is reversible—even in advanced illness—in the immediate days before death, many patients have no resolution of symptoms (38,43,45,54). In the Levkoff et al. study, almost one-third of the group members were found to be experiencing individual symptoms of delirium, although they did not meet the full criteria. These data suggest that delirium may be substantially less transient than currently believed and that incomplete manifestations of the syndrome may be frequent.

The mortality associated with delirium has been reported to be between 10% and 65% (6,33,34,205,206). Delirium is more frequent in patients with multiple medical problems, and it is likely that these processes, rather than the delirium itself, contribute to the high mortality rate. Nonetheless, delirium has been shown to be an indicator of poor prognosis (2,58,207). In the elderly, the presence of delirium identified those patients at risk for prolonged hospitalization, loss of independent community living, and future cognitive decline (208,209 and 210). In a population of advanced cancer patients, Caraceni et al. found that the survival curve of patients with delirium was significantly different from that of nondelirious patients, with delirium having a negative impact on prognosis (58).

CONCLUSION

Delirium is a highly prevalent disorder in medically ill cancer patients and is associated with both patient and family distress. Frequently, this condition presents significant management problems. In many instances, delirium is overlooked in the clinical setting, and a vigilant and thorough approach to detection and assessment is essential. Given that delirium is frequently reversible, the management should align with the overall goals of care for the patient and appropriate treatment strategies should be implemented based on detailed assessment of contributory factors. Further research is needed to assess many aspects of this condition, both in the general medical population and the oncology setting.

DEPRESSION AND ANXIETY

DAVID K. PAYNE
MARY JANE MASSIE

Emotional distress is a normal response to a catastrophic event such as the diagnosis of cancer or another life-threatening medical disease. The diagnosis of cancer induces stresses that are caused by the patient's perceptions of the disease, its manifestations, and the stigma commonly attached to this disease. For most individuals, the primary fear is a painful death. Patients also fear becoming disabled and dependent, having altered appearance and changed body function, and losing the company of those close to them. Each of these fears is accompanied by a level of psychological distress that varies from patient to patient. This variability is related to medical factors (e.g., site and stage of illness at the time of diagnosis, treatments offered, course of the cancer, and the presence of pain); psychological factors (e.g., prior adjustment, coping ability, emotional maturity, the disruption of life goals, and the ability to modify plans); and social factors (e.g., availability of financial and emotional support from family, friends, and coworkers) (1). Understanding these factors allows the clinician to predict and manage distress that exceeds a threshold arbitrarily defined as normal. The presence of intolerable distress or prolonged distress that compromises the usual function of the patient requires evaluation, diagnosis, and management.

NORMAL RESPONSES TO THE STRESS OF CANCER

Individuals who receive a diagnosis of cancer, or who learn that relapse has occurred or treatment has failed, show a characteristic emotional response: a period of initial shock and disbelief, followed by a period of turmoil with mixed symptoms of anxiety and depression, irritability, and disruption of appetite and sleep. The ability to concentrate and carry out usual daily activities is impaired, and thoughts about the diagnosis and fears about the future may intrude (2). These normal responses to crisis or transitional points in cancer resemble the response to stress that has been described in relation to other threatened or actual losses (3,4,5 and 6).

These symptoms usually resolve by 7–10 days with support from family, friends, and a physician who outlines a treatment plan that offers hope. Interventions beyond those provided by physicians, nurses, social workers, and clergy are generally not required, unless symptoms of emotional distress interfere with function or are prolonged or intolerable. Prescribing a hypnotic (e.g., zolpidem tartrate or triazolam) to permit normal sleep and a daytime sedative (e.g., a benzodiazepine, such as alprazolam or lorazepam) to reduce anxiety can help the patient through this crisis period. Some patients continue to have high levels of depression and anxiety (both are usually present, although one may predominate) that persist for weeks or months. This persistent reactive distress is not adaptive and frequently requires psychiatric treatment. These disorders are classified in the current *Diagnostic and Statistical Manual of Mental Disorders Fourth Edition (DSM-IV)* (7) as adjustment disorders with depressed mood, anxiety, or mixed anxiety and depressed mood, depending on the major symptoms. For these patients, mental health professionals working in oncology use short-term supportive psychotherapy based on a crisis intervention model. This approach offers emotional support, provides information to help the patient adapt to the crisis, emphasizes past strengths, and supports previously successful ways of coping. Patients and their families are seen at least weekly, and anxiolytic or antide-pressant drugs are prescribed as indicated. As symptoms improve, medication can be reduced and discontinued. Having the patient talk with another patient who has been through the same treatment is often a helpful adjunct (8).

PREVALENCE OF PSYCHIATRIC DISORDERS IN PATIENTS WITH CANCER

There are many myths about the psychological problems of patients with life-threatening illness, the conclusions of which range from “all patients are distressed and need psychiatric help” to “none is upset and no one needs help.” One of the first efforts in the field of psychooncology was to obtain objective data on the type and frequency of psychological problems in cancer patients. These data are useful to plan for the provision of services and use of support staff in cancer centers and oncology units.

Using criteria from the *DSM-III* (9) classification of psychiatric disorders, the Psychosocial Collaborative Oncology Group (PSYCOG) determined the psychiatric disorders in 215 randomly selected hospitalized and ambulatory adult cancer patients in three cancer centers (10). Slightly over half (53%) of the patients evaluated were adjusting normally to stress; the remainder (47%) had clinically apparent psychiatric disorders. Of the 47% with psychiatric disorders, over two-thirds (68%) had reactive or situational anxiety and depression (adjustment disorders with depressed or anxious mood), 13% had a major depression, 8% had an organic mental disorder, 7% had a personality disorder, and 4% had a preexisting anxiety disorder. Thus, nearly 90% of the psychiatric disorders observed in this study were reactions to, or manifestations of, disease or treatment. Only 11% represented prior psychiatric problems, such as personality disorders or anxiety disorders. Comparable research in children is lacking, but clinical data appear to reflect a similar spectrum of problems. The physician who treats patients with cancer can expect, for the most part, to find a group of psychologically healthy individuals who are responding to the stresses posed by cancer and its treatment with symptoms that can be relieved with the short-term use of medication.

Disorders in Cancer Patients with Pain

In the PSYCOG study (10), 39% of those who received a psychiatric diagnosis were experiencing significant pain. In contrast, only 19% of patients who did not receive a psychiatric diagnosis had significant pain. The psychiatric diagnosis of the patients with pain was predominately adjustment disorder with depressed or mixed mood (69%); however, it is of note that 15% of patients with significant pain had symptoms of major depression. In a study of cancer pain syndromes, unmanaged pain emerged as a causal factor in patient's reports of increased anxiety (11,12).

Both data and clinical observation suggest that the psychiatric symptoms of patients who are in pain must initially be considered a consequence of uncontrolled pain. Acute anxiety, depression with despair (especially when the patient believes that pain means disease progression), agitation, irritability, uncooperative behavior, anger, and inability to sleep may be the emotional or behavioral concomitants of pain. These symptoms are not labeled as a psychiatric disorder unless they persist after pain is adequately controlled. Clinicians should manage pain (13) and then reassess the patient's mental state after pain is controlled, to determine whether the patient has a psychiatric disorder.

IMPACT OF DEPRESSION AND ANXIETY ON MANAGEMENT OF PATIENTS WITH CANCER

The timely diagnosis and effective management of depression and anxiety in cancer patients contribute not only to an improvement in quality of life but also enhanced

patient involvement in oncological treatment. A meta-analysis of the effects of depression and anxiety on compliance with medical treatment suggests that depressed patients are three times more likely to be noncompliant than nondepressed patients (14). Additionally, depression may impair patients' capacity to understand and process information about their prognosis (15).

SCREENING FOR PSYCHOLOGICAL DISTRESS IN PATIENTS WITH CANCER

The presence of psychological distress can have a significant impact on patients' lives. Despite this understanding, however, in the context of a busy oncology clinic, the focus on psychological symptoms is likely not paramount. Coupled with this time pressure is the concern on the part of many patients that alerting their health care providers to their psychological distress may divert their physicians from pursuing the most aggressive cancer regimen. To address this issue, brief pencil and paper screening measures such as the Hospital Anxiety and Depression Scale, the Zung Depression Scale, or a Visual Analog Scale measuring psychological distress can rapidly identify patients whose levels of distress warrant further evaluation (16,17). Teaching oncology staff members to use brief, semistructured interviews can improve their recognition of anxiety and depressive symptoms (18).

PREVALENCE OF DEPRESSION IN PATIENTS WITH CANCER

In De Florio and Massie's review of 49 studies, the prevalence of depression in cancer patients ranged from 1% to 53% (19). Most of this variance can be attributed to the lack of standardization of methodology and diagnostic criteria. For example, in a study of 152 oncology patients, Kathol and colleagues found a 13% difference (25% versus 38%) in the prevalence of depression depending on the diagnostic system used (20,21).

Using both *DSM-III* criteria, which were modified to eliminate physical symptoms characteristic of cancer, and validated depression rating scales, Bukberg and colleagues found a 42% (24% severe, 18% moderate) prevalence of depression among 62 (30 female, 32 male) patients hospitalized on oncology units (22), and Plumb and Holland found a 33% prevalence of depression among 80 (40 female, 40 male) hospitalized patients with advanced cancer (23). The Bukberg et al. finding of 42% prevalence of depression approximates the Kathol et al. finding of 38%, using the *DSM-III* criteria.

The existing data can answer many of the questions commonly asked about the prevalence of depression in patients with cancer: (a) Are there gender differences? (b) Are hospitalized patients more depressed than ambulatory patients? (c) Are those with advanced disease more depressed? In the aforementioned review of 49 studies (19), 29 included both males and females. Six studies did not examine or report gender differences, and the remaining 23 found no significant gender differences in the prevalence of depression.

Many clinicians believe that hospitalized patients with advanced cancer are more depressed than ambulatory patients. However, as more studies have been done over time, hospitalization status explains little of the large variance. Now, because of insurance restrictions, many seriously ill cancer patients who would have been hospitalized are treated in ambulatory settings.

Advanced disease has been correlated with a higher prevalence of depression in several studies. The reported prevalence of depression in patients with advanced cancer ranges from 23% (23) to 53% (24). Bukberg and colleagues found that greater physical disability measured by the Karnofsky Performance Status Scale was associated with depression in their study of 62 patients with cancer (22). Their 42% overall prevalence of depression reflected a range of 23%, in those with Karnofsky scores greater than 60, to 77% in those with Karnofsky scores <40.

Consultation data provide another source of information about depression in patients with cancer. At Memorial Sloan-Kettering Cancer Center, 59% of 546 consultations were requested for evaluation of depression, suicidal risk, or both (25). When the consultant's actual impressions were reviewed, depressive symptoms were by far the most common; adjustment disorders with depressed mood accounted for 54% of diagnoses, and major depression accounted for 9%. Breitbart reviewed data on 1080 consultation requests to the Psychiatry Service at the same institution and observed that evaluation of suicidal risk was the reason for referral in nearly 9% of referrals; suicide risk was found in 71 patients (6.5%) (26). One-third of the suicidal patients had a major depression, more than half had an adjustment disorder, and nearly 20% had a delirium or an organic brain syndrome.

DIAGNOSIS OF DEPRESSION IN PATIENTS WITH CANCER

The practice guidelines for depression developed both by the American Psychiatric Association (27) and the Agency for Health Care Policy and Research (28) are practical guides to the management of depression in adults. These guidelines provide an overview of depression in both physically healthy and medically ill patients.

The diagnosis of depression in physically healthy patients depends heavily on the presence of somatic symptoms, including anorexia, fatigue, insomnia, and weight loss. These indicators are of little value as diagnostic criteria for depression in cancer patients, as they are common to both cancer and depression. In cancer patients, the diagnosis of depression must depend on psychological, not somatic, symptoms. These psychological symptoms are dysphoric mood, feelings of helplessness and hopelessness, loss of self-esteem, feelings of worthlessness or guilt, anhedonia, and thoughts of death or suicide (29).

Mood Disorder Due to Cancer, Other Medical Conditions, or Substances

When evaluating depressed patients, it is imperative to determine whether organic factors underlie the depressive syndrome. A depressive syndrome caused by the direct physiological effects of cancer is called “mood disorder due to cancer” in the current *DSM-IV* nosology. Although the key feature of this disorder is a prominent and persistent depressed mood that resembles a major depression, the presence of encephalopathy precludes the diagnosis of mood disorder due to cancer unless depression had been diagnosed before confusional symptoms developed. The patient with a delirium due to cancer may have mild cognitive deficits, such as poor memory or decreased concentration, and may have decreased control over sexual or aggressive impulses. Tumor involvement of the central nervous system, metabolic disturbances, and the presumed organic processes associated with carcinoma of the pancreas may cause this disorder. The case of pancreatic carcinoma represents a special problem because it is often unclear whether depressive symptoms are due to an indirect effect of the cancer on the brain (possibly alteration of serotonergic function) or to a psychological reaction to this devastating cancer (30).

Among the metabolic causes of mood disorder due to cancer are electrolyte disturbances (e.g., hypercalcemia), endocrinopathies (e.g., hypothyroidism), and nutritional disorders (e.g., vitamin B12 deficiency). Infections may also be responsible (e.g., Epstein-Barr virus infection) (29).

DSM-IV defines disturbances in mood due to the direct physiological effects of a substance (i.e., a drug of abuse or a medication) as a “substance-induced mood disorder.” This diagnosis would be appropriate when depression is related to drug therapy such as b-adrenergic antagonists (31) (Table 40-1) or anticancer drugs, particularly corticosteroids, vinblastine sulfate, vincristine sulfate, procarbazine hydrochloride, asparaginase (32), tamoxifen citrate (33), or interferon (32) (Table 40-2).

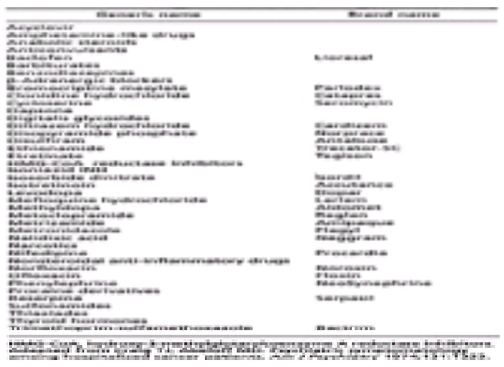

TABLE 40-1. DRUGS ASSOCIATED WITH DEPRESSIVE SYMPTOMS

Drug	Cancer
Corticosteroids	
Vinblastine sulfate	Breast, lung
Vincristine sulfate	All, brain
Interferon	Renal, Kaposi's sarcoma
Procarbazine hydrochloride	Brain
Asparaginase	All
Tamoxifen citrate	Breast
Cyproterone	Prostate

TABLE 40-2. ANTICANCER DRUGS ASSOCIATED WITH DEPRESSION

In the medically ill, the evaluation of every depressed patient must include a thorough medical, endocrinologic, and neurological assessment. A cognitive evaluation must be performed. Many clinicians prefer to use at least one easily reproducible instrument (e.g., the Mini-Mental State Examination) (34) to document mental status at the time of the initial evaluation and subsequent evaluations. All such brief instruments have limitations because they assess only selected aspects of cognition.

If the depressive disorder is believed to be caused by a medical condition or by a drug, the clinician should first attempt to treat the disorder or change the drug. Often, antidepressants are started concurrently in an effort to alleviate symptoms more quickly or because the clinician anticipates that the depression that complicates the underlying disorder will not be relieved by addressing the medical condition alone. When the primary cause of the depression cannot be corrected (e.g., the chemotherapeutic agent must be continued), antidepressant therapy is also initiated.

Depression with Psychotic Features

Although rare, depression accompanied by delusions, hallucinations, or grossly disorganized behavior is sometimes encountered in medically ill patients. In this population, the presence of depressive symptoms (e.g., flat affect, lack of interest in daily activities) coupled with psychotic symptoms more often reflects a delirium, and before the diagnosis of depression with psychotic features is made, the presence of underlying organic causes for these mental status changes should be explored. When psychotic features are present, an antipsychotic and an antidepressant are usually started concurrently. High-potency neuroleptics (e.g., haloperidol, olanzapine, and risperidone) are usually preferred because of their low anticholinergic potential, which reduces the risk of delirium and other anticholinergic side effects (e.g., cardiac arrhythmias, constipation, urinary retention, and blurred vision). These high-potency neuroleptics also lower seizure threshold less than low-potency neuroleptics (e.g., chlorpromazine and thioridazine) and are preferable when the risk of seizures is a concern. Molindone hydrochloride, an intermediate-potency neuroleptic, has been reported to have the lowest epileptogenic potential and may also be a good choice for a patient with psychotic symptoms and seizures that are difficult to control with anticonvulsants (35).

Depression in the Elderly

Older individuals are at greater risk for depression and suicidal acts, whether physically healthy or not. In addition to the loss of good health, the elderly cancer patient often has sustained other losses, including physical ability (e.g., hearing loss) and financial stability. Grief after the death of a spouse or friends may be unresolved, and self-esteem may be damaged through retirement or changed social standing. Although the clinical presentation of depression can be similar to that described for younger adult patients, other presentations are more typical of this phase of life (36). For example, the chief complaints may be cognitive, such as poor memory or concentration. By taking a thorough history and by interviewing relatives or friends to document the patient's history, the clinician learns that depressive features may antedate the cognitive complaints. When asked specific questions, the patient often says “I don't know” instead of attempting to answer. Objective testing (e.g., with the Mini-Mental State Examination) often reveals better results than those expected based on subjective complaints. This constellation is typical of the clinical syndrome *depressive pseudodementia* and often responds well to treatment with antidepressants.

Suicide

Suicidal ideation requires careful assessment to determine whether the patient has a depressive illness or is expressing a wish to have ultimate control over intolerable symptoms. Thoughtful clinical judgment is required to make this differentiation, especially in the patient with advanced disease. Breitbart (26) has outlined factors that place a cancer patient at a high risk for suicide as follows: poor prognosis and advanced illness; depression and hopelessness; uncontrolled pain; delirium; prior psychiatric history; history of previous suicide attempts or family history of suicide; history of recent death of friends or spouse; history of alcohol abuse; and few social supports. Other risk factors include male sex; advanced age (sixth and seventh decades); presence of fatigue; and oral, pharyngeal, lung, gastrointestinal, urogenital, and breast cancers (Table 40-3).

Related to mental status
Suicidal ideations
Lethal plans (hoarding medications)
Depression and hopelessness
Delirium and disinhibition
Psychotic features (hallucinations and delusions)
Loss of control and impulsivity
Irrational thinking
Related to cancer
Uncontrolled pain
Advanced disease and poor prognosis
Site (oral pharyngeal, lung, gastrointestinal, urogenital, breast)
Exhaustion and fatigue
Medication effects (steroids)
Related to history
Prior suicidal attempts
Psychopathology
Substance abuse (alcohol)
Recent loss (spouse or friends)
Poor social support
Older male
Family history of suicide

TABLE 40-3. SUICIDE RISK FACTORS IN CANCER PATIENTS

Cancer patients have twice the risk of actually committing suicide as the general population (37,38 and 39). Many factors, such as poor prognosis, delirium, uncontrolled pain, depression, and hopelessness, are often linked in a patient with advanced disease, together increasing the risk of suicide. Hopelessness is an even stronger predictive factor than depression itself (40). Cancer patients usually commit suicide by overdose with analgesics or sedative drugs prescribed by their doctors. Men use violent means, such as hanging or gunshot, more often than women.

The management of the suicidal cancer patient includes maintaining a supportive therapeutic relationship; conveying the attitude that much can be done to improve the quality, if not the quantity, of life even if the prognosis is poor; and actively eliciting and treating specific symptoms (e.g., pain, nausea, insomnia, anxiety, and depression). The most useful psychotherapeutic modalities are based on a crisis intervention model using cognitive techniques (e.g., giving back a sense of control by helping the patient to focus on that which can still be controlled) and supportive methods, usually involving family and friends. One should keep in mind that the spouse and other family members are also at increased risk for suicide and that they also often require evaluation and support (1).

At Memorial Sloan-Kettering Cancer Center, virtually all hospitalized patients who have attempted suicide have had poorly controlled pain, mild encephalopathy, disinhibition secondary to drugs, and hopelessness combined with distress about the inability to communicate their concerns about their discomfort to caregivers. If a patient is suicidal, a 24-hour companion is provided to establish constant observation, monitor the suicidal risk, and reassure the patient. Need for observation is evaluated daily; companions are discontinued when the patient is no longer suicidal and is judged to be in control and able to act rationally.

TREATMENT OF DEPRESSION

Before planning an intervention, the patient should be evaluated for a history of previous depressive episodes and substance (including alcohol and cocaine) abuse, family history of depression and suicide, concurrent life stresses, losses secondary to cancer (e.g., financial, social, and occupational), and the availability of social

support. An assessment of the meaning of illness to the patient and his or her understanding of the medical situation (including prognosis) is essential. Depressed patients with cancer are usually treated with a combination of supportive psychotherapy and antidepressants (8,29); electroconvulsive therapy (ECT) is used less often.

Psychological Treatment

The goals of psychotherapy are to reduce emotional distress and to improve morale, coping ability, self-esteem, sense of control, and resolution of problems (41). Cancer patients are often referred for, or request, psychiatric consultation at times of crisis in illness—at the time of diagnosis or diagnosis of recurrence, at the beginning of any new treatment, when standard or experimental treatments fail, or when patients perceive themselves as dying. The referral is often an emergency and, because of the acute crisis, the patient often readily accepts an intervention.

Various models of intervention for the acutely or chronically medically ill have been described, including timelimited dynamic psychotherapy, short-term dynamic therapy (42), and cognitive-behavioral therapy (43). Often, 4–15 sessions are required to treat the acute problem. The patient considers his or her recent losses (good health, body integrity, self-esteem, family support, presumed longevity, financial security, and opportunity for job satisfaction) in the context of a past history of loss or success, and is helped to chart a future direction that incorporates life and body alterations brought on by the diagnosis of a chronic lifethreatening illness. As mentioned above, the most useful model is based on a crisis intervention model that involves an active therapeutic role.

Brief psychoeducation interventions that orient patients and family members to the oncological setting and provide opportunities for questions can lead to reductions in anxiety and depression (44). Educational interventions, such as clarifying information and explaining emotional reactions to the patient, family, and staff, are useful. Cognitive techniques are also useful to help the patient correct misconceptions and exaggerated fears. Patients are encouraged to consider an array of different possible explanations or outcomes for their situation and then to determine which aspects they can still improve. This approach provides the patient with a sense of control over his or her situation and helps the individual to avoid focusing only on the worst eventualities.

Emotional support is also provided. Listening to the patient carefully and allowing him or her to express feelings, fears, and anger in a nonjudgmental setting is often therapeutic. Legitimization of the difficulty of the situation and of the right to be upset reduces the fear of being perceived as weak or inappropriate. Reassurances should be realistic and consistent with the available knowledge of the situation. The desire of patients to maintain hope is, of course, respected, as are the defense mechanisms of denial, repression, and regression, as long as these do not interfere with diagnostic or therapeutic processes or with important personal matters that must be addressed. As the patient's history of loss is explored, the clinician identifies and reinforces his or her successful ways of coping. At the termination of psychotherapy, patients are reassured to hear that the clinician is available for future visits if symptoms recur or if the disease worsens (1).

Another important aspect of the treatment of the depressed cancer patient is social support provided by family, friends, and community or religious groups. Although family is enlisted to provide emotional support, family members must be encouraged to minimize family conflicts, which add an additional emotional burden and can be addressed more appropriately after the depression has resolved. This process may also identify vulnerable family members who cannot provide emotional support and indeed may also need psychosocial help. These family members are encouraged to seek individual or group support for themselves.

Drug Therapies

Antidepressants

Although there are many reports of the efficacy of antidepressants in depressed patients with cancer (45,46 and 47), there is only one double-blind, placebo-controlled study (48) demonstrating efficacy. This observation reflects the difficulty in conducting controlled studies of drugs in medically ill cancer patients. Nonetheless, there is much clinical experience with antidepressant drugs in this population. The antidepressant agents that can be considered for use in cancer patients are (a) the newer agents, including selective serotonin reuptake inhibitors (SSRIs); (b) tricyclic antidepressants (TCAs); (c) psychostimulants; (d) lithium carbonate; and (e) the monoamine oxidase inhibitors (MAOIs) (49) (Table 40-4).

Drug	Starting daily dosage, mg (p.o.)	Therapeutic daily dosage, mg (p.o.)
Newer agents		
Serotonin reuptake inhibitors		
Fluoxetine hydrochloride	20	20–60
Sertraline hydrochloride	50	50–150
Paroxetine hydrochloride	10	10–50
Citalopram hydrobromide	10	10–50
Others		
Amoxapine	25	100–150
Maprotiline hydrochloride	25	75–150
Trazodone hydrochloride	50	150–300
Bupropion hydrochloride	75	200–300
Venlafaxine hydrochloride	18.75	75–225
Nefazodone hydrochloride	50	50–300
Mirtazapine	15	15–45
Tricyclic antidepressants		
Amitriptyline hydrochloride	25	50–150
Doxepin hydrochloride	25	50–200
Imipramine hydrochloride	25	50–200
Desipramine hydrochloride	25	50–150
Nortriptyline hydrochloride	25	50–150
Protriptyline hydrochloride	20	10–30
Psychostimulants		
Dextroamphetamine	2.5 at 8 a.m. and noon	5–30
Methylphenidate hydrochloride	2.5 at 8 a.m. and noon	5–30
Pemoline	18.75 at a.m. and at noon	37.5–150
Monoamine oxidase inhibitors		
Isocarboxazide	10	20–40
Phenelzine sulfate	15	60–90
Tranylcypromine sulfate	10	20–60
Lithium carbonate	300	600–1200
Benzodiazepine		
Alprazolam	0.25–1.00	0.75–4.00

TABLE 40-4. ANTIDEPRESSANT MEDICATIONS USED IN CANCER PATIENTS

Newer Antidepressants

The SSRIs fluoxetine hydrochloride, sertraline hydrochloride, paroxetine hydrochloride, and citalopram hydrobromide are often prescribed first because they have fewer sedative and autonomic effects than TCAs. The most common side effects are nausea, headache, somnolence or insomnia, and a brief period of increased anxiety; hyponatremia is an uncommon adverse effect (50). These drugs can cause appetite suppression that usually lasts a period of several weeks, but the anorectic properties of these drugs have not been a limiting factor in this population. Paroxetine hydrochloride has no active metabolites, and sertraline hydrochloride has fewer than fluoxetine hydrochloride; both have a shorter half-life than fluoxetine hydrochloride. Their characteristics reduce the risk of accumulation during dose finding and allow more precise titration. Paroxetine hydrochloride has demonstrated effectiveness in the management of depression in patients with malignant melanoma receiving high-dose interferon-a (51).

Bupropion hydrochloride, trazodone hydrochloride, maprotiline hydrochloride, amoxapine, venlafaxine hydrochloride, nefazodone hydrochloride, and mirtazapine are prescribed less frequently than the SSRIs. Bupropion hydrochloride is considered if patients have a poor response to a reasonable trial of other antidepressants. It may be somewhat activating in medically ill patients and should be avoided in patients with seizure disorders, brain tumor, other factors that predispose to seizures, or malnutrition. Trazodone hydrochloride is strongly sedating and in low doses (100 mg at bedtime) is helpful in the treatment of the depressed cancer patient with insomnia. Effective antidepressant doses are often greater than 300 mg/day. Trazodone hydrochloride has been associated with priapism and should therefore be used with caution in men. Maprotiline hydrochloride should be avoided in patients at high risk for seizures. Amoxapine has strong dopamine-blocking activity; hence, patients taking other dopamine blockers (e.g., antiemetics) have an increased risk of developing extrapyramidal symptoms and dyskinesias. Venlafaxine hydrochloride is a selective inhibitor of uptake pumps for both serotonin and norepinephrine. In addition to antidepressant effects, venlafaxine hydrochloride, along with many of the SSRIs, is useful in the management of autonomic instability hot flashes in women with chemotherapy-induced menopausal symptoms. Nefazodone hydrochloride is structurally similar to trazodone hydrochloride and requires a twice-a-day dosing schedule. Mirtazapine does not block the reuptake of neurotransmitters but rather acts as an antagonist that increases noradrenergic and serotonergic activity. In low doses it is effective for treatment of insomnia and loss of appetite; in higher doses it is more activating and has greater antidepressant effects. Additionally, it may have antiemetic effects (52).

When treating depression in the elderly, medications are started at a low dose, and the dosage is increased more slowly than with a younger adult patient. Also, drugs with few anticholinergic effects are preferred due to greater sensitivity of the elderly to anticholinergic complications (e.g., delirium, urinary retention, and cardiac arrhythmias) (53).

The use of herbal supplements has increased in the population in general and in patients with cancer specifically. Many of these supplements (e.g., kava, valerian, St. John's wort, hops, lemon balm, and SAM-e) have potential interactions with psychotropic medications. For example, kava interacts with benzodiazepines; St. John's wort and SAM-e interact with antidepressants; and hops, valerian, and lemon balm interact with central nervous system depressants. Jenkins et al. have compiled and synthesized current understanding about the potential impact of these herbal supplements (54).

In contrast to adults, there are no clear data to support the efficacy of antidepressants in children (55). Nevertheless, clinicians often find it helpful to prescribe antidepressants to treat specific symptoms associated with depression. When the target symptoms are insomnia, poor appetite, or anxiety, a sedative TCA (e.g.,

amitriptyline hydrochloride or doxepin hydrochloride) is usually prescribed. When the clinical picture is dominated by lack of energy or motivation, an SSRI or an energizing tricyclic, such as desipramine hydrochloride, may be selected. As in the elderly, these drugs are started at a low dose.

Tricyclic Antidepressants

TCAs are still used in the oncology setting for both adults and children with cancer. Dosing is typically initiated at 10–25 mg at bedtime, especially in debilitated patients, and the dose is increased by 25 mg every 1–2 days until beneficial effect is achieved. For reasons that are unclear, depressed cancer patients often show a therapeutic response to a tricyclic at much lower doses (75–125 mg daily) than are usually required in physically healthy depressed patients (150–300 mg daily). Patients are usually maintained on a TCA for 4–6 months after symptoms improve, after which time the dose is gradually lowered and discontinued (49). The effects on appetite and sleep are frequently immediate; the effects on mood may be delayed.

The choice of TCA depends on the nature of the depressive symptoms, medical status, and side effects of the specific drug. The depressed patient who is agitated and has insomnia benefits from the use of a TCA that has sedating effects, such as amitriptyline hydrochloride or doxepin hydrochloride. Patients with psychomotor slowing benefit from use of the compounds with the least sedating effects, such as protriptyline hydrochloride or desipramine hydrochloride. The patient who has stomatitis secondary to chemotherapy or radiotherapy, or who has slow intestinal motility or urinary retention, should receive a TCA with the least anticholinergic effects, such as desipramine hydrochloride or nortriptyline hydrochloride.

Patients who are unable to swallow pills may be able to take an antidepressant in an elixir (amitriptyline hydrochloride, nortriptyline hydrochloride, or doxepin hydrochloride) or in an intramuscular form (amitriptyline hydrochloride or imipramine hydrochloride). Hospital pharmacies can prepare some TCAs (e.g., amitriptyline hydrochloride) in rectal suppository form, but absorption by this route has not been studied in cancer patients. Intramuscular administration causes discomfort because of the volume of the vehicle; hence, 50 mg is usually the maximum dosage that can be delivered per intramuscular injection. Parenteral administration of TCAs may be considered for the cancer patient who is unable to tolerate oral administration because of impaired swallowing, the presence of gastric or jejunal drainage tubes, or intestinal obstruction. Although three TCAs (amitriptyline hydrochloride, imipramine hydrochloride, and clomipramine hydrochloride) are available in injectable form, the U.S. Food and Drug Administration has approved imipramine hydrochloride and amitriptyline hydrochloride for oral and muscular administration and clomipramine hydrochloride for oral use only. Formal informed consent and close monitoring of the electrocardiogram is recommended when these medications are used intravenously.

Imipramine hydrochloride, doxepin hydrochloride, amitriptyline hydrochloride, desipramine hydrochloride, and nortriptyline hydrochloride are used frequently in the management of neuropathic pain in cancer patients. Dosing is similar to that in the treatment of depression. Analgesic efficacy, if it occurs, is usually observed at a dose of 50–150 mg daily; higher doses occasionally are needed. Although the initial assumption was that analgesic effect resulted indirectly from the effect on depression, it is now clear that these tricyclics have a separate specific analgesic action, which is probably mediated through several neurotransmitters, most prominently norepinephrine and serotonin (56).

Lithium Carbonate

Patients who have been receiving lithium carbonate for bipolar affective disorder before cancer should be maintained on it throughout cancer treatment, although close monitoring is necessary when the intake of fluids and electrolytes is restricted, such as during the preoperative and postoperative periods. The maintenance dose of lithium carbonate may need reduction in seriously ill patients. Lithium carbonate should be prescribed with caution in patients receiving cisplatin due to potential nephrotoxicity of both drugs.

Although several authors have reported that the leukocytosis produced by lithium carbonate could be beneficial in neutropenic cancer patients (57,58), the functional capabilities of these leukocytes have not been determined. The bone marrow stimulation appears to be transient. In patients without prior affective disorder, lithium carbonate does not produce mood changes.

Monoamine Oxidase Inhibitors

If a patient has responded well to an MAOI for depression before treatment for cancer, its continued use is warranted. Most psychiatrists, however, are reluctant to start depressed cancer patients on MAOIs because the need for dietary restriction is poorly received by patients who already have dietary limitations and nutritional deficiencies secondary to cancer illness and treatment.

Psychostimulants

In cancer patients, the psychostimulants (i.e., dextroamphetamine, methylphenidate hydrochloride, and pemoline) promote a sense of well-being, decrease fatigue, and stimulate appetite (59,60). An advantage of these drugs is a rapid onset of antidepressant action compared with that of the TCAs. Psychostimulants can potentiate the analgesic effects of opioid analgesics and are commonly used to counteract opioid-induced sedation (61). Occasionally they can produce nightmares, insomnia, and even psychosis.

Treatment with dextroamphetamine and methylphenidate hydrochloride is usually initiated at a dose of 2.5 mg at 8 a.m. and noon. Pemoline, a chewable and less potent psychostimulant, is usually initiated at a dose of 18.75 mg at 8 a.m. The dose and dosing interval should be adjusted to optimize effects. Typically, patients are maintained on a psychostimulant for 1–2 months, after which time approximately two-thirds are able to be withdrawn without a recurrence of depressive symptoms (62). Those who develop recurrence of depressive symptoms can be maintained for long periods (e.g., >1 year). Tolerance may develop, requiring dose adjustments. Pemoline should be used with caution in patients with renal impairment; liver function tests should be monitored periodically with longterm treatment (63).

Electroconvulsive Therapy

ECT is indicated for medically ill patients who are depressed and are refractory to antidepressants, or have depression with psychotic or dangerously suicidal features. Patients who have significant contraindications to treatment with antidepressant drugs are also considered for this approach. The safe and effective use of ECT in the medically ill has been reviewed by others (64).

PREVALENCE OF ANXIETY IN PATIENTS WITH CANCER

Cancer disrupts the social roles of patients, their interpersonal relationships, and the ways in which they view their future (65); most people who have cancer are both fearful and sad. In the general population, anxiety is associated with female gender, younger age, and lower socioeconomic status (66). These patterns do not appear in cancer patients, suggesting that demographic factors may become less important in disease-related anxiety. Evaluation of anxiety symptoms is a frequent reason for psychiatric consultation in the oncology setting, accounting for 16% of requests in one study (25). In this study (25), 25% of patients were diagnosed as having either an anxiety disorder (4%) or an adjustment disorder with anxious mood (21%); in contrast, 57% were diagnosed as having either major depression (9%) or an adjustment disorder with depressed mood (48%). In the PSYCOG study, approximately 21% of the sample had symptoms of anxiety (10), and in several controlled studies cancer patients have been found to have higher levels of anxiety than healthy individuals. Patients with cancer are approximately twice as likely to have severe anxiety compared to controls (67,68). For example, 27% of women undergoing mastectomy had moderate to severe anxiety compared to 14% of controls, and 28% of advanced melanoma patients were anxious in comparison to 15% of controls.

Most studies of psychiatric symptoms in cancer patients have reported a higher prevalence of mixed anxiety and depressive symptoms than anxiety alone (10). Correlations between measures of depression and anxiety on both clinician-rated (69) and self-report measures (70) are high. In all likelihood, this observation indicates that these measures tap a common psychological trait: negative affect (71).

Anxiety increases with the diagnosis of cancer, peaks before surgical interventions, and frequently remains high thereafter, declining gradually during the first postoperative years (67). Others have reported that anxiety increases as cancer progresses, and psychological health declines along with the decline in physical status (70,72). Chemotherapy administration is a source of anxiety that may develop into a conditioned anticipatory response, which may persist for years after the cessation of the chemotherapy (73,74 and 75). Radiotherapy treatment is also associated with increased anxiety, accompanied by concerns about increased bodily vulnerability and worries about whether the radiation will cause further bodily damage (76). The anxiety experienced during chemotherapy and radiation therapy may paradoxically increase at the termination of treatment, as patients feel unprotected, see their physician(s) less often, and worry about the effectiveness of treatment. Patients who are participating in clinical trials and feel that they have been randomized to a less aggressive treatment modality may also experience increased anxiety (77).

DIAGNOSIS OF ANXIETY IN PATIENTS WITH CANCER

A small percentage of cancer patients have anxiety disorders that antedate the diagnosis of cancer and are exacerbated by the stress associated with cancer diagnosis or treatment (78). For most patients, anxiety symptoms are reactions to cancer and its treatment and are associated with feelings of foreboding, apprehension, or dread. Although anxiety symptoms can be either cognitive or somatic, the most salient symptoms are usually somatic and include tachycardia, shortness of breath, sweating, abdominal distress, and nausea. Loss of appetite, diminished libido, and insomnia, symptoms also associated with depression, are common in patients with anxiety, as are feelings of hyperarousal and irritability. In patients with panic attacks, symptoms related to increased autonomic discharge increase dramatically.

In addition to somatic symptoms, the anxious cancer patient is often plagued with recurrent unpleasant thoughts about cancer, including fears of death, disfigurement, disability, and dependency. The thinking style of the anxious patient is characterized by overgeneralization and catastrophizing; negative outcomes seem inevitable, and patients view themselves as helpless in a hopeless situation. Anxious patients may see their environment as threatening and often are motivated to flee, a reaction that commonly precipitates treatment refusals or demands for premature hospital discharge (78).

Phobia, Panic Disorders, Generalized Anxiety Disorder, and Posttraumatic Stress Disorder

Phobias, panic disorder, posttraumatic stress disorder (PTSD), and generalized anxiety disorder may antedate the diagnosis of cancer or first appear as patients are diagnosed and undergo cancer treatment. Because they cause extreme distress and have the potential to interfere with adequate medical management, it is important to accurately diagnose and treat these anxiety disorders (79).

There is a range of phobias that can be exacerbated by exposure to the medical environment—phobias about needles, blood, hospitals, and doctors are common. The common characteristic of all phobias is extreme anxiety on exposure to a feared object(s) or situation(s), and a persistent anxiety in the anticipation of these situations. Agoraphobia (the most common phobia in the general population) and claustrophobia may appear *de novo* in patients who are confined in the frightening hospital environment without their usual environmental supports. Patients who require magnetic resonance imaging or radiation therapy or who must be confined in intensive care or reverse-isolation settings frequently experience increased anxiety (80).

Although usually diagnosed before cancer, panic disorders can present in the context of a cancer diagnosis (81). In contrast to phobias, in which there is a clearly defined situation or object of dread, panic disorder often presents as sudden, unpredictable episodes of intense discomfort and fear, accompanied by shortness of breath, diaphoresis, tachycardia, feelings of choking or being smothered, and thoughts of impending doom. Symptoms of a preexisting panic disorder may intensify during cancer treatment; severe untreated symptoms may result in abrupt termination of cancer treatment. In contrast to panic disorder, generalized anxiety disorder is characterized by continuous and pervasive worry, difficulty in controlling the worry or apprehension, and the presence of symptoms of autonomic hyperactivity and hypervigilance.

In addition to heightened psychological distress associated with cancer treatment, cancer patients may experience the symptoms characteristic of PTSD after the completion of treatment. This disorder is similar to that reported by individuals who have been subjected to other types of trauma (e.g., combat, rape, or natural disaster) (82). In one study almost half (48%) of a group of cancer survivors reported symptoms related to PTSD, with 4% meeting the criteria for current PTSD diagnosis and 22% meeting the criteria for a lifetime diagnosis of PTSD (83). Patients with this disorder may repeatedly reexperience frightening events associated with their cancer diagnosis or treatment and have a chronic exaggerated startle response, nightmares, or autonomic hyperactivity.

Anxiety Disorder Due to Cancer, Other Medical Conditions, or Substances

Anxiety in cancer patients may be caused or exacerbated by medications used to treat cancer or other conditions, abnormal metabolic states, or uncontrolled pain. Anxiety may also be conditioned by events related to chemotherapy or radiation therapy. Although previous diagnostic nosologies did not allow for the classification of anxiety symptoms resulting from medically related causes, the *DSM-IV* (7) has included the diagnostic categories of anxiety disorder due to a medical condition (e.g., cancer) and substanceinduced anxiety disorder.

Some drugs, such as the corticosteroids, can produce anxiety, and others (e.g., neuroleptics) can cause restlessness and agitation that is described as anxiety by the patient. The akathisia produced by neuroleptics (e.g., metoclopramide and prochlorperazine), for example, is frequently misdiagnosed as anxiety (84). Drug intoxication (e.g., cocaine) and withdrawal symptoms (e.g., from alcohol, benzodiazepines, or opioids) also have anxiety as a common symptom. Bronchodilators, b-adrenergic drugs, and psychostimulants (including caffeine) can cause anxiety, irritability, and tremulousness. Thyroid replacement medication can produce symptoms of anxiety, especially when the dosage is being adjusted (85).

Metabolic disturbances such as hypoglycemia, hypoxia, and undetected anemia may be manifested by symptoms of anxiety, restlessness, and agitation, followed by confusion and disorientation. Encephalopathy associated with systemic infection and the remote effects of specific tumors (pancreatic [86], thyroid [87], pheochromocytomas [88], and parathyroid [89]) may also result in high levels of anxiety. Some patients with central nervous system neoplasms report anxiety as a prominent symptom (90).

Chemotherapy and radiation therapy can be associated with increased anxiety. Repeated exposures to highly emetogenic chemotherapeutic agents may lead to the development of anticipatory nausea and vomiting (ANV), a conditioned response to environmental cues (e.g., the sight of the hospital or the smell of the alcohol swabs) that surround the chemotherapy experience. There is evidence that ANV may be linked to a preexisting anxiety diathesis and may persist for years after the cessation of chemotherapy (75,91). Patients undergoing radiation therapy may experience a level of apprehension and anxiety that may persist as treatment progresses (92). Worsening side effects and the fear associated with the cessation of treatment may perpetuate the anxiety. The psychological distress associated with radiation therapy may exceed the physical distress resulting from the treatment itself (93,94 and 95).

Anxiety as a Manifestation of Other Psychiatric Disorders

In the medically ill, anxiety may be a manifestation of either depression or delirium. Increasingly, depression and anxiety are viewed as syndromes existing on a continuum; there is an overlap in the symptomatology between these two mood states. Depression may be distinguished from anxiety by the presence of the psychological symptoms such as hopelessness, anhedonia, worthlessness, and suicidal ideation. Delirium frequently has anxiety or restlessness as a prominent feature but is distinguished from anxiety by the presence of disorientation, impaired memory and concentration, fluctuating level of consciousness, and altered perceptions, including hallucinations and delusions (96).

TREATMENT OF ANXIETY

The most effective management of anxiety in cancer patients is multimodal, including psychotherapy, behavioral therapy, and pharmacological management. During the initial evaluation of the patient's symptoms, both emotional support and information are given to the patient (97). Exploration of the patient's fears and apprehensions about disease progression, upcoming procedures, or psychosocial concerns often alleviates a substantial degree of the anxiety. Patient concerns usually include death, physical suffering, increased dependence, changes in social role functioning, spiritual matters, and worry about finances or employment (98).

Psychological Treatment

Relatively short-term psychological interventions have proven to be effective in reducing the distress associated with cancer (99). The efficacy of psychological treatments without the use of drugs depends on the duration and severity of the patient's anxiety. In the case of mild to moderate anxiety, the use of psychological techniques alone may be sufficient (100). In addition to effectively treating distress in patients presenting with anxiety, a meta-analysis of psychological interventions suggests that these interventions, such as cognitive-behavioral techniques, can effectively prophylax against the development of anxiety in patients diagnosed with cancer (101).

Careful patient selection is important for the success of psychological approaches. Cancer patients most likely to benefit from psychological interventions are those who have anxiety that has not been controlled by other means, have a need for self-control and are reluctant to take medication, and have experienced or acknowledge the efficacy of such approaches. Individuals who are poor candidates for psychological approaches are those who have delirium or dementia, are disinterested or demonstrate noncompliance in learning to use psychological techniques, and have a history of serious psychiatric illness (102).

The psychological interventions for anxiety in cancer patients comprise four categories: psychoeducational, behavioral, cognitive-behavioral, and group interventions (103). In general, the most effective treatment programs for anxiety involve a treatment package that includes a variety of behavioral, cognitive-behavioral, and psychoeducational techniques (104).

Psychoeducational interventions are particularly useful for anxious cancer patients who have difficulty understanding medical information about their prognosis and

planned procedures and treatments. As patients begin surgical, chemotherapeutic, or radiotherapeutic interventions, providing information about predictable side effects helps to normalize the experience and reduce anxiety (105,106). Similarly, explaining the predictable emotional phases associated with cancer may alleviate anxiety. Providing information to a patient's family can improve the coping of family members, which in turn enhances the patient's sense of support (2,107).

The rationale for the use of behavioral techniques, including relaxation training, guided imagery, or hypnotherapy, is the substitution of more adaptive behavior (e.g., increased coping ability) for less adaptive behavior (e.g., anxiety). Progressive relaxation involves instructing the patient to sequentially relax parts of the body through either tensing and relaxing the muscle groups (active muscle relaxation) or through concentrating on relaxing parts of the body without tensing the muscles (passive muscle relaxation). Both approaches are effective in reducing anxiety, although in medically debilitated patients passive relaxation may be more manageable (108). Relaxation has been demonstrated to be effective in the management of anxiety in cancer patients, and when compared to alprazolam, relaxation was found to be only slightly less effective (109,110 and 111). Guided imagery is a component of a progressive relaxation training program, and a behavioral treatment that includes both guided imagery and relaxation has been demonstrated to be more effective in lowering distress than either component alone (112,113). Hypnosis can be effective in the management of psychological distress associated with procedures (114) and in the management of treatment-related side effects such as ANV and pain. Desensitization, response prevention, thought stopping, modeling, and distraction are other behavioral techniques that may be useful in the management of anxiety and phobias (102).

Behavioral techniques have also been demonstrated to be effective in the treatment of ANV. As noted previously, ANV appears to be correlated with preexisting trait anxiety (91) and with state anxiety at the time of the chemotherapy infusions (115). Progressive muscle relaxation has been shown to decrease nausea and vomiting, as well as anxiety, in patients who are receiving emetogenic chemotherapy (109,112,116). An approach to ANV that combines behavioral approaches and a cognitive approach in which the patient's thoughts and feelings about chemotherapy are explored and modified may be most effective (117).

Individual psychotherapy (103), including cognitivebehavioral approaches (118), can be effective in the treatment of cancer-related anxiety. According to the cognitivebehavioral model, emotional distress arises or continues because of maladaptive beliefs and thinking patterns. Patients are encouraged to identify these maladaptive thoughts, reconsider them more logically, and experiment with alternative viewpoints and behaviors that give them greater control over their situation. Adjuvant psychological therapy is a structured cognitive-behavioral intervention that teaches patients to identify negative thoughts, rehearse impending stressful events, implement ways of handling them more effectively, plan and carry out practical activities that create a sense of mastery, express feelings openly to one's partner, and increase both self-esteem and a fighting spirit by identifying and fostering personal strengths (119). Follow-up studies of this intervention have consistently demonstrated significantly lower scores on anxiety and psychological distress as compared to controls (119,120). When compared to nondirective supportive counseling, adjuvant psychological therapy produced greater reductions in levels of anxiety in cancer patients (121).

Group interventions have also been shown to reduce psychological distress in cancer patients (103). These interventions have benefited patients with a variety of cancer diagnoses (122) and stages of cancer (123). In one study, patients who participated in support groups for at least a year reported less tension than did controls (123). The techniques employed in these groups included fostering a sense of supportive commonality among the members, education, emotional support, stress management, coping strategies, and behavioral training.

Pharmacological Treatment

Although a significant percentage of patients with advanced cancer receive antianxiety drugs (124), the severity of symptoms is the most useful guide in deciding whether a pharmacological approach to the management of anxiety should be tried. Patients with mild reactive anxiety may benefit from either supportive measures or behavioral measures alone.

For patients who experience persistent apprehension and anxiety, the first-line drugs are the benzodiazepines (Table 40-5). Lorazepam (0.25–2.00 mg four times daily) and alprazolam [0.25–1.00 mg t.i.d. (three times daily)] are useful for anxiety and other indications, such as nausea (lorazepam) and panic (alprazolam). Both lorazepam and alprazolam have been shown in controlled trials to reduce postchemotherapy nausea and vomiting, as well as ANV (125,126). Lorazepam also has amnestic properties; when given before chemotherapy or a procedure, this effect may reduce the likelihood that a conditioned aversion will develop (127). A longer-acting benzodiazepine, such as clonazepam (0.5–1.0 mg twice daily), may provide more consistent relief of anxiety symptoms and have mood-stabilizing effects as well. For insomnia, the benzodiazepines temazepam (15–30 mg qhs) and triazolam (0.25–0.50 mg qhs), as well as the non-benzodiazepine hypnotics zolpidem tartrate (10–20 mg qhs) and zaleplon (10 mg qhs), may be effective. Nonsedating neuroleptics such as haloperidol (5 mg qhs) or olanzapine (2.5–5.0 mg qhs) may be more effective for the patient who is both anxious and confused. For patients with compromised hepatic function, the use of shorter-acting benzodiazepines, such as lorazepam, oxazepam, and temazepam, is preferred; these drugs are metabolized by conjugation with glucuronic acid and have no active metabolites.

Drug	Approximate dose equivalent	Starting daily dose, mg (p.o.)	Absorption	Metabolites
Benzodiazepines				
Alprazolam	0.5	0.25–1.00 t.i.d.	Intermediate	Yes
Diazepam	10	10–15 t.i.d.	Slow/intermediate	No
Lorazepam	1	0.5–2.0 t.i.d.	Intermediate	No
Chlordiazepoxide	10	10–25 t.i.d.	Intermediate	Yes
Diazepam	5	2.0–10 b.i.d.	Fast	Yes
Clorazepate	7.5	7.5–15.0 b.i.d.	Fast	Yes
Clonazepam	0.25	0.25–1.00 b.i.d.	Intermediate	Yes
Temazepam	30	15–30 qhs	Intermediate	No
Triazolam	0.25	0.25–0.50 qhs	Intermediate	No
Antihistamines				
Hydroxyzine	10	10–50 t.i.d.		
Diphenhydramine hydrochloride	25	25–50 t.i.d.		
Neuroleptics				
Haloperidol	0.5	0.5–2.0 b.i.d.		
Thioridazine	10	10–50 t.i.d.		
Olanzapine	5			
Other				
Zolpidem tartrate	10	10–20 qhs		

b.i.d., twice daily; qhs, at bedtime; t.i.d., three times daily.

TABLE 40-5. ANTIANXIETY MEDICATIONS USED IN CANCER PATIENTS

Drowsiness and somnolence are the most common adverse effects of benzodiazapines. Reductions in dose and the passage of time eliminate these effects. Mental status changes, such as impaired concentration, memory, or delirium, may result from benzodiazepine usage and are more common in elderly patients, those with advanced disease, and those with impaired hepatic function.

Structurally unlike other anxiolytics, buspirone hydrochloride (5–20 mg t.i.d.) is useful for patients with generalized anxiety disorder as well as those in whom there is the potential for benzodiazepine abuse. Buspirone hydrochloride is not effective on an as-needed basis; its effects are not apparent for 1–2 weeks. Additionally, patients who have been prescribed benzodiazepines in the past may find that buspirone hydrochloride does not alleviate their anxiety as effectively as benzodiazepines.

For the treatment of panic disorder and agoraphobia, the benzodiazepine alprazolam and antidepressant medications (TCAs, SSRIs, and MAOIs) have demonstrated effectiveness. Although alprazolam rapidly blocks panic attacks, withdrawal can be difficult after prolonged use. The TCA imipramine hydrochloride is often used for panic disorder; its anticholinergic side effects, however, are not well tolerated by debilitated cancer patients. In the oncology setting, the SSRIs sertraline hydrochloride and paroxetine hydrochloride, which have fewer side effects than the TCAs, are effective in the management not only of depression but also of panic disorder (128). Although MAOIs are effective in the management of panic disorder and depression, the risk of hypertensive crisis from concomitant ingestion of drugs or tyramine-containing foods make these medications less desirable for cancer patients.

In anxious patients with severely compromised pulmonary function, the use of benzodiazepines that suppress central respiratory mechanisms may be unsafe. A low dose of an antihistamine (e.g., hydroxyzine, 10–50 mg t.i.d.) can be useful for these individuals.

CONCLUSION

Depression and anxiety are common symptoms in cancer patients. These symptoms warrant evaluation and the use of pharmacological and psychosocial interventions to relieve suffering. Psychological distress should not be regarded as an unavoidable consequence of cancer.

SUBSTANCE ABUSE ISSUES IN PALLIATIVE CARE

STEVEN D. PASSIK
KENNETH L. KIRSH
RUSSELL K. PORTENOY

In the palliative care setting, the occurrence of substance abuse poses a complex clinical challenge. Some patients have a known history of addiction to illicit drugs or prescription medications, and some seek care while active abuse is evident. In these cases, drug use must be controlled as part of a comprehensive care plan. In other cases, the challenge relates to management of less egregious aberrant drug-taking behaviors in patients without known substance use disorders. When, for example, a patient with advanced disease and pain unilaterally escalates drug doses, uses analgesics to treat other symptoms, or gives prescriptions to others, the clinician must assess the behavior, understand the implications, and plan accordingly. Thus, the problem of chemical dependency in the medically ill spans a continuum from formal psychiatric disorders to problematic behaviors in the absence of these disorders.

With the pressure of regulatory scrutiny and the duty to treat pain but contain opioid abuse or diversion, clinicians may believe that they must avoid being duped by those abusing prescription pain medications at all costs. Although the differential diagnosis of aberrant drug-related behavior is complex, clinicians who hold this view tend to simplify the clinical implications to “addiction” or “not addiction.” This is not in the best interests of either the patient or the clinician. If the fear of regulatory oversight makes practitioners feel as if they must be right—that they have to “see through” the patient's or family's denials to guard against the possibility of being duped—undertreatment and avoidance of prescribing can result. This unfortunate outcome is not demanded by existing laws or guidelines. The clinician has an obligation to be thorough, thoughtful, logically consistent, and careful (not to mention humane and caring), but not necessarily right. Clinical management can be tailored for the multiple possibilities that might be giving rise to the behaviors noted in the assessment, and asserting control over prescriptions can be accomplished without necessarily terminating the prescribing of controlled substances entirely. Although these situations defy simple solutions, knowledgeable clinicians can implement strategies that simultaneously address the need for compassionate care and management of problematic drug use.

PREVALENCE OF ILLICIT DRUG USE

Approximately one-third of the population in the United States has used illicit drugs and an estimated 6–15% have a substance use disorder of some type (1,2 and 3). As a result of this high prevalence, and the association between drug abuse and life-threatening diseases such as acquired immunodeficiency syndrome (AIDS), cirrhosis, and some types of cancer (4), problems related to abuse and addiction are encountered commonly in palliative care settings. In diverse patient populations with progressive life-threatening diseases, a remote or current history of drug abuse presents a constellation of stigmatizing physical and psychosocial issues that can both complicate the management of the underlying disease and undermine palliative therapies. Clearly, the interface between the therapeutic use of potentially abusable drugs and the abuse of these drugs is complex and must be understood to optimize palliative care.

Substance abuse appears to be very uncommon within the tertiary care population with cancer. In 1990, only 3% of inpatient and outpatient consultations performed by the Psychiatry Service at Memorial Sloan-Kettering (MSK) Cancer Center were requested for management of issues related to drug abuse. This prevalence is much lower than the prevalence of substance use disorders in society at large, in general medical populations, and in emergency medical departments (1,2,5,6 and 7). A relatively low prevalence was also reported in the Psychiatric Collaborative Oncology Group study, which assessed psychiatric diagnoses in ambulatory cancer patients from several tertiary care hospitals (6). After structured clinical interviews, fewer than 5% of 215 cancer patients met the *Diagnostic and Statistical Manual for Mental Disorders-III* criteria for a substance use disorder (8).

The relatively low prevalence of substance abuse among cancer patients treated in tertiary care hospitals may reflect institutional biases or a tendency for patient underreporting in these settings. Many drug abusers are poor, feel alienated from the health care system, may not seek care in tertiary centers, and may be disinclined to acknowledge the stigmatizing history of drug abuse. For all these reasons, the low prevalence of drug abuse in cancer centers may not be representative of the true prevalence in the cancer population overall. In support of this conclusion, a recent survey of patients admitted to a palliative care unit observed findings indicative of alcohol abuse in over 25%. Additional studies are needed to clarify the epidemiology of substance abuse and addiction in cancer patients and others with progressive medical diseases. These patients can be adequately and successfully treated only when their addiction problems are noted by staff and the patient's special needs can be addressed (9).

DEFINITIONS OF ABUSE AND ADDICTION

Both epidemiological studies and clinical management depend on an accepted, valid nomenclature for substance abuse and addiction. Unfortunately, this terminology is highly problematic. The pharmacological phenomena of tolerance and physical dependence are commonly confused with abuse and addiction, and all the definitions applied to medical patients have been developed from experience with addict populations. The clarification of this terminology is an essential step in improving the diagnosis and management of substance abuse in the palliative care setting (Table 41-1, Table 41-2).

Term	Definition
Physical dependence	Pharmacological property of some drugs defined solely by the occurrence of abstinence on abrupt dose reduction, discontinuation of dosing, or administration of an antagonist drug
Tolerance	Diminution of one or more drug effects (either favorable effects or adverse effects) caused by exposure to the drug; may be pharmacological or associative (related to learning)
Substance abuse	Use of a substance in a manner outside of sociocultural conventions; according to this definition, all use of illicit drugs is abuse and use of a licit drug in a manner not dictated by convention (e.g., according to physician's orders) is abuse
Addiction	Commonly used term that does not appear in current psychiatric nosologies but can be taken to mean the aberrant use of a substance in a manner characterized by loss of control, compulsive use, preoccupation, and continued use despite harm

TABLE 41-1. PROPOSED TERMINOLOGY OF SUBSTANCE ABUSE

TABLE 41-2. DEFINITIONS OF SUBSTANCE DEPENDENCE AND SUBSTANCE ABUSE RECOMMENDED BY *DIAGNOSTIC AND STATISTICAL MANUAL FOR MENTAL DISORDERS-IV*

Tolerance

Tolerance is a pharmacological property defined by the need for increasing doses to maintain effects (10,11). An extensive clinical experience with opioid drugs in the medical context has not confirmed that tolerance causes substantial problems (12,13). Although tolerance to a variety of opioid effects, including analgesia, can be reliably observed in animal models (14), and tolerance to nonanalgesic effects, such as respiratory depression and cognitive impairment (15), occurs routinely in the clinical setting, analgesic tolerance seldom interferes with the clinical efficacy of opioid drugs. Indeed, most patients attain stable doses associated with a favorable balance between analgesia and side effects for prolonged periods; dose escalation, when it is required, usually heralds the appearance of a progressive painful lesion (16,17,18,19,20,21 and 22). Unlike tolerance to the side effects of the opioids, clinically meaningful analgesic tolerance, which would yield the need for dose escalation to maintain analgesia in the absence of progressive disease, appears to be a rare phenomenon. Clinical observation also fails to support the conclusion that analgesic tolerance is a substantial contributor to the development of addiction.

Physical Dependence

Physical dependence is defined solely by the occurrence of an abstinence syndrome (withdrawal) after abrupt dose reduction or administration of an antagonist (10,11,23). There is great confusion among clinicians about the differences between physical dependence and addiction. Physical dependence, like tolerance, has been suggested to be a component of addiction (24,25), and the avoidance of withdrawal has been postulated to create behavioral contingencies that reinforce drug-seeking behavior (26). These speculations, however, are not supported by experience acquired during opioid therapy for chronic pain. Physical dependence does not preclude the uncomplicated discontinuation of opioids during multidisciplinary pain management of nonmalignant pain (27), and opioid therapy is routinely stopped without difficulty in the cancer patients whose pain disappears after effective antineoplastic therapy. Indirect evidence for a fundamental distinction between physical dependence and addiction is even provided by animal models of opioid selfadministration, which have demonstrated that persistent drug-taking behavior can be maintained in the absence of physical dependence (28).

Addiction

The terms *addiction* and *addict* are particularly troublesome. These labels are often inappropriately applied to describe both aberrant drug use (reminiscent of the behaviors that characterize active abusers of illicit drugs) and phenomena related to tolerance or physical dependence. The labels *addict* and *addiction* should never be used to describe patients who are only perceived to have the capacity for an abstinence syndrome. These patients must be labeled *physically dependent*. Use of the word *dependent* alone also should be discouraged, because it fosters confusion between physical dependence and psychological dependence, a component of addiction. For the same reason, the term *habituation* should not be used.

Definitions of addict and addiction must be based on the identification of drug-related behaviors that are outside of cultural or societal norms. The ability to categorize questionable behaviors (e.g., consuming a few extra doses of a prescribed opioid, particularly if this behavior was not specifically proscribed by the clinician, or using an opioid drug prescribed for pain as a nighttime hypnotic) as nonnormative presupposes that there is certainty about the parameters of normative behavior. In the area of prescription drug use, this is problematic because there are no empirical data that define these parameters. If a large proportion of patients were discovered to engage in a specific behavior, it could be normative and judgments about deviance would be influenced accordingly. This issue was recently highlighted in a pilot survey performed at MSK Cancer Center, which revealed that inpatients with cancer harbor attitudes supporting misuse of drugs in the face of symptom management problems and that women with human immunodeficiency virus (at MSK for palliative care) engage in such behaviors commonly (29). The prevalence of such behaviors and attitudes among the medically ill raises concern about their predictive validity as a marker of any diagnosis related to substance abuse. Clearly, there is a need for empirical data that illuminate the prevalence of drug-taking attitudes and behaviors in different populations of medically ill patients.

The core concepts used to define addiction may also be problematic as a result of changes induced by a progressive disease. Deterioration in physical or psychosocial functioning caused by the disease and its treatment may be difficult to separate from the morbidity associated with drug abuse. This may particularly complicate efforts to evaluate the concept of “use despite harm,” which is critical to the diagnosis of addiction. For example, the nature of questionable drug-related behaviors can be difficult to discern in the patient who develops social withdrawal or cognitive changes after brain irradiation for metastases. Even if impaired cognition is clearly related to the drugs used to treat symptoms, this outcome might only reflect a narrow therapeutic window, rather than a desire on the patient's part for these psychic effects.

Definition of Addiction in the Medically Ill

Previous definitions that include phenomena related to physical dependence or tolerance cannot be the model terminology for medically ill populations who receive potentially abusable drugs for legitimate medical purposes. A more appropriate definition of addiction notes that it is a chronic disorder characterized by “the compulsive use of a substance resulting in physical, psychological, or social harm to the user and continued use despite that harm” (30). Although this definition was developed from experience in addict populations without medical illness, it appropriately emphasizes that addiction is, fundamentally, a psychological and behavioral syndrome. Any appropriate definition of addiction must include the concepts of loss of control over drug use, compulsive drug use, and continued use despite harm.

Even appropriate definitions of addiction have limited utility, however, unless operationalized for a clinical setting. The concept of “aberrant drug-related behavior” is a useful first step in operationalizing the definitions of abuse and addiction, and recognizes the broad range of behaviors that may be considered problematic by prescribers. Although the assessment and interpretation of these behaviors can be challenging, the occurrence of aberrant behaviors signals the need to reevaluate and manage drug taking, even in the context of an appropriate medical indication for a drug (Table 41-3).

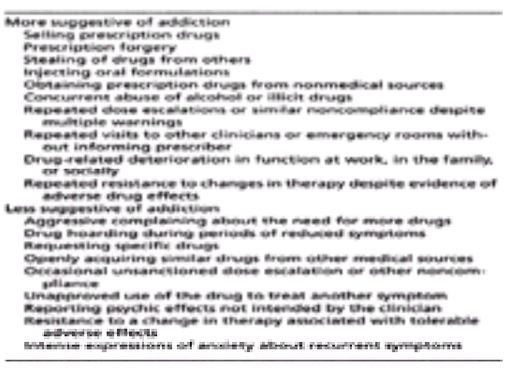

TABLE 41-3. SPECTRUM OF ABERRANT DRUG-RELATED BEHAVIORS ENCOUNTERED DURING TREATMENT OF THE MEDICALLY ILL WITH PRESCRIPTION DRUGS

If drug-taking behavior in a medical patient can be characterized as aberrant, a “differential diagnosis” for this behavior can be explored. A true addiction (substance dependence) is only one of several possible explanations. The challenging diagnosis of pseudoaddiction (74) must be considered if the patient is reporting distress associated with unrelieved symptoms. In the case of pseudoaddiction, behaviors such as aggressively complaining about the need for higher doses or occasional unilateral drug escalations indicate desperation caused by pain and disappear if pain management improves (Table 41-4).

Addiction (substance dependence disorder)
"Pseudoaddiction"
Psychiatric disorder associated with impulsive or aberrant drug taking
Personality disorders, including borderline and psychopathic personality disorders
Depressive disorder
Anxiety disorder
Encephalopathy with confusion about appropriate therapeutic regimen
Criminal intent

*Categories are not mutually exclusive.

TABLE 41-4. DIFFERENTIAL DIAGNOSIS FOR ABERRANT DRUG-RELATED BEHAVIORS[a]

Alternatively, impulsive drug use may indicate the existence of another psychiatric disorder, diagnosis of which may have therapeutic implications. Patients with borderline personality disorder can express fear and rage through aberrant drug taking and behave impulsively and self-destructively during pain therapy. Passik and Hay (31) reported a case in which one of the more worrisome aberrant drugrelated behaviors, forging of a prescription for a controlled substance, was an impulsive expression of fears of abandonment, having little to do with true substance abuse in a borderline patient. Such patients are challenging and often require firm limit setting and careful monitoring to avoid impulsive drug taking.

Similarly, patients who self-medicate anxiety, panic, depression, or even periodic dysphoria and loneliness can present as aberrant drug takers. In such instances careful diagnosis and treatment of these additional problems can at times obviate the need for such self-medication. Occasionally, aberrant drug-related behavior appears to be causally related to a mild encephalopathy, with confusion about the appropriate therapeutic regimen. This may be a concern in the treatment of the elderly patient. Low doses of neuroleptic medications, simplified drug regimens, and assistance with organizing medications can address such problems. Rarely, problematic behaviors indicate criminal intent, such as when patients report pain but intend to sell or divert medications.

These diagnoses are not mutually exclusive. A thorough psychiatric assessment is critically important, both in the population without a prior history of substance abuse and in the population of known abusers, who have a high prevalence of psychiatric comorbidity (32).

In assessing the differential diagnosis for drug-related behavior, it is useful to consider the degree of aberrancy. The less aberrant behaviors (such as aggressively complaining about the need for medications) are more likely to reflect untreated distress of some type, rather than addictionrelated concerns. Conversely, the more aberrant behaviors (such as injection of an oral formulation) are more likely to reflect true addiction. Although empirical studies are needed to validate this conceptualization, it may be a useful model when evaluating aberrant behaviors.

EMPIRICAL STUDIES USING THE ABERRANT DRUG-TAKING CONCEPT

The spectrum of the aberrant drug-taking concept has been used as a heuristic guide to the assessment of problematic drug taking in several recent studies. Although the studies performed to date all involve small samples, they have shown the usefulness of the spectrum concept as an assessment tool yielding important implications for clinicians.

The first study examined the relationship between aberrant drug-taking behaviors and compliance-related outcomes in patients with a history of substance abuse receiving chronic opioid therapy for nonmalignant pain. Dunbar and Katz (33) examined outcomes and drug taking in a sample of 20 patients with diverse histories of drug abuse who underwent a year of chronic opioid therapy. During the year of therapy, 11 patients were adherent with the drug regimen and 9 were not. The authors examined patient characteristics and aberrant drug-taking behaviors that differentiated the two groups. The patients who did not abuse the therapy were abusers of solely alcohol (or had remote histories of polysubstance abuse), were in a solid, drug-free recovery as evidenced by participation in 12-step programs, and had good social support. The patients who abused the therapy were polysubstance abusers, were not participating in 12-step programs, and had poor social support. The specific behaviors that were recorded more frequently by those who abused the therapy were unscheduled visits and multiple phone calls to the clinic, unsanctioned dose escalations, and obtaining opioids from more than one source.

A second study examined the relationship between aberrant drug taking and the presence or absence of a psychiatric diagnosis of substance use disorder in pain patients. Compton et al. (34) studied 56 patients seeking pain treatment in a multidisciplinary pain program who were referred for “problematic drug taking.” The patients all underwent structured psychiatric interviews and the sample was divided between those qualifying and those not qualifying for psychiatric diagnoses of substance use disorders. The authors then examined the subjects' reports of aberrant drug-taking behaviors in a structured interview assessment. The patients who qualified for a substance use disorder diagnosis were more likely to have engaged in unsanctioned dose escalations, received opioids from multiple sources, and have the subjective impression of loss of control of their prescribed medications.

Passik and researchers at a major cancer center (29) examined the self-reports of aberrant drug-taking attitudes and behaviors in samples of cancer (N = 52) and AIDS (N = 111) patients on a questionnaire designed for the purposes of the study. Reports of past drug use and abuse were more frequent than present reports in both groups. Current aberrant drug-related behaviors were seldom reported, but attitude items revealed that patients would consider engaging in aberrant behaviors, or would possibly excuse them in others, if pain or symptom management were inadequate. It was found that aberrant behaviors and attitudes were endorsed more frequently by the women with AIDS than by the cancer patients. Overall, patients greatly overestimated the risk of addiction during pain treatment. Experience with this questionnaire suggests that both cancer and AIDS patients respond in a forthcoming fashion to drug-taking behavior questions and describe attitudes and behaviors that may be highly relevant to the diagnosis and management of substance use disorders.

These studies help us clarify the meanings ascribed by clinicians to the various behaviors that occur during longterm administration of a potentially abusable drug. Ultimately, such studies may define the true “red flags” in a given population.

Far too often, anecdotal accounts shape the way clinicians view drug-related behaviors. Some behaviors are regarded almost universally as aberrant despite limited systematic data to suggest that this is the case. Consider for example the patient who requests a specific pain medication, or a specific route or dose. Although this behavior may reflect a patient who is knowledgeable and assertive— favorable characteristics in other contexts—it is often greeted with suspicion on the part of practitioners. Other behaviors may be common in nonaddicts, and although aberrant, they may have little predictive value for true addiction. For example, the finding that many nonaddicted cancer patients use anxiolytic medications prescribed for a friend or other (29) more than likely reflects the undertreatment and underreporting of anxiety in oncology patients than true addiction.

RISK OF ADDICTION IN THE MEDICALLY ILL

Opioid administration in cancer patients with no prior history of substance abuse is only rarely associated with the development of significant abuse or addiction (35,36,37,38,39,40,41,42,43,44,45,46 and 47). Indeed, concerns about addiction in this population are now characterized by an interesting paradox: Although the lay public and inexperienced clinicians still fear the development of addiction when opioids are used to treat cancer pain, specialists in cancer pain and palliative care widely believe that the major problem related to addiction is not the phenomenon itself, but rather the persistent undertreatment of pain driven by inappropriate fear that it will occur.

The very sanguine experience in the cancer population has contributed to a desire for a reappraisal of the risks and benefits associated with the long-term opioid treatment of chronic, nonmalignant pain (22,48). The traditional view of this therapy is negative and early surveys of addicts, which noted that a relatively large proportion began their addiction as medical patients administered opioid drugs for pain (49,50 and 51), provided some indirect support for this perspective. The most

influential of these surveys recorded a history of medical opioid use for pain in 27% of white male addicts and 1.2% of black male addicts (51).

Surveys of addict populations, however, do not provide a valid measure of the addiction liability associated with chronic opioid therapy in populations without known abuse. Prospective patient surveys are needed to define this risk accurately. Studies of relatively short-term opioid exposure have been reassuring. The Boston Collaborative Drug Surveillance Project evaluated 11,882 inpatients who had no prior history of addiction and were administered an opioid while hospitalized; only four cases of addiction could be identified subsequently (52). A national survey of burn centers could find no cases of addiction in a sample of more than 10,000 patients without prior drug abuse history who were administered opioids for pain (53), and a survey of a large headache clinic identified opioid abuse in only 3 of 2369 patients admitted for treatment, most of whom had access to opioids (54). These surveys do not define the risk of abuse or addiction during long-term, open-ended opioid therapy. They nonetheless suggest the clinical impression that patients with serious medical illness and no history of substance abuse can be given potentially abusable drugs with relatively little risk of abuse or addiction. Other supporting data derive from surveys of cancer patients and postoperative patients, which indicate that euphoria, a phenomenon believed to be common during the abuse of opioids, is extremely uncommon after administration of an opioid for pain; dysphoria is observed more typically, especially in those who receive meperidine hydrochloride (55).

The inaccurate perception that opioid therapy inherently yields a relatively high likelihood of addiction has encouraged assumptions that are not supportable given the current understanding of addiction. Perhaps most important, the relevance of a genetically determined predisposition to addiction (56) tends to be minimized or dismissed by such a view. A more critical evaluation of the extant literature (19,20,21 and 22,56,57) actually yields little substantive support for the view that large numbers of individuals with no personal or family history of abuse or addiction, no affiliation with a substance abusing subculture, and no significant premorbid psychopathology, will develop abuse or addiction *de novo* when administered potentially abusable drugs for appropriate medical indications.

ADDICTION RISK IN PATIENTS WITH CURRENT OR REMOTE DRUG ABUSE

There is very little information about the risk of abuse or addiction during, or after, the therapeutic administration of a potentially abusable drug to patients with a current or remote history of abuse or addiction. Anecdotal reports have suggested that successful long-term opioid therapy in patients with cancer pain or chronic nonmalignant pain is possible, particularly if the history of abuse or addiction is remote (33,60,61). Indeed, a recent study showed that patients with AIDS-related pain were able to be successfully treated with morphine sulfate regardless of whether they were substance users or nonusers. The major group difference found in this survey was that substance users required considerably more morphine sulfate to reach stable pain control (62).

These data are reassuring but do not obviate the need for caution. For example, although there is no empirical evidence that the use of short-acting drugs or the parenteral route is more likely to lead to problematic drug-related behaviors than other therapeutic approaches, it may be prudent to avoid such therapies in patients with histories of substance abuse.

CLINICAL MANAGEMENT

Out-of-control aberrant drug taking among palliative care patients (with or without a prior history of substance abuse) represents a serious and complex clinical occurrence. Perhaps the more difficult situations involve the patient who is actively abusing illicit or prescription drugs or alcohol concomitantly with medical therapies. Whether the patient is an active drug abuser, has a history of substance abuse, or is not complying with the therapeutic regimen, the clinicians should establish structure, control, and monitoring so that they can prescribe freely and without prejudice.

Multidisciplinary Approach

A multidisciplinary team approach is usually optimal for the management of substance abusers in the palliative care setting. If available, mental health professionals with specialization in addictions can be instrumental helping palliative care team members develop strategies for management and patient treatment compliance. Providing care to these patients can lead to feelings of anger and frustration among staff. Such feelings can unintentionally compromise pain management and contribute to feelings of isolation and alienation by the patient. A structured multidisciplinary approach can be effective in helping the staff better understand the patient's needs and develop effective strategies for controlling pain and aberrant drug use simultaneously. Staff meetings can be helpful in establishing treatment goals, facilitating compliance, and coordinating the multidisciplinary team.

Assessment

The first member of the medical team (frequently a nurse) to suspect problematic drug taking or a history of drug abuse should alert the patient's palliative care team, thus beginning the multidisciplinary assessment and management process (63). A physician should assess the potential of withdrawal or other pressing concerns and begin involving other staff (e.g., social work or psychiatry) to begin planning management strategies. Obtaining as detailed as possible a history of duration, frequency, and desired effect of drug use is crucial. Frequently, clinicians avoid asking patients about substance abuse because of fear that they will anger the patient or that they are incorrect in their suspicion of abuse. This stance can contribute to continued problems. Empathic and truthful communication is always the best approach.

The use of a careful, graduated interview approach can be instrumental in slowly introducing the assessment of drug use. This approach entails starting the assessment interview with broad questions about the role of drugs (e.g., nicotine, caffeine) in the patient's life and gradually becoming more specific in focus to include illicit drugs. Such an approach is helpful in reducing denial and resistance.

This interviewing style also may assist in the detection of coexisting psychiatric disorders. Comorbid psychiatric disorders can significantly contribute to aberrant drug taking behavior. Studies suggest that 37–62% of alcoholics have one or more coexisting psychiatric disorders and that drug history may be a clue to comorbid psychiatric disorders (e.g., drinking to quell panic symptoms). Anxiety, personality disorders, and mood disorders are the most common encountered (3,64). The assessment and treatment of comorbid psychiatric disorders can greatly enhance management strategies and reduce the risk of relapse.

Development of a Treatment Plan—General Considerations

Clinicians must control and monitor drug use in all patients, a daunting task in some active abusers. In some cases, a major issue is compliance with treatments for the underlying disease, which may be so poor that the substance abuse actually shortens life expectancy by preventing the effective administration of primary therapy. Prognosis may also be altered by the use of drugs in a manner that negatively interacts with therapy or predisposes to other serious morbidity. The goals of care can be very difficult to define when poor compliance and risky behavior appears to contradict a reported desire for disease-modifying therapies.

Clear treatment goals are essential in managing aberrant drug-related behaviors. Depending on the history, a complete remission of the patient's substance use problems may not be a reasonable goal. The distress of coping with a lifethreatening illness and the availability of prescription drugs for symptom control can undermine the effort to achieve abstinence (65). For some patients, “harm reduction” may be a better model. It aims to enhance social support, maximize treatment compliance, and contain harm done through episodic relapse (Table 41-5).

Involve a multicisciplinary team
Set realistic goals for therapy
Evaluate and treat comorbid psychiatric disorders
Prevent or minimize withdrawal symptoms
Consider tolerance when prescribing medications for pain and symptom control
Apply accepted guidelines for opioid therapy*
Accept patients' self-report of distress
Frequently reassess the adequacy of pain and symptom control
Recognize specific drug abuse behaviors
Use nonopioids and psychological techniques as indicated, but not as substitutes

*Recently published guidelines for long-term opioid pharmacotherapy are available.

TABLE 41-5. GUIDELINES FOR THE MANAGEMENT OF PATIENTS WITH SUBSTANCE ABUSE DISORDERS

To establish goals, the clinician should first establish a relationship based on empathic listening and accept the patient's report of distress. Second, it is important to

use nonopioid and behavioral interventions when possible, but not as substitutes for appropriate pharmacological management. Third, the team should consider tolerance, route of administration, and duration of action when prescribing medications for pain and symptom management. Preexisting tolerance should be taken into account for patients who are actively abusing drugs or are being maintained on methadone hydrochloride. Failure to address tolerance through proper dose selection and titration can result in undermedication and contribute to the patient's attempts to self-medicate. The use of medications with slow onset and longer duration (e.g., fentanyl transdermal and sustained-release opioids) may help to reduce the risk of aberrant behaviors in those with addictive disorders. Patients who are perceived to be at high risk should not be given short-acting opioids for breakthrough pain. Finally, the team should make plans to frequently reassess the adequacy of pain and symptom control.

Urine Toxicology Screening

Urine toxicology screening has the potential to be a very useful tool to the practicing clinician, both for diagnosing potential abuse problems and for monitoring patients with an established history of abuse. However, recent work suggests that urine toxicology screens are employed infrequently in tertiary care centers (66). In addition, when they are ordered, documentation tends to be inconsistent regarding the reasons for ordering as well as any follow-up recommendations based on the results. Indeed, the survey found that nearly 40% of the charts surveyed listed no reason for obtaining the urine toxicology screen and the ordering physician could not be identified nearly 30% of the time. Staff education efforts can help to address this and may ultimately make urine toxicology screens a vital part of treating pain in oncology patients.

Patients with Advanced Disease

Managing addiction problems in patients with advanced medical illness is labor and time intensive. This begs the question as to why a clinician should even bother to address such a complex health concern in the patient with advanced disease. In fact, many clinicians might opt to overlook a patient's use of illicit substances or alcohol entirely, viewing these behaviors as a last source of pleasure for the patient. However, addiction has a deleterious impact on palliative care efforts. Proper addiction management plays an important part in the success of palliative efforts to reduce suffering. Addiction behaviors may result in increased stress for family members, family concern over the misuse of medication, a potential for masking symptoms important for the patient's care, poor compliance with the treatment regimen, and diminished quality of life. Complete abstinence may not be a realistic outcome, but reduction in use can certainly have positive effects for the patient and family (67).

Outpatient Management

There are a number of strategies for promoting treatment adherence in an outpatient setting. (Table 41-6 outlines management strategies for outpatients who require palliative care and are actively abusing drugs.) A written contract between the care team and patient helps to provide structure to the treatment plan, establishes clear expectations of the roles played by both parties, and outlines the consequences of aberrant drug taking. The inclusion of spot urine toxicology screens in the contract can be useful in maximizing treatment compliance. Expectations regarding attendance at clinic visits and the management of one's supply of medications should also be stated. For example, the clinician may wish to limit the amount of drug dispensed per prescription and make refills contingent on clinic attendance. The clinician should consider requiring the patient to attend 12-step programs, and have the patient document his or her attendance as a condition for ongoing prescribing. With the patient's consent, the clinician may wish to contact the patient's sponsor and make him or her aware that the patient is being treated for chronic illness that requires medications (e.g., opioids, etc.). This action reduces the potential for stigmatization of the patient as being noncompliant with the ideals of the 12-step program. Finally, the team should involve family members and friends in the treatment to help bolster social support and functioning. Becoming familiar with the family may help the team to identify family members who are themselves drug abusers and who may potentially divert the patient's medications. Mental health professionals can help family members with referrals to drug treatment and codependency groups, as a way to help the patient receive optimal medical care.

Use written contracts
Use frequent clinic visits
Give small quantities of medications per prescription
Renew prescriptions contingent on clinic attendance
Use 12-step programs where possible
Use spot urine toxicology screens
Involve family in treatment planning

TABLE 41-6. MANAGEMENT STRATEGIES FOR OUTPATIENTS WHO REQUIRE PALLIATIVE CARE AND ARE ACTIVELY ABUSING DRUGS

Inpatient Management

The management of patients with active substance abuse problems who have been admitted to the hospital for treatment of a life-threatening illness both includes and expands on the guidelines discussed for outpatient settings. These guidelines aim to promote the safety of patient and staff, contain manipulative behaviors by patients, enhance the use of medication appropriately used for pain and symptom management, and communicate an understanding of pain and substance abuse management. The first point of order is to discuss the patient's drug use in an open manner. In addition, it is necessary to reassure the patient that steps will be taken to avoid adverse events such as drug withdrawal. For certain specific situations, such as for preoperative patients, patients should be admitted several days in advance for stabilization of the drug regimen. Also, it is important to provide the patient with a private room near the nurses' station to aid in monitoring and to discourage attempts to leave the hospital for the purchase of illicit drugs. Further, the team should require visitors to check in with nursing staff before visitation. In some cases it may be necessary to search the packages of visitors to stem the patient's access to drugs. As a final point, the team should collect daily urine specimens for random toxicology analysis and frequently reassess pain and symptom management (Table 41-7).

Have regular contact with floor staff and facility administrators to apprise them of necessary strategies
Document strategies in the medical record and note justification
Obtain private room close to nursing station
Search possessions and packages brought by visitors
Restrict patient's mobility (to room, floor, etc.)
Collect urine for toxicology screens daily

TABLE 41-7. MANAGEMENT STRATEGIES FOR INPATIENTS WHO REQUIRE PALLIATIVE CARE AND ARE ACTIVELY ABUSING DRUGS AT THE TIME OF ADMISSION

As with pain regimens, management approaches should be tailored to reflect the clinician's assessment of the severity of drug abuse. Open and honest communication between the clinician and patient reassures the patient that these guidelines were established in their best interests. In some cases, these guidelines may fail to curtail aberrant drug use despite repeated interventions by staff. At that point, the patient should be considered for discharge; however, our experience suggests that this is only necessary in the most recalcitrant of cases. The clinician should involve members of the staff and administration for discussion about the ethical and legal implications of such a decision.

Methadone Hydrochloride

Oral methadone hydrochloride can be used safely and effectively as an analgesic (68,69,70 and 71). The use of this drug has been increasing in recent years. Once-daily methadone hydrochloride is rarely useful as an analgesic and patients receiving maintenance methadone hydrochloride for opioid addiction cannot achieve pain relief merely by increasing the dose. Indeed, practitioners sometimes assume that patients receiving methadone hydrochloride from a maintenance program do not need further pain medication, but this is simply not true (72,73). Methadone hydrochloride can be used for pain management by increasing the dose and dividing it during the day. Alternately, an entirely separate pharmacological therapy can be chosen and incorporated into the patient's treatment plan.

Patients in Recovery

Pain management for patients in recovery presents a unique challenge. Depending on the structure of the recovery program (e.g., Alcoholics Anonymous, methadone hydrochloride maintenance programs), a patient may fear ostracism from the program's members or may have an increased fear regarding susceptibility to readdiction. The first choice should be to explore nonopioid therapies with these patients, which may require referral to a pain center (72). Alternative therapies may include the use of nonopioid or adjuvant analgesics, cognitive therapies, electrical stimulation, neural blockades, or acupuncture. If the pain condition is so severe that opioids are required, certain measures should be considered based on the outcome of a thorough assessment, reviewing the goals of care, informed consent, and the life expectancy of the patient. In some cases, then, it is necessary to structure opioid use with opioid management contracts, random urine toxicology screens, and occasional pill counts. If possible, an attempt should be made to include the patient's recovery program sponsor in the treatment planning process to garner their cooperation and aid in successful monitoring.

CONCLUSION

Although the most prudent actions on the part of clinicians cannot obviate the risk of all aberrant drug-related behavior, clinicians must recognize that virtually any drug that acts on the central nervous system, by any route of drug administration, can be abused. The problem does not lie in the drugs themselves. The effective management of patients with pain who engage in aberrant drug-related behavior necessitates a comprehensive approach that recognizes the biological, chemical, social, and psychiatric aspects of substance abuse and addiction, and provides practical means to manage risk, treat pain effectively, and assure patient safety.

An accepted nomenclature for abuse and addiction and an operational approach to the assessment of patients with medical illness are prerequisite to an accurate definition of risk in populations with and without histories of substance abuse. Unfortunately, there are very limited data relevant to risk assessment in the medically ill. Most data relate to the risk of serious abuse or addiction during long-term opioid treatment of chronic pain in patients with no history of substance abuse. There is almost no information about the risk of less serious aberrant drug-related behaviors, the risk of these outcomes in populations that do have a history of abuse, or the risk associated with the use of potentially abusable drugs other than opioids.

PROGNOSTICATION IN ADVANCED DISEASE

ELIZABETH B. LAMONT
NICHOLAS A. CHRISTAKIS

One meaning of *prognosis* is that it is a physician's estimate of the future course of a patient's disease and especially of their survival. Prognoses are important to physicians and patients in all phases of cancer care, and they inform both medical and nonmedical decisions. In early-stage disease, prognoses help physicians and patients to weigh the likely benefit of given therapies (e.g., adjuvant chemotherapy). In advanced stage disease, prognoses may be of additional importance, as they may herald a switch from primarily curative or life-prolonging care to primarily palliative care and in so doing set off a cascade of both clinical and personal decisions. Despite its importance and ubiquity, reliable prognostication in advanced disease is not straightforward. Numerous studies have revealed substantial optimistic bias in physicians' prognoses for their terminally ill cancer patients. It seems likely that this optimistic bias may contribute to the short survivals observed in patients referred for hospice care and to other types of decisions doctors and patients make near the end of life. Research that is focused on improving physicians' prognostic abilities is therefore of critical importance to palliative care.

PROGNOSTIC INACCURACY

Although prognosis is a central element of a significant amount of oncologic research, formal and explicit prognostication is not often required in the clinical care of cancer patients. Nevertheless, there are two instances in the care of advanced cancer patients where physicians are asked explicitly to prognosticate: (a) when they are enrolling patients on experimental chemotherapy protocols, and (b) when they are referring patients for hospice care. Each therapy has discrete and opposite eligibility requirements pertaining to survival— that is, to be considered for enrollment on phase I experimental chemotherapy protocols, patients typically must have an estimated survival of longer than 3 months. To be considered for enrollment for hospice care under the Medicare Hospice Benefit, patients must have an estimated survival of less than 6 months. Because of these formal requirements, physicians' ability to determine fine gradations in survival among patients in their last 6 months of life may mean the difference between aggressive and palliative care.

Optimism in Formulating Prognoses

How good are physicians at determining which patients are in their last 6 months of life? The answer may be found in literature pertaining to aggressive and palliative therapies for advanced cancer patients. From the experimental chemotherapy literature, Janisch and colleagues analyzed survival data from 349 advanced cancer patients after enrollment in phase I therapies (1). Overall, they found that the median survival was 6.5 months, well above the requisite 3 months described in most eligibility requirements. However, 25% died within 3 months (i.e., inconsistent with the prognostic standard), although very few of those with a performance status of more than 70 died before 3 months. Given the low clinical response rates associated with phase I therapies, it is unlikely that survival was enhanced by the therapies themselves. Therefore, results from this study suggest that physicians enrolling patients on phase I protocols are generally able to predict which patients have longer than 3 months to live. An alternate explanation is that other eligibility requirements, like performance status and laboratory tests, select for patients with longer than 3 months to live, obviating the utility of the physicians' prognostic assessment. Because the study was not designed to test physician prognostic accuracy, it is difficult to draw strong conclusions about the actual role of physician prognostication.

Within the palliative oncology literature, there are several studies specifically designed to determine physicians' prognostic accuracy in predicting survival of patients admitted to hospice programs (2,3,4,5,6 and 7). Investigators in these studies have measured physicians' prognostic accuracy by comparing patients' observed survival to their predicted survival (these predictions are not necessarily ones communicated to patients; rather, they are ones physicians formulate for themselves). Results of the studies, summarized in Table 42-1, show that, in aggregate, physicians' overall survival estimates tended to be incorrect by a factor of approximately three, always in the optimistic direction (2,3,4,5,6 and 7).

Primary investigator	Reference	Year	Number of doctors	Number of patients	Median estimated survival (wk)	Median actual survival (wk)	Estimated survival/actual survival
Parkes	2	1972	NR	103	4.9	2.9	1.8

TABLE 42-1. SUMMARY OF STUDIES COMPARING PHYSICIANS' ESTIMATED SURVIVAL TO PATIENTS' ACTUAL SURVIVAL

Studies of physicians' abilities to predict terminally ill cancer patients' survival are not limited to patients in palliative care settings but have also been evaluated in ambulatory patients undergoing anticancer therapy. Mackillop and Quirt measured oncologists' prognostic accuracy in the care of their ambulatory cancer patients by asking them to first predict patients' likelihood of cure and then to estimate the duration of survival for those whose likelihood of cure was zero (8). At the 5-year point, patients who were alive and disease-free were termed “cured”; the dates of death of the incurable patients also were determined. The researchers reported that oncologists were highly accurate in predicting cure. That is, for subgroups of patients (not individual patients) the ratio of the observed cure rate at 5 years to the predicted cure rate was quite high, at 0.92. However, the same oncologists had difficulty predicting the length of survival of individual incurable patients. They predicted survival “correctly” for only one-third of patients, with the errors divided almost equally between optimistic and pessimistic.

Optimism in Communicating Prognoses

Once a prognosis has been formulated, a physician must decide how to communicate it. This is the distinction between foreseeing and foretelling the patient's future (9). Although, as noted above, there is unconscious optimism in the prognoses physicians formulate regarding their advanced cancer patients' survival, there is also additional—and conscious—optimism in the prognoses physicians subsequently communicate to their patients. For example, one study asked physicians referring terminally ill cancer patients for hospice care how long they thought the patient had to live and also what prognosis, if any, they would provide to their patient if the patient inquired (10). It found that the median survival the physicians would communicate to patients was 90 days, their median formulated survival was 75 days, and the median observed survival was 24 days. This study revealed that the prognoses patients hear from their physicians may be more optimistic than what their physicians actually believe, which again is more optimistic than what actually occurs. Figure 42-1 shows the relationship between these three types of prognoses

(communicated, formulated, and observed).

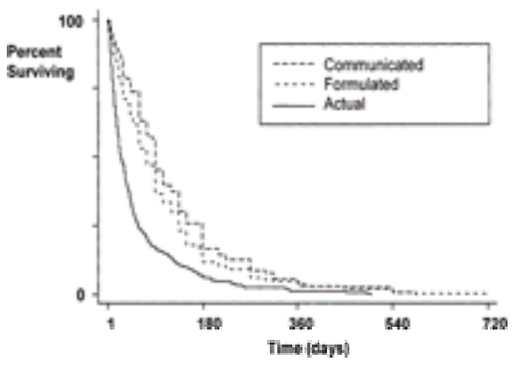

FIGURE 42-1. Relationship between physicians' communicated and formulated prognoses and their advanced cancer patients' actual survival after referral to hospice palliative care. [From Lamont EB, Christakis NA. Prognostic disclosure to patients with cancer near the end of life. Ann Intern Med 2001;134(12):1096–1105, with permission.]

In sum, although physicians are asked to foresee gradations of survival in advanced cancer patients enrolling in certain therapies (either aggressive or palliative), they are able to do so accurately less than a third of the time and, when in error, they generally tend to overestimate survival. This overestimation in formulated survival is compounded by an overestimation of communicated survival. Therefore, through their physicians' step-wise prognostic errors, advanced-stage cancer patients may become twice removed from the reality of their survival, both times toward a falsely optimistic prognosis.

PROGNOSTIC ACCURACY

Within palliative oncology, there is a growing literature focused on identifying predictors of survival of advanced cancer patients that might aid physicians in their prognostic estimates for similar patients. This literature is motivated not only by the centrality of prognosis to the care of such patients but also by physicians' inability to prognosticate accurately and their discomfort in doing so. Multiple prospective and retrospective cohort studies have consistently identified three broad classes of survival predictors: patients' performance status, patients' clinical signs and symptoms, and physicians' clinical predictions. New research seeks to increase the predictive yield of these clinical factors through models of increasing complexity that integrate these elements with each other and with new elements into easy-to-use composite measures. Additional new research in the broader oncologic arena of translational research seeks to exploit survival aspects of new biological markers [i.e., molecular (e.g., p53 [11], Her-2/neu [12])], although the extent to which these will aid in clinical prognostication in advanced disease is not yet established.

Performance Status

A performance status is a global measure of a patient's functional capacity. Because it has been consistently found to predict survival in cancer patients (13), it is frequently used as a selection criteria for patients entering clinical trials and also as an adjustment factor in the subsequent analyses of treatment effect. Several different metrics have been developed to quantify performance status, and among them, the Karnofsky performance status (KPS) is the most often used. The KPS ranges from values of 100, signifying normal functional status with no complaints nor evidence of disease, to zero, signifying death. The complete spectrum of values for the KPS scale is reproduced in Table 42-2.

Value	Level of functional capacity
100	Normal, no complaints, no evidence of disease
90	Able to carry on normal activity, minor signs or symptoms of disease
80	Normal activity with effort, some signs or symptoms of disease
70	Cares for self, unable to carry on normal activity or to do active work
60	Requires occasional assistance, but is able to care for most needs
50	Requires considerable assistance and frequent medical care
40	Disabled, requires special care and assistance
30	Severely disabled, hospitalization is indicated although death is not imminent
20	Hospitalization is necessary, very sick, active supportive treatment necessary
10	Moribund, fatal processes progressing rapidly
0	Dead

TABLE 42-2. KARNOFSKY PERFORMANCE STATUS SCALE

Multiple studies (1,3,6,14,15,16,17,18,19,20,21,22,23,24,25,26 and 27) have reported associations between cancer patients' survival and their performance status. The direction of the association is positive— that is, as a patient's performance status declines, so, too, does their survival. The magnitude of the association is described differently in different studies depending on the statistical methods used, but several studies report that among patients enrolled in palliative care programs, a KPS of less than 50% suggests a life expectancy of fewer than 8 weeks (3,6,14,16,27,28). The association between KPS value and survival in advanced cancer patients enrolled in palliative care programs is described in Table 42-3.

Index	Value	Median survival (d)	References
Karnofsky performance status	10–20	7–16	3,6,14,16,27,28,
	30–40	8–50	35
	≥50	50–90	
Anorexia	Present	≤58	14,28,35
Confusion	Present	≤38	28,35
Dysphagia	Present	<30	14
Dyspnea	Present	<30	14
Xerostomia	Present	<50	35
Leukocytosis	>8500 cells/μl	≤30	37
Doctor estimate	3 mo	30	2,4,7

TABLE 42-3. PREDICTORS OF SURVIVAL WITH ADVANCED CANCER UNDER PALLIATIVE CARE

Patients' Signs and Symptoms

Patients' clinical signs and symptoms have also been studied with respect to survival in advanced cancer. The usefulness of such indicators, even in preference to biological details of a patient's condition, was first outlined in a classic paper by Alvan Feinstein in 1966 (29,30). Recently, Vigano and colleagues engaged this topic in their qualitative systematic review of prognostic factors in advanced cancer (31). In examining 136 different variables from 22 studies, they found that, after performance status, specific signs and symptoms were the next best predictors of patient survival. The presence of dyspnea, dysphagia, weight loss, xerostomia, anorexia, and cognitive impairment had the most compelling evidence for independent association with patient survival in these studies. Table 42-3 contains the range of median survivals for the various symptoms reported in univariate analyses from these and other studies.

For example, numerous investigators have documented that dyspnea is inversely associated with survival in this patient population (14,16,26,33). The presence of dyspnea is associated with a survival of fewer than 30 days according to work by Maltoni et al. (14). Other investigators have described dyspnea as doubling the hazard of death (32). Similarly, others have shown inverse associations between dysphagia and survival (14,16,33,34), with Maltoni et al. describing an associated median survival of fewer than 30 days (14). Anorexia, confusion, and xerostomia are also inversely associated with survival (14,28,35), with median survival times of fewer than 60 days. These findings suggest that for advanced cancer patients such as those referred to palliative care programs, the presence or absence of these symptoms may help physicians to estimate patient survival.

Several groups of investigators have evaluated associations between biological markers (i.e., laboratory values) and survival in advanced cancer patients. For example, in their retrospective analysis of 339 phase I chemotherapy patients with advanced cancer at the University of Chicago, Janisch and colleagues found that among routine pretreatment laboratories, only platelet count elevation and serum albumin depression were associated with shorter survivals in a multivariate model that included KPS (1). Among a sample of 207 consecutive advanced non–small cell lung patients, Muers and colleagues found that in addition to performance status and symptoms, lymphocyte count, albumin, sodium, and alkaline phosphatase were all predictive of survival (36). Similarly, Maltoni and colleagues examined 13 hematological and urinary parameters at baseline and every 28 days in a group of 530 patients in Italian palliative care centers (37). In a multivariate model that included performance status, the investigators describe high total white blood cell count, low lymphocyte percentage, and low pseudocholinesterase as associated with diminished survival. Their Kaplan-Meier curves suggest that patients with elevated white blood cell counts (>8500 cell/μl) had median survivals of 1 month or less. The Janisch, Meurs, and Maltoni results are consistent; Janisch et al. found a strong correlation between platelet count and absolute neutrophil count and therefore dropped absolute neutrophil count from the final model. There may be a similar degree of correlation between albumin and pseudocholinesterase, both serum proteins. From these studies one can conclude that there appear to be negative associations between survival and bone marrow parameters (e.g., platelets, white blood cells) as well as positive associations between survival and synthetic parameters (e.g., serum proteins) in this patient population.

Physicians' Clinical Predictions

As noted previously, numerous studies suggest that physicians' predictions regarding patients' survival in palliative care programs are frequently incorrect and that the direction of the error is almost always optimistic. However, the overly optimistic estimates *are* correlated with actual survival (6,7,38). That is, although physicians are not wellcalibrated with respect to survival (i.e., they are systematically optimistic), they nevertheless have discriminatory abilities (39). They are able to order patients in terms of how sick they are or how long they have to live. This fact suggests that physicians' clinical predictions may be a useful, but not exclusive, source of information regarding patient survival. Thus, integration of clinical predictions with other known prognostic factors may be beneficial in predicting patient survival. For example, Muers and colleagues found that the addition of physician clinical prediction to their previously mentioned prognostic model (that contained performance status, symptoms, and laboratory values) improved the model's predictive power (36). This suggests that physicians are able to measure and quantify factors relevant to survival that are unmeasured by the previously mentioned factors. Similarly, Knaus and colleagues, in their Study to Understand Prognoses and Preferences for Outcomes and Risks for Treatments patients, found that multivariate regression models that included physicians' prognostic estimates were more accurate than the models without the physician input (40). Hence, although it is true that statistical models can be more accurate than human intuition alone (36,40,41), it is also true that physicians provide valuable prognostic information that, thus far, has not been captured in the objective models. Such integrated models hold the greatest promise for improving physicians' predictive accuracy in advanced cancer patients. Maltoni et al. explicitly combined this information with other known predictors of patient survival in their predictive tool (42).

Integrated Models

Investigators have also sought to model patient survival by combining and interacting these previously identified clinical predictors. Bruera and colleagues described a parsimonious model that combined three independently predictive elements (dysphagia, weight loss, cognitive failure) (34). They reported that the presence of all three poor prognostic factors among advanced cancer patients admitted to palliative care predicted death within 4 weeks, with a sensitivity of 0.74 and a specificity of 0.71. In this study, this measure performed better than physicians' clinical estimates of survival.

Using data from the National Hospice Study, Reuben and colleagues evaluated the initial performance status and symptomatology of 1592 terminal cancer patients admitted to hospice care and found that interacting the two survival predictors led to better prognostic modeling (16). That is, the survival associated with a given performance status depended on the number and type of additional symptoms. For example, patients with an initial KPS of 50% or more and no symptoms had a median survival of 172 days. This survival decreased to 125 days when dyspnea was also present at the initial evaluation. The survival decreased to 67 days when dyspnea, dysphagia, weight loss, and xerostomia were all present at the initial evaluation.

The most recent generation of studies describe integrated models that combine these and other prognostic variables into a single prognostic score. For example, Morita and colleagues developed a regression model predicting survival from performance status and certain clinical signs and symptoms (33). Coefficients from the regression were then transformed into partial scores, and summing the values of each partial score led to a final score termed the *Palliative Prognostic Index* (PPI). After developing the PPI in a sample of 150 patients, the investigators then tested the approach on a second sample of 95 patients, finding that the PPI predicted 3-week survival with sensitivity of 83% and a specificity of 85% and 6-week survival with sensitivity of 79% and a specificity of 77%. Table 42-4 contains a description of the PPI scoring system and Table 42-5 a summary of predictive relevance of PPI scores. Several other groups have developed similar scoring systems that rely on integration of all or some of the previously described classes of prognostic indicators of patients with advanced cancer and under palliative care (25,35,42). Such scoring systems need to be sensitive to a variety of methodological concerns (30,39,43,44 and 45). Further research is needed to determine if these scoring systems are useful in the clinical care of cancer patients and if they are applicable to patients who are not yet enrolled in palliative care programs or who are dissimilar from such patients. With respect to the clinical usefulness of the scoring systems, treating physicians will need to determine if the tools' test characteristics (e.g., sensitivity and specificity) fall above certain minimum thresholds for use in clinical decisions. Because of the issue of “zero time” (30,46) (i.e., the analytical impact of the selection of the time at which measurement of survival begins), many of the algorithms that rely on KPS, symptoms, or laboratory values obtained *after* referral to hospice may not be applicable to advanced cancer patients *before* referral to hospice.

Prognostic domains	Partial score value
Performance status	
10–20	4.0
30–50	2.5
≥60	0
Clinical symptoms	
Oral intake	
Moderately reduced	1.0
Severely reduced	2.5
Normal	0
Edema	1.0
Dyspnea at rest	3.5
Delirium	4.0

The scores from each prognostic domain are added, and the sum total is associated with a likelihood of survival either <3 weeks or <6 weeks. From Morita T, Tsundoa J, Inoue S, et al. The Palliative Prognostic index: a scoring system for survival prediction of terminally ill cancer patients. Support Care Cancer 1999;7:128–133, with permission.

TABLE 42-4. DESCRIPTION OF THE COMPONENTS OF THE PALLIATIVE PROGNOSTIC INDEX: A SCORING SYSTEM FOR SURVIVAL PREDICTION OF TERMINALLY ILL CANCER PATIENTS

Palliative Prognostic Index score	Median survival (d)
0.0–2.0	90
2.1–4.0	61
>4.0	12

[a]Median survival value was estimated from survival curve in paper.

Other Sources of Prognostic Information

Other sources of information regarding survival in advanced cancer are studies that include cancer patients who do not undergo anticancer therapy. Both natural history studies and randomized therapy trials that include a "best supportive care" arm describe patients who do not undergo anticancer therapy. Typically, natural history studies are single institution case series of untreated patients with mortality follow-up. For example, Kowalski and Carvalho described the survival pattern of patients with recurrent or metastatic squamous cell carcinoma of the head and neck (47). The median survival they report is 4 months. Others have looked at this issue in breast cancer (58) and hepatocellular cancer (48). Survival information can also be found by examining the survival of patients on the "best supportive care" arms of randomized clinical trials [e.g., trials in advanced non–small cell lung cancer (49,50,51 and 52), hepatocellular cancer (53), 5-fluorouracil refractory stage IV colon cancer (54), stage IV pancreatic cancer (55), stage IV gastric cancer (56)]. Table 42-6 contains a description of results of some of these trials (47,48,49 and 50,52,55,56,57 and 58).

Tumor site	Histology	Dx stage	Median survival*	N*	Reference
Breast	NR	NR	2.3 yr	1022	58
Colon	Adenocarcinoma	IV	5 mo	12	57
Gastric	Adenocarcinoma	IV	5 mo	38	56
Head and neck	Squamous cell	1/3 recurrent	4 mo	808	47
Lung	Non-small cell	IIIb/IV	4.1 mo	98	52
			5.3 mo	57	49
			5.9 mo	150	50
Liver	Hepatocellular	NR	1 mo	127	48
Pancreas	Adenocarcinoma	NR	3 mo	39	55

Dx, diagnosis; NR, not reported.
*Values pertain to the subset of untreated patients.

TABLE 42-6. MEDIAN SURVIVALS FROM STUDIES THAT INCLUDE UNTREATED PATIENTS

Prognostic Consultations

Another way for physicians to improve the accuracy of their prognostic estimates is to elicit prognostic estimates from disinterested colleagues. Through informal, "curbside" consultations or through more formal avenues such as tumor boards, physicians may find colleagues helpful in determining patient prognoses. This recommendation stems in part from results of several studies revealing that survival predictions averaged across physicians are more accurate than a prediction from a single physician (59,60) and from results of studies that show that disinterested physicians may provide more accurate predictions (7) than physicians with an emotional or other stake in the outcome of a patient's care. This technique may improve predictive accuracy and minimize optimistic bias by enhancing the "signal-to-noise ratio" in predictions or by decreasing "ego bias."

CONCLUSION

Prognostication in advanced cancer is a difficult task that may become easier as physicians become more comfortable with the process and as researchers begin to develop better clinical prediction tools. Such efforts will help abate the pervasive and systematic optimism in both the formulated and communicated prognoses physicians develop near the end of life. Ultimately, such improvement might be evident through increasing survival times after referral to palliative care programs. As physicians' predictive accuracy improves, survival after referral to hospice may approach physicians' ideal of 3 months (61) rather than the current survival of 3 or 4 weeks (7,62). More broadly, however, such improvement may provide patients with a better understanding of their expected survival and thereby allow them to make informed medical and social choices regarding their treatment path at the end of life, whether curative or palliative (63,64).

EPIDEMIOLOGY OF CANCER AT THE END OF LIFE

JANE M. INGHAM
LYNN E. KACHUIK

Although many advances have occurred in the prevention and treatment of cancer, death from this condition remains a common occurrence. The end-of-life experience associated with cancer varies widely and may be influenced by the type and extent of the disease and by the palliative interventions provided. Physical and emotional symptoms become more common as cancer progresses, and although there is evidence suggesting that they are often underused, many effective palliative interventions do exist to address these symptoms. Knowledge of the epidemiology of cancer-related mortality, symptoms, and end-of-life concerns is essential for physicians who care for patients and patients' families as they experience the advanced phase of illness. Such knowledge is necessary for several reasons: to facilitate optimal delivery of care and symptom management; to contribute to an informed public discussion about end-of-life care for cancer patients; to promote development of research initiatives targeted toward improving quality of life in the latter stages of illness; and to develop standards, guidelines, and treatment strategies for end-of-life care.

Oncology texts typically discuss the epidemiology of cancer in terms of prevalence, incidence, and patterns of disease. Consequently, there is a wealth of epidemiological data pertaining to the demographics of the population dying from cancer, including information about causes and locations of death. Yet there is a paucity of data describing the signs and symptoms of cancer and other factors that contribute to the quality of life at this end of the continuum of care. Due to the lack of empirical data, anecdotal personal narratives, although sometimes perceptive, have frequently been given great credence (1,2,3 and 4). This chapter reflects an attempt to provide the reader with some insight into the experience of advanced cancer toward the end of life. The first section of the chapter reviews aspects of the epidemiology of cancer-related death, including causes, mortality shifts, rates, life expectancies, patterns of institutionalization of medical care, and interactions between cancer patients and the health system. The chapter's latter section reviews the known prevalence of symptoms in the setting of progressive cancer, the nature of the dying process, and some of the problems that have, to date, hindered the development of a good understanding of the epidemiology of the symptom experience in the setting of advanced disease.

When describing the cancer experience, it must be acknowledged that there is a wide variability in this experience between countries. The epidemiological data presented in the chapter address some of the known differences, although much of the available information presented here focuses on the experience of cancer patients in the United States and other developed countries.

Although cancer impacts more than just the physical and emotional domains, the social ramifications of the epidemiology of cancer are not reviewed in this chapter. This is not to imply that these aspects of the cancer experience (including the impact of cancer on families, the social consequences of living with advanced cancer, the care delivered by health systems, and the honoring of the preferences of cancer patients) are not important, but the task given to the authors of this chapter was to address the “physical” aspects of the advanced cancer experience. Many of the issues related to the “social” impact of cancer are addressed in other chapters within this text.

MORTALITY STATISTICS

Leading Causes of Death

Before considering the epidemiology of the symptoms of advanced cancer and the end-of-life experience, it is helpful to have an understanding of where cancer ranks in comparison to other leading causes of death as well as the epidemiology of advanced cancer itself. It is also important to recognize that specific issues, including lifestyle, genetics, and health care, impact the cancer experience from country to country. Disease patterns vary from country to country as does access to care and many other factors.

World Health Organization statistics estimate that 56 million deaths occurred worldwide in 1999, and that 12.6% of these were due to cancer; of note, 31.1% were due to infectious or parasitic disease and 36.7% were due to circulatory or chronic obstructive pulmonary disease (5). Presently, cancer is proportionately more common as a cause of death in developed countries than in developing countries. Patterns of disease, however, indicate that the majority of deaths worldwide occur in developing countries, and that most of these deaths are still due to communicable diseases (6). Demographic shifts indicate that developing countries will have an increasing number of deaths due to noncommunicable disease (including cancer). By 2020, it is expected that deaths due to communicable and noncommunicable diseases will be equal (6).

Cancer Mortality

Statistics related to causes of death within developed countries share common patterns. The statistics of developed countries generally parallel those of the United States. In the United States, cancer was the second of the three leading causes of death in 1998, responsible for 23.2% of deaths (7,8). Cardiovascular disease was the cause of death in 31% of deaths and cerebrovascular disease in 7% (7,8). Cancer accounted for 27% of deaths in the United States in 1998 in those younger than 65 years of age and 22% of those older than 65 years (8). During the same year, there were 1.26 million new cases of cancer (excluding basal and squamous cell skin cancer and *in situ* carcinomas, except urinary bladder) and 541,519 cancer deaths (Table 43-1) (8). From 1990 to 1995, the overall age-adjusted cancer mortality rate in the United States declined by approximately 3.1%, the first sustained decline in cancer mortality since record keeping began in the 1930s (Fig. 43-1) (9).

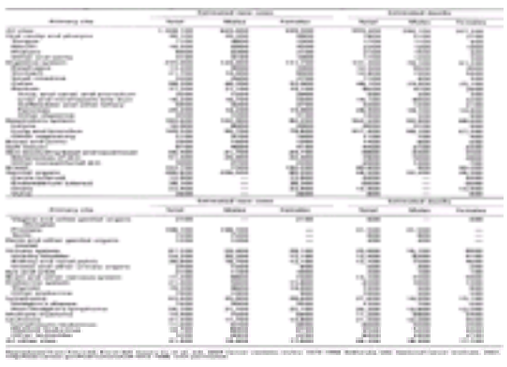

TABLE 43-1. ESTIMATED NEW CANCER CASES AND DEATHS FOR 2001 (ALL RACES, BY SEX)

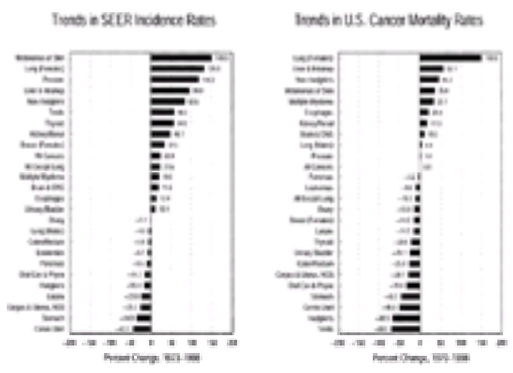

FIGURE 43-1. Trends in U. S. cancer incidence and mortality rates, 1973–1998. SEER, Surveillance, Epidemiology, and End Results. (From Ries LAG, Eisner MP, Kosary CL, et al., eds. SEER Cancer statistics review, 1973–1998. Bethesda, MD: National Cancer Institute, 2001 http://seer.cancer.gov/Publications/CSR 1973–1998, 2001, with permission.)

The estimated numbers for new cases of specific cancers and causes of cancer death in the United States are reported in Table 43-1 (8). Cancer of the lung is responsible for the largest number of deaths in the United States, with more than 154,000 deaths attributed to this condition in 1998, and almost 170,000 new cases estimated to be diagnosed (8). As is evident in Table 43-1, projected figures for 2001 indicate that little to no change is expected to occur, with 169,000 projected new lung cancer cases and 157,400 projected deaths (8). Data specific for each sex in the United States indicate that although the most common sites of new cancers in men are prostate (31%), lung and bronchus (14%), and colon and rectum (10%), the leading cause of cancer death in this population is cancer of the lung and bronchus (31%), with prostate next (11%), and colon and rectum accounting for 10% (10). In women, the most common sites of newly diagnosed cancer are breast (32%), lung and bronchus (13%), and colon and rectum (11%). Cancer of the lung and bronchus causes the greatest number of cancer deaths among women (25%), with breast cancer accounting for 15% and cancer of the colon and rectum responsible for 11% (10).

An important aspect of the epidemiology of cancer relates to the time period that individuals live with the condition. One way to understand this is to review the mortality and 5-year survival figures for different cancers. Many factors influence these figures, including age, sex, race, and treatment strategies. The 5-year survival rates for a variety of cancers from the United States cancer database are included in Table 43-2 (8). Time from diagnosis to death is another statistic used to document the duration of the illness experience. In the 1986 National Mortality Follow-back Survey, data on over 16,000 decedents in the United States were extrapolated to national mortality figures. The survey concluded that of the 511,114 cancer deaths during that year, 140,944 (27.5%) occurred within 6 months of the cancer diagnosis, 83,889 (16.4%) occurred 6–12 months after diagnosis, and 80,832 (15.8%) occurred 1–2 years later (11).

Mortality Shifts

There are a variety of demographic factors that affect the patterns of disease and the management of any associated symptoms and distress. One of the most important factors is age. Causes of death, mortality rates, and trends in cancer death are different for different age groups. Cancer is most commonly a disease of the elderly, and therefore it is in this population that the symptoms of cancer most commonly require management. Age itself also affects mortality rates for specific illnesses. Mortality is higher as age increases (12). A worldwide shift toward an increase in life expectancy is therefore a key factor that will impact on demands on society to provide care for the elderly with cancer. The 1999 world population statistics report a total population of 6 billion, with a predicted increase to 8.9 billion by 2050. The average worldwide life expectancy has increased from 48 to 66 years in the past 50 years (6). In the United States, overall life expectancy has increased from 70.8 years in 1970 to 75.8 years in 1995 (13,14). With increasing life expectancies worldwide, and in spite of new cancer treatments and the declining incidence of certain cancers, it is presently expected that there will be a proportionate increase in cancer diagnoses and deaths from cancer (9,15,16,17,18,19,20 and 21).

Between 1994 and 1998, the median age at death for all cancers in the United States was 72 years, and for most cancers, the highest number of deaths occurs between 65 and 84 years (8). Although cancer is most common in the elderly, it is important to keep in mind that other age groups can be significantly impacted by cancer. For example, although malignant neoplasms were represented among the four major causes for death for every age group in the 2000 preliminary mortality figures for the United States, malignant neoplasms continue to be the *leading* cause of death in the 45–64 year age group (22).

In addition to age, many social and disease-related factors are likely to impact the ranking of the causes of death and the likelihood of death from cancer. There have been shifts in mortality rates, including an increase in lung cancer mortality rates, since 1973 (Fig. 43-1) (8). A major social factor affecting causes of death from cancer, and also from other causes, is smoking, which increases the prevalence of tobacco-related diseases. Other diseases, such as infection with the human immunodeficiency virus (HIV), can also increase the incidence of cancer in the population. In the United States, the HIV infection rate climbed an average of 16% annually from 1987–1995; however, since 1995 the HIV infection rate has been declining significantly, decreasing each year (by 28.8% from 1995 to 1996; by 47.7% from 1996 to 1997; by 20.6% from 1997 to 1998; and by 3.6% from 1998 to 1999) (22). Despite this decline, HIV disease continues to be the fifth leading cause of death among the 25–44-year age group (22). Worldwide HIV infection remains on the increase and significantly impacts mortality.

Interpretation of Mortality Data

When interpreting mortality data, it is important to note that most of this information is derived from death certificates. Death certificate data is often nonspecific and provides little detail that describes the end-of-life cancer experience. For example, “metastatic lung cancer” may be the identified cause of death, whereas respiratory or liver failure occurring as a consequence of metastatic lung cancer may have been the immediate cause of death. Although more detail would be helpful, it is seldom available. Autopsy data would provide more accurate information, but the rate of autopsies is low. For example, 268,553 autopsies were performed in the United States in 1993, representing only 9.7% of the deaths that occurred in that year (23). Autopsy rates were particularly low when death was attributed to one of the leading causes of death. For example, in 1993, the autopsy rate for death from malignant neoplasms was 2.5%. Less common causes of death, including those related to homicide, suicide, and accidents, were far more frequently investigated with autopsy. The autopsy rates in such cases were, respectively, 97.3%, 54.7%, and 48.4% (23).

Although premortem investigations in cancer patients often clarify the diagnosis and the extent of disease, the very low autopsy rate and the reliance on death certificate data for causes of cancer-related death significantly impact the evaluation of the dying process, both in individual cases and for the purpose of epidemiological research. Some of the information that is *not* available as a consequence of this problem includes data describing the specific “cause/s” of death for

many cancers. Although in individual cases the cause of death is often apparent to the clinician, statistical information is not available for many cancers to point to whether respiratory failure, liver failure, generalized cachexia, or other problems are the common contributory factors to death in specific types of cancer. This potential for inaccuracy, inherent in all data derived from death certificates, has important implications for the care of the dying. The lack of detailed, accurate information can impede the advancement in the medical understanding of the pathophysiology of symptoms and distress at the end of life. It may also contribute to delays in the development of symptom-specific palliative interventions (24).

Another important issue to consider when interpreting the data is that they do not reflect the burden of disease. A relatively new concept has evolved that could, over time, help to shed light on this issue worldwide—"disability adjusted life years." This concept attempts to quantify the burden of illness in relation to defined diseases by combining premature mortality and disability (25). Coupling this concept with statistics on causes of death may reveal information about the impact of cancer toward the end of life. World Health Organization indices suggest that the most burdensome medical conditions worldwide may be ischemic heart disease, stroke, and neuropsychiatric disease (25). Although there has been little information available about specific cancers and disability adjusted life years, more effort is currently being put into analysis of this concept so as to estimate the national burden of disease, in total and by disease entity. Brown et al. have published an excellent review of the indicators relating to burden of illness of cancer with respect to quality of life and economic cost (26). Within this publication, the authors report a personal communication from M. McKenna suggesting that the four most prevalent cancers (lung, breast, colorectal, and prostate) have the highest scores for disability-adjusted life years, with lung cancer far exceeding the others because its associated life expectancy is short and consequently large values of years of life are lost per individual (26). As information becomes available about this concept as it relates specifically to cancer, it may provide a helpful means of beginning to quantify the impact of cancer worldwide (26,27).

Place of Death

Although the demographics of cancer-related illness and death are useful in that they provide some understanding of the end-of-life experience, other information relating to cancer mortality is needed to provide an overall picture of the illness experience. The place in which death occurred provides some insights into this experience. In a survey undertaken in the United Kingdom of 98 cancer patients, of whom 84 (86%) agreed to be interviewed, 58% expressed a preference to die at home, 20% preferred the hospital, and 20% preferred an inpatient hospice (28). Sixty-seven percent of these patients, given improved health-related or social circumstances, indicated that they would prefer to die at home. Despite these preferences, most deaths in developed countries occur in medical institutions (29). High rates of institutional deaths are evident in Finland (75%), Sweden (79%), and Iceland (80%), whereas lower rates are recorded in some parts of Europe, in particular, Bulgaria (25%), Spain (30%), and Italy (37%) (29).

Death certificate data from the United States for 1990 indicate that of the 2.2 million annual deaths, approximately 62% occurred in hospitals, 16% occurred in nursing homes, and 17% occurred in homes (National Center for Health Statistics, *unpublished data*, general mortality, 1990, 1994). Home death was more common for patients with malignant neoplasms than for deaths from other causes, with 25.8% dying at home, 58.2% in hospitals, and 13.3% in nursing homes. These statistics also vary depending on age at which death occurs, the range being between 48% and 91%. For example, the place of death for individuals dying before the age of 14 years is highly likely to be a hospital (69–91%), whereas, at the other end of the age spectrum (those 85 and older), a high proportion of deaths (38%) occur in nursing homes.

Although hospital deaths are reported to be most common (National Center for Health Statistics, *unpublished data*, general mortality, 1990, 1994), this does not clarify the site of treatment during the weeks before death. A recent survey of the deaths of elderly individuals found that 45% spent the night before their deaths in a hospital and 25% were in a nursing home (30). Clinical experience suggests that moves between hospitals, homes, subacute care facilities, and hospices are not infrequent in the last weeks of life, but little research exists to specifically elaborate on this phenomenon in the cancer population.

Many social and disease-related factors also influence the place in which death occurs. For example, although hospice participation has been associated with a higher likelihood of death at home (31), the availability of hospice-associated inpatient beds increases the likelihood of death occurring in the inpatient setting (32). A cancer patient's symptom profile may also influence the site of death. For example, data from the 1981 National Hospice Study suggest that disorientation increases the likelihood that death will occur in the inpatient setting (32,33). The economics of health care delivery clearly influence national differences in sites of death and the site of death within a specific country. In developing countries in which access to health care may be limited, death is less likely to occur in an institution. In the United States, the increase in deaths at home or in hospices during the last two decades, which has been particularly evident in patients with cancer, may reflect changes driven in part by the development of a Medicare hospice benefit (34). The increase in the rate of nursing home deaths, particularly among the very elderly, may be related to changes in hospital reimbursement policies, such as prospective payment, utilization review, and preadmission screening (34,35). Some geographical trends also may relate, in part, to variations in the availability and reimbursability of hospice and home health care services. Differences may be compounded by variances in the availability of services in rural and urban areas.

Medical Involvement in Care Toward the End of Life

Those who die as a consequence of chronic illness in developed countries commonly have significant contact with health care professionals before death. The 1986 National Mortality Followback Survey reported that 81% of the 16,000 decedents studied received some institutional care during the last year of life, with 44% receiving between 1 week and 1 month of this care (11). Over 48% had seen a physician more than ten times during the last year of life. Almost 9% received hospice care at home, and less than 0.5% received inpatient hospice care. In a retrospective study of cancer deaths in the state of New York, investigators found that all of the patients surveyed had seen a doctor in the 6 months before death (36). Such contacts afford physicians many opportunities to play pivotal roles in the lives of those with advanced disease and their families by identifying specific needs and mobilizing resources to meet them.

Although physician contact with patients nearing the end of life may be common, the Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments (SUPPORT), although not specific to cancer patients, suggested that deficiencies were present in physicians' patient care roles at the end of life. For example, in the population in that study with colorectal cancer, physicians incorrectly identified patient preferences for cardiopulmonary resuscitation in 30% of cases (37). In addition, a lack of face-to-face contact between cancer patients and their physicians in the United States is evident as the time of death becomes very near (36). In the New York State survey of cancer deaths, 17% of patients had no contact with their physician, although more than half of these patients spent at least 1 of the last 2 weeks at home; 31% had only telephone contact during this period. The lack of face-to-face contact in the last 2 weeks of life is of concern because this is a time when symptoms are highly prevalent, and direct physician assessment and management of such concerns can be very important.

Systems of Care

An additional factor to consider when discussing care of the dying is the "system" of care in which medical care is provided. Access to health professionals with expertise in palliative or hospice care can be important toward the end of life. In some countries, "systems" specific to end-of-life care offer this type of access, whereas in others this type of care is incorporated into the system of care available through the entire course of illness. In the United States, *hospice* is defined broadly as a philosophy of care; however, from a practical perspective, it most commonly refers to a system of care distinct from the care system in the acute-care and hospital system. Toward the end of life, many cancer patients shift their care from an acute-care or hospital-based system to hospice care. Other patients who may have been cared for by a primary physician or a community-based oncologist may shift to hospice care but remain linked with their primary physician or oncologist for medical care. Patients who elect hospice do so, for the most part, at a time when they seek to focus on comfort and quality of life *without* pursuing life-prolonging interventions. Hospice offers an array of services delivered through a team approach, and aims to ensure quality of life for the patient and family, most commonly in the home setting.

In 1996, the National Hospice Organization estimated that 390,000 patients, or approximately 17% of deaths nationally, were treated in hospices in the United States (38). For 2000, the same organization reported that 600,000 individuals were receiving hospice care at the time of death, representing 25% of the deaths that occurred nationally (39). Of the deaths that occurred while patients were enrolled on hospice programs, 61% were reported to have occurred at home. The majority of hospice patients in the United States have a cancer diagnosis. It has been estimated that 58% of those in hospice care in the United States have a primary diagnosis of cancer and almost 40% of those who die of cancer receive hospice care (40). Despite this, and despite eligibility criteria that include those with a prognosis of less than 6 months' life expectancy, survival data suggest that patients spend only brief periods as hospice patients. There is a clear pattern of late referral to hospice. The National Hospice Organization reports a median hospice stay of only 25 days in the United States in 2000; 34% of deaths occurred within 7 days of admission (39). In a survey of 6451 hospice patients, 80.2% of whom had cancer, Christakis and Escarce found that the median survival after enrollment was 36 days, with 15.5% of the patients dying within 7 days (41). Survival was found to vary substantially according to cancer diagnosis even when adjustments were made for age and coexisting conditions. Table 43-3 contains the survival data for the cancer patients in this study. Of note, patients with breast, prostate, and central nervous system cancers had longer survival periods after enrollment than did patients with lymphoma, leukemia, or pancreas and colon cancer.

Diagnosis	Number of patients	Median survival (d)	Percentage who died within 7 d	Percentage who lived longer than 180 d
Leukemia or lymphoma	291	23.0	20.6	14.1
Urinary tract	256	34.0	14.1	12.9
Colon or rectum	678	24.5	15.8	12.4
Pancreas	289	21.0	18.3	10.0
Female genital tract	223	38.0	17.3	14.8
Upper gastrointestinal tract	221	28.0	13.1	9.0
Head or neck	101	44.0	17.8	13.9
Lung	1378	21.0	14.2	11.8
Breast	364	53.0	13.5	9.0
Central nervous system	141	46.0	7.1	14.2
Prostate	400	43.5	14.0	13.7
Liver or biliary tract	205	24.0	22.4	8.8
All other cancers	548	32.5	15.1	12.0

TABLE 43-3. SURVIVAL ACCORDING TO CANCER DIAGNOSIS AMONG MEDICARE BENEFICIARIES ENROLLED IN HOSPICE PROGRAMS

Settings of Care and Quality of Care

Very little information exists about the variation in the quality of care delivered, or the “quality of life,” for patients in different settings. The 1981 National Hospice Study assessed 1754 terminal cancer patients in the United States and found that quality of life was similar for cancer patients in hospice and conventional care systems (42). Although some indicators in this study suggested that control of pain and other symptoms might have been better in the inpatient hospice setting (32,33), interpretation of the quality-of-life data in this survey is difficult owing to a variety of methodological problems. Although hospice programs generally offer an excellent spectrum of services and skills for patients with advanced disease, recent data are not available to compare the quality of life of hospice patients to that of hospital- or community-based patients who do not receive hospice care.

Other gaps in our understanding of quality of care and the quality of life near the time of death relate to information about care in subacute facilities and nursing homes, as well as in different parts of institutions, such as in intensive care units (ICUs) and oncology units. For example, in hospitals, even the *proportion* of intensive care–related deaths compared with ward deaths is unknown. Not only is quality-of-life data unavailable for patients in these settings, but there have also been little data thus far to quantify the proportion of patients who receive particular treatment interventions, such as palliative therapies, cardiopulmonary resuscitation, and mechanical ventilation.

An important study that has shed some light on the endof-life experience is the SUPPORT study, which investigated the experiences of 4301 seriously ill medical inpatients hospitalized in one of five teaching hospitals in the United States. This study found that a median of 8 days was spent in an ICU, in a coma, or with ventilator support, during the admission before death (43). The data from this study were combined with the information from another study of elderly patients to further explore the end-of-life experience associated with medical illness (37). The published data on lung or colon cancer patients in this population provide some particular insight into the cancer experience. For example, ICU admission was not as common for cancer patients as it was for other illnesses; only 3% of colon cancer patients underwent a resuscitation attempt; and only 2% received ventilator support.

Thus, in summary, the impact of the location or setting of care on quality of life during the dying process remains, to a large degree, unquantified. Although the proportion of patients dying in hospitals and at home varies with age, diagnosis, and numerous sociodemographical factors, the reasons for this variability and its implications for patient morbidity and quality of life are, to a very significant degree, still unknown.

“Trajectory of Illness”

Both performance status and level of consciousness contribute to the concept of a “trajectory of illness” or “trajectory of dying.” These are concepts that have been used to describe the similarities and differences in patient experiences over the course of illness and toward death (44,45,46,47 and 48). There is little information available to accurately describe the common trajectories for each particular cancer. The clinical perception of the experience for cancer patients, to date, reflects a combination of the trajectories B and C described in Figure 43-2 (48). Clearly the trajectory of illness is an individual experience, and is closely related to numerous other factors, including the disability that a particular cancer may cause, preexisting disabilities, the prognosis of that cancer, and the impact of treatment strategies focused on quality of life and maintenance of function. As treatments that are both symptom- and disease-specific evolve, it is feasible that the common trajectory of disease could begin to change. For example, it could reflect more of a combination of trajectories A and C.

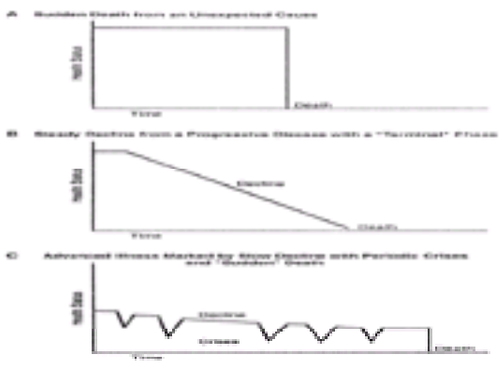

FIGURE 43-2. A–C: Death trajectories: This figure represents greatly simplified examples of three possible trajectories toward death. [Reprinted with permission from “*Approaching Death: Improving care at the end of life.*” Committee on Care at the End of Life; Field, M.J.; Cassel, C.K., Ed.; Institute of Medicine (U.S.). Copyright 1997 by the National Academy of Sciences. Courtesy of the National Academy Press, Washington, DC. (48).]

The trajectory of illness and death is an important consideration for a variety of reasons. First, because the preference of most individuals with cancer is to maintain function and quality of life for the maximum length of time, the trajectory of illness reflects in part whether this preference is being achieved. An understanding of the common trajectories is important to facilitate planning for expected contingencies. For example, if trajectory A were to reflect the more common course of disease progression, patients and families might need to be aware that precipitous functional decline and sudden death are possibilities. Trajectory B is likely to be associated with higher needs for physical assistance and support toward the end of life. Further, these issues are highly relevant when consideration is given to health system–related interventions for patients and their families. For example, the role and functioning of hospice programs would most likely need to be reconsidered if new treatments result in disease trajectories that differ significantly from those experienced now.

SYMPTOMS AND SIGNS OF ADVANCED CANCER (INCLUDING TOWARD THE END OF LIFE)

Despite growing interest in quality-of-life outcomes, oncological literature contains very little information about the nature of the advanced illness experience, the dying process, and the discomfort or distress associated with different cancers. Optimal health care planning, on an individual and a societal level, must anticipate potential problems to facilitate appropriate management. Without a clear understanding of the advanced illness experience and dying process, including recognition of common sources of distress for patients and families, the medical care of this population risks being suboptimal. Only a few studies undertaken in the hospice or palliative care setting have described the experience of the last months, days, or hours of life for patients with cancer. Until recently, there have been fewer data on hospitalized patients than on patients in palliative care and hospice settings, and this also represents a significant gap in knowledge. This section of the chapter reviews some of the data that exist to describe the “physical” experience of patients with cancer as they near the end of life.

Important Factors to Consider When Interpreting Surveys and Studies of Symptoms

At this juncture, before elaborating on the details of reports that address symptoms occurring toward the end of life, it is important to note that many of the existing surveys that attempt to specifically quantify symptom distress in cancer have a number of limitations. These limitations must be considered when interpreting all

surveys and studies of symptoms. It is hoped that investigators will begin to address some of these issues in future investigations.

A crucial issue to consider when interpreting symptom prevalence studies relates to study methodology. In interpreting reports of symptom-related distress, the subjectivity of reports must be considered. Symptoms are inherently subjective experiences, a factor that must be considered both at the bedside and when interpreting published reports of symptoms. *The Oxford Dictionary* has defined a symptom as “a physical or mental phenomena . . . specifically a *subjective* indicator perceptible to the patient and as opposed to an *objective* one (cf. sign)” (49). Symptoms must be distinguished from physical signs and observations that may not have been perceived by the patient as distressing. Proxy reports are common in the end-of-life setting, and although such reports can provide information that is obviously helpful—especially at times in illness when patients are unable to clearly communicate distress—they cannot provide subjective information. Although many patients have cognitive impairment near the very end of life (see the section Mental Status and Consciousness Before Death), the experiences in the last year of life in most patients with advanced cancer lend themselves well to surveys and studies that describe self-reported symptoms. Some use of proxy reporting to explore the important dimensions of distress in the very last week of life is necessary, but when such reports are used they must be interpreted with appropriate caution. There is a definite need for a common language and validated tools to begin to accurately quantify the experience of patients who are unable to communicate in this situation.

A second methodological issue relates to the fact that very few studies specifically explore the *dimensions* of symptoms. Symptoms are multidimensional, with dimensions including frequency, severity, and distress (50). In addition, there are associated correlates, including physical and psychological functioning. A simple report of the prevalence of a symptom does not provide information about the distress associated with the symptom, nor does it provide sufficient understanding of either symptom severity or impact (50,51 and 52). There is a paucity of data to clarify the impact of symptoms in the setting of far-advanced disease on function, physical or psychosocial needs, or the more global constructs of suffering and quality of life (53,54,55 and 56).

An example of the importance of the “dimensions” of symptoms is related to distress. Particularly at the end of life, the goals of the patient are likely to interface closely with distress. For example, a patient who is close to the end of life may consider comfort a higher priority than function and may reach a point where he/she does not consider impaired function distressing. Another patient, perhaps at an earlier stage of illness, may have great distress as a consequence of impaired function. Of note, in one survey of priorities toward the end of life of terminally ill patients in the United States, the majority highly prioritized freedom from pain and clarity of thought (57). Therefore, although reports of some symptoms (e.g., pain) are likely to correlate with at least some degree of distress, the mere presence of a symptom (e.g., fatigue) does not always correlate directly with distress.

Finally, with regard to data collection methodology in cancer patients, any report of global distress should be interpreted in the light of a high likelihood that more than one symptom is contributing to distress and impaired function. It is crucial that this variable be considered. For example, one study of cancer patients found that, although inpatients had more symptoms than outpatients, the mean number of symptoms per patient was 11.5 plus-or-minus 6.0 with a range of 0–25 symptoms (52).

Problems with study methodology are all related to the concept of “self-report” of symptoms. Given the prevalence of impaired consciousness as the very end of life approaches (see the section Mental Status and Consciousness Before Death), the exploration of some of these issues can be challenging in settings in which this problem is prevalent. It must be noted, however, that opportunities for further research abound in this population, as many patients do retain their ability to communicate until the very last days or hours of life (11,30,58,59 and 60).

Another problem in interpreting reports of symptoms and distress in cancer patients is that many investigations fail to describe in detail the medical and pharmacological interventions used for symptom management. This is one of the major problems encountered in the reporting of symptom distress toward the end of life. When such descriptions are absent, it cannot be ascertained if the high incidence of pain or any other reported symptom reflects a worsening pathological condition, undertreatment of the symptom (or symptom distress), or both. Nonetheless, it is known that the undertreatment of pain and other symptoms is likely to contribute to symptom distress, despite the existence of many effective treatment strategies. For example, it has been demonstrated that many cancer patients in the United States continue to receive inadequate analgesia (61,62). In a survey of 1308 oncology outpatients being treated by the physician members of the Eastern Cooperative Oncology Group, 67% reported recent pain and 36% described pain severe enough to impair function (61). This study also reported that over 40% of patients who reported pain did not receive adequate analgesia. Eighty-six percent of the physicians believed the majority of cancer patients with pain were undermedicated (62). Poor pain assessment was rated by 76% of physicians as the single most important barrier to adequate pain management, and 61% indicated that physicians' reluctance to prescribe opioids was another barrier. In a similar survey in France, 69% of cancer patients rated their worst pain at a level that impaired their ability to function, and undertreatment was again a prominent factor (63). As a consequence of these problems, it is difficult to ascertain the degree to which the distress reported in many surveys could have been alleviated. In summary, it is quite possible that much of the reported distress in existing surveys could have been alleviated with appropriate, state-of-the-art palliative interventions. Many such interventions are described in other chapters within this textbook.

In addition to considering “symptom-directed therapies” when interpreting reports of medical interventions and their impact on symptoms, one must also consider the potential impact of therapies directed toward the cancer itself. Many treatment strategies have evolved significantly over the years, and these changes impact both symptoms and the trajectory of the end-of-life experience for some cancers. The reports discussed below, some of which are now somewhat dated, may no longer reflect the current course of illness for some cancers.

Symptoms Present in the Setting of Advanced Cancer

Despite the gaps in treatment and knowledge and problems with the methodology of symptom assessment, a number of existing studies highlight the spectrum of symptoms experienced by cancer patients who live with advanced cancer and are nearing the end of life. These studies also provide some insights into the requirement for further studies to characterize the end-of-life experience and the dying process. The “end of life” can be defined in various ways; this review focuses on the symptoms present in the setting of advanced cancer and specifically discusses the last week and days of life in an attempt to illuminate, at least to some degree, the dying experience.

Many investigators have explored the spectrum of symptoms experienced by cancer patients at various points during the course of the disease. To explore the advanced illness experience, a number of studies have focused on the prevalence and impact of symptoms in the setting of advanced malignant disease (51,52,64,65,66,67,68,69,70,71,72,73,74,75,76,77,78,79,80 and 81). Patients in the advanced stages of cancer commonly report fatigue, pain, anxiety, and anorexia, each with prevalence rates greater than 50% (51,52,77,78,81,82,83,84,85,86 and 87). Moreover, most patients with advanced cancer experience multiple symptoms (52,81,83,85). In an example of a study that used excellent methodology to assess an advanced cancer population, Portenoy et al. evaluated 243 cancer patients, almost two-thirds of who had metastatic disease. Over half were inpatients at the time of assessment (52). Across tumor types, 40–80% experienced lack of energy, pain, drowsiness, dry mouth, insomnia, or symptoms indicative of psychological distress. Although symptom characteristics were variable, the proportion of patients who described a symptom as relatively intense or frequent always exceeded the proportion describing it as highly distressing. In seeking to evaluate symptom distress, this study did not describe interventions for treatment of symptoms and their efficacy.

Studies of the experience of children with cancer are even less common than studies in the adult population. One study that highlights the spectrum of symptoms and the associated distress is from Collins et al., who studied 160 children with cancer between the ages of 10 and 18 years (45 inpatients, 115 outpatients) using a modified version of the Memorial Symptom Assessment Scale (88). Symptom prevalence ranged from 49.7% for lack of energy to 6.3% for problems with urination. The most common symptoms (those with a prevalence of greater than 35%) were lack of energy, pain, drowsiness, nausea, cough, lack of appetite, and psychological symptoms (feeling sad, feeling nervous, worrying, feeling irritable). Of the symptoms with prevalence rates greater than 35%, those that caused high distress in more than one-third of patients were feeling sad, pain, nausea, lack of appetite, and feeling irritable. The mean number of symptoms per inpatient was 12.7 (range, 4–26), which was significantly more than the mean number, 6.5 (range, 0–28), of symptoms per outpatient. Patients who had recently received chemotherapy had more symptoms than patients who had not, and patients with solid tumors had significantly more symptoms than patients with either leukemia, lymphoma, or central nervous system malignancies. As with the Portenoy et al. study, this study sought to evaluate symptom distress but did not describe interventions for the treatment of symptoms.

Among the physical symptoms experienced by patients with advanced cancer, pain and dyspnea are the two that have been most frequently, specifically surveyed. Large studies have documented that pain is experienced by 70–90% of patients with advanced cancer (89,90,91 and 92). In a survey conducted by Addington-Hall of 2074 patients who died from cancer in the United Kingdom, observers noted that 88% of patients had been in pain at some point during the last year of life, with 66% reporting to have found the pain “very distressing” (93). Other common symptoms reported in more than half of this population during the last year of life were loss of appetite, constipation, dry mouth or thirst, vomiting or nausea, breathlessness, low mood, and sleeplessness (93). Again, it must be noted that these studies do not address the degree to which symptom management strategies were implemented.

With regard to pain, some studies have specifically looked at the experience of patients at the very end of life. For example, the National Hospice Study (N = 1754), conducted in 1986 in the United States, indicated that pain became more prevalent in cancer patients during the last weeks of life (72). Although a large proportion of these patients were unable to be interviewed directly, 25% of those who could self-report indicated that persistent or severe pain was present within 2 days of death; this proportion was an increase from 17% in the previous 6 days. Another survey demonstrated that 80% of cancer outpatients experienced pain as death approached (67). A study focusing on the use of analgesics revealed that only 35% of patients dying in the home care setting and 9% in hospital-based hospice care did *not* use analgesics during the last week of life (75), but there may be serious limitations in the knowledge and skills of health professionals that have, to date, impacted the effective prescribing of these medications. A demonstration of this may be found in the SUPPORT study in the United States. In this large study of hospitalized patients, 50% of the 1400 patients who had been conscious before death were reported by caregivers to have experienced moderate to severe pain for at least half of

the time during their last 3 days of life (43). The data from this study were combined with data from another survey to clarify the perceptions of family members who observed the dying experiences of 3357 patients, of whom approximately 12% had lung cancer and 5% had colon cancer (58). In the groups with cancer, 40–46% of patients were judged by their relatives to have had moderate to severe pain for more than half of the time during the last 3 days of life.

To a lesser degree than pain, cancer-related dyspnea has also been explored. This symptom has been reported to be in the range of 20–78% in the advanced cancer setting (74,76,79,94). This wide variation likely reflects variability in the definition of dyspnea, in the methods used to elicit the symptom, and in methods of patient selection. These studies also involved patient populations with differing cancers, stages of illness, and treatment strategies. In many of these studies, distress was not clearly quantified, and, as is often the case with pain studies, details of symptom management strategies were not reported. Of note, it is also possible with this particular symptom that at least some of the observers in these studies may have provided reports of dyspnea when what was witnessed was actually the very common occurrence of heavy (and probably nondistressing) breathing at the end of life. These considerations must be taken into account for all of the studies on dyspnea discussed in this section. In the 1986 National Hospice Study, dyspnea was reported to have been seen in 70% of 1754 patients during the final 6 weeks of life, with the prevalence increasing as death approached (74). Higginson and McCarthy studied a group of 86 cancer patients and noted that dyspnea was a severe and often uncontrollable symptom near death (76). In a survey of hospice inpatients with cancer, dyspnea was present in 55.5% of all patients on admission to the inpatient hospice and 78.6% of those who died within 1 day of admission (79). In the SUPPORT study, dyspnea was reported to have been perceived by others to have been moderate to severe for the last few days of life for 30% of colon cancer patients and for almost 70% of those with lung cancer. Again, “perceived” distress with the observation of “heavy” breathing may be an issue in this report. There is a great need for focused studies that explore the prevalence, associated distress, and management of dyspnea.

Although the most common symptoms of advanced cancer are generally considered to be physical (e.g., pain, fatigue, or nausea), this finding can be ascribed to survey methodology that often does not address psychological symptoms. When specific psychological measures are incorporated into survey methodologies, high prevalence rates for psychological symptoms have been reported (65,68,70,80,95,96). For example, depressed mood and anxiety have been commonly reported in response to specific questions addressed to ambulatory cancer patients (52). Other chapters in this textbook provide more detail about the prevalence of, and treatment strategies for, psychological symptoms.

Impact of Symptoms in Advanced Cancer

As discussed, data that relate *only* to the prevalence of symptoms do not provide sufficient understanding of symptom severity, distress, or impact (50,51 and 52). Only a small amount of information is available to quantify the specific impact of symptoms in advanced disease on function, physical or psychosocial needs, or on the more global constructs of suffering and quality of life. The use of some of the newly developed instruments for assessment of these constructs may, over time, improve our understanding of these issues (50,97,98,99,100,101,102,103,104 and 105).

Chang et al. recently surveyed 240 patients with advanced cancer at a Veterans Affairs Hospital in the United States (81). This survey, using excellent symptom assessment methodology, provides some insights into the impact of increasing numbers of symptoms on the presence of other symptoms, performance status, and quality of life. The median number of symptoms was eight per patient (range, 0–30 symptoms), but those patients with “moderate intensity pain” had a median number of 11, and those with a “moderate-intensity lack of energy” reported a median of 13. The five most prevalent symptoms were lack of energy (62%), pain (59%), dry mouth (54%), shortness of breath (50%), and difficulty sleeping (45%). Patients with a level of pain or fatigue that was “moderate” were noted to have more symptoms than those with lesser intensity ratings for these symptoms. As was the case in the Portenoy study (52), referenced in the section Symptoms Present in the Setting of Advanced Cancer, the proportion of patients who described a symptom as relatively intense or frequent always exceeded the proportion describing it as highly distressing, although symptom characteristics were variable (Table 43-4). As the number of intense symptoms increased, performance scores decreased. In addition, the number and intensity of symptoms also correlated with quality-of-life scores, even when the symptom-specific items from the quality-of-life measures were removed (81).

Symptom	Prevalence (%)	Severe distress (%)
Lack of energy	62	60
Pain	59	52
Dry mouth	54	12
Shortness of breath	50	16
Difficulty sleeping	45	20
Feeling drowsy	44	16
Worrying	40	12
Feeling nervous	37	20
Cough	33	18
Weight loss	33	11
Lack of appetite	29	15
Feeling irritable	28	17
Sexual interest	18	7

The National Mortality Followback Survey (see the section Cancer Mortality) also provides some insights into the impact of illness at the end of life. This was undertaken by the collection of information from death certificates and from the responses to a proxy survey questionnaire completed by the caregiver of each decedent (106). Although the most recent survey, conducted in 1993, evaluated over 18,000 decedents, specific information is not available about the 32% of individuals who had a history of cancer. Nonetheless, the reports of the functional impairment of the population as a whole during the last year of life revealed that 37% patients had some trouble with preparing meals, 54% with walking, and 34% with eating. Nearly half (42.1%) of patients spent 14 days or more (and 15% spent more than 6 months) of the last year of life in bed for more than half the day (106). The differential impact of symptoms on these limitations was, unfortunately, not quantified in the survey, but information about this, along with data specific to cancer, could provide insights into the end-of-life experience of cancer patients. In the survey by Addington-Hall (discussed in the section Symptoms Present in the Setting of Advanced Cancer) of 2074 cancer deaths in the United Kingdom, district nurse assistance was needed for at least 60% of the deceased, home help in 20%, and “meals on wheels” in 9% (although relatives bore the brunt of caring for 81%). In spite of this, 31% were reported to have needed “more help” with activities of daily living. It would seem that symptoms may have been limiting in these instances, but the exact relationship of symptoms to activities of daily living was not elaborated on (93).

Some investigators have attempted to correlate the presence of symptoms with prognosis (84,107,108). Such analyses are very complex, with conclusions that are likely to vary greatly in relation to different cancers, age groups, and other variables. The National Hospice Study in the United States (84) found that the Karnofsky Performance Status was the strongest predictor of survival in terminally ill patients. Within this study it was also reported that five symptoms—dry mouth, shortness of breath, problems eating, recent weight loss, and trouble swallowing—had some predictive value in relation to survival time. When low levels of performance were present, prognosis was poor regardless of which symptoms were present. In a recent large Italian study of cancer patients in a palliative care setting, Caraceni et al. found that the presence of delirium, along with some other factors (including low performance status), was predictive of shorter survival (108). Further studies are needed to accurately describe the impact on prognosis of symptoms and their treatment.

Symptom Distress in the Immediate Period before Death

A survey of 486 dying patients undertaken by Dr. William Osler between 1900 and 1904 represents the first important survey of the dying process. In this survey, a questionnaire was completed by the nurse who attended the patient at the hour of death (109,110). This survey was not confined to cancer patients. Osler described most patients as dying comfortably with “no sign of death one way or another . . . like their birth, death was a sleep and a forgetting.” Despite this, many patients experienced distressing symptoms at least transiently. The distress was described as “bodily pain or distress” (N = 90), “mental apprehension” (N = 11), “positive terror” (N = 2), and “bitter remorse” (N = 1). The study did not go on to describe the palliative interventions used to treat this distress, although it is known that Osler used opioid analgesia and held the view that uncontrolled symptoms should be adequately treated.

Subsequent to this survey, other investigators have explored aspects of the dying process, including mental status and consciousness before death, individual awareness of impending death, and the distress experienced by the dying. Many of these studies have focused on cancer patients, mainly in the United Kingdom, Europe, and Canada, with very few conducted in the United States. Some investigators have attempted to explore the time “near to death” by addressing symptoms thought to be markers of impending death at specific times, such as at admission to a hospice or a palliative care unit (82,83,96,111,112 and 113). Some studies have looked at care delivery near the end of life by attempting to examine the differences in the quality of care provided by inpatient hospice, palliative care, and home care services (33,87,114,115,116 and 117). Several investigations, including those summarized in Table 43-5, have used methodology that reflects an attempt to focus

specifically on the “dying process” or the last week of life (30,42,60,84,85 and 86,94,118,119,120,121,122,123,124,125 and 126).

Symptoms	Bedard (123) N = 152[a,b] (%)	Coyle (85) N = 90[a] (%)	Fainsinger (86) N = 100[a,b] (%)	Hinton (121) N = 82[a] (%)	Lichter (122) N = 220[a,b] (%)	Saunders (118) N = 200[a,b] (%)	Ward (102) N = 200[a,b] (%)
Pain	15–30	54	99	71	51	35	62

Symptoms were recorded if any two surveys demonstrated a prevalence of greater than 25% or if any one survey demonstrated a prevalence of 50% or more for a specific symptom.
[a]Hospice or palliative care inpatients only.
[b]Data provided by patient or primary caregiver.
[c]Cancer center inpatients and outpatients.
[d]Medications or overall distress included as one or as prevalence.
[e]General patients, type of care not specified.
[f]Data provided directly by patient.

TABLE 43-5. SYMPTOM PREVALENCE IN THE LAST WEEK OF LIFE IN PATIENTS WITH CANCER

Unfortunately, there are still large gaps in our knowledge, particularly regarding death from specific cancers in the hospital or home care setting. Data from hospice programs and numerous pain studies suggest that most deaths can be peaceful (86,118,123), although many studies suggest that at least transient distress is common and requires close attention and treatment. Among the large surveys, Osler's report suggested that approximately one-fifth of dying patients experienced some bodily pain or distress (109). This proportion is smaller than suggested in more recent surveys. For example, Brock et al. surveyed caregivers of elderly decedents in the United States, and although not all of these patients had cancer, it was reported that during the 24 hours before death, 44% of dying patients were short of breath, and 33% were in pain (30,60). The SUPPORT study reported that in the groups of patients with cancer, 40–46% were judged by their relatives to have moderate to severe pain for more than half of the time during the last 3 days of life (58). In addition, 30% of colon cancer patients and almost 70% of those with lung cancer were reported to have moderate to severe dyspnea for the last few days of life. Again, it is important to note the difficulty inherent in interpretation of this study, which used family observers to quantify distress. Nonetheless, the fact that this was the perception of families of patients at this time of life is very concerning, especially when it is known that a myriad of treatment strategies for these symptoms exist, and, as demonstrated by the hospice studies, death can usually be peaceful with close monitoring and treatment of distress.

Longitudinal studies can also provide insight into the patient experience in the setting of far advanced cancer at the end of life. Coyle et al. (85) reviewed the records of 90 cancer outpatients, ranging in age from 23 to 82 years, to describe their experiences during the 4 weeks before death. Two-thirds of these patients had cancers of the lung, colon, or breast, and all were cared for at home during this time. Only 19% of patients were able to engage in some form of limited activity outside the home. Fifty-seven percent died at home, 41% in the hospital, and 2% in an emergency room. At various times in the last 4 weeks of life, patients spontaneously identified 44 different symptoms distressing enough to interfere with activity. The number of symptoms volunteered per person ranged from one to nine, with 71% describing three or more distinct symptoms at 4 weeks before death. Fatigue (58%), pain (54%), weakness (43%), sleepiness (24%), and cognitive impairment (24%) were the most prevalent symptoms (Table 43-6). Although the spectrum of symptoms reported was similar at 4 weeks and 1 week before death, there were changes in prevalence. The prevalence of sleepiness increased from 24% to 57%, whereas the prevalence of pain decreased from 54% to 34%. Although the population depicted in this survey had been referred because of difficult pain problems, the degree of distress remains informative. Eighteen of these patients acknowledged suicidal ideation, and an additional four patients were suicidal, each elaborating a specific plan. The latter patients were clinically depressed and required psychiatric intervention. Four patients made a specific and spontaneous request for euthanasia without direct or indirect prompting from the clinician. Again, this survey highlights the common occurrence of symptoms and the importance of close medical and nursing monitoring of cancer patients near to the time of death to ensure that distress is alleviated promptly.

Symptom	4 weeks before death [N (%)]	1 week before death [N (%)]
Fatigue	52 (58)	47 (52)
Pain	49 (54)	31 (34)
Generalized weakness	39 (43)	44 (49)
Sleepiness	22 (24)	51 (57)
Mental haziness, confusion	22 (24)	25 (28)
Anxiety	19 (21)	16 (18)
Weakness of legs	16 (18)	15 (17)
Shortness of breath	15 (17)	25 (28)

TABLE 43-6. PREVALENCE OF SYMPTOMS VOLUNTEERED BY ADVANCED CANCER PATIENTS 4 WEEKS AND 1 WEEK BEFORE DEATH (N = 90)

Impact of Medications on Symptom Management and Comfort at the End of Life

Specific strategies have evolved in the fields of pain management and palliative care to address common symptoms toward the end of life; these have been described in the literature and discussed at length in other chapters within this textbook. Effective treatment strategies exist for the most common symptoms, including pain, dyspnea, fatigue, confusion, and sleep disturbances. Clearly, however, there are some symptoms (e.g., fatigue) that may be somewhat difficult to resolve *completely* at the very end of life despite the existence of useful treatment strategies. Also, sedation occasionally may be a side effect encountered in the course of attempts to achieve symptom control at the very end of life. Accurate assessment of the impact of drugs used for symptom control, and assessment of the degree to which sedation is a necessary symptom management intervention, has been hampered by several problems. These include poor symptom assessment methodology and evidence that suggests many clinicians are still lacking the knowledge and skills needed to optimally implement known treatment strategies (61,62,127,128).

The debate regarding the role of sedative medications in the management of unendurable symptoms at the end of life highlights this dilemma. Ventafridda et al. triggered a controversy in the palliative care literature by reporting that 52.5% of dying patients required sedation to obtain relief from symptoms (124). This finding contrasted sharply with data from hospice programs, which suggest most deaths are peaceful (118,123). Ventafridda's results also differ from the results of a survey of 100 cancer patients in a palliative care setting in which the majority of deaths were comfortable, with only 18% of patients requiring sedating treatment for pain or delirium (86). In this latter study, 57% of patients were unresponsive by the day of death. Routine symptom assessment measures were used by Fainsinger et al. in this latter study, but interpretation of the data was difficult in both studies. First, symptoms were evaluated by observers, and second, no detailed descriptions of the palliative interventions were included. The proportion of patients who have intolerable symptoms, therefore, remains unresolved.

Further studies of treatment strategies, incorporating comprehensive symptom assessment measures, are needed to clarify the impact of therapy on symptom management for the dying. Research into these issues must be broadened to include individuals whose death occurs at home or outside of palliative care and hospice settings. Although the role of sedative drugs for management of refractory symptoms in the dying is controversial (86,124,126,129,130,131,132 and 133), the major concern for society continues to be the underuse of palliative strategies for the management of distress.

Mental Status and Consciousness before Death

A final aspect of the “physical” experience of advanced cancer relates to the ability to communicate toward the end of life. Although the prioritization of this by patients who have reached the last few days of life has not been explored, patients with advanced cancer have rated the ability to communicate effectively as a high priority (57). One indicator of this ability at the end of life is the level of consciousness before death. Consciousness is clearly influenced by a diverse range of factors, many of which are disease-specific. These factors include the rapidity of physical deterioration, coexisting organ failure, and the use of sedative medications.

A review of the mental disturbances that impact clarity of thought can shed light on the ability of patients to communicate. The occurrence of such disturbances—in particular, the occurrence of cognitive decline and delirium—in the setting of advanced cancer and toward the end of life has been specifically explored in several small studies. The 1986 National Mortality Followback Survey explored issues of orientation during the last year of life and has provided some insights into the experience of

the general population toward the end of life (11). Among the 16,000 individuals (who died of various diseases) surveyed, 61% were described as “never or hardly ever . . . having trouble understanding where he or she was during the last year of life.” Fifteen percent were described as having this difficulty for the “last few hours or days,” 13% for “some of the time,” and 8% for “all or most of the time.” Another large survey of 1227 deaths of the elderly in the United States indicated that 60% had no difficulty with orientation or with recognizing their families during the 3 days before death, and 51% had no difficulty on the day before death (30,60). No specific data about the subpopulations of cancer patients were included in the reports of these surveys.

In advanced cancer patients, the potential causes of delirium and impaired cognition may be divided into direct tumor-related effects and indirect effects (134). The latter category includes drugs, electrolyte imbalance, cranial irradiation, organ failure, nutritional deficiencies, vascular complications, paraneoplastic syndromes, and many other factors (134,135,136,137,138,139,140 and 141). Although no large, prospective survey has assessed the relative contributions of the many factors that can cause cognitive impairment in cancer patients, a survey of 140 cancer patients referred for a neurology consultation demonstrated a multifactorial etiology in most of the patients presenting with encephalopathy (141,142). The common reasons for this state were metabolic causes, drugs, and central nervous system metastases. Drugs, especially opioids, were associated with altered mental status in 64% of patients, metabolic abnormalities in 53%, infection in 46%, and recent surgery in 32%. A structural brain lesion was the sole cause of encephalopathy in 15% of patients. Although delirium improved in 67% of patients in this study, it was a poor prognostic factor for overall outcome (141). Bruera et al. studied 66 episodes of cognitive failure in 39 patients admitted to a palliative care service and cited drugs, sepsis, and brain metastasis as the most frequently detected etiological factors (143). Within this population, 22 (33%) improved, 10 spontaneously and 12 as a result of treatment. These studies demonstrate that although cognitive decline is common in the setting of advanced cancer, an active approach to the diagnosis and treatment of cognitive decline has significant benefits (143).

In the period at the very end of life, Massie et al. found that 11 (85%) of 13 terminally ill cancer patients were delirious in the immediate period before death and noted that the early symptoms of delirium were frequently misdiagnosed as anxiety, anger, depression, or psychosis (69). Recently, data from the SUPPORT study were combined with data from another group of elderly patients (total N = 4622) to evaluate aspects of the dying experience including the level of consciousness before death (58). Eighty percent of the lung cancer patients and almost 70% of the colon cancer patients in this study were reported to be conscious 3 days before death; 55% and 40% of these groups, respectively, were also reported to be able to communicate effectively at this time. A survey of 100 cancer patients who died at St. Christopher's Hospice in the United Kingdom described 10% as alert, 67% as drowsy or semiconscious, and 23% as unarousable or unconscious during the 24 hours before death (118). Finally, a survey of 154 inpatient and home care cancer patients found that one-third were able to interact 24 hours before death; this decreased to one-fifth at 12 hours before death and one-tenth in the hour before death (59).

Although these studies reveal that a high proportion of cancer patients maintain alertness until they are close to death, it is apparent that impaired cognitive functioning is prevalent, although often reversible (up until the very last days of life).

CONCLUSION

Although many studies have described the experience of patients during the advanced stages of cancer, a large number of questions remain unanswered about the physical and emotional experience of these individuals. There is a need to expand the epidemiological knowledge base particularly as it relates to specific cancers, sites of care, and aspects of the symptom experience. Information is also required about how patients are cared for and by whom; whether patients' goals for end-of-life care are being met; and which setting—home, hospital, or hospice—is most likely to meet these goals for a variety of subpopulations with differing problems and symptoms. Access to care, physicians' knowledge of palliative care, patient-physician communication, and patient-family-physician communication must be further explored. Special consideration also needs to be given to unique populations, including the pediatric, the elderly, and the mentally handicapped. Much of the distress that may occur at the end of life is responsive to palliative interventions, but a broader understanding of the many aspects of the end-of-life experience is needed for the further development of health care strategies and standards for the care of the dying. Strategies and standards must be further developed so that optimal care can be provided for all patients and families at this most difficult time.

DEFINITIONS AND MODELS OF PALLIATIVE CARE

J. ANDREW BILLINGS

> Palliative care is a vast wasteland in American medicine, and nowhere is it less well understood or more neglected than in the academic health science center (1).

Palliative care clinicians face two troublesome issues in introducing themselves to a patient, family, or health care professional. First, the term “palliative care service” is still unfamiliar to many people. A simple, straightforward, concise explanation is called for, yet just a few words rarely suffice. Other specialists—for example, a cardiologist (“a heart doctor”) or an orthopedist (“a bone surgeon”)—are unlikely to be asked to define their field of expertise, nor feel challenged by the task. Second, a full explanation of palliative care necessarily refers to death, a potentially frightening topic that the patient and family, as well as the palliative care clinician, may wish to avoid, at least in the first moments of an interview. The clinician, before touching on such difficult matters as end-of-life care, wants first to listen to the patient and family (2) and understand their perspectives and information preferences, as well as to avoid saying something “wrong.” A nuanced description of palliative care services, especially for strangers facing dying, is a challenge. Phrases such as “terminal care,” “life-threatening illness,” or even “seriously ill” may stick in the clinician's mouth. One searches for euphemisms in these opening moments, yet struggles to establish a relationship that is based on authenticity and measured frankness.

To complicate this awkward situation, interpretations of the meaning of palliative care and of its scope vary within the palliative care community, reflecting the evolving nature of this not-yet-fully-formed young field. The scope of palliative medicine remains an issue for debate, ranging from absurdly broad definitions as “alleviation of symptoms,” “improving quality of life,” or treating patients “not responsive to curative treatment” to extremely narrow notions of care in the last 6 months or less of life. Discussions of definitions and standards also raise a few, significant, unsettled political conflicts about the field's future. Differences also exist across countries, and hence the focus in this chapter is on the United States, where the distinction between palliative care and hospice is an important issue. Approaches to identifying a final phase of life during which palliative care is appropriate have not been clinically useful (3,4,5 and 6). We lack elementary standards for palliative care programs—staffing, professional training of staff, eligibility of patients and families for services, scope of services, and so forth. This unfortunate state may be viewed generously as an early stage in the development of a field that still is formulating its most basic features.

Nonetheless, any description of palliative care and the hospice movement should hark back to Cicely Saunders, who developed the first modern palliative care program at St. Christopher's Hospice in London (7). She described the hospice philosophy, or hospice approach to care—skilled care that addressed physical, psychosocial, and spiritual needs of the patient and family—which forms the basis for palliative care programs throughout the world. Many current programs characterize themselves as hospices or may use the word to indicate a freestanding unit where dying persons reside and receive care, similar to St. Christopher's Hospice. The word “hospice,” however, had unacceptable connotations in French-speaking Canada, leading Balfour Mount around 1973 to coin the term “palliative care” for describing his new program at the Royal Victoria Hospital in Montreal (8), the first hospice-like unit based in an academic teaching hospital (9). “Palliative care” and the related term “palliative medicine” have become the labels of choice throughout the world for programs based on the hospice philosophy, and as discussed more fully below, are now being used increasingly in the United States (10,11,12,13,14,15,16 and 17). “Palliative care” overlaps with “terminal care,” “death-and-dying,” “hospice,” “end-of-life care,” “thanatology,” “comfort care” (18), care of “patients who may die soon and their families” (19), “supportive care” (20,21) (this term sometimes refers to comfort care, sometimes to support of the compromised host or critically ill patient, particularly those suffering adverse effects of cancer treatment), and, more recently, “hospice palliative care” (21). The diversity of meanings of these terms and their unfamiliarity to many persons can bewilder patients, family members, and colleagues in the health professions.

How palliative care practitioners label themselves, how they and others define the work, and what standards they adopt may have profound effects on the future of the hospice movement and on palliative care as a discipline. The absence of a consensus and common language among palliative care practitioners hinders progress in establishing the field. This chapter attempts to provide some clarification and to stimulate further discussion about the definition and standards for palliative care.

COMMON DEFINITIONS OF PALLIATIVE CARE

> ... the meaning of a word is its use in the language (22).

“To palliate” literally means “to cloak.” This phrase can be used to describe measures that ease suffering—that alleviate without curing—but also can connote glossing over or even giving a deceptively attractive appearance to a significant underlying problem. Thus, for clinicians, palliation can be viewed disapprovingly as merely covering up problems. Terms such as “comfort measures only” or “palliation only” suggest withholding, passivity, or giving up, whereas “best supportive care” at least suggests high quality and action. However, as currently used in American medicine, “palliative care” has become a widely accepted term for an approach to the management of a terminal illness that focuses on symptom control and support rather than on cure or life prolongation.

Anticancer treatments, such as chemotherapy or radiation, that are used to improve quality of life without an expectation of prolonging life may be described as having “palliative intent.” Interventions that were previously dismissed as ineffective in terms of survival, disease-free survival, tumor response, or performance status are now being reexamined in terms of relief of specific symptoms, psychosocial well being, functional status, and overall quality of life. Such approaches underscore the lack of clear boundaries between treatment of an underlying disease and the alleviation of symptoms. They also point to the complexity of the concept of palliation and the difficulty of assessing or measuring quality of life. As asked by Kornblith, “Does palliative care palliate?” (23) For instance, in the case of radical radiotherapy for non–small cell lung cancer, the overall outcome might reflect the patient's evaluation of the relative value of reduced hemoptysis and chest pain without an improvement in dyspnea, cough, or other symptoms, yet transiently increased general symptoms and decreased functioning and wellbeing associated with the course of radiotherapy, all with no improvement in survival or “quality-adjusted time,” and an expected general trend of deteriorating multidimensional quality of life (24).

Two widely cited definitions of “palliative care” deserve note. First, the World Health Organization, in its 1990 publication *Cancer Pain Relief and Palliative Care,* defined the term as “the active total care of patients whose disease is not responsive to curative treatment” (25).

This definition is not very helpful to patients and should be offensive to medical colleagues, who, it implies, deal only with inactive or partial care or with curative treatment! The term “active” is presumably included here to dispel notions that palliative care is passive or focused simply on avoiding interventions but seems to add little to the meaning of the definition. What is inactive care? Palliative care clinicians certainly cannot claim special expertise in the vast number of diseases that do not respond to curative treatment. Ideally, our definition should focus on the positive aspects of the work, such as helping patients and families live well or promoting their quality of life. Here, the emphasis on failure—“not responsive to curative treatment”—seems unnecessarily gloomy but perhaps is fairly gentle and acceptably euphemistic about terminal care and death. The commonly stated but problematic distinctions between palliation and curative or life-prolonging (or “life-extending”) treatment (or treatment with “aggressive intent”) are not invoked.

One strength of this definition is the assertion that palliative care should address all forms of suffering (26): “total care.” Related terms are “total pain or suffering,” “holistic care,” “total palliative care,” and “multidimensional care.” Unfortunately, such claims can sound a bit overinflated or unrealistically ambitious. “Holism” is a bankrupt term, a red light that often signals nonsense. It has lost its cachet in thoughtful social science circles (27), and the term is now regularly used synonymously with “alternative” or “complementary” medicine. Thus, holism, rather than implying a multifaceted, inclusive vision of health and illness, often stands for an unproven or idiosyncratic approach to care and a rejection of mainline medicine. A derogatory term, “symptomatologists,” has been introduced by Kearney (28) and might be used to describe caregivers who focus on various complaints and manifestations of disease but do not address the overall suffering of the person (26). “Comprehensive care” is a preferable term, especially because it already has established meaning in health services literature and avoids pretentious or confusing implications of the

other terms (29). Other characteristics of palliative care that might be related to or subsumed by the term “comprehensive” are “interdisciplinary,” “coordinated,” “integrated,” “accessible,” “case management,” “disease management,” and perhaps “humanistic” care.

This World Health Organization definition is typically followed by a longer attempt at clarification:

> Control of pain, of other symptoms, and of psychological, social, and spiritual problems is paramount. The goal of palliative care is achievement of the best possible quality of life for patients and their families. Many aspects of palliative care are also applicable earlier in the course of the illness, in conjunction with anticancer treatment.

These additional assertions are helpful, although they do not clearly distinguish palliative care from other clinical fields. Many clinicians recognize the importance of comfort and support in terminal disease as well as in nonterminal disease. Arguably, all of medicine can be viewed as seeking the goal of quality of life. Moreover, the association of palliative care solely with cancer is misleading.

A second definition of palliative care, used by the authors of *The Oxford Textbook of Palliative Medicine,* the major textbook in the field, first published in 1993, has also been widely cited:

> The study and management of patients with active, progressive, far-advanced disease for whom the prognosis is limited and the focus of care is the quality of life (30).

This definition is more concise and more precise than the World Health Organization phrases. By choosing a word such as “focus,” it avoids making palliative care a conflicting or totally separate approach from “conventional,” “curative,” “aggressive,” or “life-prolonging” measures. As discussed later, the distinction between hospice and other forms of care, as established in the United States by the Medicare Hospice Benefit, is clinically bizarre and creates a false dichotomy, suggesting that palliation can occur only in exclusion of other forms of treatment. A Canadian Palliative Care Association definition also stresses that palliative care “may be combined with therapies aimed at reducing or curing the illness, or it may be the total focus of care” (31). Indeed, palliative care must embrace all the “high-tech,” expensive, “aggressive” measures that can enhance patient and family care at the end of life (32). Certainly, palliative care should not be consigned to the final days of life when other approaches are abandoned. Moreover, as John Rowe stresses:

> Real quality of care for these [dying] patients is not more care or even less care, but the right care . . . This concept . . . doesn't rely on emerging data from molecular biology. It is not considered to be on the cutting edge by many of our faculty. But it is, in my mind, the essence of what all of us who are physicians swore when we took the Hippocratic oath (1).

The Oxford text definition also suffers from jargon and confusing terminology. What is a “limited” (or “unlimited”) prognosis? Is this designation preferable to “incurable” or “terminal?” Who will attend to the subtle distinction about the disease being both active and progressive? Where is the family in this explication?

None of these definitions is brief or clear enough to answer a patient's or family member's questions: What does palliative care mean? Or, what does a palliative care service do? Indeed, the definitions may be too abstruse and too vague even for clinicians or health care policy experts who are familiar with the jargon.

PROBLEMATIC PRECEPTS OF PALLIATIVE CARE

A variety of guidelines and positions statements on the care of the dying are available (33). The American College of Physicians–American Society of Internal Medicine has produced a set of core principles and readings (34). Definitions of palliative care are sometimes accompanied by precepts or clarifications (35,36). When viewed critically, many of these are meaningless, silly, grandiose, inappropriate for a health care discipline, or simply inaccurate. Although palliative care may be the standard bearer for some important aspects of modern medicine, particularly a focus on alleviating and preventing suffering, an emphasis on comprehensive care, and the use of interdisciplinary teams, many slogans should be quickly recognized as inappropriate for a discussion of a clinical specialty, regardless of its scope or sense of mission. Here, we should be mindful of Doyle's admonition “never to believe that we have a monopoly on care, concern, or compassion,” and of hospice's tendency to “self-righteousness” (37).

Some terms and phrases that are used in definitions or precepts—for instance, “patient-centered care,” “care *versus* cure,” “whole person care,” “treating the person, not the disease,” “compassion,” “skill,” “dignity,” “recognition of patient values,” or “culturally sensitive services”—may suggest important standards distinguishing good from bad palliative care but do not constitute essential parts of a definition. They may also imply that palliative care has a special claim on such virtues. Such terms can muddy the waters and engender misgivings from even those sympathetic to the new field. For instance, although palliative care should certainly be tailored to the needs and wishes of the patient and family, this feature does not distinguish it from other fields of medicine any more than do skill or compassion. Quality of life is a concern in all areas of medicine, and any intelligent approach to assessing quality of life begins with an understanding of patients' knowledge about their condition and potential management strategies, their values, and their personal costbenefit calculations.

The term “dignity” (as in “death with dignity”) is often used, although it seems vague and potentially laden with the care providers' values (38). As one physician reported, “I have never been particularly dignified in the sense that so many people use that word, nor have I even cared much about it. I am not sure I will want to pursue this quality when I am dying, let alone have my care significantly influenced by other caregivers' notions of what constitutes a dignified death.” Similar concerns can be raised about such terms as “develop a sense of awe,” “allow natural death,” “artifical nutrition and fluids,” “find meanings for life,” or “develop a sense of worthiness,” all of which may be appropriate goals for some patients, not for others. Nonetheless, spiritual issues, such as meaning, hope, transcendence, connectedness, and purpose, deserve a great deal of attention in palliative care services.

We also often read that hospice or palliative care “affirms life and regards dying as a natural process.” But what does it mean not to affirm life? Do other clinicians disapprove of life or truly regard dying as an abnormal process? A particular theology seems to be creeping into clinical work. Certainly, palliative care clinicians may be less likely than other clinicians to view death as a failure or as an inevitable enemy and may be more likely to see positive opportunities for growth and reconciliation in the face of dying. They also probably acknowledge dying more openly than many colleagues, but these attitudes cannot be definitions, any more than a proclivity to favor cardiac catheterization or surgical approaches for managing ovarian cancer defines, respectively, a cardiologist or a gynecologic oncologist.

Similarly, we regularly read that hospice or palliative care “neither hastens nor postpones death,” which appears to be a statement of ideology or intentions, perhaps reflecting an aversion to euthanasia or, tellingly, to life-prolonging treatment. This maxim may reflect some of the religious orientation of the hospice movement and even its distant historical background of seeking to save souls, but does not seem appropriate for defining a field of health care. Regardless, the statement has no empirical basis and does not reflect the obvious fact that hospice or palliative care practices often postpone or hasten death. For instance, patients who are eating poorly, losing weight, and becoming progressively weakened and who then receive careful mouth care, vigorous nutritional support, expert pain control, and other comfort measures are likely to live longer (and wish to keep living longer) with these palliative interventions. Likewise, vigorous application of opioid analgesics or sedatives to treat a patient's severe pain, dyspnea, emotional suffering, or terminal distress may cause drowsiness and reduced intake of food and fluids, as well as predispose to aspiration and thus potentially hasten death.

HOSPICE AND PALLIATIVE CARE IN THE UNITED STATES: A PARTING OF WAYS OR A NEW COALITION?

> Competition is greatest between those who occupy the same position in the economy of nature (39).

Hospice in the United States may be viewed as the first wave of the hospice movement. In the 1960s, volunteer hospice programs brought the hospice approach to scattered communities, focusing on home care and cancer. In the early 1980s, with the institution of the Hospice Medicare Benefit that provided funding for hospice programs, the hospice movement grew dramatically, reaching a major portion of dying cancer patients and a significant number of terminally ill persons with noncancer diagnoses. Hospice became a widely recognized feature of the health care industry. Around the turn of the century, when lengths of stay in hospice declined, the movement reached a point of possible stagnancy, leading to new ideas about promoting the hospice approach. Opportunities exist for substantial growth of hospice programs, even within the current model of care (40). Palliative care is a second wave, embracing the hospice philosophy of care—the “gold standard” for end-of-life care—and seeking to bring this approach to a wider group of patients than currently served by hospice programs in this country. Palliative care also seeks more actively to integrate the hospice approach into clinical practice rather than promoting a totally separate care system for selected dying persons and their families. Most palliative care practitioners in this country have not forsaken hospice, but rather are trying to apply the model more broadly and also more sensibly than currently fostered by federal and state hospice regulations and by health care insurance. All hospice care can be viewed as a segment of palliative care.

In the United States, hospice has come to mean specifically a governmentally regulated organization or program for dying persons and their families (1), typically focusing on home care and limited to patients with the following:

- An expected prognosis of £6 months.

- A focus on comfort measures—this is sometimes (but not always) defined by hospice programs as a desire to forego a variety of “aggressive” and often expensive management approaches (usually including cardiopulmonary resuscitation; blood product replacement; acute care hospitalization; and some forms of radiotherapy, surgery, and chemotherapy), at least insofar as these treatment modalities are being used in an attempt to cure or prolong life rather than to palliate symptoms.
- A general preference for care at home (except where inpatient hospice is available and specifically sought).
- A capacity to acknowledge that they desire a focus on comfort care, as indicated by signing an enrollment form or having the form signed by a proxy.
- Health insurance that covers hospice, unless the patient or family is willing to pay for services or the hospice program will provide free services.

Many hospice programs also require that the patient have a primary caregiver—someone to oversee care and to be readily available to the patient in the home. Typically, although not necessarily, the primary caregiver lives in the home. Other eligibility requirements, which one hears about occasionally from patients or family members but are not embodied in federal hospice regulations or the Patient Self-Determination Act, are that the patient and family agree to forego cardiopulmonary resuscitation, calls for emergency services, and/or further hospitalization.

Moreover, as documented for home care patients with amyotrophic lateral sclerosis, although hospice staff may be perceived as more knowledgeable and empathetic than conventional home care clinicians, hospice may provide fewer hours of formal care, particularly home health aide time (41). Thus, patients and families are often forced to choose between hospice care with insufficient home health aide support and a conventional home care approach that includes significantly more home health aide hours.

Hospice programs in the United States have been increasingly boxed in by the eligibility requirements created by Medicare and other insurers and by the limitations on reimbursement that make it difficult for them to cover expensive treatments or provide as much home health aide time as conventional programs (42,43,44 and 45). Many programs have become extremely cautious with admission or recertification in the face of the threat posed by an unsympathetic and perhaps ill-conceived government audit that scrutinizes long-stay patients and those with noncancer diagnoses. Hospice programs have increasingly been relegated to care in the last few weeks of life (46,47). At the same time, health maintenance organizations and insurers have attempted to “unbundle” hospice services, providing and paying for only part of the hospice package (e.g., home nursing without social service, chaplaincy, volunteers, or bereavement care).

Eligibility requirements that may make sense from a fiscal vantage in designing the hospice benefit or in running a program under the current reimbursement scheme make little sense to a clinician concerned with overall care of the dying and their families. For instance, many patients who are receiving purely comfort care and seem appropriate for hospice-like services can be expected to live for years. Many “aggressive” or “high-tech” or simply expensive interventions are appropriate for patients in the very late phases of a terminal illness and should not be foregone just to qualify for comprehensive hospice home care services. The use of antiretroviral regimens or of treatments to prevent blindness from cytomegalovirus in far-advanced acquired immunodeficiency syndrome would be common examples. Similarly, patients who may be ineligible for some hospice programs because they do not have a primary caregiver may still want to receive care at home and can benefit greatly from the support offered by hospice. Patients who need the greater home health aide hours offered by conventional home care programs and thus choose to forego hospice enrollment still may wish a palliative care approach. Patients who are aversive to the word “hospice” or who are reluctant to sign forms that redefine their insurance benefits or who have difficulty acknowledging that they are imminently facing death may benefit from and should be able to receive palliative services.

Much to the dismay of palliative care providers, hospice in the United States has become a program for imminently dying persons, caring for many patients only in the last few days or week of life (4). Only a small proportion (roughly 20%) of dying persons are cared for by hospice programs in this country. Palliative care seeks involvement with patients and families as soon as the diagnosis of a life-threatening illness is confirmed, occasionally even earlier, as commonly conveyed in Figure 44-1. Indeed, patients may present with symptoms before they have a terminal diagnosis. While undergoing curative or life-prolonging treatments, they regularly experience physical and psychosocial distress related to their underlying condition or its management. Palliative care specialists may be needed to address such distress. Palliative care is not just for the imminently dying, nor should be hospice (48).

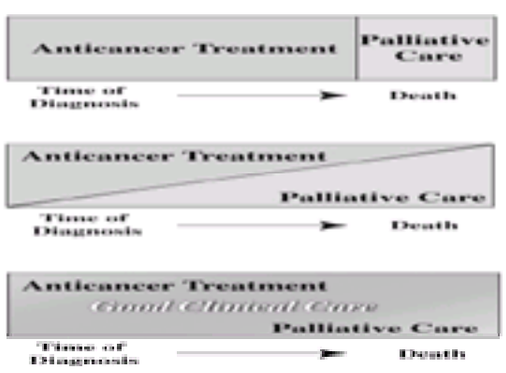

FIGURE 44-1. The top drawing depicts the common pattern of acknowledging approaching death only in the last days of life. The middle drawing depicts integration of palliative care at the time of diagnosis and increased use as the disease progresses. (After World Health Organization.) The bottom drawing conveys the lack of a clear boundary between anticancer treatment and palliative care.

In the United States, the greatest threat to hospice from palliative care would seem to be the possibility that the hospice philosophy will be distorted and supplanted by the newer programs. Palliative care teams, as a generality, differ significantly from hospice teams in this country. Hospice grew up as a grassroots, counterculture, community-based, nurse-led, and somewhat antiphysician, antiacademic movement with a strong emphasis on psychosocial care, spirituality, avoiding inappropriate interventions, using simple measures for comfort, and “letting go.” It retains much of this flavor today. Palliative care, on the other hand, is developing in academic centers and thus is “evidence-based,” centered in hospitals, and often focused on inpatient care and consultation, led by physicians who see themselves as specialists, and sympathetic to a full range of treatment options in advanced illness. Notably, none of the definitions of palliative care cited earlier in this paper includes interdisciplinary care as a basic feature. [“Interdisciplinary” in some settings is used unself-consciously to describe the collaboration of two specialists (e.g., a neurologist and oncologist) but is used here to describe the breadth of the hospice team.] Social workers, chaplains, bereavement counselors, and volunteers play an uncertain role in the future of palliative care (49). A pain- or symptom-control team that does not provide comprehensive, interdisciplinary care to patients and families may provide a needed service, but should not be confused with palliative care. Similarly, although the impact of conventional cancer treatments on quality of life and symptom control deserves much more study, palliative cancer therapy alone is not palliative care (50). Until clear standards are established for palliative care programs, including valid, professionally recognized credentialing of clinicians and accountability for standards of quality care, apprehension is inevitable that palliative care will dilute or distort the hospice philosophy and reverse the gains from the establishment of certified hospice programs in this country over the past three decades.

Hospices rightly object to terms such as “hospice-like” care because so many conventional home care programs have claimed to provide services that are equal to that of hospice but in fact do not offer many of the standard benefits of hospice, including interdisciplinary care, specially trained and supported clinicians, volunteer and bereavement services, and free medications and durable medical equipment. At the same time, some home care or hospice programs are establishing “bridge” or “prehospice” programs, paid for under conventional home care, that may facilitate early admission and avoid some of the difficulties posed by hospice admission or recertification requirements. Bridge programs represent an effort within hospice and home care organizations to extend some hospice services to patients and family that currently are not enrolled in hospice, including patients for whom conventional home care reimbursement is more favorable (e.g., for covering repeated hospitalizations or expensive interventions). These programs may also facilitate earlier and more appropriate transfers to hospice. Such bridge programs may be presented as hospice-like, but they have not been systematically studied in such a way as to assess their impact or allow a meaningful comparison with hospice care. Similar questions arise with palliative care services, which lack meaningful standards of care or accreditation of providers. Bridge programs and palliative care programs both exemplify, in part, an attempt to extend the hospice philosophy of care to more patients and families, while sidestepping the regulatory constraints of certified hospice programs, as well as the current constriction of hospice services.

Proposals from within the hospice community have attempted to deal with the limited hospice eligibility requirements. The National Hospice and Palliative Care Organization's Committee on the Medicare Hospice Benefit and End of Life Care has proposed that the 6-month prognosis requirement be eliminated and that alternate eligibility models be piloted. MediCaring (51) is an alternative program, using a hospice-like approach for patients with serious chronic illnesses.

Many opportunities remain for cooperation among palliative care programs and hospice. Briefly, hospice is generally the home care program of choice for eligible dying patients and families. Palliative care programs provide a conduit for wider education about and earlier referrals to hospice. Insofar as many palliative care services are based in hospitals, they are generally better able than hospice programs to participate in the key treatment decisions, including the transition to comfort care, which often occur in the inpatient setting. Palliative care programs tend to be based in academic institutions and can provide broader training of physicians and other health care professionals and students about good end-of-life care, which includes hospice care. Few academic palliative care programs will want to start their own home hospice programs, and most will want to work closely with hospices in a variety of communities to ensure continuity of excellent care when patients go home. Hospices

are needed as training sites for students in the health professions (52). Additionally, although a great strength of hospice in the United States has been its emphasis on quality home care and the management of chronic, progressive, fatal disease, palliative medicine can contribute to care in a variety of other settings—the acute care hospital, including the intensive care unit and the emergency ward, as well as offices and extended care facilities— and has a role in deaths from acute conditions.

Palliative Care as a Specialty

Finlay (52a) suggests distinguishing the following:

- The “palliative approach” or philosophy of care, which may be viewed as a core basis of clinical work
- “Palliative interventions” that include common approaches to alleviating suffering in clinical care and are used by many clinicians
- “Specialist palliative care,” which is the domain of clinicians with accredited training and implies minimum program and professional standards

(A similar distinction exists between the hospice approach or philosophy of care and hospice programs.) Thus, palliative care is a discipline or body of expertise and an approach to care that should infuse all medical services. Most palliative care will be provided by generalists and by specialists in established medical disciplines, such as oncology or cardiology. Some of the expertise required to provide palliative care, such as radiation therapy, interventional cardiology, or intensive care, will remain the domain of specialists in other fields. Just as a primary care physician does not need to be a cardiologist to help a patient with congestive heart failure, a clinician does not need to be a palliative care specialist to care for terminally ill persons. Conversely, cardiologists are available to clinicians and families for consultation and referral, typically for helping ensure that the best possible care is being provided and to offer specialized services. Likewise, palliative care programs and palliative medicine specialists are being developed to provide the consultation and referral opportunities that will allow for stateof-the-art care for more terminally ill patients and their families.

Much of the discussion in this chapter is meant to define specialist palliative care services, a program that helps deliver a specialized form of care. A palliative care specialist, such as a palliative medicine specialist or a palliative care nurse practitioner, is a clinician with distinctive training in this field who works in conjunction with a specially trained, interdisciplinary palliative care team. A large literature documents unmet needs of terminally ill patients and their families, as well as a lack of expertise of both generalists and specialists in meeting these needs (16,17,53,54,55 and 56), so a case can easily be made for a separate discipline of palliative care that entails such features as the following:

- Diagnostic and management skills and the ability to act as a consultant to other clinicians for a multitude of illnesses and complex conditions, including syndromes that are usually seen only in the late phases of an illness
- Expertise in the pharmacological basis for alleviating suffering, as well as in nonpharmacologic approaches
- Communication skills—widely recognized as challenging and beyond the everyday competency of most clinicians—that reflect expertise in the psychological, social, and spiritual aspects of care for patients and families, including bereavement care
- Caring for seriously ill patients in the home or other alternatives to the acute care hospital
- Team care
- Educating generalists and other specialists about palliative care
- Conducting research in palliative care

As a fledgling field, palliative care now can boast of multiple clinical centers and training programs; a variety of fine textbooks (57), journals, and educational conferences; and a small research enterprise. A recent Supreme Court ruling on legalization of physician-assisted suicide has been interpreted as acknowledging a right to “good palliative care.” The Institute of Medicine report (1) reviewed the difficult question of whether palliative medicine should become a specialty or an area of exceptional competence within existing fields but did not make a firm conclusion. Certainly, the justification for a new field would include an ability to address unmet patient and family needs, offer expertise with difficult cases and unfamiliar treatment methods, train medical students and graduate physicians, and carry out research.

Palliative medicine has been recognized as a specialty in the United Kingdom since 1987, in Australia and New Zealand since 1988, and more recently in Canada. A variety of criteria have been cited as the requisites for identifying a distinct discipline: “a defined need, a separate and specific body of knowledge, skills, and attitudes, a shared set of principles, public acceptance, defined standards of practice, a literature devoted to the field and a research base” (58). In the United States, some discussion about principles may still exist, but standards of practice are clearly lacking.

Many of the values and skills embodied in the notion of palliative care are more readily identified with generalist or primary care practice than with specialist or consultive practice. If palliative care practitioners are specialists, they **cannot** delineate their work as the following:

- Organ- or organ-system based (e.g., nephrologists principally take care of the kidney, neurologists the nervous system),
- Disease-based (e.g., oncologists principally take care of cancer), or
- Age-based (e.g., pediatricians provide general medical care to children)

However, palliative care is end-of-life care, directed to dying persons and their families at all phases of terminal illness. It cannot be a subset of oncology or any other subspecialty because palliative care deals with every failing vital organ and a variety of diseases occurring at all ages. Similarly, although palliative medicine may be developing primarily as hospital consultation service (12) and might be viewed as an inpatient specialty, analogous to “intensivists” or “hospitalists,” the bulk of patients requiring palliative care are outpatients. A focus only on institutional care would undermine a comprehensive approach and contribute to further fragmentation of end-of-life care.

Palliative care practitioners, then, are like generalists, providing comprehensive, accessible, first-line care, but only to a subset of patients and their families—those facing a terminal illness. This approach is similar to how geriatricians may define themselves as generalists for the elderly.

Regardless of the orientation of palliative care practitioners as specialists or generalists, they need to interface effectively with patients, families, and health care providers who have a variety of needs, wishes, and resources. They need to work closely and comfortably with clinical colleagues who provide the bulk of preterminal care. For instance, when a skilled, dedicated primary care provider is managing a case, the palliative care practitioner might act solely as a consultant, providing advice directly to the referring physician. Only part of the palliative care team—for instance, the social worker, chaplain, or volunteer—might become directly involved with the patient or family, complementing the work of the primary care doctor. On the other hand, if the patient is being followed, for instance, by a neurosurgeon who views his or her job as largely completed after recovery from surgery, patients, families, and health care providers may prefer that the palliative care team assume a primary care role, taking responsibility for not only the management of the terminal illness but also for coordinating the input of the specialists, ensuring good communication and overseeing general medical management. For a patient undergoing chemotherapy or radiation for a cancer, care might be comanaged with the oncologist or radiation therapist; the palliative care clinician would share some responsibility for symptom management but perhaps take a dominant role in supervising home care services or providing psychosocial and spiritual support.

From this perspective, palliative care in the United States must be flexible and collaborative (59), yet retain responsibility for ensuring coordination of comprehensive care and at times providing a full range of appropriate services. Palliative care programs must have the capability of offering a range of consultative and primary care services. A simple consultative approach that focuses on symptoms, particularly physical symptoms, without addressing broader psychosocial and spiritual aspects of patient and family suffering—exemplified by some pain services or pain and symptom control teams—is neither state-of-the-art symptom control nor true palliative care.

A few arguments against establishing a separate specialty of care deserve note. One concern is that terminally ill persons will become recognized as a distinct class of patients who are referred to specialists, thus reducing the skills of generalists and other clinicians in the care of these patients and isolating the patients from their usual health care team. Second, most of the needs of the dying are shared with other patients with “life-threatening and complex” diseases, and a smarter approach to reforming the health care system would embrace these constituents.

TYPES OF PALLIATIVE CARE PROGRAMS

In the United States currently, palliative care programs can be divided into those that are covered under a hospice benefit and those, generally labeled as palliative care programs, that rely on conventional channels of reimbursement and possibly also hospice reimbursement. Programs can also be divided up according to the sites in which care is offered and whether staffing at the site is provided by a dedicated hospice/palliative care team or by usual staff in consultation with such a team.

For state and federal certification, hospice programs are obliged to provide both home care and acute inpatient care. Home care may include nursing home care, and indeed, some hospices provide primarily nursing home care. Residential facilities or boarding houses run by hospice programs may provide home care in a special setting where the hospice benefit is used to pay for medical-nursing services, whereas room and board is covered by the patient or sources other than health insurance. Home care under hospice may include brief periods of “continuous care,” which involves around-the-clock presence of nurses or home health aides address a need for more intensive service. Respite care, typically offered in a nursing home setting, may also be available. Acute inpatient care may be provided in scattered

hospital beds; in a dedicated inpatient unit located in a hospital, extended care facility, or nursing home; or less frequently, in a free-standing inpatient unit. Acute hospital days under hospice generally constitutes a small fraction (<5%) of the total days in hospice. Rare hospice programs in this country offer day care.

Palliative care programs in this country may assume similar configurations as provided under the hospice benefit but now generally consist of inpatient consultation teams, dedicated inpatient units of various sizes in acute care hospitals or extended care facilities, ambulatory care clinics, and specialized home care programs (including "bridge" services affiliated with a hospice). Eligibility for services tends to be much broader than under the Medicare Hospice Benefit but may include less attention to psychosocial and spiritual issues or home care.

Most care in hospice is provided in consultation with and under the orders of a primary care physician, although a hospice medical director or other hospice physician may direct care in some programs. In palliative care, the option for primary care management of patients also exists.

ELEMENTS OF A DEFINITION

Palliative care is characterized by the following:

1. Focusing on a particular clinical condition: *terminal illness* or *end-of-life care.* Unlike hospice in this country, the field does not need to specify a prognosis. In describing itself as caring for the dying, euphemisms should be avoided, but a definition need not be so blunt as to frighten patients and their families (e.g., speaking about "incurable" or "terminal" disease) nor be so kindly as to become hopelessly vague (e.g., describing patients as "advanced"). For health care colleagues, *"terminal illness"* or *"end-of-life care"* are relatively clear notions and allow flexibility to participate in the earlier phases of "active, progressive" fatal conditions that eventually become "far-advanced." For patients and families, *"life-threatening illness"* may be the most appropriate and acceptable descriptor, although this term includes conditions, such as acute trauma, that are not typically within the palliative care domain.
2. Employing a distinct method of evaluation and management, a special expertise:

   - *Comprehensive* (meaning addressing all forms of suffering)
   - Interdisciplinary (or collaborative) care

The terms are included here because of their importance in distinguishing the mission of this field. Admittedly, most clinical disciplines do not specify a method of care except for the implied distinction between medical and surgical specialties. Within a field, we may hear about a "minimally invasive surgeon" or an "interventional radiologist," but all palliative care is comprehensive in scope and interdisciplinary in practice.

3. Directing care to the *patient and the family* and, by implication, extending care into the period of bereavement.
4. Focusing on a specific management goal: *promoting quality of life* (or *alleviating and preventing suffering* or, particular for patients and families, *living as well as possible*). This goal need not exclude other goals, including cure or remission. MacDonald summarized this concept nicely as a fourth phase of cancer prevention (60). Alternative terms that may be more acceptable to patients and families are *"comfort care"* or *"supportive care,"* although the former tends to imply passivity and withholding, as suggested by "comfort measures only," whereas the latter is regularly used to designate treatments clearly aimed at prolonging or sustaining life.

Hence, palliative care is comprehensive, interdisciplinary care for patients living with a terminal illness and for their families, focusing primarily on promoting quality of life. Key elements for helping the patient and family live as well as possible in the face of life-threatening illness include ensuring physical comfort, psychosocial and spiritual support, information sharing and establishing a treatment plan reflective of patient values and goals, and provision of coordinated services across sites of care.

This explication does not mention anything about supporting the service providers, an essential feature of any palliative care program, yet one that does not seem to deserve inclusion in a brief definition statement. The definition also does not specifically address the components of an interdisciplinary team and, like other definitions above, does not specifically mention volunteers or bereavement services.

WHAT DO YOU SAY?

For statements that are intended primarily for clinicians and other health professionals, I speak of "comprehensive care, provided by an interdisciplinary team, for patients and families living with a life-threatening or terminal illness, particularly where care is focused on alleviating suffering and promoting quality of life." I might then go on to clarify:

> Major concerns are pain and symptom management, psychosocial and spiritual support, information sharing, and advance care planning to address patient values and goals, and coordination of care across multiple sites, including arranging for excellent services in the community.

In talking with patients as a consultant, I might say:

> Palliative care is a special service we offer, a team approach to providing the best care and support for persons living with a life-threatening illness and for their families. Our goal is to help you live as well as possible with your condition. We are a nurse, social worker, chaplain, and physicians who work with your current health care team to ensure, insofar as you need it, that you and your family have access to excellent pain control and other comfort measures, get the information you want to participate in decisions about your care, receive emotional and spiritual support and practical assistance, obtain expert help in planning for care outside the hospital, continue getting good services in the community, and overall enjoy life as best you can, given your illness. We try to coordinate and tailor a package of services that best suits your values, beliefs, wishes, and needs in whatever setting you are receiving care.

STANDARDS

Discussions about definitions, philosophies, or precepts can be useless if not translated into meaningful, robust standards of practice. Two kinds of standards are commonly applied: program standards, which describe the organization and delivery of palliative care services, and professional standards, which apply to the training and skills of members of the palliative care team.

Program Standards

In hospice, Medicare regulations provide guidance about hospice eligibility, as described above, but also identify the members of the interdisciplinary team, prescribe regular team meetings, and indicate how services are reimbursed (61). As scant as these regulations may seem, they may be seen as generally successful in establishing standards for hospice programs. No standards of this sort exist for palliative care programs in this country. This means that anyone can use the term "palliative care service" to describe a program, and that patients, families, clinicians, administrators, regulators, and policy makers have no guarantee of a minimal standard of service when referring to such a program.

A remarkable process for developing standards has been initiated by the Canadian Palliative Care Association (62,63 and 64), and is available on-line at http://www.cpca.net. Sections include a lexicon of key terms, a statement of values, and a highly detailed listing of principles and norms for a variety of program features. Under Assessment, for instance, the document describes a principle of comprehensive and timely evaluation and describes such norms as respecting confidentiality; identifying and prioritizing patient expectations and needs; and assessing religious values, beliefs, and practices.

Professional Standards

No meaningful standards exist for professional participation in a hospice or palliative care program. Anyone with a medical license can serve as a hospice medical director. Certification programs in medical and nursing aspects of palliative care (the American Board of Hospice and Palliative Medicine, the Palliative Care Nursing Society) have been developed but hold little face value. The American Board of Hospice and Palliative Medicine, after certifying roughly 800 physicians, has committed itself to revising its examination procedure to conform better to current standards of educational testing. The board has also outlined a process for establishing palliative medicine as a recognized medical specialty that would eventually include a requirement for fellowship training to become certified.

Do definitions and standards matter? A few examples drawn from "real life" suggest some of the issues:

- A pathologist with a deep commitment to end-of-life care but no clinical training after medical school becomes a hospice medical director.
- A long-standing palliative care program in a predominantly rural region has never had a medical director, regular physician oversight, or even routine

opportunities for the clinical staff to obtain medical consultation on their patients.
- An academic palliative care program includes no regular participation from the chaplaincy and provides no organized bereavement services.
- One clinical fellowship program in palliative care enrolls only cancer patients, whereas another serves only patients and families who meet the admission requirements for hospice in the United States.

CONCLUSION

Throughout the world now, palliative care is developing as an area of special clinical competence and is growing rapidly in the United States (65). Palliative care has attracted clinicians from disparate backgrounds and interests, and hence the field currently embraces a diversity of views about its scope, goals, and methods. This diversity is a virtue. Where different viewpoints and expertise are shared, cross-fertilization occurs, and untested assumptions are challenged. However, diversity implies disagreement or conflict within the field and hence confusion for those trying to understand it. Diversity currently also means lack of meaningful standards. The challenge today for palliative care is to avoid orthodoxy, yet move ahead with greater unanimity about the nature of the field and with improved standards for palliative care professionals and programs.

HOSPICE

JUNE Y. LELAND
RONALD S. SCHONWETTER

> Not every patient can be saved, but his illness may be eased by the way the doctor responds to him—and in responding to him the doctor may save himself. But first he must become a student again; he has to dissect the cadaver of his professional persona; he must see that his silence and neutrality are *unnatural*. It may be necessary to give up some of his authority in exchange for his humanity, but as the old family doctors knew, this is not a bad bargain. In learning to talk to his patients, the doctor may talk himself back into loving his work. He has little to lose and everything to gain by letting the sick man into his heart. If he does, they can share, as few others can, the wonder, terror and exaltation of being on the edge of being, between the natural and the supernatural.
>
> —Anatole Broyard, *Intoxicated by My Illness* (1)

HISTORY OF HOSPICE

The modern hospice movement began in 1967 in London under the direction of Dame Cicely Saunders, with the opening of St. Christopher's Hospice. Saunders emphasized the need for effective symptom control, the care of the patient and family as a unit, and the interdisciplinary team approach. Treatment approaches included the continuum of care, the use of volunteers, and follow-up with family members after the death of the patient. Dr. Saunders introduced the concept of applying research to the care of the dying and developed the idea of giving pain medication around the clock rather than by request. In addition to the remarkable achievements of Dr. Saunders, fellows and students from St. Christopher's hospice have contributed significantly to the development of hospice and palliative care programs around the world (2). Dr. Robert Twycross developed the World Health Organization's Collaborating Center for Hospice/Palliative Care in Oxford. Dr. Balfour Mount opened the Palliative Care Service at the Royal Victorian Hospital in Montreal in 1975. Florence Wald, Dean of the Graduate School of Nursing at Yale University, opened the New Haven Connecticut Hospice in 1974: the first hospice home care program in the United States without an inpatient service.

Economic forces have shaped the location of death in the United States, while cultural forces have influenced the acceptance and understanding of death. The hospice movement began at a time when Elisabeth Kübler-Ross was developing her theories on death and dying. Death was occurring in impersonal modern institutions where increasingly technologic and life-sustaining measures were the main focus of medical care. The hospice movement began in part as a reaction to and against the impersonalization of dying. A major factor in the growth of the hospice movement in the United States was the perception by nurses, patients, and families that the traditional medical care system failed to meet the needs of the dying patient (3). Hospice developed more as a concept of care rather than a place for care. From the beginning, the focus has been on care in the patient's own home.

In 1974, the National Cancer Institute funded the Connecticut Hospice in New Haven, the first home care–based hospice in the United States. This demonstration center provided home care for terminally ill patients and their families. Subsequently, hospices were funded through grants and private donations, and relied heavily on lay and professional volunteers (4).

A Health Care Financing Administration hospice demonstration program was initiated in 1980. In 1982, Congress passed the Tax Equity and Fiscal Responsibility Act, which authorized Medicare to reimburse hospices for the care of terminally ill patients who met specific criteria. This marked the birth of the Medicare Hospice Benefit (MHB), which would define hospice care in the United States and become the first federally mandated, managed-care program in the country. Reimbursement by Medicare and other insurance programs was supported in part under the assumption that hospice care would replace hospital inpatient care and theoretically be less expensive. A stipulation was added to the MHB that 80% of hospice patient care days per certified agency, per year must be used for home care.

HOSPICE PHILOSOPHY

The modern hospice movement focuses on the multidimensional symptoms of the patient and the family rather than only on the terminal disease. Beyond controlling symptoms, hospice enables the patient and family to confront the issues that accompany approaching death. The emphasis on “Total Pain” from sources including physical, psychological, social, and spiritual exemplifies hospice care. Pain management and management of other nonpain symptoms, such as anorexia, nausea, fatigue, anxiety, and depression, often allow other sources of pain or suffering to surface. The focus of care is individualized to meet patient and family needs.

As supported by the World Health Organization, the philosophy of hospice care for the terminally ill is based on several concepts (5).

1. Death is a natural part of the life cycle. Hospice will not seek to hasten death or to postpone it.
2. Pain relief and symptom control are clinical goals.
3. Psychological and spiritual pain is as significant as physical pain, and addressing all three requires the skills and approach of an interdisciplinary team.
4. Patients, their families, and loved ones are the unit of care.
5. Bereavement care is critical to supporting surviving family members and friends.
6. Care is provided regardless of ability to pay.

A primary goal of hospice and palliative care is to promote an alert, dignified, and pain-free life for its patients in a manner that is respectful of their individual needs (6).

Hospice emphasizes the coordinated approach to care as a means to enhance the combined skills of caregivers. The approach is comprehensive and case managed. Frequency and types of visits are determined by the needs of the patient and family or caregivers. Psychosocial and spiritual support and counseling, to cope with the significant challenges and crises, are reviewed as the illness progresses. The core members of the hospice team include

1. The patient's attending physician
2. A hospice medical director
3. Nurses with advanced training in end-of-life clinical care
4. Social workers with clinical experience appropriate to the counseling and casework needs of the terminally ill
5. Spiritual counselors with education and experience in pastoral counseling
6. A volunteer coordinator with skills in organization and communication
7. Trained volunteers

Additional professionals (therapists, dietitians, pharmacists, and nursing assistants) may join the team as needed. The team collaborates on an ongoing basis with the patient's attending physician to develop and maintain a patient-directed, individualized plan of care. This plan addresses the multidimensional nature of patient and family needs. Hospice seeks to address factors considered important at the end of life by patients and family members. Pain and symptom management, communication with one's physician, preparation for death, and the opportunity to achieve a sense of completion are important to most patients (7).

There is evidence that particular aspects of the dying process are areas of concern to patients. Patient-clinician relationships, social connectedness, caregiving needs, psychological distress, spirituality/religiousness, personal acceptance, sense of purpose, and clinician communication are all areas of concern for patients near the end

of life (8). Attention to these aspects are of primary importance in the interdisciplinary approach to care.

Hospice emphasizes the need to empower families and considers bereavement a critical component of supporting surviving family members and friends. Services related to bereavement continue for at least 1 year to help the family cope with death-related grief and loss. Survivors with potentially pathological grief reactions or complicating comorbidities may be referred for appropriate counseling services.

MEDICARE HOSPICE BENEFIT

The MHB has had a major influence on the evolution of hospice and has served as a model for private insurance companies. It defines when and how care will be delivered, by whom it will be delivered, and to whom it will be delivered. In addition, it specifies a payment structure for reimbursement (Table 45-1, Table 45-2).

The patient must be terminally ill, with a life expectancy of 6 months or less if the illness runs its usual course. Two physicians, the patient's attending physician and the hospice medical director, must attest to the terminal nature of the illness.
The Medicare Part A hospice benefit, when elected, precludes all other Medicare benefits related to the terminal illness except for the professional services of the attending physician. Care is coordinated through the hospice.
The benefit consists of two periods of 90 days, followed by an unlimited number of benefit periods of 60 days each. Prior to each benefit period, the hospice medical director must recertify that the patient has a prognosis of 6 months or less if the disease runs its usual course.
The patient may revoke the hospice benefit at any time. Normal Medicare Part A benefits are immediately restored.
Certified Medicare hospice agencies are reimbursed on a per-diem basis, depending on the level of care provided.
Routine home care
Continuous home care (brief periods of medical necessity, minimum of 8 to 24 hours per day)
Respite care (maximum of 6 consecutive days)
Inpatient care
At least 80% of hospice program days per year, per agency, must be categorized as routine home care.
An annual payment cap is placed on each hospice program based on the number of enrolled patients.

TABLE 45-2. SERVICES COVERED ON A PER-DIEM BASIS BY THE MEDICARE HOSPICE BENEFIT.

COST CONCERNS

Medical care at the end of life has consumed 10–12% of the total health budget and 27% of the Medicare budget (9). There have been controversy and confusion over how much money if any can be saved by provision of hospice care to terminally ill patients. Actual cost savings estimates for hospice care over traditional care vary, but an estimate is 25–40% during the last month or less of life, 10–17% during the last 6 months, and from 0–10% if the patient is enrolled in hospice during the last 12 months of life (10). These estimates are derived from data limited by methodological issues of selection bias, time-frame differences, types of medical costs evaluated, variability of reporting, and lack of generalizability. It is possible that some of the savings realized result from a shift in costs and burdens to the caregivers rather than costs for hospitalization or higher levels of care.

HOSPICE IN MAINSTREAM MEDICINE

In the United States, approximately 20% of deaths occur with hospice, and 42% of patients have diagnoses other than cancer (11). Nationally, 78% of hospice patients are 65 or older, 55% are female, and 38% are nonHispanic white. Hospice care remains underutilized as a resource for those with advanced, ultimately fatal illness (12).

The movement that began as a revolution against impersonal end-of-life care has become increasingly mainstream with the legitimacy of specialty societies, reimbursement mechanisms, and the development of a substantial body of knowledge. Many third-party insurers include hospice care as a benefit, as does Medicare. The Department of Veterans Affairs mandated hospice services provided directly or through community referrals in 1991. This position was reaffirmed in the Millennium Bill of 2000 (13).

Hospice in mainstream medicine faces many challenges. The first challenge is related to the definition of terminal illness. Palliative care can no longer be reserved for those facing imminent death. Many are concerned that hospice care should not be limited to patients during the last 6 months of life and that patients could benefit from even earlier enrollment. The developing field of palliative medicine is beginning to address the need to provide comprehensive interdisciplinary care for patients not only in their last 6 months of life. It can encompass interdisciplinary care to alleviate suffering at any point along the trajectory of the illness. Most palliative care services, however, are provided in acute inpatient settings, in part due to Medicare reimbursement mechanisms and limitations on prospective home health care. Hospices are moving toward this broader model of palliative care in order to avoid the dichotomy of choosing between curative and supportive therapies. Perhaps the disease that best illustrates this concept is congestive heart failure. According to National Hospice and Palliative Care Organization prognostic guidelines, the same treatments used to optimally treat the disease are identical to those used in the palliation of symptoms.

A second challenge relates to the definition of "6-month prognosis." As written, the MHB is unclear regarding what percentage of patients should be expected to die within the 6-month period with a given disease (14). In reality, hospices have been the target of focused review to determine if admissions to hospice were indeed appropriate, with the accusation of fraud if patients lived beyond their predicted life expectancy. Patients increasingly appear to be enrolled closer to the time of death. The average period of hospice care fell from 74 days in 1992 to 59 days in 1998. Greater federal scrutiny of compliance with program eligibility requirements may have contributed to a decline in beneficiaries' average number of days of hospice care (15).

The National Hospice and Palliative Care Organization developed guidelines for patients with diseases other than cancer that might be considered appropriate for hospice care, listed in Table 45-3.

Condition	Criteria
Heart disease	NYHA IV, EF <20%, refractory to optimal treatment including vasodilators. Other factors suggesting poor prognosis: symptomatic arrhythmias resistant to antiarrhythmic therapy, history of cardiac arrest, unexplained syncope, cardiogenic brain embolism.
Pulmonary disease	Disabling dyspnea at rest, FEV_1 <30%, frequent emergencies, cor pulmonale, hypoxemia on O_2, hypercapnia, resting tachycardia, unintended weight loss.
Dementia	Bed or chair bound, dependent in activities of daily living, incontinent, unable to communicate beyond six meaningful words, severe medical comorbidities, nutritional compromise, tube feedings refused, or impaired nutrition on tube feedings.
Stroke	Acute phase, beyond 3 d: coma, abnormal brainstem response, absent verbal response, absent withdrawal to pain. Dysphagia precluding nutrition when artificial feedings refused. Poststroke dementia, Karnofsky score ≤50%, nutritional compromise. Recurrent aspiration pneumonia, urinary infection, sepsis, decubitus ulcers.
Renal disease	Meets criteria for transplant or dialysis but refuses; C_{cr} <10 mL/min, serum creatinine >8 mg/dL (6 mg/dL for diabetics).
Liver disease	Not considered for transplant, albumin <2.5 mg/dL, prothrombin time >5 sec over control, recurrent variceal bleeding, cachexia, alcohol use. At least one of the following: refractory ascites, SBP, hepatorenal syndrome, hepatic encephalopathy, coma.

C_{cr}, creatinine clearance; EF, ejection fraction; FEV_1, forced expiratory volume in 1 sec; NYHA IV, New York Heart Association Stage IV; SBP, spontaneous bacterial peritonitis.

TABLE 45-3. NATIONAL HOSPICE ORGANIZATION GUIDELINES FOR PROGNOSIS IN CHRONIC DISEASES

A third challenge that hospices face is the tyranny of numbers. Many smaller hospices are unable to offer technologically advanced or nonpharmacological diseaserelated treatments. In theory, large hospices, by virtue of higher average daily census, are better positioned to offer more costly or technologically advanced care. This care might be offered on a trial basis for effect or a permanent basis depending on the indications. In contrast, smaller hospices have difficulty financing expensive “palliative” treatments, such as total parenteral nutrition, palliative surgery, or chemotherapy.

Site of care presents another barrier to accessing hospice care. The provision of Medicare hospice services to nursing home residents has come under scrutiny by the Office of the Inspector General. It is a source of conflict among hospices, nursing homes, and payer sources or fiscal intermediaries. Currently, the Office of the Inspector General estimates that only 1% of nursing home residents elect the MHB (16). Many hospices have been advised not to provide care for nursing home residents receiving care under the Medicare Skilled Nursing Home Benefit even in a private-pay category. The fear of appearing as potentially inducing referrals for accessing the MHB once the patient is off the Skilled Nursing Home Benefit. Nonetheless, nursing home residents receiving hospice services can benefit greatly from hospices' expertise in providing palliative management of the dying patient's symptoms, attending to increased hygienic needs, and supplying bereavement services to family and staff (17). The interdisciplinary hospice team can serve a continuity-of-care function for the patient admitted from home, or for hands-on care in a setting where staff turnover is high. Recent studies revealed improved care and fewer hospitalizations among terminal nursing home patients when their care was augmented with hospice services (18,19).

MINORITIES AND SPECIAL POPULATIONS

Access to hospice care for the pediatric population is limited. Only 247 of 2500 hospice programs have programs specifically for children (20). Many families are not ready to accept a life-limiting prognosis given to their child. In addition, the problem of estimating prognosis may be more difficult in this population, particularly with diseases from which cure is possible or even likely. Hospice programs may require that the patient forgo potentially curative or life-prolonging therapies or not offer high-tech services such as ventilator support or chemotherapy. Differentiating between lifeprolonging therapy and symptom-management–directed therapy may be quite difficult in this population. Recently, the American Academy of Pediatrics issued care guidelines for children with life-threatening and terminal conditions to address some of these issues (21).

The prison system presents another challenge to hospice programs. Since 1987, the number of people dying in prisons has increased more than 100%, from 1400 to over 3200. There are currently 1.83 million men and women incarcerated in 1515 prisons throughout the United States facing the threat of inadequate medical care. To compound this crisis, there are only 26 prison hospice programs in the United States capable of handling increasing incidences of AIDS, tuberculosis, and other chronic illnesses that have put an enormous burden on the prison system. In addition, suicide remains one of the highest causes of death in jails— nine times the national yearly average (22). In many instances, prison facilities are not capable of delivering proper health care, especially in the inmates' final months of life. Dying inmates desperately need access to pain and symptom control and psychological counseling during the final stages of their lives. The first-ever national conference on death and dying in U.S. prisons and jails, sponsored by Project on Death in America and The Center on Crime, Communities & Culture, took place in 1998 at the New York Academy of Medicine.

HOSPICE EDUCATION

The American Board of Hospice and Palliative Medicine (ABHPM) was founded in 1995 to establish and implement standards for certification of physicians practicing hospice and palliative medicine. The board held its first certifying exam in 1996. In addition, the American Academy of Hospice and Palliative Medicine was accepted as a provisional member of the Specialty and Service Society Section of the American Medical Association in 1996. In 2001, a fellowship membership category of the American Academy of Hospice and Palliative Medicine was established (23). To date, the ABHPM has certified 835 U.S. physicians and is engaged in discussions with the American Board of Medical Specialties ultimately to establish a subspecialty of hospice and palliative medicine. Fellowship programs in palliative medicine are expanding within the United States with over 30 programs currently available. Currently, the ABHPM is developing common standards for palliative care fellowships.

FUTURE OF HOSPICE

The current health care financing system is ill equipped to deal with the reality of how most Americans die. Although people still succumb to acute illness and trauma, far more die of chronic progressive disease from which a cure is not possible. Hospices have recognized the need to care for these patients and some are moving toward offering hospice (end-stage) services as well as palliative (symptom-controlling) therapies earlier in the disease process. It could be argued that palliative care services should be a part of any illness therapy from the time of diagnosis to death, with palliative and hospice services occupying a larger focus as the disease progresses.

The current system encourages acute over palliative care and often fragments care between systems. Medicare tends to foster inpatient care and poorly supports home and community-based care outside of hospice. It is often easier to arrange a hospitalization than to arrange for personal care or a home-delivered meal for a seriously ill patient. Following the hospice model, organizations, such as Americans for Better Care of the Dying and the Institute for Health Care Improvement, are calling for better care of the dying and those with chronic illness through education, research, and advocacy.

To the credit of hospice pioneers and supporters, the evidence base for the possibility of dying with symptom control, spiritual attention, psychosocial support, and attention to caregivers, is mounting. The movement that began in part as a revolution against the cold impersonal manner of dying may yet change the face of dying, not only for those identifiable as having a “six-month prognosis” but for all of those facing life-limiting illness at any stage. Hospice is hoping to see Medicare change its reimbursement system for care near the end of life to improve access for those in need. It has allowed death and dying to be an increasing part of mainstream medicine, and it continues to try to expand its services to those who can benefit from care.

MULTIDIMENSIONAL PATIENT ASSESSMENT

J. CAMERON MUIR
ANNMARIE MCDONAGH
NICOLE GOODING

From the earliest times in medicine, there has been a signifi-cant emphasis on the relief of suffering. As Hippocrates said, “I will use treatment to help the sick” and “to help, or at least to do no harm” (1). From the time of Hippocrates (~500 BC) through the nineteenth century, the focus of health care has been the relief of suffering associated with injury and disease. However during the last half of the nineteenth century and into the twentieth century, health care has become almost entirely focused on the *disease* and has often neglected to care for the *person*. As a result, the disease has been treated while the suffering that the patient is experiencing is often left unaddressed. It has only been during the past two decades that there has been a resurgence of the ethic of pal-liative care. This resurgence is most likely due to recognition of the limits of the current curative model of care. Although we have become more proficient at staving off death, it still will occur 100% of the time (2). It is through a skilled mul-tidimensional patient assessment (MDPA) that the various elements of suffering can be identified and addressed, from diagnosis of a cancer, through treatment, and into remission, disease progression, and death.

In this chapter we will review the components of a mul-tidimensional patient screening and assessment, which is often also referred to by the patient/family as “holistic or whole person” care. Particular emphasis will be placed on the role of an interdisciplinary team and a distinction will be made between the traditional “medical model” and the interdisciplinary “bio-psychosocial-spiritual model” of care, which is so well modeled in the field of hospice and pallia-tive care. The different components of the MDPA will then be described with particular emphasis on knowing how and when to integrate other disciplines' skills and assistance.

INTERDISCIPLINARY ASSESSMENT

There is a growing appreciation that a patient's experience of his or her advanced illness is complex: from physical symptoms, to coping, financial concerns, caregiver burden, social/family changes, and spiritual concerns. Furthermore, no one person—regardless of his or her professional disci-pline— will be able to manage all of these issues (3,4 and 5). In fact, attempts to do so may result in either harm to the health care provider through exhaustive efforts to deal with everything alone, leading to stress and burnout (6,7), or harm to the patient and family, because the health care pro-vider either completely misses an issue due to lack of skill in that area, or by trying to do something that he or she is not adequately trained to do.

Each health care discipline has expertise and skills in providing care to the patient and family and in identifying their specific needs and clarifying goals of treatment within a holistic framework. One might ask, “What discipline is most appropriate for performing an initial assessment?” Although there are few data to support an answer to this question, there is some anecdotal evidence from evaluation of the systems currently in place and what seems to work. There are two predominant models of care provided in health care: the traditional “medical” model and the interdisciplinary/palliative care model. There are significant differences between the two models of care (8,9).

The traditional medical model is the predominant model of health care and can be characterized as disease focused, with the physician as the leader. Physicians run most ambulatory clinics that see patients with “problem lists” and “chief complaints”; a history is taken, and then a physical examination is performed. Based on clinical findings, patients undergo diagnostic testing in an attempt to reveal a diagnosis for which some form of therapy is instituted to cure or at least improve the disease. This model often fails to take two critical elements into account: the nonphysical needs of the patient and family and the fact that the vast majority of medical diseases in the twenty-first century are chronic, often progressive diseases that ultimately cannot be cured, only palliated.

In the medical model, the primary mode of communication between health care providers is often the written chart note, with the involvement of other medical specialists, as well as other professional disciplines. This system is often haphazard and uncoordinated.

The interdisciplinary/palliative care model is team driven, with the focus of care being the patient and family rather than the disease (10,11). Interdisciplinary care recognizes that the discipline that often spends the greatest amount of time with a patient and family is usually the nurse and the nurse is also equipped with the *broadest* assessment skills. The nursing assessment in palliative care, whether performed on a unit or in an ambulatory or community setting, is of paramount importance.

The nurse coordinates the plan of care for the patient and family as well as the interdisciplinary team, which can include physicians, social workers, and pastoral caregivers, among others (12). The nurse should have excellent physical assessment skills and a strong knowledge of current innovations in pain and symptom management as well as astute psychological and spiritual evaluation strategies to ensure the plan of care is congruent with the goals of the patient and family. The nurse is often in a position to develop the strongest therapeutic relationship with the patient and family.

The nurse works with the patient and family using skilled compassion and concern, empowering the patient to exercise control in decision making where possible, which can only enhance the patient's sense of control. The nurse continually reassesses patient and family goals, treatment preferences, coping abilities, and support needs. The nurse is the conduit for information and critical assessments, as well as evaluation of the patient and family goals within the interdisciplinary team. The physician can provide expertise about the disease, treatment options, risks and benefits, likely outcomes, and symptom management interventions. In addition, they can help to anticipate critical decisions and guide and support the patient and family through the process. In order to assess patient and family coping and identify individual strengths and community resources, a social worker is essential to the team. In addition, they are also most adept at evaluating and negotiating financial and insurance resources. Pastoral caregivers can be invaluable in helping to understand the patient's spiritual strengths and concerns and assist the patient and family in maintaining/reframing hope and establish meaning in the setting of advanced disease.

A key element of interdisciplinary palliative care is a strong emphasis on *coordination* of care. This is most commonly achieved through team meetings, where different disciplines verbally communicate each of their assessments in order to synthesize a comprehensive care plan that will meet the patient and family needs. For an interdisciplinary team to be most effective, candid communication between team members is vital.

The distinction between interdisciplinary and multidisciplinary practice is critical. In the traditional multidisciplinary team, care of the patient is directed by the physician (Fig. 46-1). Many other members of the health care team may be involved in the delivery of care, however, efforts are often uncoordinated and fragmented.

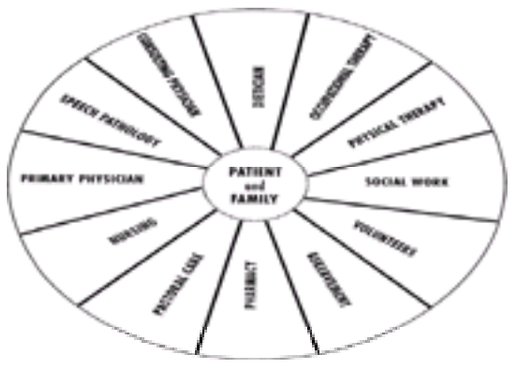

FIGURE 46-1. Multidisciplinary team. [From Krammer LM, Muir JC, Gooding-Keller N, et al. Palliative care and oncology opportunities for oncology nursing. Oncol Nurs Updates 1999;3(6):1–12, with permission.]

The primary mode of communication between disciplines is the medical chart. The result is often ineffective communication between professions, lack of accountability, and a tendency for each discipline to independently develop their own patient care goals. To contrast, in an interdisciplinary model, leadership is shared and communication between team members is collaborative (13).

Although individual health care providers may have discipline-specific goals as part of the plan of care, it is key that the team remains focused on the patient-driven goals. Communication between team members will be more effective if the focus of team interaction remains on the patient and family. Maintaining this focus is more successful when the team allows time to discuss the challenges individual professionals are facing in association with the patient and family and if the team regularly reviews the plan of care. This model allows for team members to *directly* interact with the patient and family and to provide consultation with each another in order to achieve the goals identified by the patient and family (Fig. 46-2). Thus, the sum (from the patient's point of view) is greater than the individual parts.

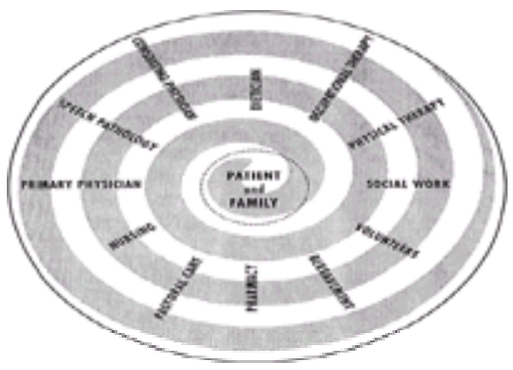

FIGURE 46-2. Interdisciplinary team. [From Krammer LM, Muir JC, Gooding-Keller N, et al. Palliative care and oncology opportunities for oncology nursing. Oncol Nurs Updates 1999;3(6):1–12, with permission.]

An effective interdisciplinary team mandates collaboration, decision making, leadership, and conflict resolution. *Collaboration* is defined as the ability to work jointly with others, especially in an intellectual endeavor. It is the process of collaboration that empowers team members to act as decision makers within the group. For example, if a question on pain management arises, various members of the team will provide observations and opinions from their professional perspective. The resulting plan of care will have a broader intellectual base, a multidimensional assessment of the patient's pain will have been performed, and interventions will be developed in an effort to maximize the relief of all components of the patient's experience of pain.

Using a true collaborative process, the decision maker would not determine a treatment plan based on his or her own perspective, rather the decision would reflect the team's input. Through this type of collaboration, effective patient-driven quality outcomes can be achieved. Good leadership provides a safe environment for an individual team member to lead in changing or adding to a plan of care, and a cohesive and supportive team is developed. As examples, the doctor who is able to step aside and glean insight into the patient's coping from the social worker or the nurse who knows when to consult the chaplain, illustrates collaborative practice by all four of these very different disciplines. Strong leadership is imperative to facilitate the peak professional growth of each team member and ensure that the focus of care is always directed toward the patient and family (10).

Due to the interdependency among team members, conflict inevitably arises. Conflict can be both beneficial and can challenge effective interdisciplinary team functioning. Lack of conflict may stifle creativity and professional growth. The challenge is not to avoid conflict but to manage it effectively so that patients, families, and team members can reap its benefits (14). Respect and trust in each member's skills, knowledge, and expertise are essential. Different ideas and opinions often stimulate innovative solutions for patient care problems. However, conflict can be destructive when it becomes personalized or is viewed as threatening to a team member's role.

Within a team there is often overlap of assessment and management skills. A nurse may be highly skilled at symptom assessment and be able to develop a full management plan. A physician may identify that the patient and family rely heavily on their faith as a source of strength in coping. Furthermore, the social worker may help to recognize that a patient's nausea is only brought on by discussion about leaving the hospital. In the following section, the components of the multidisciplinary assessment will be discussed. Which discipline is involved in assessing each of these areas will be different in each setting based not only on the individual team members but also on the unique needs of each patient and family.

COMPONENTS OF A MULTIDIMENSIONAL PATIENT ASSESSMENT

History of Illness and Treatment Responses

The initial elements of the MDPA parallel that of the traditional medical model. The assessment begins with an illness history that begins with determination of the primary diagnosis and course of treatment. In addition, attention should be paid to assessing the therapies that have been utilized, not only their impact on the disease but also their impact on the patient's symptoms from the disease and what therapies have exacerbated or ameliorated these symptoms. One must also elicit information about other illnesses and therapies that the patient has that may be important contributors to suffering and complicate subsequent therapies. One should have information on the extent/stage of disease, and familiarity with the diagnostic testing that confirmed the extent of disease.

Physical Assessment

The physical assessment is designed to screen for the presence of physical symptoms contributing to suffering. To ascertain the “subjective” symptom burden, one must inquire as to their presence and severity. Specific assessment tools can assist in the screening for multiple symptoms (15,16,17 and 18). The Edmonton Symptom Assessment Tool (15) is a concise, user-friendly, palliative care assessment tool (Fig. 46-3). Use of these tools may be helpful in building a therapeutic relationship by reminding patients that relief of their suffering is important to the caregivers. The physical assessment also includes understanding how symptoms impair function, sleep, movement, eating, mood, etc. In addition to the physical assessment completed by both the nurse and physician, there are a number of other disciplines whose input can be critical. Physical and occupational therapy assessments may reveal deficits and suggest interventions that can be essential to maintaining functional capacity, ensuring patient safety, conserving energy, and decreasing fatigue. A speech therapy assessment can provide valuable information regarding swallowing function, while a nutritional assessment by a dietitian can aid in determining caloric intake needs, thereby reducing cancer-related cachexia.

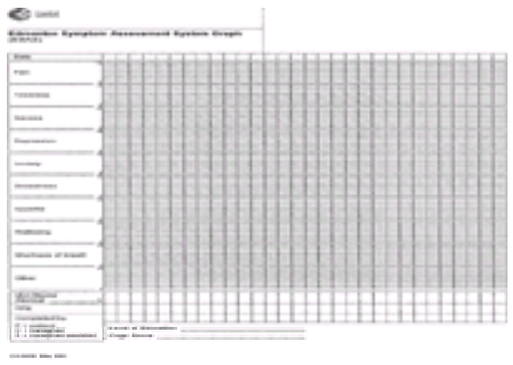

FIGURE 46-3. Edmonton Symptom Assessment Scale. (Reprinted with permission from http://www.palliative.org/PC/ClinicalInfo/AssessmentTools/ESAS.pdf.)

It is important to emphasize that most symptoms have physical, emotional, spiritual, and functional components. For example, dyspnea can be due to airway impingement by tumor, coupled with an emotional fear of suffocating. This in turn leads to limits on activity, and the patient asks, “What have I done to deserve this?” Each symptom should be thoroughly assessed to determine both the physiological/pathological etiologies and the nonphysical components so as to guide appropriate therapies.

The assessment of cognitive function is particularly important and can be readily determined via the Folstein mini-mental state examination (19). It is important to determine whether a patient has either acute (e.g., delirium) or chronic cognitive deficits (e.g., dementia) that would impair decision-making capacity and/or safety. Some palliative care programs utilize a mini-mental status evaluation as part of routine clinical practice for all patients.

Decision-Making Capacity

The principle of autonomy (or self-determination) dictates that a person who possesses the ability to make his or her own decision should be allowed to do so (1). When facing advanced cancer, there are a number of critical decisions that individuals must make: decisions about whether or not to receive anticancer therapy treatment to what type of therapy, whether or not to enter a clinical trial, as well as advance care planning decisions (living wills, durable power of attorney for health care, resuscitation wishes, etc.). Potential crises can be avoided if advanced care planning decisions are discussed while the patient is fully cognizant.

When there are any questions about a patient's decisionmaking capacity, a full mental status examination should be completed. Every effort should be made to treat a reversible cause of altered mental status to return the patient to a state in which they possess decision-making capacity. It is important to be aware that only a court judge can determine someone as “competent” or “incompetent.” It is the health care provider's clinical determination of “decision-making capacity” that serves as a guide for sharing critical clinical information and obtaining informed consent (1).

Information Sharing

A key part of the MDPA is assessing the patient's wishes and desires for the sharing of information. While Western medical ethics emphasizes autonomy, truth telling, and informed consent, it is important to recognize that not all cultures and practices agree with this approach. Robert Buckman, MD, has written a helpful six-step protocol for communicating difficult information (20). In this method, one must remember to ask patients how much they know about their disease with an open-ended question such as, “What is your understanding of your disease?” followed by active listening. This should be followed with a second, perhaps more important question that is again open-ended: “How much do you want to know about your disease?” followed by active listening. When one is still not certain about how to proceed in the sharing of information, a follow-up question that is useful is, “If I have some important information to share about your medical condition, with whom would you want me to share it?”

Psychological Assessment

A psychological assessment should be done to evaluate mood and coping. It is important for team members to develop a sense of familiarity with each of these areas and, most important, to recognize when there are issues that need further assessment and/or intervention by another health care discipline. Most palliative care and hospice teams rely heavily on social workers and nurses to provide expertise in detailed assessments of mood and coping. When the initial assessment suggests significant needs, then referral to a mental health provider can be helpful. Social workers generally have a well-developed network of mental health providers in the community that can be called on for counseling (individual, group, couples), support groups, and, potentially, pharmacological therapy.

The assessment of mood is vital in the palliative and supportive oncology arena (21). Anxiety and depression are common among cancer patients. Depression is common in advanced cancer and often undiagnosed and untreated (21,22). Many clinicians believe that it is “normal” to be depressed when one has advanced cancer. Although it is true that mood disorders are common in advanced cancer, depression is not normal and warrants pharmacological and nonpharmacological therapy. Involvement of a mental health provider to provide further assessment and intervention may be beneficial. The health care provider must always be alert to the possibility of significant depression leading to suicidal ideation (23). If this is suspected, one must make an immediate assessment of whether or not the patient has a plan to act on this idea and whether they will “contract for safety” (let someone know if they feel that they might act on their plan). In any case, the presence of suicidal ideation requires prompt intervention.

The diagnosis of advanced cancer is often devastating to a patient and the family (24). There are a number of responses that a person can have to this threat to his or her personhood, including fear, anger, avoidance, denial, intellectualization, intense grieving, and existential questioning. All of these coping mechanisms are normal and may be adaptive and beneficial to the patient and family at that particular time. It is imperative that the health care provider continually assesses the emotional coping of patients and families to determine when there may be problematic coping. It is helpful to assess not only current coping strategies used by the patient and family but also strategies used in the past. This will assist the team to anticipate ineffective coping styles and to develop individualized strategies for the patient and family members. General open-ended questions (e.g., “people often feel a number of different emotions as they are living with cancer, what are you feeling?”) followed by active listening can be very helpful. With good psychosocial support from the cancer care team, most patients can effectively live with their cancer as they reach acceptance and, ideally, peace with their illness and their life.

Social Assessment

In the MDPA it is important to keep in mind that the patient and family, rather than the disease, are the primary focus of care. One needs to glean a basic understanding of the patient's family and family dynamics, their culture and community, and relevant information about their finances. The social worker, often in conjunction with the nurse, can help to obtain critical social information.

Each patient and family will experience illness within the context of their particular worldview. Being sick, even slightly, can be a disabling experience, both physically and psychologically, with attendant feelings of loss of control and helplessness becoming paramount. This is particularly so in terminal illness. For example, the change of role within the family can become a critical issue. Perhaps the patient who is the primary income generator is unable to work and thus unable to provide materially or the main family caregiver is too ill to continue lifelong habits of looking after other family members. For the entire family there often needs to be major adjustments made. Financial, social, and emotional adaptations will occur with varying effectiveness. In order to open communication and provide whole person care, the patient and family must be integral members of the team and thus involved in treatment decisions and in development of an appropriate care plan (25).

A patient's entire family system is affected by the diagnosis of a life-threatening illness (26,27). The patient's relationship to his or her world changes with the news that his or her life span has been defined, thus altering their family interactions (28). The patient's roles within the family—as a provider, a caregiver, a parent, a spouse, or a sexual partner—may be challenged (26,28). Therefore the particular issues and needs of family members, in addition to the patient, must also be assessed. Furthermore because care may be provided by family members in the home setting, the family should also be consulted and educated about the diagnosis, treatment options, the illness trajectory, symptom burden/treatment, and care giving—with the patient's permission (28).

What constitutes “family” will vary for patients. It is vital to determine whom the patient considers to be his or her “family” or “community of care,” whom they wish to be included in decision making, and whom he or she identifies as his or her means of support. Family units can be composed of the traditional nuclear and extended family, but also may be a same-sex couple, members of a religious order, members of an ethnic/cultural community, or simply a group of friends. Focused discussion with the patient should occur up front to determine whom they identify as “family,” with whom they wish to share information, and how much and what type of detail they

wish to share.

Social workers use the genogram or family tree to facilitate understanding of a particular family's structure and dynamics. The genogram helps to identify the family structure in a clear and comprehensive way. It highlights relationships, strengths, and weaknesses and can often clarify some of the family norms around disease/illness and coping. Gathering the information to develop a genogram also facilitates the partnership between the health care team and the patient and family. The information gleaned should be documented in the medical record and reassessed periodically.

As discussed earlier (see the section Decision-Making Capacity), the importance of addressing advance care planning for the patient and family is critical (29) and is best addressed early in the course of illness, and frequently reassessed, rather than left for discussion at 3 a.m. in the emergency room when a crisis occurs. Early discussions regarding prognosis, likely course of the disease, events to anticipate, and clarifying advance directives (e.g., living wills and/or designation of a durable power of attorney for health care) all can serve to mitigate subsequent dilemmas, increase control, and lessen angst. This helps the patient and his or her family to prepare for changes in the patient's condition and facilitates open communication between the patient, family, and the health care team (26). This type of communication minimizes the sense of abandonment that many patients fear and helps facilitate a sense of control (27,30).

It is important to determine specific cultural or other particular practices of the patient and family in order to be sensitive and respectful. If the health care provider encounters an unfamiliar culture, custom, or tradition, he or she should use this as an opportunity to learn about it from the patient and family or from a local expert. This will not only enhance the health care provider's knowledge base and skill set but also show significant respect for the patient and family that will help to build a therapeutic relationship (31). The social worker or chaplain is often an initial resource for these issues.

A critical component of the social assessment is to determine patients' financial issues or concerns. Medications are expensive and often are not covered by insurance, resulting in either significant out-of-pocket expenses for the patient or lack of adherence to a medication regimen. Finally, one should always be aware of the burden that many patients and families feel as they are going through their illness. The Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatment (SUPPORT) study found that 31% of all families spent most or all of their savings on the treatment of their terminal illness, with 29% reporting loss of the major source of income (32). Both nurses and, in particular, social workers can be extraordinarily helpful in determining the family resources and potential concerns.

Spiritual Assessment

A spiritual assessment can provide another link to a better understanding of a patient's suffering (33). A pastoral care provider is an invaluable member of a team in this regard. The fundamental component of the spiritual assessment is to listen to patients to determine the meaning of the illness to them. This may or may not have anything to do with formal religion, but may reflect more of a struggle over patients' own issues of “ultimate concern”; fears about the future for both themselves and their loved ones; desire to not be a burden to their family members; issues of losses of control, independence, hope, and their changing role within their family, community, or workplace; fears about their own death; and the questions around dying.

Many of these concerns, if not assessed and addressed, grow and can lead to spiritual crisis where feelings of guilt, unworthiness, hopelessness, and abandonment fulminate. One must listen and then ask open-ended questions like, “How have you tried to make sense of what's happening to you?” or, “What are some of the things that give you a sense of hope?” (2), and then be prepared to listen to the response to understand the patient's sense of meaning.

If the patient and/or family have a particular faith tradition, it is important to emphasize that a religious leader or the faith community may be a useful source of strength (34). A skillful pastoral care provider can be extremely effective in addressing spiritual angst, even when the patient and family do not identify with a particular religious or spiritual doctrine.

Practical Assessment

The final area of assessment is the practical assessment (35). Issues to consider here are whether or not the patient will need help at home in the form of a formal caregiver. If so, how many caregivers will be needed to ensure safety and good care, and what are the possible care options given the patient and families' financial resources. The assessment should include a determination of the patient and family needs in terms of activities of daily living. For example, shopping for food and food preparation; bathing, dressing, and hygiene; and transportation issues, such as determining how the patient will get back and forth to the clinic, are all issues that, although they are often perceived as “nonmedical,” often have an impact on the ability to deliver appropriate medical care. Planning for likely changes in patient function can help to reduce the chance of a crisis developing. Nurses are particularly skilled at anticipating the practical problems that may befall the person with advanced disease.

Prior to the patient becoming bed-bound, the need for equipment, such as a hospital bed, bedside commode, or shower chair, should be discussed. Before the patient loses the ability to swallow, issues of nutrition and medication administration should be explored with the patient and family, so that an anticipated plan can be put in place.

SUMMARY AND CONCLUSIONS

As medical technologies and therapies have converted many illnesses into chronic conditions that people have to live with for months or perhaps years, it is important to remember that medical illness affects every aspect of individual and family life. In the setting of palliative and supportive oncology, there are a number of domains of whole patient assessment that should be obtained on the initial visit that are perhaps different from those currently obtained in the traditional medical model. Although these additional domains of assessment may seem overwhelming both in time and emotion for one clinician, it is what our patients and their families are expecting. Thus, it is imperative that our training in oncology nursing, social work, and medicine (surgical, radiation, and medical oncology) has the principles of Primary Palliative Care that are embodied in the MDPA as core competencies in clinical practice (2).

Furthermore, medical professionals, regardless of their own discipline-specific training, must learn to more fully respect and collaborate with colleagues in other disciplines, to integrate their assessments, share the burden of the issues that will be revealed, and ultimately achieve better outcomes for patients and families in terms of whole person care. Ultimately, through this effort, the health care provider will also find, as others have documented, that, through interdisciplinary teamwork, “the sum is greater than the individual parts,” leading to greater personal and professional satisfaction for all clinicians involved in palliative and supportive oncology.

CROSS-CULTURAL ISSUES

JAMES L. HALLENBECK

People experience both health and illness in cultural contexts. A better understanding of culture helps the clinician avoid certain pitfalls, thereby improving the chances of good outcomes. Very sick and dying patients in our society are often dependent upon care from people of very different cultural backgrounds, making misunderstanding and conflict common. Culture, as a topic area, is almost infinitely broad. A comprehensive discussion of culture and palliative care would require considerations from anthropologic, sociologic, historical, and philosophic perspectives, among others. Such a discussion is beyond the scope of this chapter, although I will draw on some perspectives from beyond standard medical texts and journals.

Various definitions of culture exist in the literature. Helman defines culture as “a set of guidelines (both explicit and implicit) which individuals inherit as members of a particular society, and which tells them how to view the world, how to experience it emotionally, and how to *behave* in it in relation to other people, to supernatural forces or gods, and to the natural environment” (1). This definition suggests culture, as a noun, exists as a pervasive set of guidelines shaping the individual. Of course the existence of any such guidelines and associated patterns of behavior and organization results from the actions of many people. The ongoing construction, shaping, and reshaping of culture demonstrates that culture, as a *verb*, is in fact more than an inheritance; it is a dynamic *process* wherein people interact with each other and thereby actively create an ever-changing world experience. Another way to view culture is as a complex and overlapping set of descriptors, adjectives, and adverbs, giving meaning, shading, and even texture to various patterns of human organization and behavior.

The following discussion proceeds on the assumption that clinicians, patients and their families share a common goal—an optimal outcome relative to a particular episode of illness or clinical encounter. Unfortunately, consensus is often lacking as to what might constitute an optimal outcome and what action(s) may give rise to such an outcome. While any group of people share some common aspects of human experience (e.g., at a minimum all people struggle with similar human bodies), individuals and groups may participate in and view the world in terms of health and illness in radically different ways (2,3). We are for the most part unaware of the degree to which our views differ from others. As Hall put it, “culture hides much more than it reveals, and strangely enough what it hides, it hides most effectively from its own participants” (4). It is often only when we encounter others in conflict that we begin to become aware of alternative viewpoints. In such encounters there is an understandable, but regrettable tendency to affirm one's own view through reinterpretation of the other's viewpoint according to one's own position or, where this fails, by dismissing the other's perspective as incorrect, nonsensical, or bad (5,6). The inherent difficulty of transcending one's own viewpoint is a significant barrier to collaborative efforts to obtain optimal outcomes for both clinicians and patients. However, those involved have little choice but to struggle in the direction of understanding and collaboration. Barring this, disagreements will undoubtedly be resolved by explicit or implicit force (7). Better communication and mutual understanding will not resolve all disagreements arising in crosscultural encounters. However, the probability of achieving good outcomes will be significantly increased by efforts to understand the other and in turn to be understood.

Outcomes of care are also strongly affected by social forces and institutions that encourage certain courses of action and limit others, with profound effects both good and bad (8). Although clinicians may like to believe that their skillful therapies are the most important factors in achieving good health outcomes, other forces outside of their direct control may in fact be equally critical. For example, Morrison found that a ratelimiting step in getting patients needed opioids in innercity New York was the availability (or rather lack thereof) of such medications in neighborhood pharmacies (9). Pharmacies in nonwhite neighborhoods were significantly less likely to have adequate opioids for the treatment of severe pain than pharmacies in predominantly white neighborhoods. Getting pain relief to the patient was as dependent upon complex historical and socioeconomic factors giving rise to poverty and crime as it was on physician prescribing practices.

Clinicians would do well to consider the social forces affecting care and outcomes. Although most forces will admittedly be beyond the clinician's direct control, knowledge of both the opportunities and barriers such forces offer may enable the clinician to “work the system” for the good of the patient. For example, in attempting to support a frail patient trying to receive medical care at home alone, the clinician must wrestle with various societal forces that “created” a situation in which frail patients find themselves alone at home and a health care and social support system that is poorly equipped to provide such care. Rather than give up altogether, the clinician needs to become familiar with how to access what support *is* available. How does one recruit community support from various organizations that may view the patient as “one of their own”? Support may be found from groups organized around such cultural attributes as ethnicity, age, disability or disease, gender or sexual orientation, among others. Engaging such support, although not traditionally considered medicine, may in fact be “just what the doctor ordered.”

IMPORTANCE OF CULTURE TO PALLIATIVE CARE

We live in an increasingly pluralistic society. Although American culture as we now conceive of it evolved out of a history of European immigrant subjugation of Native Americans, waves of immigration from other societies have contributed to making the United States a culturally diverse nation. The extent of such ethnic diversity varies dramatically by geographic region. Pluralism exists not only in terms of ethnicity but other cultural attributes. National or geographic origin, current home (geographic, urban/rural), gender, sexual orientation, marital status, family, professional and community roles, religion, economic and educational status—these cultural attributes and others contribute to our cultural personae. Certain cultural attributes become defining to the extent they can be considered subcultures in their own right. For example, we now name generations (Baby Boomers, Generation X). Some subcultures are now large enough that individuals and families can live within them with limited, often superficial exposure to people from other subcultures.

Pluralism exists also among health care workers (10). When people become ill, particularly chronically ill, they are more likely to come under the care of others from very different backgrounds than their own (5). Relationships in such situations are often imposed. That is, health care workers, whether physicians working in an intensive care unit or nurse's aides in a nursing home, and patients have limited choices as to who will care for whom. Because handson care, such as that provided by nurse's aides, is devalued in our society, immigrant and underclass workers make up a substantial portion of this workforce. These workers have little choice but to accept positions at the bottom of the social ladder, which in our society includes the provision of the most intimate care for chronically ill and dying patients. Conversely, patients and families are increasingly dependent upon care provided by such workers. It should come as no surprise that imposed relationships at such a fragile stage in the life cycle create a problematic environment. Efforts to understand each other are not only desirable, they are essential if there is any hope of obtaining reasonable outcomes.

Although culture lurks in the background of all human experience, it comes alive and overt during transition periods in the human life cycle. In such dramatic transitions as birth, coming of age, marriage, and more recently retirement, culture provides mechanisms to make human what would otherwise be mere biology—birth, puberty, mating, and aging. Dying is obviously a major life transition and as such is heavily invested with culture. However, more subtle transitions usually precede actual death. Consider, for a moment, cancer as an example. Becoming a “cancer patient” implies a transition to a new category of being. The newly diagnosed cancer patient may transition to states of “survivorship” or cure, remission, or terminality—all with profound implications for how the person is understood by self and others to exist within the broader context of society (11).

Cultural transitions are often marked by ritual and rites wherein meaning is expressed and created through particular behaviors. Beyond this, ritual is used to change reality or at least to create a particular human expression of reality. For example, in a comingof-age ritual one *becomes* a man or a woman, making *human* the more biological process of puberty. Rites and rituals related to palliative care are most obvious in considering death and dying practices such as funerary rites (12,13,14 and 15). More subtle may be myriad behaviors, some of a very personal nature, that are used to engage with the multiple transitions involved in becoming chronically ill. Ritual is involved in the process of making a person a patient in a hospital. Wristbands and hospital gowns serve ritual purposes beyond mere technical efficiency. The ritual use of wigs or caps after hair loss through chemotherapy is another example that may serve the purpose of maintaining a certain image of self (in addition to keeping one's head warm). Conversely, “going bald” after hair loss may serve a ritual purpose of declaring acceptance as a new member of a class of cancer patients.

The importance of ritual as a cultural activity related to dying (and birth) is highlighted by Grimes in his book, *Deeply into the Bone— Reinventing Rites of Passage*.

> If we do not birth and die ritually, we will do so technologically, inscribing technocratic values in our very bones. Technology without ritual (or worse, technology *as* ritual) easily degenerates into knowledge without respect. And knowledge without respect is a formula for planetary annihilation. It matters greatly not only *that* we birth and die but *how* we birth and die (13, p13).

Serious illness and dying as life transitions also challenge how individuals construct their life stories. Gaining a better understanding of such stories, often entitled *illness narratives*, as discussed later in this chapter (see the section Explanatory Models and Illness Narratives), is critical to good palliative care (16,17,18,19,20 and 21). Such narratives give some insight into the personhood of the patient. Palliative care and supportive oncology differ radically from traditional biomedicine in taking the *personhood* of the patient in all its multifaceted dimensions as the focus of care. Such personhood cannot be seriously considered separate from its cultural context, which both shapes and is shaped by that personhood.

CULTURAL EDUCATION AND PALLIATIVE CARE

Biomedical curricula rarely include cultural aspects of care in their content, despite studies calling for such inclusion (22,23,24,25 and 26). A study in 1992 queried 126 medical schools regarding possible courses in “cultural sensitivity.” Of 98 respondents only 13 schools reported offering such courses and all but one were elective. Fifty-nine schools indicated that they had incorporated cultural sensitivity in other courses such as courses on medical ethics (27). A systematic review of the literature from 1963–1998 published in 1999 found 17 reports of curricula meeting search criteria (28). Thirteen of these programs were in North America and 11 were exclusively for students in year 1 and 2 of medical school. The focus of most of the content was on ethnicity, attitudes, health beliefs, and language barriers. Only one program is reported to have considered anthropological and sociological theories (29). The lack of breadth and apparent lack of depth of training suggested in this review is discouraging. However, there are some encouraging signs of change. Recently, Carrillo and colleagues published a description of a course for medical students and residents consisting of four 2-hour modules covering *basic concepts core cultural issues, understanding the meaning of the illness, determining the patient's social context, and negotiating across cultures,* which seems to be more in keeping with recent anthropologic and sociologic trends (30). In an intervention designed to assist internal medicine programs in the United States in improving palliative care education, Weissman found that teaching regarding cross-cultural issues was high on the list of unmet needs of residency training programs (31). In response to this, a module on addressing cross-cultural concerns was developed for that intervention and incorporated into the curriculum (32). This suggests that physicians are experiencing some tension regarding their lack of training in cultural issues, which bodes well for future educational efforts.

ETHNICITY

What little clinician training that has occurred regarding culture has focused heavily on ethnicity, as have palliative care texts and articles (33,34,35,36,37,38,39,40 and 41). The tendency in most such texts is to describe beliefs and practices of particular ethnic groups relative to health care. Lipson, for example, provides overviews of how 24 ethnic groups construct illness, relate to symptoms such as pain, decision making, relations with clinicians, preparations for dying, grief practices, and death rites, among others (34). Although this and similar texts may be helpful to clinicians struggling to care for patients from very foreign ethnic groups, some caution is in order. Excessive reliance on such texts risks stereotyping by underestimating the extent of cultural diversity within ethnic groups (42,43). Culture tends to be portrayed more as a determinant *thing* separate from personhood, like the genetic code, rather than an active *process* of social engagement. An exclusive focus on ethnicity and associated “beliefs and practices” also tends to narrowly define culture and limits the ability to appreciate other important aspects of culture (6, pp1–24, 10). For example, problematic, cross-cultural encounters between individuals and health care systems may too easily be ascribed to differences in belief systems, with inadequate attention to social forces associated with ethnicity such as arise from poverty or racism. A cursory or narrow read of such texts (far narrower than intended by the authors) might leave the reader imagining culture as an “inconvenient barrier to a rational, scientifically based, health care system, a feature of ethnic “others,” as Koenig put it, rather than as dynamic process of social engagement in which clinicians participate every bit as much as patients and their families (10).

Ethnicity is a useful starting point for considering the myriad social forces that affect care and associated outcomes, as long as one understands that considerably more than “beliefs and practices” associated with ethnicity are at work. Correlated with ethnicity are such important factors as immigrant status, educational background, socioeconomic status, geographic and demographic distribution relative to health care resources, communication styles, gender, and other social roles (44,45,46,47,48,49 and 50). Space does not allow a detailed discussion of all these factors, although they undeniably affect clinician interactions with patients and families, and outcomes in profound ways.

CULTURE OF BIOMEDICINE

Let us consider biomedicine as a culture, particularly as it has evolved in the United States. Originating in Western Europe, the evolution of biomedicine has been guided by complex historical, religious, philosophical, and economic forces (8,51,52). Biomedicine has now become, arguably, the dominant medical system throughout the world, being integrated or at least coexisting with numerous other medical systems. This term, now preferred by most anthropologists, may be new to many clinicians. As Kleinman states, “If you ask biomedical professionals what word they would use to describe their field, most will say, in a powerfully succinct usage that does capture a sense of the hegemonic selfperception that has become almost a caricature worldwide, 'Why not just call it medicine?'” (3, p25). Insight into cultural aspects of biomedicine is critical for the practitioner trying to work with individuals across culture. This is especially true for those working in palliative care, which exists “at the margin” of biomedicine. Some might argue that as biomedicine depends upon scientific inquiry and rationality it has somehow risen above the messiness of culture. Any such statement would only reflect an arrogance common to the culture of biomedicine, highlighting a restricted world view. Biomedicine has undeniably resulted in astonishing and useful therapies, but it is *not* culture free. Biomedicine is not a monolith and in such a brief inquiry, stereotyping is a serious risk (53). Still, what characteristics and tensions can we identify within the world of biomedicine?

While sharing with other medical systems a fundamental charge to heal the sick, the emphasis in recent decades has been increasingly to fix broken bodies (18,52). Citing *Stedman's* definition of “medicine” as a profession, “the art of preventing or curing disease; the science that treats disease in all its relations,” Hahn points out that, “A prominent feature of Stedman's definition of the domain of medicine is the designated subject of medical work: medicine prevents and cures, studies and treats, not persons, nor their bodies, but the disease of bodies. In describing the domain of medicine, there is no mention of persons” (18, p133). Pursuing a Western rationalist belief that the *good* is best approached through scientific inquiry, biomedicine has developed a *mechanistic* approach to care. Through a progressively refined and reductionist understanding of the origins of illness, labeled *disease*, the hope (and the myth) is to eliminate physical disease entirely. As an important corollary, suffering will magically vanish once the physical disease from which it originates is eliminated and proper functioning restored. Although suffering is not entirely ignored in biomedicine, it does take second place to biology as an issue of concern. The belief that suffering is entirely derivative to biological malfunctioning is naïve on two fronts. First, it simply takes no account of aspects of suffering not arising from the body (54,55,56 and 57). As evidenced throughout this book, suffering is far more complex than this. Second, almost too obviously, biomedicine to date has failed to eliminate disease. Given our continuing mortality, inevitably the elimination of one illness must, by default, increase the probability of becoming ill and eventually dying from something else. As Fabrega writes, “The curing of disease, the technical repair of the machinery of the body, and the illusion that most, if not all, diseases can be undone, cured, or eradicated are guiding imperatives rather than a sensitive appreciation of the inevitability of sickness and a furtherance of caring for the suffering it entails” (52, p299). Suffering continues. Indeed, biomedicine “creates” new forms of illness and associated suffering, as the field of supportive oncology, dealing in large part with the sequelae of oncologic treatment, is ample testimony (58). The evolution of palliative and supportive care, pain clinics, and hospices as social phenomena on the margin of biomedicine can be understood in part as reactions to the failure of this dominant myth of biomedicine (Table 47-1).

Individualism	⟷	Reductionism
Autonomy		Paternalism
Disease in the individual body		Mechanistic/technologic approach to illness
Consumerism		Bureaucratization
Egalitarianism	⟷	Capitalism
Health care as a right		Health care as commodity

Lacking in modern biomedicine
- Focus on suffering as primary object of medicine
- Inclusion of a concept of a life force in model
- Illness as something transcending the individual

TABLE 47-1. TENSIONS IN THE CULTURE OF BIOMEDICINE

Individualism and egalitarianism, so central to our society, have also affected the culture of biomedicine. Biomedicine defines disease as something that resides within

the individual body (3). Such a narrow focus tends to ignore societal forces that broadly impact health. For example, we tend to focus on deranged cells in a particular patient's lungs to identify a disease we call lung cancer rather than identify a complex societal illness related to tobacco production and use, involving corporations, governments, tobacco farmers, and the resultant devastation affecting whole groups of people. Individualism also gives rise to the dominance of autonomy as a principle of bioethics and the recent tendency toward consumerism in medicine (59,60 and 61). Countercurrents to individualism also exist, resulting in considerable tension. Curiously, the emphasis on *disease* in the individual body as the proper object of concern itself negates the personhood of the individual (3, pp21–40). The high-tech, high-cost, big-business nature of modern biomedicine defines health as a commodity, rather than an aspect of personhood, to be purchased by consumers. Tensions inevitably arise from the simple fact that both the consumers of health care and of the commodities marketed by health care as an industry are the same people. Reports in the lay and professional press too numerous to cite speak of the dehumanizing nature of modern biomedicine as experienced by patients, and increasingly, practitioners.

Egalitarianism has been a philosophic underpinning of our democracy. Egalitarianism in health care tends to play out in terms of an evolving belief in a *right* to health care. In the early 1960s this notion gave rise to Medicare and Medicaid as institutions to provide care to elders, the disabled, and the poor as special classes of citizens deserving protection. Recently, a rights-based advocacy has arisen relative to palliative and end-of-life care. A “right to die” has also been advocated. The Supreme Court cases, *Washington vs Glickman* and *Vaco vs Quill*, revolved heavily around whether such a right exists (62,63). A strong countercurrent to such egalitarianism is a capitalist tradition in the United States regarding biomedicine as an *industry*, like others, to be affected by market forces and guided by an elite class of professionals, physicians. It is noteworthy that the American Medical Association, as spokespersons for this industry, strongly opposed both Medicare and Medicaid when first proposed in the 1960s as threats to private enterprise and “the American Way” (8, p126, 51, pp367–370). How else are we to understand the fact that the United States is the only Western industrialized nation without some form of nationalized health care, other than as a manifestation of industrialized medicine, strongly influenced by a spirit of rugged individualism?

Kleinman also points out that that biomedicine is unusual in its inattention to any concept of a “life force” (3, p36). Most other medical systems include some notion of a life force and commonly frame the understanding of health and illness in terms of balance and imbalance between aspects of energy (often positive and negative) that give rise to a life force (6, pp101–110). Examples include Chinese (yin-yang) and Mexican (hot-cold), among others (64). A medicine that identifies healing as a process of *balancing* seems philosophically closer to the spirit of palliative care than a medicine based on *cure*. Palliative medicine could benefit from a deeper understanding of such medical systems.

Biomedical culture influences care not only at a macro level, but also at more intimate levels. Good, for example, writes of the complex process of acculturation by which people become physicians in the world of biomedicine through multiple acts of engagement with a world rather foreign from lay life. A quoted medical student states,

> It often seems like as medical students we kind of slide into doing these kind of things which can have just unimaginably great consequences for patients and we just sort of do it because we've incrementally learned about the biology and the science and the pathology and the pharmacology and we kind of inch into it and suddenly there we are saying, “I'll write the orders that such and such be done to this patient” (65, p81).

Our cultural personae as clinicians are shaped to a large degree by innumerable small interactions with teachers, colleagues, and our patients. Attention to such details of everyday life in biomedicine is as important as attention to macro forces and belief systems and is particularly important for those in palliative care trying to change biomedical culture. Educational efforts that do not appreciate and work with the details of everyday clinical life will ultimately fail.

Palliative medicine and supportive care working at the margin of biomedicine constitute a radical challenge to many of biomedicine's tenets. The emphasis on the person and family as the unit of care and the attention paid to suffering highlight the nature of this challenge. It should come as little surprise that resistance to such change has been engendered on the part of many in biomedicine.

BIOETHICS

When cross-cultural and other conflicts arise in biomedicine, at least those conflicts identified as such by clinicians, the tendency is to try and resolve these conflicts through bioethics, as codified in law, accrediting agency, and local policies, and through ethics consultations. Leaving aside whether all such conflicts are in fact conflicts of ethics, this is a cultural phenomenon worthy of consideration. Bioethics, as a process of dispute resolution, seeks good outcomes through a weighing of ethical principles as understood to be manifest in a particular case (66). Modern bioethics also attempts to balance viewpoints—those of patients and families as well as clinicians—in seeking resolution. As such, bioethics can be a vehicle for the promotion of mutual understanding—clearly a good thing. However, without reflection upon cultural biases giving rise to bioethics, the discipline risks becoming an agent of social control for the culture of biomedicine and thus risks squelching true mutual understanding.

Anthropologic critiques of bioethics are limited, but raise important issues of concern (67,68 and 69). Often noted as “ethnocentric” positions of bioethics are the following:

- The dominance of abstract ethical “principles” as prime movers for decision making, based on tenets of Western philosophy.

  Classically four such principles are identified—autonomy, beneficence, nonmaleficence, and justice (70). The process of using abstract principles as prime movers betrays a cultural bias. So too does the choice of specific principles. For example, *interdependence,* valued by so many non-Western cultures as a principle for decision making, might be included as a counterweight to autonomy (71).
- A tendency to make “practical” such abstractions through the practice of ethics consultations, especially in the United Sates.
- Codification of such abstractions in a plethora of laws, regulations, and policies, reflecting the bureaucratic and litigious tendencies of American society (72).
- The dominance of autonomy as a guiding principle (73,74).

  Spinning off from autonomy is an almost unassailable insistence on surrogate decision making and associated substituted judgment as the only proper vehicles for deciding a course of action relative to patients lacking capacity. The anthropologic basis for surrogate decision making is ighly questionable (75). The first U.S. legal case to invoke the principle of surrogate decision making (Quinlan) occurred in 1976. The term *substituted judgment* was first used in a 1980 Massachusetts case (in re Spring) suggesting the historical roots of this “belief system” are shallow (72, pp172–173). Even a cursory examination of decision making for incapacitated patients across world cultures would find very few examples of groups espousing surrogate decision making as a guiding value. One could argue that the primacy given to surrogate decision making reflects the limited view of a very small subculture of Western bioethicists (and the courts and policy makers who seem to share this view) (5).
- Suffering as a derivative, not a primary concern of ethics.

Kleinman suggests that bioethics could be improved by an infusion of “ethnographic work,” resulting in an inquiry grounded less in abstract principles and more in the cultural contexts of participants. He argues that such an approach may be a means of protecting patients from ethnocentric tendencies of biomedicine.

> As part of this ethnographic work, bioethicists need to elicit the perspectives of the participants and place them in the contexts of family, workplace, and medical system. To interpret these grounded perspectives, however, they will need to construe the local context in the light of larger societal influences. Thus, by bringing the life world of the patient into biomedical deliberations, bioethicists also bring with that biographical narrative a much larger societal analysis.
>
> The bioethicist's involvement should be to facilitate communication and to help negotiate conflicting orientations. In this work, it is necessary to protect the participants from the dehumanizing imposition of hegemonic principles like autonomy and justice (3, pp54–55).

Of note in this quotation is his inclusion of both “larger societal influences,” what I have termed social forces, and personal narrative as relevant to bioethics, and his suggestion that negotiation facilitated through better communication is more relevant that the pursuit of some abstract good (71).

EXAMPLE OF NONDISCLOSURE

Let us consider a request for nondisclosure as an example of a classical “ethical” dilemma, which may in fact be better addressed through ethnographic inquiry (76,77). The scene is well known to most clinicians. A relative requests that the clinician not inform a patient of some bad news such as a diagnosis of cancer or a terminal prognosis (78). Such a request appears to conflict with autonomy as a guiding principle and multiple health care policies that stress the importance of informed consent. The dilemma is doubly difficult because the request, usually from family members, that clinicians either not talk or frankly lie to the patient inhibits open communication that might resolve the issue.

A narrowly applied bioethics could do serious harm in such a case. Rigidly insisting that the patient has “the right to know” could both alienate family members and

damage the patient by forcing undesired information. Anecdotal case reports suggest that some patients, if bluntly told of their prognosis, will in fact lose the will to live, as families sometimes warn. Orona and Veatch both suggest a possible resolution to the problem based on a twist of logic, which recognizes that autonomy can be reframed as a choice *not* to act independently but to defer to others (73,79). The trick is how to identify such a choice on the part of the patient without giving undesired information. In practice, as Kleinman suggests, skill must be used in exploring the "local world" of the patient and the family and then negotiate, where possible.

Requests for nondisclosure seem more likely from individuals from *high-context* cultures (to be discussed further later [see the section Intercultural Communication]) (80,81). High-context cultures place more weight on the contextual and relational aspects of communication as compared to more linear, verbal communication typical of Western biomedicine. Charlton's review of nondisclosure cites articles demonstrating that Spaniards and Italians (both relatively high-context Southern European cultures) were more likely to not desire disclosure for themselves as compared to Australians (a relatively low-context culture) (76). Conflict resolution in high-context cultures is often more dependent upon the quality of the relationship between individuals than on the power of verbal argument. Thus, prior to tackling directly a problem such as a request for nondisclosure, the clinician is advised to try and understand both the patient and family context in which this request is being made and the relationship that is evolving between the family and the clinician/health care system. To the extent a strong, trusting relationship can be fostered, conflict resolution will proceed more smoothly. Conflict resolution in real situations is usually more dependent upon communication skills than an abstract understanding of dueling ethical principles. By way of example, let us consider what skills might be useful in addressing a request for nondisclosure.

COMMUNICATION SKILLS IN ADDRESSING NONDISCLOSURE

At the simplest level the clinician should state and demonstrate *respect* in the face of such a request (32). Recalling that family-based decision making and nondisclosure are common worldwide, and recognizing that courage is often needed to make such a request in the face of a powerful health care system that generally disapproves of nondisclosure, may help the clinician engender respect.

Exploration of the context may begin with the person(s) making the request for nondisclosure. Why are they making this request? How do they understand the roles of participants, both in the family and clinicians relative to care? What do they fear might happen if the person knew? What are their hopes?

Just as cultures are not monoliths, neither are families. It is quite possible for a family to believe the patient does not want to know when in fact he or she does. The clinician might then inquire how the family and specifically the patient have dealt with similar situations in the past. The clinician might ask questions such as, *"Do you think or know that she would agree with this? Have you discussed this approach with her? How has she dealt with similar situations in the past?"*

Exploration is not a one-way street; it is not the same as *taking* a history. Clinicians are advised to share their (often equally foreign) biomedical viewpoints and to share dilemmas being confronted, including policies that require informed consent. For example, beyond the mundane (getting consent forms signed), clinicians may share that they too wish only the best for the patient. One might say that in one's experience some people even in cultures that practice nondisclosure really want to know and that if this were so, nondisclosure might cause the patient distress and this would bother the clinician. The clinician might explain that he or she values truth telling and could not lie if asked directly a question. Hopefully finding the presumed common ground of wishing the best for the patient will foster some mutual understanding.

The clinician probably will want to explore the patient's understanding and concerns. The intent and desire to explore *without* coercing the patient regarding disclosure may be explained to family members. At a simple level one may simply need to confirm that the patient wishes to "defer" decision making to the family, although a richer exploration is encouraged. What to do if the patient states that she wants to know the truth or be in charge should be worked out before such an encounter. Most clinicians will want to be clear on certain ground rules such as not lying. If the patient requests to be informed, rather than simply tell, the clinician may change roles and act to facilitate improved communication between the patient and family.

Dealing with difficult dilemmas in real life cannot be done as proscriptively as the above might imply. The above is presented to offer the clinician some guidance as to how to explore and negotiate such a situation and to illustrate an approach to conflict that is hopefully more grounded in the "local moral worlds" of the participants than in ethical abstractions.

INTERCULTURAL COMMUNICATION

As the above discussion highlights, good communication is critical to the practice of medicine in general and palliative care in particular (82). Generic communication skills, such as the ability to listen, will not be discussed here. A number of recent texts explore intercultural communication in healthcare (83,84 and 85). Cultural aspects of communication specific to palliative care are beginning to be addressed in the literature and will be discussed further here (86,87).

The most obvious cultural communication barrier is language. Communication will be largely ineffective and prone to serious misunderstanding without competent translation. Relying on family members as translators, although sometimes unavoidable, is problematic, as messages between clinician and patient may be filtered (88). Professional medical translators, where available, are generally recommended although their use does not eliminate communication challenges (89). Skilled interpreters can do more than translate words. They may act as "cultural guides," facilitating broader understanding (90,91 and 92).

In considering language as a cultural barrier, the tendency is to view the other's language as the problem, something that needs only be *translated*. More difficult is recognition of the barriers intrinsic to the language of biomedicine. For example, the word *symptom* means a *clue* to something more important (usually the *disease*). A patient's complex, internal experience is translated into a vocabulary of symptoms as understood in the biomedical world, denigrating the primacy of this experience in the process. This linguistic bias handicaps those in palliative care who argue for the importance of "symptom management." An additional problem of the language of biomedicine is its scientific, technologic, and cognitive emphasis and relative neglect of more human concerns such as emotion. Patients and families often attempt to express their concerns through this biomedical language, trying to speak to us in our peculiar, foreign tongue. For example, distress in witnessing a family member near death may be expressed as a demand for some medical intervention such as intravenous hydration. In part this may be because people have become familiar with the bias of biomedicine to focus on *doing* rather than feeling. In hearing such a statement clinicians are prone to hear and respond to the technical aspects of the communication and ignore the affective subtext of distress (93,94). Thus, the specialized language of biomedicine can pose particular communication challenges for those attempting to address more human concerns, as palliative care leaders have rightfully advocated is necessary.

Cross-cultural communication in palliative care is particularly difficult because key content issues, such as serious illness, difficult decisions, and dying, are very sensitive for many people. Discussion of certain topics may frankly be taboo (95). In many cultures and for many people words have power. To speak of illness or dying is to increase the chance of illness or death occurring. Carrese, discussing Navajo difficulties with Western bioethics quotes a Navajo medicine man:

> In my practice, when I'm working with the patient, I am very careful of what I say, because any negative words could hurt the patient. So, with Western medicine, a doctor could be treating a patient, and he can mention death, and that is sharper than any needle (96).

Communication is far more than simple transmission of data from one source to another. Without some understanding of the context within which communication occurs, mutual understanding is impossible.

A branch of anthropology has focused on intercultural communication, based largely upon the pioneering work of anthropologist Edward Hall (97). Hall recognized that cultural contexts are not some inert boxes within which communication exists, but important aspects of communication itself. Hall and others have identified some cultures as being relatively high and others as relatively low in context (98). High-context cultures tend to depend more on the context of the situation than on verbal expression for communication. Context refers to things such as *who* is speaking to *whom*, the setting for the discussion, their relationship (including issues such as dominance, trust, or mistrust), the physical use of space and shared meanings. Nonverbal communication is closely linked to context. Context may be imbedded in verbal communication as well. The very different meanings in two expressions for dying, "kick the bucket" and "passing on," derive from shared contextual meanings (99). High-context people tend to become offended by overly direct verbal communication and a lack of attention to relationship building by low-context individuals. In contrast low-context cultures and individuals tend to stress direct verbal communication. Low-context people may become frustrated by vagueness and lack of direction in discussions with high-context individuals. Much of what is important to high-context people is frankly invisible to low-context people. Each cultural style has advantages and disadvantages. High-context groups are relatively stable, buttressed by a network of supporting relationships, but may have difficulty adapting to change. Low-context groups are less stable and more prone to social disruption, but better suited to rapid change and efficient data exchange. Science as a means of exploration and communication is low in context (100).

Biomedicine, arising from a Western, predominantly Northern European scientific tradition, is similarly very low in context. Although such a low-context approach may serve well where efficiency is needed and accurate transmission of data is required across cultures and languages, it becomes problematic when dealing with the more human issues commonly arising in palliative care.

Just as cultures may be higher or lower in context, so too can different human activities. Very personal, taboo, or dangerous activities tend to be more imbedded in context than impersonal affairs. Sexuality, for example, as a human activity is high in context (4, pp68–69). In the United States, we do not have to know much about verbal or nonverbal communication to understand the meaning implied in the context of a couple being in the back seat of a drivein movie. So too, for most of us,

serious illness, dying, and death are very personal and dangerous. The wealth of idioms across cultures lending context to dying as an activity, such as “passing away” or “kicking the bucket,” testify to the high-context nature of serious illness (99).

A major communication problem arises in palliative care when low-context clinicians practicing within the world of biomedicine deal with high-context events such as dying. Low-context clinicians in dealing with high-context encounters may benefit from first identifying encounters as such. Hints to a high-context encounter [such as a request for nondisclosure as discussed above (see the section Example of Nondisclosure)] include much indirectness in the conversation and the involvement of multiple participants. Although the low-context tendency is to “get down to business” and resolve a dilemma quickly, this approach often backfires in a high-context encounter when inadequate attention has been paid to relationship building. The low-context clinician may need to practice slowing down, and exploring and building a relationship prior to negotiating a specific course of action. This is often frustrating for the clinician. It may be very difficult for a low-context individual to appreciate that within a high-context world often the fastest, most direct path between two points is not a straight line, but a *curve*. To plunge too directly into sensitive discussions risks the relationship, fosters mistrust, and ultimately necessitates even more time for problem resolution.

EXPLANATORY MODELS AND ILLNESS NARRATIVES

Serious and life-limiting illnesses pose threats to personhood (16,17,19,20 and 21,101). Most of us—at least early in life—live optimistically, creating a life story for ourselves and our loved ones that ends, as should all fairy tales, with us living “happily ever after.” Serious illnesses are radical interruptions in these stories (16,17,102). The story has been interrupted and negated and a “blank page” introduced that invites filling (6, pp166–184). Sick individuals and involved others struggle to make some sense of this negation, to fill in the blank by interpreting the illness and eventually incorporating it into a revised life story that incorporates tragedy as well as triumph.

Kleinman introduced the term *explanatory model* as a means of understanding this process of interpretation (103). “Explanatory models are the notions that patients, families, *and practitioners* have about a specific illness episode” (104, p121) (italics mine). As this quotation points out, clinicians also have their own explanatory models for illness, most typically revolving around the concept of *disease.* Kleinman has suggested that eliciting a patient's explanatory model (and reciprocally reflecting and sharing one's one model) can further mutual understanding and help form a basis for collaborative decision making (104, pp227–251). He writes that in the face of illness two questions seem to dominate—*why* did this happen and *what* should be done about it. Specific questions useful in eliciting an explanatory model include the following: *What*— do you call the problem, do you think the illness does, do you think the natural course of the illness is, do you fear? *Why* do you think this illness or problem has occurred? *How* do you think the sickness should be treated, do you want us to help you? *Who*— should you turn to for help, should be involved in decision making? Such an exploration should not be *taken*, as clinicians often take a medical history, but should consist of *“empathic listening, translation,* and *interpretation”* (104, p228). In more recent writings Kleinman explicitly warned against using the explanatory model as a form of interrogation:

> I meant the explanatory models technique to be a device that would privilege meanings, especially the voices of patients and families, and that would design respect for difference. I intended it to be a *modus operandi* to get at what is at stake in suffering. . . . I saw explanatory models as a methodology for clinical self-reflexivity, for pressing against biomedical crystallizations, for laying hold of the sources of clinical miscommunication. I wanted to encourage the use of open-ended questions, negotiation, and listening, not the usual mode of clinical interrogation (3, pp8–9).

Exploring explanatory models is critical to effective communication. This is a process not only of listening to the patient, but of sharing and interpreting the clinician's personal explanatory model and the explanatory models of biomedicine as these apply to the patient's illness (105). Such exploration serves as a basis for collaboration and negotiation as to goals and choices. More concretely, exploration itself is often therapeutic.

Kleinman points out that explanatory models are not complete accounts of illness in and of themselves. They are part of broader *illness narratives,* which in turn are actively created out of rich life experiences in response to a disruption in life stories—a process of *integration* in the face of the disintegrating forces of illness (16,17,21). This process, of healing work in the face of certain unalterable realities of illness, seems to get at the heart of what palliative care is all about.

Kleinman suggests that an “ethnographic” approach is useful in exploring such narratives (104, pp227–251). Much like an anthropologist, the clinician is advised to approach the “culture” of the patient with friendly curiosity. How are symptoms understood by the patient? How are people with such an illness generally regarded and treated within that person's culture? What are the roles people are supposed to play out relative to such an illness? What nitty-gritty social forces are at work in shaping the story (such as poverty, the environment, or politics)? In the process of such an inquiry into the illness of the patient, the clinician/ethnographer interprets the story, in essence making sense out of the unknown or at times out of apparent nonsense.

GRIEF AND ILLNESS NARRATIVES

Illness narratives exist not as completed, published texts but rather as active processes of “writing” narratives in engagement with and creation of local worlds. For example, the active, creative aspects of illness narratives can be better understood by considering grief and mourning, which are strongly flavored by culture (38). Rando defines grief as a *reaction* to loss and mourning as “actions undertaken to cope with, adapt suitably to, and accommodate that loss and its ramifications” (106, p4). Rando stresses the *processes* of mourning, both in anticipatory mourning and bereavement, as means of coping and healing. Although the grief literature does not usually cite illness narratives, certain parallels are clear. Take, for example, Rando's writing about the psychosocial loss known as “assumptive world violation.”

> The assumptive world is the mental schema that contains all a person assumes to be true about the self, the world, and everything and everyone in it. . . . The assumptive world is the internal model against which the individual constantly matches incoming sensory data in order to orient the self, recognize what is happening, and plan behavior. (Parkes 1988). . . Any type of illness or death-related loss brings violations of those assumptive world elements predicated specifically upon the existence of the lost person or object. . . . (These models) are frequently shattered by and during life-threatening or terminal illness and constitute a main area of loss and major targets for intervention (106, p61–62).

It is not much of a leap to see the process described by Rando as an interruption in the life story and mourning as a process of creating a new life story that accommodates this “violation.” The “assumptive world” is itself a cultural world, as is the new world created in the process of mourning. Interventions taken to facilitate such mourning must be cognizant of the active process of narrative reconstruction, which occurs in a cultural context.

SUMMARY

Understanding culture and its relation to palliative care is challenging. Culture encompasses both the grandest and the most intimate aspects of human experience. Although biomedicine has tended to define illness as a pathophysiologic process distinct from personhood and culture, palliative care can afford no such luxury. A major challenge for palliative care is to use the tools and technologies so skillfully developed in the world of biomedicine in service of the person and the family, who experience illness and suffer in rich cultural contexts. Better understanding, both of the other's culture and our own, as well as cross-cultural skill development, should aid us in this task.

COMMUNICATION AT END OF LIFE

JAMES A. TULSKY
ROBERT M. ARNOLD

Palliative care aims to meet the disparate needs of patients and families during a time of life-limiting illness. Good communication is indispensable to uncovering patient and family needs and individually negotiating the goals of care. Everyone defines a good death differently (1), and whether patient suffering is caused by pain, nausea, unwanted medical intervention, or spiritual crisis, the common pathway to treatment is through a provider that is able to elicit these concerns and is equipped to help the patient and family address them.

Good communication brings real and tangible benefits. In patients with cancer, the number and severity of unresolved concerns has been shown to predict high levels of emotional distress and future anxiety and depression (2,3 and 4). Conversely, considerable evidence suggests that improved physician-patient communication correlates with improved health outcomes, patient satisfaction, and emotional well-being (5,6,7,8 and 9). For example, primary care patients exhibit decreased anxiety and are more satisfied with their physicians if they discuss advance care planning (9a). Finally, communication itself appears to be therapeutic, as simply telling one's story may improve objective health outcomes (10).

This chapter is designed to (a) review recent literature concerning health care provider communication, (b) survey basic communication issues relevant to palliative care, particularly the role of affect in communication, and (c) give the reader practical advice regarding some of the common topics that arise when caring for patients with life-limiting illness— giving bad news, discussing advance care planning, introducing palliative care, and talking about prognostic issues.

HEALTH CARE PROVIDERS DO NOT COMMUNICATE WELL

Unfortunately, the general quality of communication between health care providers and patients with life-limiting disease is suboptimal. Studies show that the discussion of bad news frequently does not meet patient needs or falls short of expert recommendations (2,11,12,13,14,15,16 and 17). Both physicians and nurses tend to underestimate cancer patients' concerns (18), and commonly do not elicit the full range of terminally ill patients' concerns, or attend to patients' affect (19). Rather than using facilitative communication techniques, such as open-ended questions or empathic responses when inquiring about psychosocial issues, they often block discussion of these issues by changing the subject or not attending to patients' emotional states (13,20). Even in a hospice setting, one study revealed that only 40% of patient concerns were elicited (21). As a result, cancer patients tend to disclose fewer than 50% of their concerns (20,21), which leads further to physicians' inaccurate assessments of patient distress (14). One large audiotape study of oncology visits with terminally ill patients found that physicians only dedicated 23% of their time to health-related, quality-of-life issues, including psychosocial concerns, and frequently missed opportunities to address issues that seemed to be most important to patients (22). Finally, physicians rarely talk with seriously ill patients about their goals, values, or even treatment decisions (23,24,25,26,27,28,29 and 30). A significant gap exists between the idealized model of provider-patient communication at the end of life and the reality of practice.

WHAT CAUSES POOR COMMUNICATION?

Why is the “state of the art” so poor? First, health care providers are not selected for their communication skills. Expertise in cognitive areas are not always positively correlated with empathy or an interest in understanding another person's experience. Second, until recently there has been little training regarding communication skills in general, not to mention communication about these difficult topics (31). For example, in a survey of over 3200 oncologists, few had any formal training in end-of-life care or communication skills. Oncology programs are not alone in devoting little attention to this subject. At both the medical school and residency level, inadequate attention is given to care of the dying (32). Among graduating students at two medical schools, only 48% said they had adequate role models for how to discuss end-of-life issues. At another school, 41% of medical students on a medicine rotation and 73% on a surgery rotation had never observed a staff physician talk with a dying patient. Finally, physicians have difficulty inquiring directly about the emotional status of dying patients because of their feelings about the patient or their own mortality. We will focus particularly on this issue.

Considerable evidence suggests physicians' personal feelings toward their patients are important to the doctorpatient relationship (33,34 and 35), and many have suggested that physicians' emotional responses to their dying patients may interfere with their care (36,37,38,39 and 40). Physicians dealing with dying patients are not objective observers. They are active participants whose beliefs and feelings influence the interaction. For example, a study of surrogate decision making found that physicians' predictions of their patients' wishes regarding life-sustaining treatment were closer to their own choices than to the choices expressed by their patients (41).

Caring for the dying may elicit significant stress in physicians and a variety of reactions, including guilt (“If only I'd convinced him to get that screening colonoscopy.”), impotence (“There's nothing I can do for her.”), failure (“I messed up. I'm a bad doctor.”), loss (“I'm really going to miss this person.”), resentment (“This patient is going to keep me in the hospital all night.”) and fear (“I know they're gonna sue me.”) (42). According to Spikes and Holland (38), many physicians have unconscious feelings of omnipotence, and troublesome responses stem from a physician's need to preserve his or her image as a “powerful healer” who can master any situation. Feeling that he or she has failed the dying patient, a physician may respond by acting defensively, wishing the patient would die (to avoid dealing with the patient), or treating too aggressively (to ensure that “everything has been done to save the patient”).

Empathizing with a dying patient often evokes anxiety about the physician's own mortality. Physicians respond by withdrawing (43) from terminally ill patients, avoiding threatening topics (15,20,44), employing blocking behaviors that distance them from addressing affective concerns of patients (45), or falsely reassuring them that “everything is OK” (38).

Empirical data support these claims about physicians' anxieties regarding death. Physicians score higher on death anxiety scales than other professional groups (46). They also find caring for terminally ill patients stressful. For example, in a survey of 598 oncologists, 56% reported being burned out and 53% attributed these feelings to continuous exposure to fatal illness (47). When caring for dying patients, physicians often report sadness, helplessness, failure, disappointment, and loneliness (48). These feelings, particularly if unrecognized, may affect patient care (49). A study of 25 pediatric residents explored the relationship between their orientation toward death and their response to a clinical vignette. Residents with a high death threat and anxiety scores were more likely to adopt avoidance and denial strategies for dealing with the vignette (50).

Although these issues are profound, awareness of their own emotional responses to caring for dying patients can help physicians begin to focus more objectively on the effect of their behavior on the patient.

BASIC COMMUNICATION SKILLS

Talking to dying patients is just like, and completely unlike, all other communication with patients. Whether one is explaining the implications of hypertension, or talking about impending death, basic principles of good communication are useful. The primary difference between these communication tasks is the meaning of the conversation to the patient and the provider and the attendant level of emotional significance. When the situation is more likely to make the patient (or physician) feel

vulnerable, sad, or inadequate, one should focus extra attention on the task. In this section we will address basic communication skills that are universal to all encounters.

A little effort spent on advance preparation can have a tremendous impact on the quality of the encounter. Whenever possible, important medical information, particularly bad or sad news, should be delivered during a scheduled meeting. This allows patients to prepare themselves for the type of information they will hear and to make sure that appropriate family members or friends are present. It also allows the physician to allocate the necessary time to the encounter and to come prepared with basic medical information and anticipating the most likely questions regarding treatment options, prognosis, and resources for support and guidance.

Communication best occurs face-to-face. Telephones accentuate physical communication difficulties and there is no opportunity to employ the benefits of nonverbal communication. Given that over 50% of communication is nonverbal, both parties operate at a disadvantage if they cannot see each other. The physician should sit at eye level and within reach of the patient. If possible, one's pager or cellular phone should be turned off, or at least on a quiet mode, and one should avoid interruptions.

Increasingly, we encounter non–English-speaking patients. One must absolutely employ the assistance of an interpreter in such settings. However, it is equally important to avoid using family members as interpreters. Not only does this run the risk of faulty translation or reinterpretation of the physician's statements, it also places family members into the uncomfortable position of being the physician and patient's spokesperson. The common practice of using bilingual young children as translators is particularly problematic. Most hospitals and health care facilities in regions with high numbers of immigrants employ professional translators or maintain lists of language skills among facility staff members.

Regarding the dialogue itself, considerable data exist from the medical and psychological literature to support certain general techniques that allow more accurate assessment of anxiety and depression and increased disclosure of concerns (19,51,52). One should maintain good eye contact, ask open-ended rather than closed-ended questions, focus on the patient's concerns as well as your agenda for the visit, respond to the patient's affect, ask about the patient's life outside of medicine and attend to psychosocial issues, and ensure that nonverbal behavior signifies attentiveness (Table 48-1). In contrast disclosure of concerns is inhibited by closed-ended or leading questions, focusing on physical aspects of illness, and offering of advice and premature reassurance (19).

Maintain good eye contact
Ask open-ended rather than closed-ended questions
Focus on the patient's concerns as well as your agenda for the visit
Observe and respond to the patient's affect
Ask about the patient's life outside of medicine and attend to psychosocial issues
Ensure your nonverbal behavior signifies attentiveness

TABLE 48-1. GENERAL COMMUNICATION SKILLS TO ENHANCE DISCLOSURE OF CONCERNS

One core precept is to not assume that one knows what is on the patient's agenda. For example, while many patients will want to discuss end-of-life issues, about 25% will not. This may have to do with cultural particularities or with how individuals cope with illness. Physicians are not very good at predicting which patients want more and which patients want less information. Instead of assuming, one should ask. For example, on a first visit one could say, “I want to touch base with you about how you want me to handle information we get about your illness. Some patients want to know everything that is going on with their illness, the good and the bad. Other people do not want as much information and want me to speak more generally. And some would really prefer I do not discuss bad news with them but want me to discuss these issues with their family. Have you thought about this?”.

Another important precept of communication is to “ask before telling.” Patients often carry misperceptions or incomplete information obtained from the popular media, folklore, or friends and family. It is easier to deal with this information if it is discussed directly. Thus it is usually helpful to ask patients about their understanding of their illness prior to educating them.

WHAT IS EFFECTIVE COMMUNICATION AT THE END OF LIFE?

According to dying patients, family members, and health care providers, goals for communication at the end of life include talking with patients in an honest and straightforward way, being willing to talk about dying, giving bad news in a sensitive way, listening to patients, encouraging questions from patients, and being responsive to patients' readiness to talk about death (17). Patients want physicians to achieve a balance between being honest and straightforward and not discouraging hope. For some this requires leaving open the possibility that unexpected “miracles” might happen, discussing outcomes other than a cure that can offer patients hope and meaning, and helping patients prepare for the losses they may experience. Although patients must receive adequate information to make informed choices, they wish to receive that information in an emotionally supportive way (53). Patients want to discuss emotional concerns but frequently are unwilling to bring them up spontaneously and may need to be prompted (54). Therefore, communication with patients at the end of life should be informative, patient-centered rather than physician-centered (55), and attend to patients' emotional needs. Many models have been proposed (56,57,58,59 and 60). In this chapter we will particularly focus on the role of emotions in such discussions.

ROLE OF AFFECT

Most difficulties in communication at the end of life are the result of inattention to affect. *Affect* refers to the feelings and emotions associated with the content of the conversation. Feelings such as anger, guilt, frustration, sadness, and fear modify our ability to hear, to communicate, and to make decisions. For example, after hearing bad news, most patients are so overwhelmed emotionally that they are unable to comprehend very much about the details of the illness or a treatment plan (12,61). Some studies have shown that emotion affects processing; people who are in negative moods may pay more attention to how messages are given than to the content of the messages (62,63). Thus when patients are experiencing high levels of negative affect and caregivers do not ameliorate this affect, patients may be less likely to receive health care providers' messages. Unfortunately, conversations between doctors and patients often transpire only in the cognitive realm; emotion is frequently not acknowledged or handled directly and physicians miss opportunities to do so (64,65).

Dealing with Physicians' Emotions

Physicians, as well as patients, experience many emotions as they care for people approaching the end of life. In addition to its effect on their own communication, physician affect plays an important role in patients' reactions to medical information. In one study, women were randomly assigned to view a video of an oncologist presenting mammogram results who was portrayed as either worried or not worried. Those watching the “worried” physician received less information, experienced higher anxiety levels, and perceived the situation as more severe compared with those watching the “nonworried” physician (66).

For physicians, the first step towards managing feelings of loss, helplessness, or anxiety is to acknowledge that they exist and to recognize that they are normal. When experiencing a strong emotion while interacting with a patient, one should ask oneself, “Where is this coming from?” Although it may be a result of what the physician brings to the encounter (e.g., one's own sense of mortality or how it makes one think of his or her grandmother who died), it may also be a clue into what the patient is feeling. Thus many doctors report feeling anxious when talking with a patient who has an anxiety disorder, or overly sad when talking with a depressed patient. If the physician gets a sense that he or she is reflecting the patient's emotion it may help to ask the patient about this (e.g., “I wonder if you're feeling sad?”).

If the emotion is a result of one's reaction to the encounter, the next step is to discuss this with colleagues or confidants. In most cases, however, patients do not benefit from hearing such thoughts. When considering sharing such feelings with a patient, a good rule of thumb is to ask oneself, “Am I doing this for me or for the patient?” If the answer is truly the latter, then it may be appropriate to share.

Dealing with Patients' Emotions

One barrier to engaging patient affect is the fear of being unable to manage the emotional response. This section will describe an approach to handling emotions that is

also likely to further elicit the sorts of patient concerns described earlier.

The primary goal when responding to emotions is to convey a sense of empathy. Empathy is the sense that “I could be you,” and is what patients are usually feeling when they comment about a physician that really cared for them (67). Robert Smith has created a useful mnemonic to recall four basic techniques to use when confronted by patient emotions, NURS (Name, Understand, Respect, and Support) (68). This discussion adds a final “E” for Explore. (Table 48-2).

Name the emotion
Understand the emotion
Respect or praise the patient
Support the patient
Explore what underlies the emotion

Adapted from Fischer GS, Tulsky JA, Arnold RM. Communicating a poor prognosis. In: Portenoy RK, Bruera E, eds. *Topics in palliative care*, Vol 4. New York: Oxford University Press, 2000, with permission.

TABLE 48-2. NURSE-ING AN EMOTION

Naming the emotion serves to acknowledge the feeling and to demonstrate that it is a legitimate area for discussion. Statements such as, “That seems sad for you,” can serve this purpose well, although one needs to be careful not to inappropriately label the patient. Therefore, naming is often best done in a quizzical fashion that does not presuppose the emotion (e.g., “Many people would feel angry if that happened to them. I wonder if you ever feel that way?”).

Expressing a sense of understanding normalizes the patient's emotion and conveys empathy. However, expressing understanding must be done cautiously to prevent a response such as, “How can you possibly understand what I'm going through? Have you ever had a stroke?” A typical statement might be, “Although I've never shared your experience, I do understand that this has been a really hard time for you.”

Respect reminds us to praise patients and families for what they are doing and how they are managing with a difficult situation. Offering respect defuses defensiveness and makes people feel good about themselves and more capable of handling the future. A useful statement might be, “I am so impressed with how you've continued to provide excellent care for your mother as her dementia has progressed.”

Support is essential to helping people in distress not feel alone. Simple statements such as, “I will be there with you throughout this illness,” can be tremendously comforting. Health care providers ought not feel the entire support burden on their shoulders—support offered can include other members of a team. For example, “We will send a nurse to your home to check in on you in a couple of days and if you'd like, I could ask the chaplain to visit you.”

Finally, patients will frequently make statements that deserve further exploration. For example, a patient may say, “After you gave me the results of the test, I thought that this is gonna be it.” A simple response such as, “Tell me more,” may help reveal the patient's fears and concerns about cancer that will be helpful in planning future treatment.

Hope in the Context of Palliative Care

Physicians struggle to promote hope in the patient with advanced disease and to support a positive outlook, fearing that discussing death may decrease patient hopefulness (17,69,70,71 and 72). As a result, they frequently convey prognosis with an optimistic bias or do not give this information at all (73). This is relevant to treatment choices; patients with more optimistic assessments of their own prognosis are more likely to choose aggressive therapies at the end of life (74,75). In turn, fearing the loss of hope, patients frequently cope by expressing denial and may be unwilling to hear what is said (76).

It is not clear that health care providers can either steal or instill hope. However, they can provide an empathic, reflective presence that will help patients draw strength from their existing resources. Physicians should recognize that it is not their job to “correct” the patient's hope for a miracle. The key question is whether the hope is interfering with appropriate planning and behavior. A patient who has completed his will and said his goodbyes but is still hoping for a miracle is different than a patient who is making longterm investments and does not plan for custody of a minor child despite a 3-month prognosis.

Physicians can respond in several ways (in addition to demonstrations of empathy discussed earlier). Acknowledging the hope may allow the physician and the patient to “hope for the best but prepare for the worst.” They can also recognize that people hope for many different things and leave space for patients to hope for outcomes and futures that are more likely to occur. One might say, “I know you are hoping that your disease will be cured. Are there other things that you want to focus on?” Or, “If we can not make that happen, what other shorter term goals might we focus on?” Finally, one can ask about what tasks are left undone as a way to get patients to begin to think in a shorter time course.

PRACTICAL SUGGESTIONS FOR SPECIFIC SITUATIONS

Communicating Bad News

Communicating bad news draws upon the skills discussed previously (see the section What Is Effective Communication at the End of Life?). Many protocols exist for the delivery of bad news, however the behaviors tend to be grouped into several key domains, preparation, content of message, dealing with patient responses, and ending the encounter (Table 48-3) (16,77). The primary elements of preparation have been addressed above (see the section Basic Communication Skills).

Preparation
Find out what patient knows and believes
Find out what patient wants to know
Suggest a supportive person accompany the patient
Learn about the patient's condition
Arrange the encounter in a private place with enough time
Content
Get to the point quickly
Fire “warning shot” (e.g., “I have bad news.”)
State the news clearly, simply, and sensitively
Avoid false reassurance
Make truthful, hopeful statements
Provide information in small chunks
Handle patient's reactions
Inquire about meaning of the condition for the patient
NURSE expressed emotions
Assure continued support
Wrap-up
Set up a meeting within next few days
Offer to talk to relatives/friends
Suggest that patients write down questions
Provide a way to be reached in emergencies
Assess suicidality

NURSE, Name, Understand, Respect, Support, and Explore (see Table 48-2).

TABLE 48-3. KEY ELEMENTS OF DELIVERING BAD NEWS

Content of Message

Knowledge of what the patient already knows or believes is extremely valuable to have prior to revealing bad news to a patient (77). This allows the physician to begin the explanation from the patient's perspective, aligning oneself with the patient and making communication more efficient and effective. The time that a test is ordered is a good time to assess this. One might ask, “Is there anything that you are particularly concerned about?” If the patient mentions a serious illness that might be present, the physician can follow up by asking what the patient's specific fears and concerns are.

When prepared to deliver the content of the message, the physician should begin by firing a brief “warning shot,” and then stating the news in clear and direct terms. One should avoid spending any time “beating around the bush” prior to sharing the news. After this brief exchange, the physician should remain silent and allow the patient an opportunity for the news to sink in. One can strike an empathic pose, maintain comfortable eye contact, and perhaps use a nonverbal gesture such as reaching out and touching the patient's hand. However, silence is imperative to allow the patient an opportunity to process the information, formulate a response, and to experience his or her emotions. Physicians who feel uncomfortable during this silent phase need to appreciate that the discomfort is rarely shared by the patient, who is engrossed in thought about the meaning of the news and thoughts about the future. Furthermore, very little that is said by the physician at this time will be remembered by the patient so it is best not to say it at all. If the patient makes no verbal response after, perhaps, two minutes, it can be useful to check in: “I just told you some pretty serious news, do you feel comfortable sharing your thoughts about this?”

Dealing with the Response

The remainder of the conversation should be spent primarily dealing with the patient's response. This includes using the NURSE skills to legitimize and empathize with the patient's experience. It is also important to explore the meaning the news has for the patient and to achieve a shared understanding of the disease and its implications.

For example:

MD: What is most troubling to you about having cancer?
PT: It's a death sentence—my mother died from cancer, my brother died from cancer. I guess it's my turn now.
MD: Given your experience, I can see how this is really scary for you. And cancer can be very serious. However, in your case, there are a lot of treatment options, and you have a good chance of surviving with this disease.
PT: So this won't kill me?
MD: I certainly hope not. And, I'll be there with you every step of the way fighting this illness.

Hopeful messages need to be tailored to patients' specific concerns, particularly addressing patient misconceptions and fears. Once patients' concerns have been explored, patients can be reassured more effectively. When effective treatment is available, this fact should be explained. When the treatment options are poor, hope may be found by alleviating patients' worst fears. Doctors may reassure patients that they will not be abandoned during their illness, that the doctor will remain available if things get worse, that everything will be done to maintain the patient's comfort, and that they will continue to watch for new treatment developments (78). Often people find hope and strength from their religious or spiritual beliefs, from having their individuality respected, from meaningful relationships with others, and from finding meaning in their lives (71). Exploring these with the patient over time may help to foster realistic hope. Although physicians may have a desire to make an overly reassuring statement to the patient right after revealing the diagnosis, hopeful statements that are truthful and that are made after taking the time to first explore the patient's concerns are more likely to be accepted by the patient (79). One can offer a realistic sense of hope, whether biomedical (“We'll keep our eyes open for new treatments and discuss them as they become available.”) or psychosocial (“I look forward to talking with you more about how we can help you live every day as fully as possible, despite this illness.”).

Patients may have specific questions about further tests, treatment options, and prognosis. It is important to respond to these seriously. However, many patients will suffer comprehension difficulties in such emotionally challenging situations. Information, particularly a plan, is helpful, as it allows the patient to reconceptualize the future as a safer, more predictable place. The exact details matter less than the clarity of the plan and the reassurance that the physician will be available. Give simple, focused bits of information, use nonvague language that patients can understand, carefully observe the patient's verbal and nonverbal reactions to what you say, and most important, avoid information-packed speeches.

Ending the Encounter

The clinician must end the encounter in a way that leaves the patient feeling supported and with some sense of hope. Support can be provided through meeting patients' immediate health needs and risks. One must treat pain and palliate other symptoms. Patients should be asked how they plan to cope with the news, and if their response raises any concerns about suicide this should be asked about directly and addressed. One should try to minimize aloneness through statements of nonabandonment and referral to other resources, such as support groups, counselors, or pastoral care.

Last, one should provide a specific follow-up plan: “I'd like you to keep a list of questions so I can answer them for you on our next visit this Tuesday. We'll talk about all your options again at that time . . . . Okay? And please feel free to call me.” The physician needs to remember that the goal of this conversation is not to leave a happy patient. That is rarely possible (or even desirable) after delivering bad news. Instead, one hopes to leave a patient who feels supported and cared for, and can look forward to a specific plan of action.

Advance Care Planning

Discussions about advance care planning encompass many goals. These include preparing for death and dying, exercising control, relieving burdens placed on loved ones, helping patients make decisions consistent with their values, and leaving patients feeling supported and understood (80). The first step in preparing to discuss advance care plans is deciding upon the appropriate goals for the discussion (81). What one hopes to accomplish will vary depending on the clinical situation (82). Advance care planning includes many different tasks: informing the patient, eliciting preferences, identifying a surrogate decision-maker, and providing emotional support. Frequently one cannot accomplish all of this in one conversation and focusing on the goals of the discussion allows the physician to tailor the encounter. Advance care planning is completed as a process over time that allows patients an opportunity for thoughtful reflection and interaction with others.

For a healthy, older patient, physicians might establish whom the patient would like to appoint as a health care surrogate. They might ask whether the patient already has a written advance directive and explore the patient's thoughts about dying and the general views about life-sustaining treatments. For a patient with a life-limiting chronic illness, the doctor might also discuss the patient's attitudes about specific interventions that are likely to occur (e.g., mechanical ventilation in severe chronic obstructive pulmonary disease). Finally, for a patient who will soon die, the doctor will shift the focus from future treatment in hypothetical scenarios to establishing what the goals should be for care provided in the present. In all cases, advance care planning can help patients prepare for death, discuss their values with their loved ones, and achieve a sense of control (80). It can help build trust between doctors and their patients so that when difficult treatment decisions arise, doctors, patients, and their loved ones can communicate openly and achieve resolution.

Initiating the Conversation

There are a number of ways to begin the discussion (81). Often, physicians can relate the topic to a recent serious event such as a hospitalization. Another way to begin is to ask about experiences with relatives or friends who have died. Many patients are likely to have observed serious illness closely and perhaps have had loved ones in some of the situations which the physician is describing. They are likely to have much information and misinformation about endof-life care and are likely to have thought about their own deaths. Opening a discussion in this manner can naturally lead to a discussion about how decisions were made and what the patient thought of that particular death. This will provide valuable insights into the patient's own values.

Providing Information

Patients must have adequate information to make informed decisions. It helps to start by asking patients what they understand about their medical illness. If the patient's condition is more serious than he or she realizes, then the physician will need to shift focus. The physician will want to put off discussing advance care planning, focusing the discussion instead on explaining to the patient the seriousness of his or her condition.

Studies indicate that patients are more interested in what the expected health outcome will be than in details about the interventions themselves (83,84). The primary reason for patients to consider withholding treatments is to avoid an outcome judged by them to be worse than death (85). The other reason is that the burden of the treatment, on themselves or their loved ones, outweighs the potential benefit. Therefore, patients should achieve an understanding of the impact of common, life-sustaining interventions on one's quality of life. In contrast, vivid descriptions of the nature of the treatments themselves (e.g., intubation, cardioversion, intensive care unit care) may alarm patients and be less helpful.

Eliciting Preferences

Patients state preferences after learning about potential options and evaluating these in light of their personal values. Values refer to deeply held beliefs such as a

desire for personal independence or the importance of a religious practice. By exploring patients' values and goals, clinicians can help them clarify their specific preferences. Sometimes one can ask explicitly about such values (e.g., “What makes life worth living for you?”). Alternatively, values may be elicited in the process of asking about specific treatment preferences. For example, after a patient makes a statement about end-of-life care (e.g., “I'd never want to be on one of those machines”), the clinician may respond by simply asking, “Why?” The answer to this question (e.g., “Because I never want to be a burden on my family or society”) may uncover a patient's core values that will impact greatly on treatment decisions.

Identifying what conditions the patient would find unacceptable can also help clarify a patient's preferences. A useful question is “Can you imagine any situations in which life would not be worth living?”(86). This question can be followed by asking what the patient would be willing to forgo in order to avoid such states.

For many patients, dealing with uncertainty is the most difficult aspect of decision-making. When doctors ask patients if they would want a particular treatment, like a ventilator, patients will often state that the treatment should be provided “if it will help me, but if it won't help me, don't do it.” Statements like this ignore the reality that physicians are often uncertain about the outcome. Everyone responds to uncertainty differently, and the patient's approach to this issue should be discussed explicitly as well. For example, one may ask, “What if we are not sure whether we will be able to get you off the breathing machine?” Depending on the patient's answer to this question, the doctor can explore what the chance of success needs to be in order to pursue aggressive treatment. Some patients will state that any possibility of recovery is worth pursuing while others will refuse curative treatment when the likelihood of recovery drops below a particular threshold (75). Some patients are comfortable using numbers talking about probabilities, others are less quantitatively facile (87,88 and 89). The patient's preferences should dictate the extent to which numbers are used in this discussion. Many patients will be satisfied, leaving it to the judgment of the physician and family members, with only general instructions. The option of a treatment trial is also a useful way to provide clarity in the face of uncertainty.

It is impossible to elicit meaningful preferences for every intervention in every possible situation. By focusing on a patient's values and goals, the physician can then help the patient make decisions about current or future treatments that are consistent with those goals. Discussions should move back and forth from preferences to reasons and values to information and back again, ensuring that the patient understands the implications of his or her stated preferences, and that the doctor understands the patient's values. In this way, when the physician is faced with an unanticipated clinical situation, he or she can use the patient's stated values and goals to help determine the appropriate course of action. In such discussions, it is frequently worthwhile to inquire specifically about some controversial treatments such as artificial nutrition and hydration. This is particularly true in states that require the patient's specific directive to withhold these treatments.

Patients and physicians often use vague terms that ought to be avoided. For example, a statement that a treatment should be continued as long as “quality of life is good” begs further clarification. How does the patient (or his or her surrogate, or the physician) define a good quality of life? In fact, it is always important to ensure that the patient and physician have a shared understanding of the conversation and its implications. Similarly, medical jargon should be avoided, one should always define technical terms, and patients must be encouraged to ask questions.

Choosing Surrogate Decision Makers

Identifying who is to act as the patient's health care proxy may be the most important outcome of a conversation about advance care planning. Does the patient wish this to be a single individual or an entire family? Given the literature demonstrating poor concordance between patient preferences and surrogate perceptions of those preferences, the clinician would be wise to stress the need for the patient to communicate with the selected proxy decision-maker (90). Patients should also be asked how much leeway their proxies should have in decision-making (91). Should proxies adhere strictly to patients' stated preferences or ought they to have more flexibility when making actual decisions?

These discussions can be emotionally difficult, even when they are welcome. It is important to draw upon the emotionhandling skills described earlier (see the section Role of Affect) and to acknowledge patients' feelings of sadness, fear, or anger, when they come up, and to validate those feelings by stating your understanding of their reaction. The physician can admit that the discussion can be difficult and support the patient by stating how helpful he or she has been in helping to understand his or her preferences. Another way doctors can provide support to patients is to assure them that they will do whatever they can to meet their goals (such as comfort) and to articulate what some of those things might be. In this way, doctors can assure patients that they will continue to care for them, even if they are in a condition in which they would not want life-sustaining treatment.

Communicating over the Transition

It is possible that the greatest communication challenges face physicians and patients as they discuss progression of disease, the transition from curative therapy to palliation and the referral for hospice care. Such times of transition involve the recognition of loss, redefinition of self-concept and social role, and great emotional stress. Patients are likely to feel sadness, anger, and denial. Physicians frequently have difficulty with such discussions because they feel a sense of failure, are worried that patients will feel abandoned, or that they will be overcome in the conversation by anxiety or despair (77). Furthermore, they may have their own unresolved issues about mortality or fear the patient's anticipated emotional response.

Again, it is useful to identify the goals of these conversations. They include eliciting emotional, psychological, and spiritual concerns, and providing empathic and practical support. Of course, it is also important to help patients acknowledge their illness and to make appropriate health care decisions such as enrolling in hospice. However, conversations should not be dominated by the physician's agenda, and patients must be given ample space to make decisions according to their own timetables. Physicians should employ behaviors that promote the sharing of concerns by patients and avoid behaviors such as reassurance that inhibit such sharing. See Table 48-4 for useful, open-ended questions with which one can initiate such conversations.

"What concerns you most about your illness?"
"How is treatment going for you (your family)?"
"As you think about your illness, what is the best and the worst that might happen?"
"What has been most difficult about this illness for you?"
"What are your hopes (your expectations, your fears) for the future?"
"As you think about the future, what is most important to you (what matters the most to you)?"

From Lo B, Quill T, Tulsky J. Discussing palliative care with patients. *Ann Intern Med* 1999;130:744–749, with permission.

TABLE 48-4. OPEN-ENDED QUESTIONS TO INITIATE CONVERSATIONS ABOUT DYING

As patients respond to these questions, the physician should continue to focus on the psychosocial and spiritual aspects of their illness and not allow the biomedical issues to dominate. It is important to avoid false reassurance (45). A particular form of response that can be extremely effective at these times is the “wish statement”(92). These are particularly effective in response to statements that appear to demonstrate significant denial of the severity of illness. For example:

PT: I'm going to get better. I know that this new chemotherapy they're offering at the university will make the difference.
MD: I wish that there was a treatment that would make this cancer go away.
PT: You mean that you don't think it will work.
MD: It's hard to come to terms with this, but, unfortunately, I don't believe it would help you overcome your cancer.
PT: I was afraid you might say that. What do we do now?
MD: There's a lot that we can do. Let's talk about what goals are most important for you right now.

The wish statement allows the doctor to demonstrate empathy toward the patient and align him or herself with the patient's hopes. Yet, at the same time it implicitly conveys the message that certain goals are unrealistic. In this way, the physician can address the patient's denial without losing the therapeutic alliance.

Dreaded Questions

Finally, it is useful to consider several of the questions that many physicians find most difficult to answer (e.g., “Why me?” “How long do I have to live?”). Responding to

such questions draws on the many skills described in this chapter and it is useful to keep several additional points in mind (93). The most important thing a physician can do is remain curious. One should not assume that one knows what the question is "really" about. A patient who is asking, "How long do I have?" may be wondering if she is going to live until Christmas, whether reports she has heard that the disease is fatal are accurate, or whether she is going to get out of the hospital. Acknowledge the question, but make sure you understand it before trying to answer (e.g., "That is a really tough question. What are you concerned about?"). It is also important to recognize that it is not necessarily the physician's job to solve the problem. Physicians do not have the answers to questions such as "Why me?" and may not be able to diminish the feelings of sadness and loss. What one can do is to acknowledge and normalize the feelings. In allowing patients to be heard, the physician may decrease a patient's sense of being alone in the disease, and thus decrease suffering. (An illustrative example is to imagine you have had a very bad day at work. When you come home and start to tell your family, how would you feel if they started to brainstorm different solutions to the problem? Most individuals would prefer their loved ones to acknowledge their day—"sounds like it was a really tough day"—rather than try to solve their problem.)

Having anticipated replies can be useful and several examples follow (58):

PT: How long do I have to live?
MD: I wonder if it is frightening not knowing what will happen next, or when.

This response acknowledges that underlying such a question is tremendous emotion, most likely fear. It will be important for the physician to give a factual response to this question. However, the patient will not be prepared to hear this response until the doctor has addressed his or her emotional concerns. The suggested answer above allows patients to speak about their fears and worries. When the physician needs to use a more factual response, the following is a way of being honest while maintaining hope: "On average, a person in your situation lives 3 to 4 months, but some people have much less time, and others may live over a year. I would take care now of any practical or family matters that you wish to have completed before you die, but continue to hope that you are one of the lucky people who gets a bit more time."

FM: Does this mean you're giving up on him?
MD: Absolutely not. But tell me, what do you mean by giving up?

Suggesting that a patient receive palliative care risks conveying a sense of abandonment. Physicians must be emphatic that palliative care and hospice are active forms of care that meet patients' varying goals at the end of life. However, further exploration of patients' or family's concerns about abandonment are important to understanding their perceptions and attitudes toward care at the end of life.

PT: Are you telling me that I am going to die?
MD: I wish that were not the case, but it is likely in the near future. I am also asking, how would you want to spend the remaining time if it were limited?

This wish statement helps the physician identify with the patient's loss. The previous sentence is an attempt by the physician to reframe the patient's understanding of the situation. He has acknowledged that the patient is dying, but now he seeks to understand what the patient's goals might be in light of this new information. Creating new goals in this way provides an outlet for the patient's hope.

Bereavement

Palliative care does not end when a patient dies. An awareness of bereavement can help one communicate with family and loved ones after the loss (94). Bereaved people ought to be encouraged to tell their stories of loss, including describing details of the days and weeks around the death of their loved one. Similarly, family members and friends benefit by recalling earlier positive memories of the person. Physicians can explore how the bereaved person has responded to the grief ("How have things been different for you since your husband died?"), and identify their social support and coping resources. One should not overlook the frequently enormous practical ramifications of loss such as financial difficulties, the need to leave a home, and transportation. Finally, physicians need to be aware that a significant minority of patients, 10–20%, have difficulty regaining their normal functioning after the loss. This syndrome—traumatic grief—seems distinct from depression and is characterized by excessive rumination and preoccupation with the dead individual.

Good communication skills are central to the provision of palliative care. The fundamentals of such communication are listening, recognizing one's own affective responses, attending to patients' emotional needs, and achieving a shared understanding of the concerns at hand. Specific tasks, such as delivering bad news, discussing advance care planning, helping patients through the transition to hospice care, and responding to difficult questions, require using these skills to ensure that patients' concerns are elicited and addressed, and they are informed and feel supported.

PALLIATIVE RADIATION THERAPY

PETER KIRKBRIDE
ANDREA BEZJAK

WHAT IS PALLIATIVE RADIOTHERAPY?

Palliative radiotherapy (RT) is radiation treatment administered with the intent to palliate, i.e., improve symptoms and relieve suffering. Half the patients who are diagnosed with cancer will receive radiation therapy at some point in their course of disease, with a variety of intents—eradication of tumor, prevention of recurrence, or prevention or relief of symptoms. The intent of treatment may be curative, radical, adjuvant, palliative, or prophylactic. These terms are defined in Table 49-1. It is estimated that 40–50% of all RT courses are given with palliative intent (1,2). However, these figures may be an underestimate, as high curative doses of RT are sometimes used to control tumors for as long as possible or to prevent or relieve distressing symptoms rather than to actually eliminate the cancer.

Curative	Goal of treatment is elimination of tumor and cure of the patient.
Radical	Refers to intensity of treatment and dose of radiation. *Radical radiotherapy* typically refers to high-dose radiation treatment given with curative intent. However, this may or may not cure the patient (i.e., because of risk of metastases). May be given to provide local control of tumor, even if cure is not likely.
Adjuvant	A form of treatment used in conjunction with primary therapy implemented to aid the principal treatment regimen (e.g., radiation after complete surgical resection of all known cancer to prevent or minimize the risk of local or regional recurrence after surgery).
Palliative	Treatment that aims to relieve or alleviate symptoms. Focus is on symptom control and enhancing quality of life (noncurative).
Prophylactic	Any treatment regimen given with preventative intent. Examples include prophylactic cranial radiation (to prevent brain metastases by eliminating possible microscopic tumors in the brain) and prophylactic radiation of bone metastases (to minimize the risk of fracture).

TABLE 49-1. DEFINITIONS OF TERMS USED TO DESCRIBE THE INTENT OF RADIATION THERAPY

In an attempt to define the circumstances when it is most useful, this chapter will briefly define what is meant by “palliative radiotherapy,” review the rationale for its use, and discuss the evidence on which current palliative practice is based. As background, the reader is referred to the article by Mackillop (3), in which 10 rules for the practice of radiation therapy are presented (Table 49-2) based on the ethical principles that are used to guide the practice of medicine.

Palliative radiotherapy should be part of a comprehensive program of care.
The decision to recommend palliative radiotherapy should be based on a thorough assessment of the patient.
The decision to recommend palliative radiotherapy should be based on objective information.
The risk:benefit analysis should include consideration of all aspects of the patient's well being.
The short-term risks and benefits of palliative radiotherapy are more important than those that may or may not occur in the future.
The decision to use palliative radiotherapy should be consistent with the values and preferences of the patient.
The patient should be involved in the treatment decision to the extent that she or he wishes.
Time is precious when life is short.
Delays in starting palliative radiotherapy should be as short as reasonably achievable.
Courses of palliative radiotherapy should be no longer than necessary to achieve their therapeutic goal.
Palliative and curative goals should not be considered mutually exclusive.
Palliative radiotherapy should consume no more resources than necessary.

From Mackillop WJ. The principles of palliative radiotherapy: a radiation oncologist's perspective. Can J Oncol 1996;6(suppl2):5–11, with permission.

TABLE 49-2. RULES FOR THE PRACTICE OF RADIATION THERAPY

The radiation used in RT is part of the electromagnetic spectrum and consists of high-energy photons which are generated from a series of complex interactions in a linear accelerator (x-rays), or directly from the nucleus of a radioactive isotope, usually cobalt 60 (gamma-rays). This is “external beam radiotherapy” as opposed to “brachytherapy,” in which radioactive sources are directly into or close to the tumor in the patient's body. Definitions of these and other commonly used terms are contained in Table 49-3. Radiation can cure many radiosensitive cancers although frequently high doses are needed to eradicate all malignant cells in the tumor, such as 60–70 Grays (Gy) delivered in 1.8–2.0 Gy daily treatments or “fractions” over 6–8 weeks. Side effects of RT are related to normal tissue injury, both “acute” (during or shortly after completion of RT, e.g., mucositis, diarrhea) and “chronic” (months to years after RT, e.g., fibrosis). It is indeed the normal tissue tolerance that limits the dose of RT that can be delivered and results in complications following RT. There-fore, when the cancer cannot be cured and when the goal of treatment is relief of symptoms, it is logical to administer a lower total dose of RT over a shorter period of time.

TABLE 49-3. DEFINITIONS OF COMMON RADIOTHERAPY TERMS

The time between treatments allows normal tissue cells to repair and regenerate while also allowing tumor cells that may have been resistant to the previous fraction to become more radiosensitive by becoming oxygenated or moving to a different phase in the cell cycle. It has been shown that using small daily fractions, in sizes of 2 Gy or less, significantly reduces the risk of the patient developing late complications of RT treatment such as fibrosis or necrosis. These basic radiobiological principles may be less relevant to the application of palliative RT, as complete ablation of the tumor is not usually necessary to relieve symptoms, and late effects, which take several months or years to develop, are less relevant to a population with a short life expectancy. In addition, the use of lower than radical doses minimizes the risk of acute side effects such as mucositis. These acute effects are deemed to be a necessary evil in the treatment of a patient with curative intent, but in the palliative population, they can significantl affect quality of life over a time that may represent a substantial proportion of the patient's remaining life span.

Consequently, most palliative RT is practiced using lower total doses (frequently 8–30 Gy), larger daily fraction sizes (3–10 Gy/per fraction), and shorter total treatment times (1 day to 2 weeks) than RT with curative intent. The resultant side effects are less intense (due to lower total doses) and less prolonged (due to shorter overall treatment time). The actual effect on the tumor is greater than the same total dose administered in 2 Gy/fraction over a prolonged time period (as shorter overall treatment time avoids the problem of tumor repopulation). Nevertheless, there exists controversy about the best method of palliating with RT. This chapter aims to tackle that controversy by addressing the questions which are pertinent to this area—“the What, Why, Who, When, How, and Where of palliative radiotherapy.”

WHY SHOULD WE CONSIDER PALLIATIVE RADIOTHERAPY?

Palliative RT is very effective in relieving pain and many other symptoms related to local effects of cancer and metastases, and is usually well tolerated. The traditional indications for palliative RT are illustrated in Table 49-4. In general, palliative RT can be used to treat both primary tumors and localized metastases, providing that the lesion being irradiated is directly responsible for the production of a symptom. A thorough knowledge of treatment alternatives is needed, with weighing of the toxicity and likely symptom response to other palliative measures. If the patient's symptoms are well controlled medically, it is not always necessary to irradiate, although in most cases there are significant benefits to be gained if the radiation treatment leads to a decrease in drug requirement (e.g., opioid analgesics), and therefore fewer side effects (e.g., constipation).

Pain relief (bone metastases, lung cancer causing chest pain, tumors causing nerve root and soft tissue infiltration)
Control of bleeding (hemoptysis, vaginal and rectal bleeding)
Control of fungation and ulceration
Relief of impending or actual obstruction (esophagus, large airways, rectum)
Shrinkage of tumor masses causing symptoms (e.g., brain metastases, skin lesions)
Oncological emergencies (spinal cord compression, superior mediastinal obstruction)

TABLE 49-4. INDICATIONS FOR THE USE OF PALLIATIVE RADIOTHERAPY

Palliative RT typically causes only mild and transient side effects, due to the lower total doses of radiation commonly employed. It is usually tolerated well by all but the most infirm patients. However, as many side effects of radiation therapy do not usually develop until after therapy is completed, it is important to bring this fact to the attention of those caring for patients after radiation treatment.

WHO SHOULD RECEIVE PALLIATIVE RADIOTHERAPY?

The essential axiom of palliative RT is that it should be used for patients who have local symptoms that can be attributed to the presence of a malignant tumor. This could be extended to include patients deemed to be at risk of the development of such symptoms. There are few contraindications to palliative RT. Many patients deemed not suitable for radical treatment on the grounds of poor performance status, coexisting medical conditions, or disease extent may benefit from palliative RT. For example, patients with poor lung function and limited respiratory reserve not able to undergo surgery or radical RT because of the risk of severe respiratory impairment may still benefit from low-dose thoracic RT with its consequent lower risk of toxicity. Similarly, patients with collagen vascular diseases, who often have exaggerated and severe reactions to RT, may be considered for palliative RT, although the risk-benefit ratio of the treatment needs to be thoroughly discussed. Are there patients whose disease has progressed to the point where RT is no longer worthwhile? Radiation may indeed not be appropriate for bed-bound patients in the last stages of their illness, who may not live long enough to benefit from treatment. However, it should be noted that physicians are notoriously bad at estimating patients' life expectancy (4). If a patient's condition is a consequence of severe pain and/or large doses of opioid analgesia, it may be possible to achieve meaningful benefit, bearing in mind that symptom relief will usually take at least 2–4 weeks to become apparent (see the section Lung Cancer). In such situations, the use of “one-stop-shop” approach, where a patient can be assessed, planned, and treated with a single fraction all on the same visit, may be extremely useful.

There is a common misapprehension that once a patient has received RT to a certain area this cannot be repeated. There is no doubt that if a patient has previously received radical treatment, then it is impossible to give a second high-dose course to the same area. However, in the palliative situation, when an increased risk of late radiation complications is less of an issue, it may be feasible to administer low-dose RT to a previously treated area. It is certainly possible to repeat low-dose treatments more than once depending on the location of the tumor. However, if a patient has failed to derive any benefit from an initial short course of palliative RT, further radiation treatment is unlikely to be useful.

WHEN SHOULD PALLIATIVE RADIOTHERAPY BE GIVEN?

Prevention of Symptoms

In the situation where a patient has an incurable cancer that is asymptomatic, treatment may be deferred until symptoms arise, although this should be discussed with the patient. There is one randomized clinical trial that would support this approach (5), in which 230 patients with incurable lung cancer but no symptoms that required immediate radiation were randomized to palliative radiation (17 Gy in 2 fractions) or observation (i.e., radiation at time of symptomatic progression). After a 6-month follow-up, patients in the radiation arm were no more likely to be free of chest symptoms (cough, dyspnea, etc.) and no more likely to survive than patients in the observation arm. One-third of patients in the observation arm never required radiation (chemotherapy was not utilized either). Thus, use of radiation to prevent potential symptoms (of lung cancer) is not supported by evidence. Many patients are unhappy about a “wait-and-watch” approach and would prefer to receive active treatment. Many radiation oncologists have admitted that they do use palliative RT to “give hope” (6), although in such cases, the benefits may be minimal and patients may still be exposed to side effects. Despite the lack of evidence, prophylactic (preventative) palliative radiation may be used if the physician feels the patient is at high risk of developing fracture, cord compression, airway obstruction, or superior vena cava compression.

Treatment of Symptoms

There is no threshold of symptom severity that a patient needs to cross to require palliative RT. Treatment is equally useful whether the disease is producing mild or severe symptoms with little difference in palliative effect if treating a small or large-volume tumor. On some occasions, such as with patients with pain from multiple bone metastases, it may be more appropriate to treat with analgesics as this may cause better overall relief with less side effects than RT. Some patients may become completely pain free if their analgesics are adjusted appropriately. In those circumstances, it may be possible to defer radiation therapy.

Radiotherapeutic Emergencies

A true radiotherapeutic emergency is when failure to deliver treatment within a few hours or days could result in death or catastrophic irreversible damage. Severe pain,

distressing as it may be to the patient, is not an emergency, although it should be treated with great urgency. RT cannot produce pain relief immediately; thus, pharmacological measures are essential while RT is being organized and delivered. Table 49-5 lists indications for emergency RT in a large academic cancer center in Canada, the Princess Margaret Hospital, Toronto. In these circumstances, the patient should be seen by a radiation oncologist on the same day the lesion is diagnosed, and appropriate treatment should be started promptly.

Established spinal cord compression
Established superior vena cava obstruction
Life-threatening lower airway obstruction
Life-threatening hemorrhage
The following critical complications of radioresponsive tumors:
Ocular compression with blindness
Peripheral nerve compression, including cauda equina syndrome, with established motor dysfunction
Life-threatening renal insufficiency caused by kidney infiltration or ureteric obstruction
Life-threatening mass brain lesion
Malignant hypercalcemia refractory to other measures where radiotherapy constitutes appropriate definitive treatment
Progression of cancer documented following decision to treat with radiation therapy

[a]As identified by The Department of Radiation Oncology, Princess Margaret Hospital, Toronto, Canada, 1998.

TABLE 49-5. SITUATIONS REQUIRING THE EMERGENCY USE OF RADIATION THERAPY, PROVIDING NO OTHER TREATMENT IS APPROPRIATE [a]

Although RT should be administered without delay, relief may not be immediate. The time course for the benefits of RT depends on the situation but is rarely less than a few days. With the exception of a few very radiosensitive tissues and cells, such as lymphocytes, RT does not cause immediate cell death, but rather leads to failure of cells to divide, which then die at their next scheduled division. This is the reason why both the beneficial effects and the acute toxicities of RT take several days to become manifest. Occasionally, when treating bone metastases, large-fraction, wide-field treatment, such as half-body irradiation (HBI), can produce same-day benefits, but this is not the norm.

Opportunity Cost

Although individual radiation treatments often take only 10–20 minutes to deliver, time spent traveling and waiting for treatment can add up to several hours. A protracted course of RT, especially for patients living some distance from the treatment center, may occupy the vast majority of their waking hours. “Time is precious when life is short” (3). For each individual patient, the benefits of the treatment need to be compared with the cost in terms of lost opportunities for them to spend their remaining days as they choose (7). Although it appears likely that large single fractions are as efficacious as longer courses in many situations (see the section How Much Radiation Should Be Given?), if they are not, they may still be appropriate in patients when the opportunity cost of a two-week treatment would be extremely high. Any reduction in palliative benefit would be at most minimal, and concerns about the duration of the effect of single treatments are probably not relevant in patients with extremely limited prognosis.

HOW MUCH RADIATION SHOULD BE GIVEN?

Fractionation schedules for palliative radiation therapy have evolved based on clinical experiences rather than as a result of careful science. Although experimental treatment models have been developed and continue to be refined to increase the understanding of the effects of total dose, fraction size, and treatment time on outcome for radical courses of radiation therapy, until recently there has been minimal literature published on how these variables influence noncurative radiation therapy. Many palliative fractionation regimes exist because of physicians' personal preferences, often based on wide-ranging (and occasionally dubious) influences, such as departmental policies, machine availability, training, and concern about acute and late side effects (8).

Initially, schedules were developed pragmatically by physicians who realized that (a) a full radical dose of radiation was inappropriate in a patient who could not be cured, (b) symptoms could be significantly relieved by smaller total doses, and (c) shorter treatment times were more convenient for patients and their families. In 1948, Paterson at the Christie Hospital in Manchester recommended that palliative radiation be given over 1, 4, or 8 days and that “a useful palliative dosage was one-half or better still twothirds of a tumor lethal dose” (9). In 1966, in the first edition of Fletcher's textbook, it is recommended that doses ranging from 20 Gy in 5 fractions (long bones, vertebral column), through 30 Gy in 10 fractions (pelvis), to 40 Gy in 15 fractions (mediastinum) should be deployed (10). Neither author can substantiate these recommendations with data, but they are the foundations for palliative RT practice in Europe and North America.

Most literature on the subject was purely descriptive in nature until the last 10 years. Very few controlled clinical trials were carried out and palliative prescriptions were almost entirely based upon physicians' clinical experiences or those of their seniors. In addition, financial considerations have taken on a greater importance, especially in the last few years, with demand for radiation therapy often outstripping supply in publicly funded health systems. This has been reflected in an increasing tendency to use shorter and cheaper radiation treatment regimes. In privately funded health systems, such as in the United States, there are fewer constraints; in some situations, the physicians are remunerated on the basis of the number of fractions of treatment delivered. Thus, there may be pressure to prolong treatment times. However, audits of patterns of palliative RT practice in the last 15 years have stimulated much debate and increased research comparing different palliative prescriptions for various clinical scenarios.

WHERE IN THE BODY CAN PALLIATIVE RADIOTHERAPY BE EFFECTIVE?

When patients have cerebral metastases, palliative RT usually involves a course of treatment to the whole brain even if the patient has only one or two lesions confined to one part of the brain. However, patients with metastatic cancer in bone may only receive RT to part of their hemipelvis, even though they have disease involving all the pelvic bones. Why does this apparent paradox exist?

In the latter case, the decision can be explained by the fact that the larger the volume of tissue irradiated, the higher the risk of toxicity. If a patient is suffering pain only in the right ischium, then it is preferable to treat just this area rather than the entire pelvis, which would expose the patient to increased likelihood of acute side effects such as diarrhea, nausea, and vomiting. For the patient with cerebral metastases, there are likely to be occult micrometastases elsewhere in the brain, and thus treatment is aimed at not only relieving symptoms but also reducing the chance of future relapse (11).

The following sections deal with the sites most commonly irradiated palliatively. Non–small cell lung cancer (NSCLC) is the primary tumor most commonly treated with palliative intent. Bone and brain are the most common sites of metastatic disease for most cancer types and occupy a large percentage of the workload of a typical RT department. RT can also be useful to palliate pelvic disease, lymph node metastases, and spinal cord compression. Although liver metastases are common, they are less often treated with RT due to the toxicity of irradiating large volumes of hepatic tissue even to relatively small doses. Other measures are more commonly employed. Nevertheless, some centers do advocate the use of hepatic irradiation in patients with symptomatic, nonchemotherapy responsive liver metastases (12).

Lung Cancer

Lung cancer is the most common cancer in North America and the most common cause of cancer deaths in both men and women. The majority of patients either present with stage IV (metastatic and incurable) disease or develop metastases some time after the initial diagnosis. Although advances have been made with palliative chemotherapy, palliative radiation continues to play an important role in the management of endobronchial or extrinsic lesions causing atelectasis, postobstructive pneumonia, shortness of breath, cough, hemoptysis, pain, and large airway obstruction. RT is not effective at relieving shortness of breath that results from widespread or parenchymal disease, pleural effusion, or lymphangitic carcinomatosis. Symptoms due to nerve compression (e.g., superior sulcus/Pancoast tumors and intercostal neuropathic pain) are more difficult to palliate and may require high doses of radiation aimed at eradication of the tumor.

The relevant issues in assessing palliation in patients with lung cancer are the following: (a) symptom relief, including the rapidity of onset of symptom relief; the degree of relief (partial or complete improvement), and duration of symptom relief; (b) whether the patient has only one symptom or a conglomerate of symptoms (e.g., hemoptysis is easier to palliate than dyspnea); (c) the toxicity of treatment; and (d) any change in the patient's performance status. Obviously, the interplay of these issues is complex, and most research studies only attempt to measure some of these variables.

Numerous palliative RT trials have been performed, and some are highlighted in Table 49-6 (13,14,15,16,17,18,19 and 20). No dosefractionation schedule has to date demonstrated a clearcut advantage in terms of palliation, and until the mid-90s, there was no survival advantage to any of the regimens either (13,14,15,16,17 and 18). The third Medical Research Council study (19) was intriguing in suggesting that a higher RT dose (39 Gy/13 fractions) may result in prolonged survival in good

performance status patients, in comparison to 17 Gy/2 fractions. Given the wide variation in management of locally advanced lung cancer across countries and continents (21,22,23 and 24), many similar patients as those entered on the Medical Research Council study would likely be managed with combined chemo-RT with “curative” intent in the United States and elsewhere.

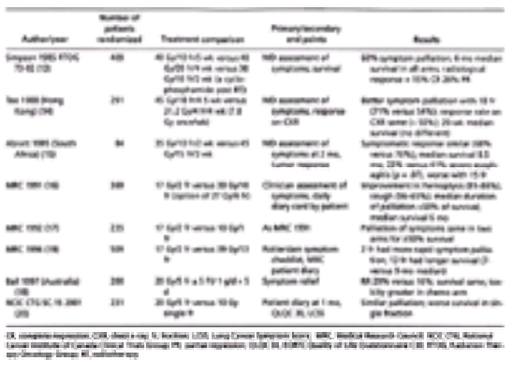

TABLE 49-6. SELECTED RANDOMIZED CLINICAL TRIALS OF PALLIATIVE RADIATION FOR LUNG CANCER

The palliation provided by thoracic RT is considerable. Many but not all studies have suggested that less protracted radiation protocols (including 17 Gy in 2 fractions 1 week apart and 10 Gy in a single fraction) (17) provide better palliation, i.e., equivalent symptom control with less toxicity and less burden to the patient and family. Using shorter treatment protocols, approximately 80–85% of patients report improvement in hemoptysis and 60% improvement in cough. Pain improved in two-thirds of patients. On average, symptom relief lasted for 50% or more of the patient's survival time. However, defining and analyzing symptom palliation in lung cancer is complex, as the effectiveness of palliative radiation may be related to the initial severity of the symptom (25). Timing of assessment is also important (26). A standard definition of palliation is lacking. These methodological concerns, although relevant to clinical trials, do not present an obstacle to recommending palliative RT in clinical practice. Chest symptoms caused by tumor mass, obstruction or invasion, such as cough, hemoptysis, collapsed lobe, pain due to vertebral or chest wall invasion, superior vena cava obstruction and such, are likely to improve with short or intermediate RT fractionation schedules, with mild to modest toxicity. External beam RT remains the gold standard form of palliative RT for lung cancer, but in patients who have already received such treatment and in cases where the tumor is causing obstruction of a major airway, direct insertion of radioactive sources into the bronchial lumen (endobronchial brachytherapy) may be considered. The response rates reported vary from 70–90% in appropriately selected patients (27).

Bone Metastases

RT remains the gold standard for palliation of painful bone metastases. A review of retrospective studies of palliative RT for bone noted that response rates reported varied from 65–100% (28). Noteworthy was the use of both single fractions, in doses as high as 18 Gy, and more radical fractionation schemes, e.g., 50 Gy over 5 weeks. However, the response criteria used in these reports were variable and included subjective interpretations of patients' charts. No consistent definitions of the terms “complete” or “partial relief” of pain in the context of RT for bone metastases currently exist.

Recently, these high responses have been questioned. In randomized trials where more stringent criteria are used, the response rates are lower, typically 30–70%. A recent meta-analysis by the Cochrane collaboration (29) found that palliative external beam RT produced complete pain relief at one month after treatment in only 25% of patients. There also exists considerable controversy over the appropriate scheduling of RT, with many oncologists in Europe advocating short courses of treatment, often only a single fraction, whereas many North Americans still employ more protracted regimes.

The first evidence for the benefit of short, hypofractionated treatments came from a Radiation Therapy Oncology Group (RTOG) trial, first published in 1982, which randomized over 1000 patients between a 15- or a 5-fraction regime (for solitary metastases), or 10- or a 5-fraction prescription (for multiple metastases). The primary end point was pain relief, prospectively collected but physicianassessed with no measures of toxicity. The results of this trial were published twice, causing confusion. In the first analysis (30), it was concluded that the low-dose, shortcourse schedules were as effective as the high-dose, protracted programs, but the subsequent reanalysis (31) came to the completely reverse opinion (i.e., that more is better). In retrospect, the design of this study was flawed and the contradictory results of the two analyses make any interpretation extremely difficult.

In the last 20 years, more studies have been performed and published. Price (32) randomized 288 patients, with life expectancy more than 6 weeks, to 8 Gy single fraction or 30 Gy over 2 weeks. Pain was evaluated by selfassessment using a validated tool, and the analgesic requirement was recorded. End points included partial response, defined as an improvement in pain score with some or reduced analgesia, and complete response, defined as no pain, no analgesia. There were no differences in total pain relief, rates of pain relief, or in duration of response in those who responded. Although toxicity was not specifically reported, there was no difference in acute side effects. Other recently published trials (33,34 and 35), the Cochrane meta-analysis (29), and a recently published consensus statement (36) all support the hypothesis that single fractions are equally effective as multi-fraction treatments.

Nevertheless, the results of a recently presented Canadian trial are interesting, showing superior pain relief at 3 months in patients treated with 20 Gy in 5 fractions (46%) as compared to 8 Gy in 1 fraction (31%). The end point used was patient self-report of pain relief without an increase in analgesics. However, if the proportion of patients reporting any pain relief was recorded, irrespective of whether their analgesics changed, the response rates were identical in the two arms (71% v. 72%) (37). This suggests that higher doses of RT given over prolonged periods may indeed have a greater biological effect but that this can be compensated for by analgesics. This result illustrates the need to define end points. Wu has demonstrated that there is no current agreement on how to report the results of such studies (38). Both he and the recent consensus statement (36) have identified the need for universally accepted definitions in this area.

Although a 1993 survey of UK oncologists indicated that 67% of British oncologists used single treatments for bone metastases (39), recent surveys of their European, Canadian, and Australasian counterparts demonstrate that single fractions are used by only 11%, 16%, and either 15% (breast primary) or 45% (lung primary) of respondents in those areas (40,41 and 42). These surveys show that despite a willingness to use single fraction treatments in some patients because of convenience and efficacy, there are still concerns about duration of response, acute complications, and patient tolerance. In health care systems where the physician is remunerated on the basis of the number of fractions of treatment delivered, there could even be a financial incentive to prolong treatment times, contrary to the principles listed in Table 49-2.

“Wide-field” radiation therapy can be given to patients with widespread bony disease, using either HBI or radioactive isotopes such as strontium-89. The response rates and duration of response are comparable to those achieved with local radiation, although one study suggests superior results from fractionated HBI in terms of duration and need for retreatments (43). At present the efficacy of strontium, used either alone or in conjunction with local radiation, is confined to the treatment of bone metastases from prostatic cancer, as it has an affinity for osteoblastic lesions. There is evidence that it is beneficial in both the treatment of known painful metastases and the prevention of future lesions, and further research is ongoing, in particular using newer isotopes such as rhenium-186 and samarium-153.

Side effects from palliative RT for bone metastases will vary depending on the area of the body being treated, but nausea and vomiting may be common, especially in patients receiving treatment to the thoracolumbar spine. It would appear from studies utilizing 5-HT3 antagonists that the incidence of acute side effects, especially emesis, is similar for both single fraction and multi-fraction treatment regimes. There appears to be little risk of developing complications within the actual bones treated, as in one British trial there were no differences in the numbers of fractures or incidences of paraplegia developing in a treated area (44). For HBI, toxicity tends to increase with dose, ranging from 30–60% gastrointestinal toxicity, 20–40% hematological toxicity, and occasional pulmonary toxicity, while with strontium trials there is no significant gastrointestinal toxicity, and hematological effects, although not uncommon, are usually mild.

It is not standard practice to prophylactically irradiate all bone metastases, whether or not they are painful, but there may be benefits from irradiating if they are at risk of fracture. The criteria defined in the orthopedic literature (45) (lytic lesions greater than 2.5 cm in diameter involving the cortex) are for lesions for which surgery should be considered, but RT may also be of benefit. In breast cancer patients, it has been noted that although RT to lytic bone metastases gives rates of pain relief of 70–81%, the radiological reossification rates are 17–31% (46,47). However, in a series of 59 patients with nonfractured lesions treated primarily with RT, only four developed subsequent pathological fractures, two of which occurred during the time of radiation. Thirty-nine of those 59 patients were classified as being at high risk, but the only fractures that occurred in this group were the two that developed during treatment. Therefore, RT may be effective for initial management of patients with high-risk bone metastases from breast cancer. Nevertheless, it would seem prudent that both the radiation oncologist and orthopedic surgeon assess patients at risk for pathological fractures. If fracture does occur, most patients will receive “adjuvant” radiation, although the value of this practice has never been demonstrated. Regimes used in this situation are based on those used to treat pain, but it is not clear whether the shorter hypofractionated regimes are as effective as longer courses in producing reossification. There may be a subset of patients, perhaps those who are completely ambulatory and pain free following surgery, who do not require

additional radiation, especially if they have a poor prognosis from their underlying malignancy (e.g., lung cancer).

Brain Metastases

Solitary brain metastases can be treated by surgical resection. Several small randomized trials (48–84 patients) have compared resection followed by radiation to RT alone, with improved survival in the surgical arm in two of the studies (48,49 and 50). An alternative to surgical resection is stereotactic radiation, also known as radiosurgery, or “gamma-knife,” i.e., external beam radiation with multiple beams from multiple directions, so as to concentrate the radiation dose to a limited area of the brain. Only one very small (N = 27) randomized trial of stereotactic radiosurgery plus whole brain radiotherapy (WBRT) versus WBRT alone has been published to date (51). Two large-scale, cooperative group clinical trials that are currently under way or are soon to be completed will contribute more evidence for the role of stereotactic radiosurgery boost after WBRT for one to three brain metastases (a trial conducted by RTOG), and the role of radiosurgery vs. resection and WBRT following radiosurgery (a European Organi- zation for Research on the Treatment of Cancer trial).

The majority of patients with brain metastases present with multiple metastases and are not candidates for limited radiation. Whole brain external beam RT is usually recommended, although steroids alone may be an option in patients with very limited life expectancy (52). It has not been clearly established whether RT is beneficial in asymptomatic patients, although prevention of neurological deterioration is a frequently cited reason for RT. The RT fractionation schedules that are utilized include 40 Gy in 20 fractions, 30 Gy in 10 fractions, 20 Gy in 5 fractions, and 17 Gy in 2 fractions. In a number of randomized studies comparing these various RT schedules (53,54,55,56 and 57), no difference was observed in response rate and survival, although a quicker response was often seen with shorter fractionation schedules. Approximately 50–90% of patients reported relief of neurological symptoms, and 50% of patients had functional improvement; a distinction between the effect of steroids versus RT was not made. These assessments were for the most part done by medical personnel rather than by direct patient report; median survival was 15–20 weeks. Patient selection for RT is clearly important, as in a large multicenter British study comparing 12 Gy in 2 fractions to 30 Gy in 10 fractions (57), one-third of the 533 patients randomized were too ill or dead at the one-month follow-up assessment.

Efforts at improving the outcome of palliative brain RT continue, especially in patients with a somewhat longer life expectancy. These efforts are aided by a recursive partitioning model derived from analyzing outcomes of patients in the RTOG studies, which has identified three prognostic strata on the basis of patients' age, performance status, and the presence or absence of extracranial cancer (58,59). This model classifies patients under 60 years of age, with Karnofsky performance status of 80–100, and no cancer elsewhere, as having the best prognosis (group I, 7 months median survival). Patients lacking one of the above criteria fall into an intermediate prognosis group (group II), and those not satisfying two or more criteria have a poor outcome and are less likely to benefit from treatment (group III). If treatment is indicated for patients in this group, a short course of palliative RT is usually employed. For groups I and II, more aggressive treatments being explored include accelerated or hyperfractionated RT, whole brain RT followed by stereotactic boost (a current RTOG study), and utilizing new radiosensitizers such as Gadolinium texaphyrin (60). Some of these strategies are showing promising initial results although the real benefit will have to await the completion and maturation of randomized clinical trials currently in progress.

Advanced Pelvic Malignancies

Patients with locally advanced, inoperable, or recurrent rectal and gynecological cancers frequently develop distressing symptoms such as pain, bleeding, and mucous discharge. RT is commonly employed to palliate these symptoms and although it is undoubtedly effective in a significant number of cases, there are few published data that detail the probability of benefit, nor is there information on the appropriate fractionation. A review of the role of RT for recurrent rectal cancer estimated that 70–90% of patients receiving RT for pain relief derived benefit at least initially, with 23–50% having symptom control for 6 months. A range of doses were used to achieve these results; it was not possible to assess the optimal regime, and the authors could not discern any difference between lower and higher doses in terms of symptom relief (61).

Treatment approaches are variable and range from the use of large fractions of up to 10 Gy, often repeated at intervals (62,63), to more conventionally fractionated highdose treatment, such as the 50 Gy in 25 fractions (64). An RTOG study of 10 Gy fractions given with the radiosensitizer misonidazole projected an increased risk (41%) of grade 3/4 complications in those who survived 12 months (65). Nevertheless, the use of large single fractions remains commonplace, especially for patients with poor performance status or with limited life expectancy. Other regimes commonly used include 20 Gy in 5 fractions, 30 Gy/10 fractions, 40 Gy/16 fractions, and for patients with good performance status with no disease outside the pelvis, doses up to 50 Gy can be employed.

Lymph Node Metastases

Involvement of lymph glands by metastatic cancer is common, causing airway or nerve pain or patient distress through their appearance or by interfering with normal daily activities.

One of the most significant complications of malignant lymphadenopathy is superior vena caval obstruction (SVCO). SVCO causes facial and neck swelling, headache, dyspnea, chest wall vein distention, and occasionally syncope. It is usually due to compression of the SVC by mediastinal lymphadenopathy. Most cases (80%) are due to malignancy with the most common underlying diagnosis being lung cancer (60–70%). Other causes include lymphoma, germ cell tumors, and breast cancer.

Although not considered to be an oncological emergency, SVCO can cause distressing symptoms and should be treated urgently. Lymphoma and small cell lung cancers causing SVCO are normally treated with chemotherapy, but in the usual case of NSCLC, RT is the treatment of choice, although intraluminal stents are increasingly being used, especially for patients who progress during or after their RT.

The radiation dose regimes employed for SVCO will depend on the underlying histology and the intent of treatment. Patients with lymphoma and germ cell tumors may be treated as part of a curative protocol, using radical doses of RT given in conventional daily fractions. Most patients with NSCLC will be treated with palliative intent although occasionally it may be appropriate to use a curative regime. Doses tend to be similar to those used for locally advanced NSCLC (see the section Lung Cancer), although some oncologists use larger than normal fractions for the initial few treatments if the patient is very symptomatic, to expedite response. Response rates between 40–90% (36,38,66) have been reported depending on underlying histology, treatment regime, and patient population.

Other lymph node masses that are causing pain or distress can be treated by short courses of palliative RT, usually 20–30 Gy in 5–10 fractions. Unsightly or painful lesions in the skin or subcutaneous tissue can be managed similarly. Response rates vary depending on the underlying histology but are probably in the order of 50–70%, although sometimes only a small reduction in the actual volume of the malignant mass occurs, but this can still lead to significant symptom relief.

Spinal Cord Compression

Spinal cord compression is one of relatively few oncological emergencies. Its prompt recognition, diagnosis, and treatment may avert neurological deterioration and prevent paralysis. Spinal cord compression is usually due to extension of vertebral metastases into the epidural space or occasionally to paravertebral tumors. It may also be the result of vertebral collapse, with bony fragments causing cord compression. Up to 90% of patients with vertebral metastases experience pain before any neurological changes. Any worsening of back pain in a patient known to have or be at risk for developing bone metastases should be assessed promptly. Unfortunately, patients frequently do not bring symptoms to the attention of their physician early enough. Many present hours after they have lost the use of their limbs, bladder, and/or bowel. If paraplegia has been present for more than 24–48 hours, it may be impossible to reverse the neurological damage. The most important predictor of neurological recovery is the ambulatory status at time of treatment of cord compression: 89% of patients who are ambulatory remain so after treatment, 53% of patients with paresis (weakness) become ambulant, but only 10% of patients with paraplegia (bilateral loss of leg power, i.e., bedridden) regain their mobility after treatment (67).

Palliative radiation is preferred over surgical decompression in patients who have very radiosensitive tumors (e.g., lymphoma, myeloma), have a limited life expectancy (days to a few weeks), and would find surgery to be too burdensome, have extensive vertebral or epidural metastasis where surgery stabilization would not be possible, present long after the loss of neurological function, and have continuing pain in the region of the cord compression, or are not candidates for surgery due to their debility or other contraindications. As with bone metastases, typical palliative treatment plans for spinal cord compression are 20 Gy in 5 fractions over 1 week or 30 Gy in 10 fractions over 2 weeks. The evidence for the role of RT in spinal cord compression has been reviewed recently (68). If complete paraplegia is present for a considerable time prior to presentation, there is little hope of neurological recovery, and palliative radiation may be reserved to manage pain in the future should it become a problem.

Treatment of the spinal cord in patients who have had previous spinal radiation presents a frequent clinical dilemma. If neurological status is threatened and surgery is not advisable, reirradiation may indeed be appropriate. Many radiation oncologists use smaller fraction size to minimize the risk of late complications, specifically radiation myelitis. The risk of radiation-induced paralysis cannot be completely dismissed but needs to be put into perspective of almost definite tumor-induced paralysis if treatment is withheld. In an already paraplegic patient, attention to maximum cord tolerance is not a concern. If pain is present, the patient can be treated with palliative radiation to the dose needed to control the pain without regard for the already damaged spinal cord.

WHAT AFTER RADIOTHERAPY?

Acute side effects are common and always self-limiting but as they usually occur after the treatment has finished, they can cause considerable anxiety if a patient is not warned to expect them. The common acute effects, their time course, and recommendations for management are shown in Table 49-7. In addition, many patients receiving RT will complain of fatigue during and after their course of treatment. The exact etiology of this is unknown but is probably multifactorial.

Site	Symptoms	Time course	Management
Skin	Erythema	Settles within 1 wk of completion of therapy	None, or 1% hydrocortisone for skin irritation if skin surface unbroken.
	Skin breakdown	Occurs only after higher dose XRT but if severe may last for several weeks	If only dry desquamation ("peeling"), no specific therapy except as above. If skin breaks down and begins to become ulcerated and weepy (moist desquamation), skin care required to prevent secondary infection.
Abdomen	Nausea and vomiting	May occur after first treatments and persist for several days after completion of therapy	Antiemetics (e.g., Gravol, Stemetil) used either as prophylaxis or as therapy for established emesis. Intractable cases may respond to steroids or ondansetron.
	Diarrhea	Occurs usually late in protracted course of XRT or after completion of short course of treatment	Prevention with low-fiber diet may be all that is required. Established diarrhea best treated with simple antidiarrheals (e.g., Lomotil, Imodium).
	Dysuria, frequency	As above	Exclude UTI by culturing MSU. If no bacterial infection, increase fluid intake, but symptoms may be difficult to control.
Head and neck	Painful inflammation of mouth, pharynx (mucositis)	Occurs during later stages of prolonged course of XRT, may persist for 1–2 wk after completion of therapy	Soft diet. Treat any secondary infection such as oral candidiasis. In severe cases, local anesthetic solution may be required.
Thorax	Dysphagia (esophagitis)	As above	Soft diet, analgesics. Patients may benefit from antacids to prevent reflux.
Head	Alopecia	Occurs over a few days after starting treatment	No specific therapy. Patients should be reassured that hair will regrow.

MSU, midstream urine; UTI, urinary tract infection; XRT, radiotherapy; XRT = ray radiotherapy.

TABLE 49-7. ACUTE SIDE EFFECTS OF RADIATION THERAPY

Late complications of RT, which occur months or years after treatment, are usually not relevant to many patients receiving palliative treatment. However, the radiation oncologist still needs to be mindful of the risks of inducing irreversible problems, such as myelitis, lung fibrosis, and renal failure, especially in patients who might have a long life expectancy, such as those with metastatic breast cancer.

Due to the low doses usually used, palliative RT is not necessarily a “once-only” treatment, unlike high-dose radical treatments. Therefore, if a patient treated for painful bony metastases develops recurrent pain in the irradiated area several months later, retreatment may be possible and should be discussed with the responsible radiation oncologist.

WHERE DO WE GO FROM HERE?

There is an urgent need for more clinical research in the area of palliative RT. Until now, the vast majority of clinical trial resources have been understandably channeled into curative treatment where end points, such as local tumor control, can easily be measured and compared. However, a substantial proportion of the radiation oncology workload—that done with noncurative intent—is based more on clinical experience, training, and resource utilization than on published data (8). A recent symposium concluded that “information on the palliative benefits of RT in terms of symptom management and quality of life is simply not yet available” (69). Nevertheless, there is increasing evidence that in many clinical situations single fractions of radiation are as effective as more protracted courses. Despite the obvious advantage to patients in terms of convenience and opportunity cost, in many radiation oncology centers, especially in the United States, there has been a reluctance to adopt this method of treatment, and it is unlikely that practice will change until large North American randomized trials demonstrate the same results as those from Britain and Europe. Accordingly, groups in both Canada and the United States have undertaken studies comparing the effects of single and multiple fractions for NSCLC and bone metastases.

Although it is important that more trials are performed, it is equally important that such trials are properly designed with reliable and valid end points. Guidelines for designing such trials have been published (70). Trials should be feasible in this population, the end points should be truly palliative, and the results should be representative of and applicable to clinical practice. It is essential that these principles be incorporated into future studies. Unfortunately, most of the trials discussed in this chapter are open to criticism because of the difficulty in measuring the palliative effect of radiation. Many of the end points used are subjective and response criteria are not well defined. Most studies use physician evaluation of responses as end points rather than self-assessments by the patients. Many of the more recent trials have incorporated validated instruments such as the McGill-Melzack pain score (71), analgesic intake scores, or linear analog self-assessment scales (35).

It is also fair to note that until recently, the radiation oncology profession has not demonstrated much interest in palliative RT research. However, it is now acknowledged that this is a fertile area for clinical studies, and several cancer centers are beginning to consider a programmatic approach. At the University of Toronto, programs designed not only to provide timely access to treatment for patients requiring palliative RT but also to enhance academic activity through education and research have been recently established (72,73). It is envisaged that a large proportion of the patients will be offered participation in clinical studies.

As more data become available, it is hoped that changes in practice may occur. For example, at present all patients at one center with bone metastases, irrespective of their primary diagnosis, histological subtype, or performance status, will tend to receive the same radiation prescription. However, within this heterogeneous group, there may be patients with factors that will make them more or less likely to respond to certain RT regimes. In addition, the effects of chemotherapy or other systemic treatments, such as bisphosphonates, may be synergistic with RT. It is hoped that future patients will have individualized palliative treatment plans, which will likely vary from single fraction radiation treatments in patients with limited life expectancy to longer and more complex combined modality approaches in those with more favorable characteristics.

PALLIATIVE CHEMOTHERAPY

NEIL M. ELLISON
ERIC M. CHEVLEN

Palliative chemotherapy is a term with many potential meanings. In its broadest sense, it refers to the use of anticancer medications in the treatment of an incurable malignancy. It is only one aspect of the wide spectrum of palliative care available for the patient with malignancy. The World Health Organization defines palliative care as “the active total care of patients whose disease is not responsive to curative treatment. Control of pain and other physical symptoms as well as psychological, social, and spiritual problems is paramount. The goal of palliative care is achievement of the best quality of life for patients and their families” (1).

A myriad of cancer-related problems can affect any organ system and adversely affect overall quality of life (QOL). Health care providers intuitively realize that significant tumor responses to chemotherapy are usually associated with a decrease in malignancy-induced symptoms. The medical literature previously reported the effectiveness of palliative chemotherapy primarily in terms of tumor response rate, duration of response, and survival benefit; chemotherapy studies infrequently described palliation of symptoms or overall impact on QOL as an assessed treatment end point. Symptomatic improvement is now becoming a more important aspect in clinical trial evaluation and comprehensive cancer care. For example, a recent analysis of 300 patients treated with chemotherapy for metastatic breast cancer demonstrated that objective tumor response correlated with improvement of pain, mood, and shortness of breath. Constipation, lethargy, anorexia, and nausea also improved to a lesser degree, but there was no significant change in cough or insomnia (2). Improvement in symptoms may also occur without objective anticancer response to chemotherapy (3). In fact, it is estimated that 3000 articles describing cancer treatment effects on QOL will be published in 2002 (4). For the purpose of this discussion, palliative chemotherapy refers to the administration of medications to ameliorate the adverse signs and symptoms directly or indirectly caused by a malignancy that is incurable with the administration of chemotherapy. Excluded from our definition, however, are analgesics and psychotropic agents.

USUAL RATIONALE FOR CHEMOTHERAPY USE

Chemotherapy can be used as adjuvant, curative, or palliative treatment, depending on the type and stage of malignancy. When used in the latter two circumstances, its effect is usually described by response rate. Response rate primarily refers to objective measurements of changes in cancer size, sites of metastatic disease, and measurable serologic or other markers of tumor activity. Commonly used criteria for evaluation of solid tumor response to chemotherapy are shown in Table 50-1. Adjuvant chemotherapy refers to systemic treatment administered after all gross evidence of disease has been controlled by surgery or radiation therapy, but when the possibility of cancer recurrence is high. Adjuvant chemotherapy is given with the intent of completely eradicating any undetectable cancer cells that may be present. The benefit to toxicity ratio of adjuvant chemotherapy is extremely important. Most health care providers do not suggest very toxic or potentially lethal adjuvant chemotherapy if the likelihood of cancer recurrence is low and the percentage of patients likely to benefit is also low (i.e., residual cancer cells may not be killed with the treatment). In this instance, the treatment may harm more patients than it helps. Yet the individual with the cancer can have a very different perspective regarding this issue. Patients are often willing to undergo adjuvant therapies of prolonged duration and endure significant impairment in their QOL for a relatively small increase in the likelihood of cure (5). An additional benefit of adjuvant chemotherapy is the positive psychological effect of “doing something” to decrease the risk of cancer recurrence.

Definitions of overall response	
Response	**Definition**
Complete response	Complete resolution of all lesions (both target and nontarget) without new lesions
Partial response	Complete resolution of all target lesions and incomplete/stable response in nontarget lesions/sites without new lesions, OR Partial response of target lesions and nonprogression of nontarget lesions/sites without new lesions
Stable disease	Stable target lesions, nonprogression of nontarget lesions/sites without new lesions
Progressive disease	Progressive disease in target lesions, any response in nontarget lesions/sites, with or without new lesions, OR Any response in target lesions, progressive disease in nontarget lesions/sites, with or without new lesions, OR Any response in target lesions, any response in nontarget lesions/sites, and new lesions
Unknown	Response is not assessable, insufficient data reported

TABLE 50-1. RESPONSE CRITERIA FOR SOLID TUMORS (EASTERN COOPERATIVE ONCOLOGY GROUP)

Chemotherapy can be palliative when used in conjunction with another anticancer therapy if it decreases treatment-related morbidity, even if it does not improve the chance of cure. For example, anal or laryngeal carcinoma can often be locally controlled or cured with aggressive surgery. This success, however, comes with significant morbidity— the need for colostomy or loss of voice. Organ function can be maintained for patients with these and other malignancies by combined chemotherapy and radiation therapy (6,7,8,9 and 10). It is anticipated that more malignancies will be treated with these organ-sparing treatments in the future.

As a primary treatment, chemotherapy may either be curative or “palliative” in instances in which there is no chance for cure. The goal of curative chemotherapy is to eradicate all cancer completely and to prevent its reoccurrence. Table 50-2 lists the malignancies for which chemotherapy has been shown to provide the possibility of cure in the nonadjuvant setting. These metastatic or locally unresectable cancers are considered to be very chemotherapyresponsive. Chemotherapy should be recommended in most circumstances for these cancers. Maintenance chemotherapy (that is, treatment continued for prolonged or indefinite periods of time after complete response is obtained) has been shown to be of no benefit for a number of chemotherapy-curable or highly chemosensitive cancers (testicular cancer, small cell lung cancer, ovarian cancer, lymphomas, and Hodgkin's disease).

Proven benefit of adjuvant chemotherapy	Possible curative primary or secondary chemotherapy for locally advanced or metastatic disease
Breast cancer	Acute lymphocytic leukemia
Cervical cancer	Acute myelocytic leukemia
Choriocarcinoma	Choriocarcinoma
Colon cancer	Germ cell/testicular cancers
Ewing's sarcoma	Hodgkin's disease
Germ cell tumors	Intermediate or high-grade non-Hodgkin's lymphomas
Lymphomas	Some predominantly pediatric tumors
Osteogenic sarcoma	Osteogenic sarcoma
Ovarian cancer	Rhabdomyosarcoma
Pediatric malignancies	Wilms tumor
Testicular cancer	Ewing's sarcoma
Small cell lung cancer	
Subtypes of high-grade carcinoma of unknown primary	

TABLE 50-2. CANCERS THAT ARE POTENTIALLY CURABLE WITH CHEMOTHERAPY

Unfortunately, the majority of metastatic malignancies in adults are not curable with chemotherapy. Even for the large number of patients with colon or breast cancer for whom adjuvant chemotherapy is recommended, treatment decreases the recurrence rate by only approximately one-third. Thus, many patients who experience recurrent disease after adjuvant treatment may also receive palliative chemotherapy.

PATIENT ACCEPTANCE OF THE NEED FOR CHEMOTHERAPY

After recovering from the initial shock of cancer diagnoses, patients appear to be quite willing to accept chemotherapy's side effects in an attempt to control the malignancy. In a study of 100 patients with cancer, Slevin reported the differences between patients' attitudes toward either mild or intensive chemotherapy. This information was compared to a similar survey of doctors, nurses, and a control group matched for age, sex, and occupation (11). Study participants were asked to consider various probabilities of cure, prolongation of life, and relief of symptoms necessary for them to accept toxicities associated with mild and aggressive treatments. Cancer patients were most likely to accept intensive and toxic treatments for an extremely small probability of cure, prolongation of life, or symptom relief. For example, 53% of patients with cancer would undergo a very toxic chemotherapy regimen for a 1% chance of cure, and 42% would accept the same regimen for a 3-month prolongation of life. Twenty percent of patient-appointed surrogate decision makers would accept the treatment for a 1% chance of cure, and the same percentage would accept it for a 3-month prolongation of life. The respective endorsement by medical oncologists was only 10% for each question (11). The control group was also less likely to accept the treatment-related side effects and wanted more potential benefit for any particular risk. Medical oncologists were more likely to accept aggressive treatments than general practitioners. Oncology nurses' scores fell between those of the generalists and the control group. Radiation oncologists were the least likely of any group to accept treatment. After 3 months of actual treatment, the same questionnaire was readministered to patients. Their responses were essentially unchanged. This important study indicates that individuals' attitudes change dramatically when they actually receive the diagnosis of cancer; when the situation is real, more risks are taken. Patients younger than 40 years of age are even more likely to undergo chemotherapy for extremely little predicted chance of symptomatic or longevity benefit (12).

CHEMOTHERAPY RESPONSIVENESS OF MALIGNANCIES

The likelihood of palliative chemotherapy benefit varies among cancer types. Malignancies with moderate to high sensitivity to chemotherapy are listed in Table 50-3. Anticipated chemotherapy response rates are in the 30–80% range. The primary goal of chemotherapy for these incurable, locally advanced or metastatic cancers is to achieve a partial or complete tumor response and to prolong diseasefree and overall survival.

Bladder cancer
Breast cancer
Cervical/endometrial cancer
Chronic lymphocytic leukemia
Chronic myelogenous leukemia
Colon cancer
Esophageal cancer
Head and neck cancer
Multiple myeloma
Non-Hodgkin's lymphoma (most subtypes)
Non–small cell lung cancer
Ovarian cancer
Prostate cancer (hormone therapy)

TABLE 50-3. METASTATIC AND INCURABLE CANCERS WITH MODERATE TO HIGH RESPONSE RATES (>30%) TO CONVENTIONAL CHEMOTHERAPY AND HORMONAL THERAPY

Metastatic or locally advanced cancers that have low expected response rates to chemotherapy are listed in Table 50-4. Partial responses to chemotherapy of less than 25%, usually of short duration, have been reported for these malignancies. Complete responses are extremely rare. The oncologist can recommend chemotherapy of limited proven benefit, investigational treatments, or nonchemotherapeutic palliative supportive care as reasonable alternatives for patients with these malignancies. Most cancer specialists have anecdotal experience of an occasional patient's unexpected excellent response in these chemotherapy-resistant cancers. One is cautioned not to base treatment of the average patient on the anecdotal (and at times inexplicable or coincidental) outcome of an individual patient.

Adrenal carcinoma
Adult sarcomas
Almost all malignancies in patients with poor performance status (Eastern Cooperative Oncology Group 3 or 4)—see text
Carcinoid tumor
Gastric cancer
Hepatoma/biliary cancers
Kidney cancer
Melanoma
Mesothelioma
Most previously treated cancers
Prostate cancer (chemotherapy)
Thyroid cancer

TABLE 50-4. INCURABLE CANCERS WITH LOW RESPONSE RATES TO CHEMOTHERAPY (<30%)

Some chemotherapeutic agents have received U.S. Food and Drug Administration (FDA) approval primarily because they have improved QOL. A number of treatment studies report decreased pain or other symptomatic improvement induced by chemotherapy, despite little or no objective tumor response (13,14,15,16 and 17). Hypotheses to explain these phenomena include alteration in the local milieu of the neoplasm or the inhibition of production of circulating cytokines and neurotransmitters responsible for many adverse symptoms associated with malignancies (18,19 and 20). Changes in growth factor production could result in tumor growth inhibition, as opposed to tumor shrinkage. Decreased inflammatory responses induced by many chemotherapeutic drugs or antikinins have led to their widespread use in rheumatologic diseases (21,22). Similar local environment alterations may occur at tumor sites with a decrease in tumor-associated symptoms without necessarily influencing tumor size.

THE PHYSICIAN'S IMPACT ON TREATMENT CHOICES

The physician has considerable influence in the patient's decision about starting or continuing chemotherapy. Although the majority of adult cancer patients in one report (N = 439) wanted “all” information to be given, only 69% wanted to participate in the therapeutic decision making. Twenty-five percent wanted the physician to make all of the decisions. This latter group comprised predominantly older and sicker men (23). Although patients tend to accept their physicians' advice, this is not universal. A better-informed and educated patient or a patient who believes that his physician is ambivalent about a recommendation is more likely to decide independently (24).

Oncologists should not feel obligated to offer chemotherapy to every patient with malignancy. A group of patients for whom the predicted toxicity of treatment should preclude consideration of chemotherapy can be defined (see the section Prognostic Factors). Other patients may fall into a gray zone in which the benefit to toxicity ratio of treatment is less clear.

The practice of giving subtherapeutic doses of chemotherapy primarily to prevent patients from believing their cases are hopeless is strongly discouraged. This is more likely to reflect the physician's discomfort in dealing with a terminally ill patient than it is to address the patient's psychological needs. A more compassionate and ethical approach is to review the medical situation with the patient and family and to provide them with an informed assessment of possible treatment choices. Often this will include nonchemotherapy palliative care. This is especially true near the end of life. Patient and family desires for open communication and participation in decision making, which may be tempered by cultural differences, must be considered in these discussions.

Investigational studies of newer chemotherapy or palliative treatments are considerations when no proven beneficial anticancer treatment exists. The patient and family should understand that unproven investigational treatment may cause more harm than good. Patients and families may mistakenly believe that “no chemotherapy” means “no need for the physician to follow and treat the patient” or “nothing more can be done.” Palliative care should be offered as a positive intervention, rather than just the absence of chemotherapy. Future visits should be scheduled with the physician who is supervising the patient's care. Visits should be at intervals that meet the physical and psychological needs of the patient and family. Even when it seems likely that the patient will be too sick to keep any more appointments, they should be scheduled nonetheless. Such scheduling provides a message of ongoing concern for the welfare of the patient and caregivers.

DISCUSSING PALLIATIVE CHEMOTHERAPY WITH PATIENTS

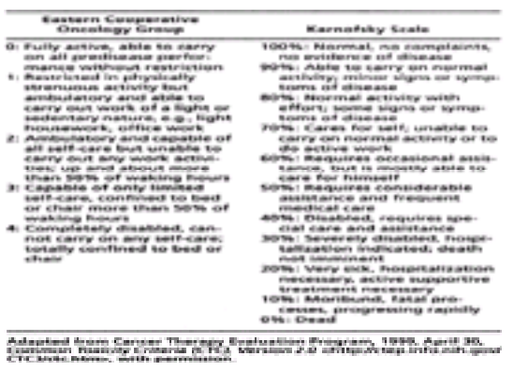
Patients and families often request statistics regarding the likelihood of tumor response, expected duration of response, possible treatment-related toxicities, and average survival prolongation that may occur with chemotherapy. This information may have significant impact on the decision to accept a recommended trial of chemotherapy. In addition to giving an honest reply, the physician should respond to these inquiries by trying to learn if there are specific factors leading to the question. What questions and decisions need to be addressed in the patient's or family's lives? Is there a contemplated retirement, a reunion, a special upcoming event, or significant unfinished business that must be completed? Are there fears about dying or spiritual issues that need interventions from other supportive caregivers?

Patients and families often misconstrue a survival estimate based on published or personal experiences as a precise number to live or die by. For example, a physician statement that the median survival is 6 months frequently leads to a 6-month survival time becoming firmly entrenched in the minds of patient and family. Similarly, an expected “20% response rate to treatment” for a published cohort of patients may be misconstrued by the patient to mean that he specifically has a 20% chance of responding to the same treatment. The patient must be informed that statistics refer to groups of patients and not individuals. Oftentimes, patients or their families insist on a numerical answer concerning therapeutic efficacy or expected longevity. They may honestly be informed with such phrases as, “I expect the time would more likely be measured in weeks than in months,” or “There is a reported response rate of 60%, which lasts on average for 4 months.” This is an opportunity to discuss possible scenarios and alternatives to the question, “What if a response does not occur?” Although these replies are not very precise—indeed, it is very difficult for a reply to these questions to be both honest and precise—they at least give the patients information to correct gross misconceptions about their prognoses. Although false hope should be avoided, it is possible to have these difficult discussions and still impart hope for comfort, maintenance of functionality for as long as possible, and finally, a death without uncontrolled pain or loss of dignity. Also important is the reassurance that the physician will continue to care for the patient and family, even if chemotherapy is no longer used (25).

When patients and their families are provided with the best possible prognostic information, decisions frequently differ from those made when less information is imparted. Patients with metastatic colon and lung cancer who believed that they had a significant chance of dying within 6 months were less likely to choose a possible life-extending therapy over comfort care (26). When informed that the likelihood of 6-month survival was 90, 75, 50, 25, or 10%, the likelihood that the patient would choose a lifeextending therapy was decreased to 51, 29, 29, 31, and 21%, respectively. In this study, patients, as compared to their physicians, more commonly overestimated their chance of surviving 6 months. For example, whereas 50% of physicians believed that a patient group would have a 6-month survival, only 12.5% of patient members of that group thought that they would survive 6 months or less. Physician estimates of prognosis were more accurate than the patient's own estimates, as evidenced by the fact that only 45% of the patient group was alive at 6 months. If chemotherapy is chosen by mutual agreement between the patient and physician, the attitude should be that all that is necessary will be done to assure that the particular patient will benefit from the treatment, even if the response rate is reported to be relatively low. This optimistic approach after a realistic discussion is appropriate and of great psychological benefit to the patient and the family, as well as the physician and other members of the health care team.

PROGNOSTIC FACTORS

A composite of patient and disease-related factors will help determine if chemotherapy is a reasonable treatment option. The single most important factor (other than tumor type) that determines possible benefit to toxicity ratio of chemotherapy is the performance status (PS) or activity level of the patient. Two measures used to quantitate this are the Eastern Cooperative Oncology Group (ECOG) and Karnofsky scales (Table 50-5). These two performance status scales have been compared in lung cancer, and in at least that setting, the ECOG scale has a somewhat better prognostic capability (27). Regardless of the cause of debility (malignancy or other comorbid medical illness), a severely weakened patient with a restricted PS (ECOG 3 or 4; Karnofsky <50%) is more likely to experience excessive toxicities from chemotherapy than a beneficial response. Exceptions occur predominantly when the malignancy causing the severe debility is exquisitely chemotherapy sensitive (28,29).



Eastern Cooperative Oncology Group	Karnofsky Scale
0: Fully active, able to carry on all predisease performance without restriction	100%: Normal, no complaints, no evidence of disease
1: Restricted in physically strenuous activity but ambulatory and able to carry out work of a light or sedentary nature, e.g., light housework, office work	90%: Able to carry on normal activity; minor signs or symptoms of disease 80%: Normal activity with effort; some signs or symptoms of disease
2: Ambulatory and capable of all self-care but unable to carry out any work activities; up and about more than 50% of waking hours	70%: Cares for self; unable to carry on normal activity or to do active work 60%: Requires occasional assistance, but is mostly able to care for himself
3: Capable of only limited self-care, confined to bed or chair more than 50% of waking hours	50%: Requires considerable assistance and frequent medical care
4: Completely disabled, cannot carry on any self-care; totally confined to bed or chair	40%: Disabled, requires special care and assistance 30%: Severely disabled, hospitalization indicated; death not imminent 20%: Very sick, hospitalization necessary, active supportive treatment necessary 10%: Moribund, fatal processes, progressing rapidly 0%: Dead

TABLE 50-5. EASTERN COOPERATIVE ONCOLOGY GROUP AND KARNOFSKY PERFORMANCE STATUS SCALES

The sites of metastatic spread may allow better, but not totally accurate, predictions of the potential initial response to chemotherapy as well as overall prognosis. This varies for different tumor types (5). For example, breast cancer metastatic to the skin, bone, and lymph nodes is usually more responsive to chemotherapy than when liver or pulmonary lymphangitic metastases are present. Chemotherapy “sanctuary sites,” such as the brain and other central nervous system structures, are usually least responsive to systemic cytotoxic treatments.

Numerous other poor prognostic features exist for specific malignancies. Data are increasingly available to support genetic aberrations and histochemical markers as predictive of short- and long-term prognosis for malignancies, as well as the likelihood of response to chemotherapy (30,31 and 32). Patients whose cancers are refractory to ongoing chemotherapy are less likely to respond to second or subsequent chemotherapy treatments. Similarly, cancers that have recurred within 6 months of cessation of chemotherapy are less likely to respond to retreatment with the same chemotherapy than are those that recur after a longer disease-free period.

DOES AGE INFLUENCE THE DECISION TO TREAT OR ACCEPT CHEMOTHERAPY?

Pharmacokinetics change with the patient's age secondary to alterations in drug absorption, distribution, metabolism, and excretion (33,34). However, advanced age is reportedly not a prognostic factor in the response to chemotherapy, as long as there are no significant comorbid medical problems (35,36 and 37). There are differences in elderly patients' tolerances and responses to chemotherapeutic agents. Patients with colorectal cancer who were older than 70 years of age had greater 5-fluorouracil (5-FU) induced mucositis than did their younger counterparts, but response and survival benefits were similar as long as their initial PS was good (38). Specific cancer molecular characteristics may be different in elderly patients (39). They may have a higher prevalence of neoplastic cells with multidrug resistance, as well as ageassociated variances in tumor-associated enzymes and even in tumor kinetics. Polypharmacy and possible adverse drug interactions may occur with increased frequency in the elderly. In one report, 58% of cancer patients older than 70 used more than four other medications, 22% more than seven, and a remarkable 7% were using more than ten (40).

Some oncologists exclude older patients from chemotherapy treatments solely because of age and presumed risk of severe treatment-related toxicity (40). Adjuvant

chemotherapy is not offered as often to very elderly patients (older than 75 years of age) with colon cancer compared to younger elderly patients (younger than 70 years of age) (41,42). Studies of adjuvant therapies for breast cancer suggest that women older than 65 are less likely to have breast conserving surgery, be referred to medical oncologists, and be offered adjuvant treatments (43,44,45 and 46). The aged are less likely to receive anticancer-directed therapies for many other different stages and types of cancer, as well (39).

Yet many studies suggest that the elderly tolerate at least some treatments as well as younger patients do (38,47,48,49 and 50). Despite the apparent bias against treating the very elderly with tamoxifen citrate, they tolerate its side effects better than younger patients (18). Paradoxically, the elderly may be more able to cope with some of the inconveniences and life-style changes inherent in receiving chemotherapy. They have reported less discomfort with procedures, less anxiety in medical situations, and less difficulty in adjustments in the work environment than their younger counterparts. (51).

Older patients agree as readily as younger patients to undergo trials of aggressive chemotherapy for curative or palliative purposes; however, older patients appear less willing to trade significant toxicity for increased survival time (12,52). Older patients are more likely than their younger counterparts to shift to a milder, less toxic treatment, even if survival is predicted to be shorter.

Individuals of any age who are residing in the same dwelling as their children more commonly accept aggressive treatments (53). Patients residing with their spouse do not as predictably opt for this same aggressive treatment. Patients who have previously received chemotherapy more readily accept aggressive and potentially more toxic forms of chemotherapy than treatment-naive individuals (52). This finding lends empirical support to the possibility that actual experience with chemotherapy may not be as difficult as patients' expectations of the difficulties. In one report, individual life goals and the sacrifices one is willing to accept were unpredictable across socioeconomic, religious, and cultural backgrounds (54). “Make no assumptions” remains very worthwhile advice.

QUALITY OF LIFE

QOL measurements were infrequently recorded or reported during the first four decades of modern chemotherapy trials. QOL measurements refer to a quantitative evaluation of numerous qualitative parameters that are instrumental in day-to-day enjoyment of life. As stated previously, QOL assessments are increasingly reported as independently assessed variables in clinical trials. Multiple QOL scales of varying complexity have been developed. Examples of parameters measured include pain and pain relief, fatigue, malaise, psychological distress, nausea and vomiting, physical functioning, treatment-related symptoms and toxic effects, body image, sexual functioning, memory, concentration, economic impact of the disease, and global QOL (55,56,57 and 58). These QOL inventories may be used in conjunction with the more commonly used measurements of chemotherapy-induced toxicities to better assess overall patient tolerance to the drug regimen administered (57,59,60,61 and 62).

A patient's QOL is a subjective parameter that can be misjudged by the health care provider and a patientappointed surrogate (61). Malignancy or treatment-induced debilities may be better tolerated by individuals with previous disabilities. Younger, more active patients may have significant difficulties with a functional compromise. The loss of hair for one patient may be more psychologically debilitating than a decrease in mobility for another. Each patient and situation is unique, and QOL is an experience that can change dramatically over time.

At times, logistic QOL issues as opposed to health-related QOL issues become quite important in the patient's decision to accept a chemotherapy regimen. Length of treatment, impact on family life, or travel distance to the treatment center may weigh more heavily on decisions for chemotherapy than do actual drug-related toxicities (62). A common misconception is that if a chemotherapy regimen is inducing a beneficial tumor response, then toxicities may be more tolerable to the patient. A study of 99 patients reported little difference in side effect ranking between those patients who thought they were getting better and those who thought that they were the same or worse (63). Interestingly, in this same study, nonphysical side effects of treatment, such as the inconvenience of coming for appointments, time spent in the treatment facility, difficulty parking at the clinic, and problems that treatment created for the patient's family or work environment, were frequently listed as more bothersome than physical side effects such as vomiting, nausea, hair loss, or fatigue. More research is required to define these complex QOL issues accurately. It appears prudent for the health care team not to judge the patient's level of debility or QOL.

An assumption by the health care team that a marked improvement in QOL with a slight decrease in overall survival would be in the cancer patient's best interest may be incorrect. In a study of health values of the seriously ill, patients and their self-designated medical decision-making surrogates were independently interviewed (61). The patients had a variety of chronic debilitating diseases with an anticipated median 6-month mortality rate of 50%. All patients had significant disease-related debility. Patients were evaluated for time trade-off—if they could live 1 year at their current level of function and health, how much time would they trade for a shorter survival in excellent health? Approximately one-third of the patients would not give up any time at their present level of debility in exchange for even 1 week less of life but in excellent health. At the other extreme, 9% preferred living 2 weeks or less in excellent health to 1 year in their current state of health. Only 2% of patients described their current health as no better than death. On average, only 3.2 months would be returned for the prospect of an absolutely healthy life instead of 1 year at their current state of disability. In general, patients rated their current state of health as better than did their designated surrogates. If surrogates were to make decisions for patients, those surrogates were more likely to give up survival time for improved health. This study emphasizes that patients' health values cannot be predicted accurately by others. In general, patients accept great sacrifices to live the maximum amount of time. When sequential interviews with the same patient were possible, health values increased with time—the longer the patient survived, the less likely he was to trade time alive for better health.

PALLIATIVE CHEMOTHERAPY—SPECIFIC EXAMPLES

Prostate Cancer

Which patients benefit from palliative chemotherapy, and when should it be recommended? Metastatic prostate cancer serves as an example of some of the difficulties in clinical decision making. It is usually a disease of older men, many of whom have significant comorbidities. Assessing treatment response is often difficult because most patients have metastases primarily in bone, a site in which a decrease in tumor size is difficult to prove. Reductions of more than 50% in prostate specific antigen levels correlate with improved survival and symptom control; smaller declines have not been shown to be clinically meaningful (64).

Despite these difficulties, well-designed phase III studies have shown a benefit of palliative chemotherapy in patients with hormone-refractory prostate cancer. Glucocorticoids used as a single agent are somewhat useful (65,66). Mitoxantrone hydrochloride plus hydrocortisone or prednisone yielded modest improvements in QOL measurements compared to glucocorticoid alone (67,68). Suramin with or without hydrocortisone (69) demonstrated pain improvement and delay in disease progression but with no benefit in overall QOL.

Colon Cancer

Treatment standards are rapidly evolving for patients with metastatic and recurrent colon cancer. Until recently, the combination of 5-FU plus leucovorin has been the standard treatment for this disease. Two randomized studies address the usefulness of irinotecan in patients who present with metastases or have progressive disease after standard therapy. Compared to infusional 5-FU irinotecan prolonged survival, but the relative impact on QOL was not significant (70). When irinotecan was compared to best supportive care (BSC) alone in this population, a survival benefit, as well as improvement in most measures of QOL, was observed (71). In a randomized trial in previously untreated patients, irinotecan alone was compared to 5-FU plus leucovorin and to the combination of all three agents. The triple-agent therapy significantly improved progression-free and overall survival without adversely affecting overall QOL (72,73). Preliminary data suggest that capecitabine, an orally administered fluoropyrimidine used in the treatment of recurrent colon cancer, provides a higher response rate with a more favorable toxicity profile than does 5-FU plus leucovorin (74,75).

Non–Small Cell Lung Cancer

There have been four prospectively randomized trials that compare single-agent chemotherapy versus BSC in previously untreated patients with advanced non–small cell lung cancer (NSCLC). Patients older than 70 years of age with good PS treated with vinorelbine tartrate scored better than controls on QOL function assessment scales (76). They reported fewer cancer-related symptoms, despite experiencing worse toxicity-related symptoms; there was a modest survival advantage for patients receiving vinorelbine tartrate. A large study comparing gemcitabine plus BSC versus BSC alone used QOL measurements as its primary end points (77). The gemcitabine-treated patients had significantly better QOL and reduced disease-related symptoms compared with those receiving BSC alone. The QOL improvement lasted greater than 4 weeks in 22% of the gemcitabine plus BSC patients, but in only 9% of the BSC patients; no survival advantage was noted.

Taxanes currently available for use in the United States, docetaxel and paclitaxel, have been tested in prospectively randomized trials of NSCLC patients and compared with BSC alone (78,79). The addition of paclitaxel to BSC improved median survival (by approximately 2 months), time to disease progression, and some aspects of QOL. In a similar trial, docetaxel plus BSC significantly improved clinical symptoms and had a favorable impact on overall survival, despite the low response rate of only 13%. QOL descriptors favored docetaxel, with significant improvement demonstrated for pain, dyspnea, and emotional functioning. Docetaxel has also been shown to be of palliative benefit as a second-line agent to treat NSCLC patients previously treated with platinum-based chemotherapy (79).

Breast Cancer

In the initial treatment of locally advanced or metastatic breast cancer, the benefits of hormonal therapy and chemotherapy on overall survival and QOL are proven (2,80). Less obvious are the benefits of such therapies when used after first-line therapies fail.

Because their toxicity is generally low and thus their therapeutic index is high, it is not surprising that secondline hormonal therapy can improve QOL in breast cancer patients. A study of 177 women whose breast cancer progressed on tamoxifen citrate found that responses to subsequent hormonal therapy correlated well with sustained or improved QOL (81).

The data concerning the palliative benefit of chemotherapy for breast cancer progressing after initial chemotherapy are less compelling. In 1999, Campora et al. noted that the median survival for metastatic breast cancer had not varied for 50 years, remaining in the range of 2.0–3.5 years (82). In their retrospective analysis of treatments in the pretaxane era, the likelihood of benefit of chemotherapy after failure of first-line anthracycline-containing therapy was never more than 15%.

The availability of the taxanes has changed the approach to patients with recurrent breast cancer refractory to anthracycline chemotherapy. Docetaxel has been compared to mitomycin plus vinblastine sulfate; it produces a longer time to progression, greater overall survival, and a similar impact on QOL (83). Studies comparing its palliative benefits to those of vinorelbine tartrate give mixed results. One study found that both taxanes, paclitaxil and docetaxil, were similar in benefit to vinorelbine tartrate, with the latter being less expensive (84). Another study found that docetaxel was better than paclitaxel and vinorelbine tartrate, both in alleviation of malignancy-related symptoms and cost-effectiveness (85).

Several approaches to overcome the limitations of palliative chemotherapy for recurrent breast cancer have been tried. The first approach is to use single agents sequentially rather than in combination. In a randomized trial, patients treated with single-agent epirubicin hydrochloride followed by single-agent mitomycin had similar survival but less treatment-related toxicity and better QOL, as compared with those treated with cyclophosphamide plus epirubicin hydrochloride plus fluorouracil followed by the combination of mitomycin plus vinblastine sulfate (86).

Another way to reduce treatment toxicity is to discontinue treatment after remission is achieved. This method seems less promising than the use of sequential single agents. A prospective randomized trial compared treating women with recurrent breast cancer with cyclophosphamide plus methotrexate plus 5-FU plus prednisone continuously versus the same drugs given for three cycles and then repeated for another three cycles on evidence of disease progression (87). QOL improved for both groups during the initial three cycles of chemotherapy; after that, intermittent therapy was associated with worse scores for physical wellbeing, mood, appetite, and QOL.

Finally, a herald of future therapies is the use of trastuzumab, a monoclonal antibody approved to treat metastatic breast cancer. It is targeted against HER2, a marker that is up-regulated in a minority of cases of breast cancer. In a phase III study, the effects of trastuzumab plus limited chemotherapy were compared with those of chemotherapy alone. Although the monoclonal antibody did not improve QOL scores, at least in the doses and schedules used in these studies, trastuzumab was not associated with worsening of health-related QOL (88). Another study showed a significant survival advantage from adding trastuzumab to standard chemotherapy of women whose metastatic breast cancer overexpresses HER2 (89).

Pancreatic Cancer

Finally, no discussion of palliative chemotherapy would be complete without a mention of the use of gemcitabine hydrochloride in the treatment of advanced pancreas cancer (90,91). It is important for historical as well as clinical reasons. In 1985, a three-way randomized trial had proven that neither 5-FU plus doxorubicin nor that combination plus mitomycin was better than 5-FU alone in the treatment of metastatic pancreas cancer (92). Although 5-FU remained the most commonly used treatment of advanced pancreas cancer, there were no studies showing that it prolonged survival or improved QOL. When the FDA approved gemcitabine hydrochloride for this indication in May 1996, it ushered in a new era in medical oncology. Gemcitabine hydrochloride was the first chemotherapy drug cleared for marketing by the FDA based on a unique clinical end point assessing the effect of the drug on measured disease-related symptoms; the end point is called *clinical benefit response*. No longer would response rate or survival be the only criteria of approval for chemotherapy; the importance of QOL as a legitimate end point in cancer chemotherapy could no longer be ignored.

WHEN TO INITIATE PALLIATIVE CHEMOTHERAPY

When curative therapy is not a realistic goal, as is the case in most adult metastatic malignancies, then multiple factors must be weighed regarding the time to initiate systemic anticancer therapy. The goal of palliative chemotherapy must be to relieve or prevent tumor-induced symptoms or to prolong survival.

Because any symptom caused directly or indirectly by the neoplasm can potentially be ameliorated by an effective chemotherapy regimen, patients who are symptomatic from malignancy or are expected to become symptomatic soon should be considered for treatment. Chemotherapy as the sole treatment has been used effectively to palliate emergencies such as superior vena cava syndrome, epidural spinal cord compression, or airway obstruction due to chemosensitive tumors (93,94,95 and 96). When these emergencies occur in patients whose tumors are more resistant to chemotherapy, they are more appropriately managed with a local treatment such as radiotherapy or surgery.

A difficult choice is whether to delay noncurative chemotherapy for the asymptomatic patient with low volume of disease in nonvital areas, because some tumor types may display indolent growth. These patients may experience no signs or symptoms from their malignancy for prolonged periods of time. In these circumstances, especially for cancers with low expected response rates to chemotherapy, the benefit to toxicity ratio of therapy may be more heavily weighted toward the toxicity side. Forestalling initial cytotoxic treatment then becomes an attractive alternative. Treatment can be withheld with close monitoring of the patient and initiated once symptomatic progression is evident or anticipated to occur soon.

A primary concern for this “watch and wait” approach is that a patient can move from “too well to treat” to “too sick to treat” quickly and unexpectedly. This is especially problematic if the patient desires a trial of chemotherapy. Treatment could be withheld, and then unexpected severe problems may prevent the patient from receiving chemotherapy, thus missing the elusive “window of opportunity.” The possibility also exists that a malignancy may demonstrate a decreased response to treatment with increased tumor size (97,98). Delay of chemotherapy theoretically allows for the potential development of more chemotherapy-resistant cells.

Prospective trials for most types of incurable malignancies do not permit a definite recommendation regarding whether to initiate treatment at the time of diagnosis or “watch and wait” for the asymptomatic patient. A candid discussion of options is essential in making this decision. Some patients would be psychologically distressed with a delay of therapy. If there are objective parameters to follow for tumor response to treatment, two to three courses of treatment with reevaluation for response is a reasonable approach. Treatment could continue for regressive disease or be discontinued or changed for tumor progression. If toxicities from treatment are severe, attenuation, change, or cessation of treatment are alternatives to consider. The case of stable disease is more problematic. Slowly growing tumors refractory to chemotherapy may not demonstrate apparent growth until after many months of treatments. It may be impossible to judge if the cancer is just displaying a slow growth phase or if the treatment is keeping the disease “in check.” This is especially true with the recently developed cytostatic agents that can be given individually or in combination with cytotoxic agents (99). One must be cautious when attributing stable disease to chemotherapy “response,” but clearly a cancer that is not growing or causing difficulties is better than one that is. If the treatment is not causing significant side effects, it would be reasonable to discuss with the patient the possibility of continuing the treatment until the time of disease progression versus discontinuing treatment and resuming it at the time of progression.

The decision to treat the asymptomatic patient becomes even more difficult if there is no disease that can be followed for response to treatment and the response rate to chemotherapy is relatively low. Prospective follow-up studies from baseline can then only report on disease progression. A “watch and wait” policy for the patient without symptoms or followable disease, with reservation of treatment until the disease becomes measurable or symptomatic, is one option. The other choice is a finite number of chemotherapy cycles (4–8 months), unless previous clinical trials have determined optimal duration of treatment.

SUMMARY

It is possible to develop an overall palliative chemotherapy approach to the patient with an incurable malignancy. Newer and more effective regimens that have fewer or milder toxicities and higher responses are increasingly available. Paradoxically, the most reasonable patient group for inclusion in clinical trials is comprised of those patients who present in the best health. This would include patients with ECOG PS 0–2, no cancer-related symptoms (e.g., weight loss), and few, if any, other significant comorbid medical problems. Unfortunately, this “ideal patient group” is often underrepresented in patients presenting with metastatic incurable malignancies. Patients with minimal comorbid conditions and malignancies of moderate to high sensitivity to chemotherapy should be offered an initial trial of treatment. Treatments could continue or be changed dependent on response, published data, and clinical situation. The more problematic situations are the cases with a relatively low response rate (<25%) to chemotherapy. If access to clinical trial protocols is available, they may be recommended. If trials are refused or not available, a limited duration of chemotherapy can be given. If a partial or complete response is observed and the patient's PS and QOL are stable or improving, then continuation of

treatment to best response, one or two cycles beyond best response, or even for very extended times would be reasonable alternatives. If the cancer is responding to treatment but the patient is doing poorly, with decreasing PS or QOL, the goals of these noncurative therapies must be reassessed and discussed with the patient. Stepwise attenuation of doses, prolonged intervals between chemotherapy cycles, different chemotherapy regimens, and chemotherapy-free rest and recovery intervals are alternatives to be considered. Included in the discussion of treatment options, especially with this group of patients, is the possibility of no further chemotherapy and provision of aggressive and state-of-the-art symptom management. The patient should be reassured of the physician's commitment to continued care. The physician must allay fears by reassuring both patient and family that although specific treatments may be discontinued, the patient will never be abandoned.

PALLIATIVE SURGERY

BRIAN P. WHOOLEY
ROBERT A. MILCH
JOHN F. GIBBS

It is projected that in the year 2002 there will be 1,284,900 new cases of cancer diagnosed in the United States, and 555,500 cancer-related deaths (1). Surgery continues to be the mainstay of curative treatment for most solid tumors. However, surgeons continue to see a large number of patients in their practices that either present with advanced-stage incurable malignancy or, in follow-up after primary surgical treatment, present with new or recurrent cancer-related surgical problems.

The term *palliative surgery* is not clearly defined. In the broadest oncologic sense, palliative surgery refers to surgery that is by nature noncurative. A palliative resection is generally defined as the surgical extirpation of a primary tumor without removal of all grossly identifiable disease or in the presence of positive margins. Palliative surgery also increasingly encompasses surgical procedures that are aimed primarily at the treatment of symptoms or complications associated with a tumor or its treatment. Regardless of whether the palliative nature of a surgical procedure is determined preoperatively or postoperatively, the primary aim should be the relief of symptoms, with preservation or improvement in the quality of life.

Palliative care of the cancer patient has received little attention and emphasis in the surgical literature. Miner and colleagues reviewed the literature on surgical palliation between 1990 and 1996 and noted a total of only 348 citations (2). Among these entries, consideration of pain control and quality of life were reported in only 12% and 17%, respectively, whereas consideration of morbidity and mortality and survival were reported in 61% and 64%, respectively. Moreover, utilization quality of life and symptom assessment tools for surgical patients is not infrequently flawed (2a). Until recently, comprehensive palliative care of the cancer patient has received little attention or emphasis in the surgical literature, much as the topics around end-of-life care have been largely neglected in standard surgical texts (2b,2c). The need to refocus surgeons' attention on palliative care has been highlighted by endorsement from the American College of Surgeons (3) and by the appearance of a growing number of surgical publications dealing with its many facets (3a,3b). It is also well recognized that graduate and postgraduate training in palliative care is spotty (4).

A recent survey of 420 responding members (24%) of the Society of Surgical Oncology was conducted to test the definition of palliative surgery, assess the extent of its use, and evaluate the attitudes and goals of surgeons regarding palliative surgery (5). Forty-eight percent reported having received no palliative care training in medical school, 30% reported having received no training in either residency or fellowship training in the area of palliative care, and 24% had received no continuing education in palliative care. In contrast, respondents reported an average of 21% of their cancer surgeries as palliative. The definition of palliative surgery was best defined preoperatively by 43% of respondents, based on postoperative factors by 27%, and based on patient prognosis by 30%. The most important finding in this survey was that quality of life parameters (e.g., symptom and pain relief) were identified as the most important goals in palliative surgery, with increased survival being the least important. This report emphasizes the need for prospective studies of palliative surgery that focus on quality of life measures.

Palliative care of a cancer patient involves the total care of a patient whose disease is not responsive to curative or life-prolonging therapy. The goal is to provide the best quality of life for the patient and family (5a). While this may focus on relief of pain and distressing symptoms, it also calls on the surgeon to function as part of an interdisciplinary team, addressing the multitude of physical, psychosocial, and spiritual issues facing patients and their families. Surgical intervention may be required at any time along the continuum from onset of symptoms to death. The test of a surgical procedure therefore in providing palliation is not whether there has been any effect on the underlying disease, but whether it leads to an improvement in the quality of life of the patient.

The decision to intervene surgically to achieve palliation is often a complex one, requiring superior judgment. It requires identification of the goals of care, so that the plan of course— which may or may not include surgical intervention— becomes a reasonable means to those ends. This decision requires consideration of procedure-related morbidity and mortality, which must be weighed against the morbidity of nonintervention and the anticipated survival time. The ultimate mode of death with or without surgical intervention must also be considered. The end point of intervention must always be either the relief or the prevention of symptoms. Cost analysis is also a necessity in this era of cost containment. Consideration should be given not only to the direct costs of intervention, but also to costs related to general care and the management of complications, both with and without intervention. It behooves the surgeon to avoid inappropriate interventions, particularly those that prolong the dying process. This unfortunate situation is likely to occur due to a lack of education and training in palliative care, and may be further accentuated by prevailing attitudes in society and in the medical profession that defy death and strive to prolong life.

An important component of the decision-making process in surgical palliation, particularly in the terminal phase of illness, is the estimated survival time. Physicians, however, are notoriously poor prognosticators. Christakis et al. prospectively analyzed the ability of 343 doctors to estimate survival time in 468 terminally ill hospice patients, 65% of whom had cancer (5b). They noted that predictions of survival were overoptimistic in 63% of cases, and that the physicians overall overestimated survival time by a factor of 5.3. The tendency of doctors to make prognostic errors was lower among experienced doctors. This undue optimism about survival prospects may have negative implications for patient care, including an overenthusiasm for surgical intervention and a tendency for late referral to hospice care. Models of prognostic indices have been developed for clinical research that have been shown to predict short-term survival reasonably well. In practice, however, there are general guidelines for determining prognosis in advanced malignant disease that surgeons need to be familiar with. The functional status of the patient is the single most important predictive factor (Table 51-1).

	Median survival time
Performance status (Karnofsky ≤50 or Eastern Cooperative Oncology Group ≥3)	3 mo
Chemotherapy related	
Disease progression after 2 cycles of chemotherapy	<6 mo
Untreated metastatic solid cancers, acute leukemia, high-grade lymphomas	<6 mo
Tumor related	
Hypercalcemia (except newly diagnosed myeloma or breast cancer)	8 wk
Pericardial effusion	8 wk
Leptomeningeal carcinomatosis	8–12 wk
Multiple brain metastases	
With radiation	6 mo
Without radiation	1–2 mo
Malignant ascites or pleural effusion	<6 mo
Abdominal carcinomatosis	3–6 mo

TABLE 51-1. GENERAL GUIDELINES FOR DETERMINING PROGNOSIS IN ADVANCED MALIGNANT DISEASE

The other key element of the decision-making process in surgical palliation is the extent of the surgical procedure. The range of surgical procedures is outlined in Table 51-2. Supportive procedures (e.g., insertion of a vascular access device) are generally well tolerated, particularly those that are performed under local anesthetic. On the other end of the spectrum is palliative resection, which may be associated with high morbidity and mortality. Patients presenting with more advanced disease or with residual disease at completion of surgery are not anticipated to do as well postoperatively compared to patients who undergo curative resection. Patients undergoing palliative procedures generally have poorer performance status. With postoperative mortality rates of 10% and morbidity rates as high as 25% commonly

reported in the palliative surgical literature, it is imperative that adequate measures of palliation be defined. It is essential that the morbidity of the surgical procedure should not exceed that of the disease. This is why it is imperative that quality of life outcomes be evaluated by improved research methods.

Palliative (intervention as treatment)
Drainage of effusions
Ascites
Pleural
Pericardial
Obstruction
Respiratory
Gastrointestinal
Genitourinary
Vascular
Tumor resection
Toilet procedure
Bleeding
Fistulas
Supportive (multidisciplinary role)
Tissue sampling
Vascular access
Nutritional support

TABLE 51-2. TYPES OF PALLIATIVE SURGICAL PROCEDURES

In this chapter we discuss the role of palliative surgery in the management of gastrointestinal malignancies that are most commonly encountered by general surgeons and surgical oncologists. Surgical procedures are emphasized whose primary aim is treatment of symptoms and complications.

GASTROINTESTINAL TUMORS

An estimated 250,600 new cases of gastrointestinal (GI) cancers will be diagnosed in the United States in 2002 (1). Taken together, gastric, pancreatic, and colorectal cancers account for 79% of the total. The majority of these patients will not be cured and will ultimately die of their disease. Colorectal cancer is the second leading cause of cancer death in the United States, with an estimated 56,600 deaths annually. Pancreatic cancer is the fifth leading cause of cancer death, with an estimated 29,700 deaths annually, whereas gastric cancer accounts for an estimated 12,400 deaths.

Symptoms and Complications

The usual presenting symptoms and complications requiring palliative surgical intervention for patients with gastric, pancreatic, and colorectal cancer are detailed in Table 51-3. Pain is a particularly distressing symptom for patients with GI malignancies and generally is indicative of local and perineural invasion. Lillemoe noted that 37 of 137 patients with unresectable pancreatic carcinoma reported significant pain (5c). Hudis reported similar data, with 37 of 77 pancreatic cancer patients having moderate to severe pain at the time of initial referral (5d). The majority were considered to have pain secondary to extensive local disease. Locally advanced rectal cancer also commonly presents with pain because of invasion of the pelvic floor, sacral plexus, or nerve roots. Moran and colleagues reported significant pain at presentation in 37 of 125 patients who underwent palliative resections for rectal cancer (5e). Longo and coworkers reported significant rectal or pelvic pain in 12 of 103 patients with advanced rectal cancer (5f).

Pain
Gastrointestinal obstruction
Biliary obstruction
Hemorrhage
Perforation
Malignant ascites

TABLE 51-3. INDICATIONS FOR PALLIATIVE INTERVENTION

Patients with advanced-stage GI malignancies can present with bowel obstruction. Meijer and coworkers at Free University Hospital in Amsterdam reported on a consecutive series of 204 patients with gastric carcinoma (6). Twenty-six patients underwent a palliative resection, and obstruction was the primary presentation in 14 of these patients. An additional 25 patients were unresectable and underwent a palliative bypass gastrojejunostomy.

Obstruction can also be seen as the primary presentation of advanced-stage colorectal cancer. Garcia-Valdecasas and colleagues reported on a series of 53 patients with colorectal cancer who presented with obstruction over a 4-year period (7). Tumor staging was significantly more advanced in these patients compared to 135 patients with colorectal cancer who underwent elective operation over the same time period (34% Dukes stage D versus 17%). Similarly, Gandrup and colleagues reported that 59 of 156 consecutive patients who were operated on for obstructing primary colorectal cancers were unresectable and required either a bypass or a diversion procedure (8).

Extensive intraperitoneal disease can also lead to GI obstruction requiring surgical intervention. Turnbull reviewed 356 patients who presented over a 9-year period to Memorial Sloan-Kettering Cancer Center with obstruction and who previously had undergone surgery for an intraabdominal cancer (9). He identified 89 patients who had obstructing carcinomatosis confirmed at operation and noted that the tumor originated in the colon in 59 patients and in the stomach in 19 patients.

GI hemorrhage may also be seen as a complication in patients with GI tumors. Moreno-Otero and coworkers reviewed 427 patients with gastric cancer and reported 36 who presented with acute upper GI bleeding (10). Fox et al. reported that gastric malignancy was the cause of bleeding in 35 of a consecutive series of 2260 patients (1.5%) treated for upper GI hemorrhage (11).

Bleeding is a common symptom of advanced rectal cancer. In a review of 103 patients with advanced rectal cancer, Longo and colleagues reported that bleeding was the most common presenting symptom, occurring in 45% of patients (5). Similarly, Bordos reviewed 34 patients who underwent palliative abdominoperineal resection and noted that bleeding was a presenting symptom in 74% (12).

Perforation is a less common complication of advanced GI cancers. Free perforation of gastric cancer is rare and occurs in 0.9–4.0% of cases (13). Starnes reviewed colorectal emergencies treated at Memorial Sloan-Kettering Cancer Center over a 5-year period and reported only six patients with spontaneous perforation of a carcinoma (14).

Malignant ascites is a serious complication and portends an extremely short life expectancy. It occurs at a rate of 10–15% with carcinoma of the stomach, pancreas, and large intestine (15). These patients are often very symptomatic because of GI and respiratory compromise associated with markedly increased intraabdominal pressure. Effective palliation of malignant ascites remains a difficult problem. Peritoneovenous shunts were introduced in 1974 by LeVeen and coworkers for the palliation of intractable ascites (16). Early concerns about post-shunt coagulopathy and disseminated metastases appear unfounded, and these complications are rare in clinical practice. In 1992, Gough and colleagues in a prospective but nonrandomized study reported on 47 patients who were palliated with shunts (17). The shunt controlled malignant ascites in two-thirds of patients, but there was no difference in survival or quality of life when compared to patients who were treated by repeated paracentesis without surgical intervention. However, a report by Schumaker and colleagues reported on 116 shunts in 89 patients and determined that the shunts were associated with substantial morbidity and mortality and a brief and only fair relief of symptoms (18). Specifically, shunt-related complications occurred in 49% of cases. Perioperative mortality was 43%, and the authors considered that 13% was directly related to shunt-associated complications. In addition, flow had stopped in 50% of shunts within 30 days. This controversy can only be resolved by a prospective randomized trial.

Specific Tumor Sites

Gastric Cancer

The incidence of gastric cancer, which had been on the decline for many decades, plateaued during the last two decades. Nonetheless, gastric cancer continues to be a significant public health problem. An estimated 21,600 new cases will be diagnosed in the United States in 2002, with an estimated 12,400 deaths (1). The high mortality associated with gastric cancer is related to both the advanced stage of the disease at presentation and also to a lack of effective adjuvant therapies. As a result, the majority of patients with gastric cancer require some form of palliative surgery during the course of their illness. Determination of resectability frequently requires assessment at laparotomy or laparoscopy, and approximately 85% of patients undergo surgical exploration. At laparotomy, approximately half of the patients will be resected; of these, approximately 40% are considered palliative at the outset (19).

Obstruction

Many authors suggest that, when technically feasible, gastric resection offers the best palliation of symptoms and other complications caused by the neoplasm (6,19,20). Resection relieves symptoms of obstruction, contributes significantly to improving quality of life, and may also give some survival benefit (6,21). Figure 51-1 outlines an approach to gastric outlet obstruction due to obstructing gastric cancer.

FIGURE 51-1. Treatment algorithm for gastric outlet obstruction due to an obstructing gastric cancer. 5-FU, 5-fluorouracil; dx, diagnosis; mets, metastases; RT, radiation therapy; tx, therapy.

The early Memorial Sloan-Kettering Cancer Center experience, reported by El-Domeiri and colleagues in 1972, noted that of 80 patients who underwent palliative resections, 9% experienced good palliation until their demise and 76% achieved satisfactory palliation for an average duration of 6½ months (22). Meijer and coworkers reported on 26 patients with stage IV disease who had palliative resections, including 14 total and 12 subtotal gastrectomies. Obstruction and pain were the major symptoms in 20 of the patients. Fifty percent had good palliation of symptoms, whereas a further 27% had moderate palliation (6). The Norwegian Stomach Cancer Trial reported in 1989 was a prospective but nonrandomized trial, and included 1165 patients with stomach cancer, of whom 182 were recorded as undergoing a palliative resection (21). Having stratified patients according to age, debility, and stage of disease, they identified operative treatment (resection versus nonresection) as an independent prognostic determinant of survival by multivariate analysis. In all of these studies, the reported morbidity and mortality rates for curative and palliative resections are comparable. Five-year survival rates of 6–12% may be realized in these patients (19).

For most lesions a subtotal gastrectomy without an extensive lymphadenectomy is preferable. The role of total gastrectomy in this setting is controversial. In the past, palliative total gastrectomy and esophagogastrectomy, particularly for proximally located tumors, were discouraged due to a prohibitively high perioperative mortality rate (ranging between 20% and 30%), and also because there was a suggestion that the quality of life of survivors was reduced (20). However, with improvements in surgical techniques and postoperative care, total gastrectomy has been increasingly performed for palliation. In some series total gastrectomy comprises as many as one-third of cases. In 1991, Monson et al. retrospectively reviewed the Mayo Clinic experience with 53 consecutive total gastrectomies for advanced disease (23). Operative mortality was 8%, and a median survival of 19 months and good or satisfactory quality of life was achieved in 87% of patients. Butler and coworkers in 1989 described 27 patients who underwent total gastrectomy for palliation of advanced gastric cancer, with an operative mortality of only 4%, and the median survival was an impressive 15 months (24). Twenty-five of 26 patients left the hospital tolerating a solid diet. Total gastrectomy is also the operation of choice for linctus plastica.

When advanced local disease is discovered at operation, with invasion of adjacent organs, an *en bloc* resection is indicated in good-risk patients. In the Norwegian Stomach Cancer Trial, 182 patients had palliative resection. Fifty-nine percent of these patients also underwent splenectomy; resection of the pancreatic tail, transverse colon, and liver was added in 7%, 4%, and 2%, respectively (21). In a patient care study conducted by the American College of Surgeons and reported in 1993, 13,295 patients with gastric cancer were treated surgically (25). Extragastric extension was documented in 38% of patients and required an extended resection. Organs involved included the colon (3%), omentum (14%), spleen (2%), pancreas (2%), and esophagus (17%).

In patients with gastric outlet obstruction secondary to an unresectable tumor, a bypass gastrojejunostomy may be performed. However, this procedure is not without risk. Ekbom reviewed 20 patients who underwent palliative gastrojejunostomy and reported a 25% mortality and a 20% incidence of GI complications postoperatively (26). Eighty percent of survivors obtained relief of preoperative symptoms for a mean interval of 5.9 months and no patient was alive at 1 year. Similarly, Bozzetti reported a 10% mortality rate for 80 patients who underwent palliative gastrojejunostomy; the median survival after bypass was 3.5 months (19). Delayed gastric emptying (DGE) is a significant problem in as many as 20% of these patients (27). The factors that contribute to DGE include infiltration of the gastric wall by tumor, disturbance of autonomic function, and the frequent inability to place the stoma in a dependent position on the stomach. An alternative to gastrojejunostomy is the Devine antral exclusion procedure. The stomach is transected just proximal to the tumor and a jejunal loop is anastomosed to the proximal stomach. Kwok reported on 20 patients with unresectable antral carcinomas that were locally advanced and infiltrating the head of pancreas or the porta hepatis (28). All were treated by antral exclusion. There was no hospital mortality, and 17 patients were able to tolerate a diet until their demise. Patients with gastric outlet obstruction who are not candidates for surgical intervention because of associated medical risks may be palliated by percutaneous endoscopic gastrostomy tube drainage. This can also be converted to a jejunostomy tube for the delivery of enteral nutrition. Alternatively, some patients may be suitable for endoscopic placement of a stent across the obstruction (29).

For unresectable tumors of the cardia, the management options include endoprosthesis placement, endoscopic laser ablation, radiotherapy, or surgical bypass. Endoscopic endoprosthesis placement has a reported mortality rate of 15–45% and a 10% perforation rate (30). Other complications include blockage and displacement. Series using improved stents report lower risks of complications and mortality (31). Nd:YAG laser ablation is safe and particularly suited to exophytic lesions involving the distal esophagus. The ability to swallow liquids and semisolids is restored in 60–90% of patients, but repeated treatment may be required to maintain patency (32). Radiation treatment has also been used with comparable success (33). Surgical bypass is performed by anastomosing a Roux limb of jejunum to the distal esophagus above the level of the tumor. Good palliation has been reported (34).

Hemorrhage

Acute GI hemorrhage is an uncommon presentation of gastric cancer. The diagnosis is made by early endoscopy but is frequently difficult to control endoscopically. Loftus and colleagues reported on the Mayo Clinic experience with 15 gastric cancer patients who underwent endoscopic therapy for acute major upper GI hemorrhages (35). They noted that 13 of the 15 patients continued to bleed after treatment. Moreno-Otero reported on 36 patients presenting with bleeding gastric cancers (10). The bleeding was selflimited in 44%, but persistent or massive in 56%. Early emergency surgical intervention in the latter group was associated with a 23% mortality. Cheung and Branicki in 1991 reported on 52 patients, of whom 30 underwent elective and 14 underwent emergency surgery (36). The mortality rate for emergency surgery was 42.9% compared to 13.3% for elective surgery. The authors attributed the high mortality rate for emergency surgery to delay in operative intervention. Patients with a self-limited hemorrhage should have early elective surgical intervention, whereas patients with persistent bleeding should have early emergency surgery. A palliative resection is performed when feasible.

Perforation

Free perforation of gastric carcinoma is rare. It occurs in an ulcerated tumor and is usually associated with advanced stage of disease. In older series simple closure of the perforation was performed in the great majority of cases, but was associated with a mortality rate as high as 68% (37). Recently, Gertsch et al. reported on 34 perforated gastric cancers. Eighty-eight percent of patients underwent emergency gastrectomy and 88% had stage III or IV tumors. The 30-day mortality was 16% in

the resected group and the median survival was 10 months (13). Therefore, optimal palliation is achieved by early surgical intervention and by palliative resection when feasible.

PANCREATIC CANCER

An estimated 28,000 new cases of pancreatic cancer occur each year in the United States (38). The incidence appears to be increasing, with most cases occurring in the seventh or eighth decade of life. Over 25,000 deaths per year are due to the disease, making it the fourth leading cause of cancer-related mortality, surpassed only by lung, colorectal, and breast cancers. The prognosis is bleak, with an overall 5-year survival of 2–3%. Surgical resection offers the only prospect of cure. However, symptomatology is often vague, and the majority of patients present with advanced disease, which precludes potentially curative therapy (39,40).

Despite recent advances in pancreatic imaging (41,42 and 43) and the development of nonoperative techniques for the relief of biliary obstruction, the majority of patients still require an exploratory laparotomy for accurate staging and palliation (44). The most common indication for palliative intervention in this group of patients is for biliary or gastric outlet obstruction. For those who do not require a palliative procedure, exploration does not confer any benefit, and is associated with significant morbidity and mortality affecting both the quality and duration of survival (44,45).

Biliary Obstruction

Between October 1983 and October 1995, 1528 patients were admitted to Memorial Sloan-Kettering Cancer Center with a diagnosis of invasive adenocarcinoma of the pancreas. Of these, 40% were jaundiced and 28% had undergone some form of biliary drainage procedure before presentation.

For patients with an unresectable pancreatic tumor, the ideal palliative procedure for biliary obstruction should be effective in relieving jaundice, have minimal morbidity, be associated with a short hospital stay, have a low symptomatic recurrence, and maintain quality of life. In recent years there has been a trend toward nonoperative biliary drainage by either endoscopic or transhepatic routes (44,46,47,48,49,50,51,52 and 53). Randomized trials have demonstrated a reduced hospital stay and similar early morbidity and mortality with endoscopic stent placement compared to surgical bypass (54,55). However, long-term complications appear to increase, with recurrent jaundice due to occluded or dislodged prosthesis and cholangitis occurring in between 13% and 60% of cases (46,47,50,56). In patients who are expected to live longer than a few months, these complications make endoscopic palliation less than optimal.

Before the advent of minimal access surgical procedures, open surgical drainage was the only other palliative option. Surgical drainage provides excellent relief of jaundice (45,57). Despite extensive controversy in the literature (44,45 and 46,48,57), both choledochoenteric and cholecystoenteric bypasses, if selected appropriately, have similar results with regards to reducing serum bilirubin. In a recent analysis of our experience, we were unable to demonstrate any difference between these two methods of biliary diversion (45). Both procedures were associated with considerable morbidity, with complications occurring in 18%. Others have reported similar figures (44,57). It is our clinical impression that, particularly after a complicated postoperative course, some patients never regain their preoperative performance status and commence a slow, inexorable slide in their quality of life until death.

Minimal access surgery offers a new approach to this problem (58,59,60 and 61). In theory, the reduced operative morbidity in combination with a surgical drainage procedure would be of benefit to the patient expected to live longer than a few months. Figure 51-2 details our current approach to the jaundiced patient with a peripancreatic mass.

FIGURE 51-2. Management of the patient with a peripancreatic mass who presents with jaundice. byp, bypass; CT, computed tomography; ERCP, endoscopic retrograde cholangiopancreatography; Lap, laparoscopy; PTC, percutaneous transhepatic cholangiography.

Gastric Outlet Obstruction

The role of prophylactic gastroenteric bypass in the management of patients with unresectable pancreatic cancer is controversial (45). Only 5% of patients have signs and symptoms of gastric outlet obstruction at the time of presentation; of the remainder, 8–28% subsequently develop this complication if a gastric bypass has not been performed at the time of the initial operation (62,63 and 64). Because of this risk and subsequent need for further surgery, many authors have liberally advocated the use of gastric bypass at the time of initial exploration. Proponents of this approach contend that the mortality of the initial surgical procedure is not increased by the addition of a gastroenteric bypass (63,64 and 65).

In contrast, some authors have reported a high mortality and morbidity, including an increased rate of DGE in patients undergoing gastrojejunostomy, resulting in poor palliation and prolonged hospitalization (45,66,67,68,69 and 70). Jacobs and colleagues reported a 29% incidence of DGE in patients who underwent both gastric and biliary bypass, whereas no DGE occurred in the group undergoing biliary bypass alone (69). Welvaart noted that DGE occurred in 67% of 37 patients undergoing both biliary and gastric bypass (70). A retrospective review from this institution of 297 patients with unresectable disease demonstrated that a prophylactic gastric bypass was associated with a significantly increased morbidity without improving survival (45). Only 3 of 38 patients who did not receive a gastroenteric bypass at their initial procedure required one subsequently. In all cases, duodenal obstruction was a preterminal event.

Currently, we reserve gastric bypass for the subset of patients who are symptomatic at presentation. We believe that to determine objective criteria for the selection of patients who would benefit from a prophylactic gastric bypass, a prospective randomized trial is required. In general, we consider those patients who present with obstruction subsequent to their initial presentation, or after therapy (i.e., after resection with recurrent disease) (Fig. 51-3) as good candidates for a gastric bypass, either by the open approach or laparoscopically. The relative merits of one method versus another remain to be determined. In the group of patients in whom gastric outlet obstruction is but one manifestation of their terminal illness, supportive care measures alone are instituted. It is important to identify this group of patients so as to avoid unnecessary pain and suffering.

FIGURE 51-3. Management of colorectal obstruction. mets, metastases; tx, therapy.

Pain

Abdominal or back pain is a major symptom in a significant proportion of patients with unresectable or recurrent pancreatic cancer. Often this is poorly managed, leading to distress and resulting in a major diminution in the patient's quality of life. The primary modalities in the management of pain remain pharmacologic and percutaneous celiac axis blockade. In patients undergoing surgery, however, intraoperative chemical splanchnicectomy should be considered. Celiac plexus blockade has been demonstrated to be effective in providing pain relief from a variety of GI malignancies (71). In 1969, Copping and colleagues first reported the technique for the relief of upper abdominal pain due to pancreatic cancer (72). Recently, Lillemoe and coworkers from the Johns Hopkins Hospital reported a prospective, randomized, double-blind study that compared intraoperative chemical splanchnicectomy with 50% alcohol to saline injection (2). The group receiving the chemical block had significantly reduced pain scores. Those patients without pain at the time of surgery had a significantly delayed onset of pain. In addition, patients with preexisting pain who received the alcohol blockade had improved survival compared to the control group. This exciting study awaits confirmation. Nonetheless, patients with pain who undergo an operative procedure should be considered for a chemical splanchnicectomy.

COLORECTAL CANCER

An estimated 148,300 new cases of colorectal cancer will occur in 2002 in the United States (107,300 colonic and 41,000 rectal) (1). The overall 5-year survival is approximately 50%. This survival statistic has not changed significantly over the past 20 years. One-third of patients are known to be incurable at presentation because of the presence of extensive local-regional or distant metastatic disease. When patients present with complications of advanced disease, or when patients present with recurrence of disease, an aggressive surgical approach is warranted in properly selected patients. The type of palliative procedure performed depends on the symptomatology, tumor location, and performance status of the patient.

Obstruction

Figure 51-3 outlines our approach to malignant colorectal obstruction. Apart from the patient whose colonic obstruction is a preterminal event, the majority of patients are eligible and benefit from some form of surgical procedure.

Approximately 20% of patients with colorectal carcinoma present as emergencies, most commonly obstruction (73). Gandrup reported that 95 of 156 consecutive patients operated on for obstructing colorectal cancers had advanced disease (Dukes stage C and D) (8). Ninety-seven patients had the obstructing lesion resected, with a 30-day mortality of 5%. Fifty-nine patients had palliative nonresective operations (diversion or bypass), and in 39 patients the tumor was completely unresectable. Complication rates were lower in patients who had primary resection of the tumor.

Patients who present with locally advanced or recurrent disease that is resectable are preferably treated by palliative resection, provided that there are no medical contraindications to resection and that they do not have widespread disease or very limited life expectancy (74).

The management of the patient with obstruction secondary to widespread recurrence or carcinomatosis is a particularly challenging problem. Most patients are initially treated with a trial of tube decompression. Turnbull and colleagues reviewed the Memorial Sloan-Kettering experience of 144 patients with obstructing carcinomatosis (9). Fifty-five patients with presumed carcinomatosis were treated conservatively. The remaining 89 patients required exploration. Fifty-nine patients had a colonic primary. Enteric bypass was the most common surgical procedure performed. Forty-eight of the 59 colon cancer patients (81%) were improved after surgery, and the mean duration of functioning bowel was 115 days. Lau reported similar results with 30 patients who underwent laparotomy for advanced unresectable, recurrent colorectal cancer (75). Normal bowel function was restored in 19 patients. The types of surgery performed included colonic bypass in 14 patients, resection in four, and defunctioning colostomy in four. For patients in whom either resection, diversion, or bypass is not an option, the permanent placement of a long intramural decompressive tube passed across the abdominal wall is an option. McCarthy reviewed 12 patients treated by this procedure and reported that 6 patients left the hospital and were capable of fluid ingestion (76).

Patients with widespread disease, at high risk for operative intervention, or with life expectancy less than 4–6 weeks can often have their bowel obstruction successfully managed nonoperatively. This includes the judicious (and frequently unnecessary) use of nasogastric intubation and intravenous fluids and aggressive pharmacologic approaches, including anticholinergics, antiemetics, antisecretagogues, steroids, and opiates (77,78).

Surgical Palliation of Rectal Cancer

Palliation of advanced rectal cancer requires special consideration. Locally invasive rectal cancers can present with complications of pain, hemorrhage, and ureteral obstruction (12). Pain can be a very debilitating problem for these patients. Deland wrote in 1936 (79), “There is hardly a more miserable man alive than the one with advanced rectal cancer.” Not infrequently, with sphincter muscle invasion, these patients also suffer from incontinence. The preferred palliation, if feasible, is surgical resection.

For low-lying lesions within 5 cm of the anal verge, an abdominoperineal resection is appropriate. Bordos and colleagues reported on their experience with 34 patients who underwent palliative abdominoperineal resection (12). The postoperative mortality was 3%, which was the same as for curative resection. Local symptoms were initially relieved in all patients undergoing palliative resection. More than half of these patients survived for 1 year, at which time less than onefourth had perineal symptoms related to recurrent tumor.

For lesions further than 5 cm from the anal verge, a low anterior resection with primary anastomosis is appropriate. Several authors have confirmed that primary anastomosis is safe deep in the pelvis, even in the presence of residual disease, with a low incidence of anastomotic leakage or recurrence with obstruction. In 1987, Moran et al. reported on 57 patients who had palliative low anterior resection and observed only one colonic obstruction secondary to local recurrence and one anastomotic leak (5e). Longo and coworkers in 1988 described 33 patients who had palliative low anterior resection and reported one patient (3%) who required reoperation because of an anastomotic leak and two patients (6%) who developed colonic obstruction because of recurrent disease (5f). If there are any concerns about the safety of performing a primary anastomosis, a Hartman's pouch and end colostomy is an alternative. A multimodality approach using either preoperative or postoperative radiotherapy might also be indicated.

It is important to differentiate a subgroup of patients with locally advanced colorectal cancer and infiltration of adjacent organs who otherwise have no other evidence of regional or distant metastases. This subgroup of patients, comprising approximately 10% of patients with locally advanced cancer, are node-negative and have a biologically indolent tumor. By extended *en bloc* resection, provided that negative resection margins are obtained, these patients can be potentially cured (80).

For patients who are found to be unresectable at laparotomy, a diverting colostomy may be required. However, the palliation achieved is inferior to that of resection. Incapacitating local symptoms of pain, tenesmus, incontinence, and hemorrhage commonly develop before the patient's demise. In the series reported by Moran, there were 17 diverting colostomies and the median survival was 6.4 months (5e). There were 28 diverting colostomies in the series reported by Longo. Postoperative mortality was 3.8% and the median survival was 5 months (5f).

In high-risk patients who are deemed unfit for major palliative resection of advanced rectal cancer, transanal excision may be an option. For lesions below the peritoneal reflection, electrodesiccation through an anoscope may be performed (81). Nd:YAGq laser therapy has been reported to achieve effective palliation in debilitated patients with disseminated disease (82). Eckhauser reported on 24 patients with unresectable rectal cancer who were palliated by endoscopic laser therapy (83). Seventeen patients presented with obstruction and seven with bleeding. Successful palliation and improvement in quality of life was achieved in all patients. The median survival was 15 months.

Surgical Palliation of Local Recurrence

Local recurrence occurs in 10–40% of colorectal adenocarcinomas treated for cure, and most appear within 2 years of surgery for the primary lesion (74). These local recurrences represent initial inadequate resection and occur in the pericolic fat and mesentery (84). Untreated, prognosis is poor and death is usually rapid—either from continued local extension, with the development of bowel or urinary obstruction, sepsis, perforation or bleeding, or as part of a disseminated disease pattern (85). Palliation of intractable pain and prevention and treatment of these complications are clear-cut indications for operative intervention, and often improve quality of life for these patients. These recurrent tumors often involve contiguous structures and require extended surgical resection. Pelvic exenteration has produced significant palliation and extended survival in some selected patients. Brophy et al. in 1994 reported on 35 such patients treated by pelvic exenteration for symptom palliation. Operative mortality was 3%, and overall morbidity was 47%. Quality of life was improved in 88% and median survival was 20 months (86).

SUMMARY

The challenges to the surgeon caring for the terminally ill patient are great: understanding the disease in the context of the illness, application of his/her skills of judgment and technique under difficult circumstances, and functioning as part of a team whose goals are those of the patient and family in maintaining comfort and quality of life as best as possible. But as the challenges are great, when done well, so too are the rewards.

PALLIATIVE ORTHOPEDIC SURGERY

FRANK J. FRASSICA
DEBORAH A. FRASSICA
DAVID J. JACOFSKY
FRANKLIN H. SIM

Metastatic bone disease is a common cause of destruction of the adult skeleton. Bone is the third most common site of metastatic disease after the lungs and the liver. Carcinomas of the breast, lung, prostate, thyroid, and kidney frequently metastasize to bone and constitute approximately 600,000 new cases each year (8). Due in large part to the venous flow in Batson's plexus, the areas commonly involved include the vertebra, pelvis, ribs, skull, and proximal long bones. Lung carcinomas have access directly into the pulmonary vasculature and these cancers may spread to distal portions of the skeleton such as the hands and feet. There are many significant problems that the cancer patient may face once osseous metastases have occurred. These problems include pain and the inability to walk or even sit upright. Fractures are very significant as the patient experiences intense pain and the affected limb becomes virtually useless until the fracture is fixed. Progressive lesions in the spinal column may lead to very grave sequelae such as paralysis of the limbs, intractable neurogenic or mechanical pain, and loss of bladder and bowel function. Clinicians who care for patients with metastatic bone disease must strive to control pain and maintain the independence of their patients. The surgeon, medical oncologist, and radiation oncologist are the clinicians who have the greatest impact on achieving these goals. Control of metastases to bone can markedly improve the quality of life for these patients and their families.

CLINICAL PRESENTATION AND EVALUATION

There are two main presentations of metastatic bone disease (6). The first involves patients with a known history of cancer who develop metastatic bone disease, and the second is when the metastatic bone lesions herald the presence of an unknown primary cancer. The evaluation strategy employed to elucidate an unknown primary site in the second scenario is beyond the scope of this chapter. However, the evaluation and treatment of the bone metastases is identical for both clinical scenarios.

Patients with bone metastases present with pain over 75% of the time (15). The pain may be secondary to bone destruction or structural insufficiency, or from direct neurological compression. Pain from bone destruction often begins as an intermittent pain and then progresses to a constant discomfort. The pain is usually deep seated and “achy” in nature. Most patients quantify the pain as severe to unbearable. Weight-bearing pain in the lower extremities is common, and this historical finding should be sought when interviewing patients. The weight-bearing component may be so significant that patients initially resort to self-prescription of gait aids such as crutches or a cane. Eventually, each step causes such discomfort that the patient ceases to ambulate. Weight-bearing pain is a harbinger of pathological fracture. When such symptoms are noted, radiographs should be obtained without delay to assess the structural integrity of the pelvis and long bones. Pain from nerve root compression may be very difficult to recognize. The pain may be very diffuse and may or may not follow a radicular pattern. Dysesthetic pain from nerve root compression due to spinal metastases is often burning in nature and severe. Compression of sensory nerves in the thoracic spine may give a very diffuse pattern, whereas cervical or lumbar root compression often follows characteristic radicular patterns. Motor weakness is a common finding with significant lesions. Compression of the spinal cord may result in long track signs such as spasticity, hyperreflexia, and an unsteady gait. Thoracolumbar nerve compression may result in compression of the cauda equina (the nerve roots within the thecal sac distal to the end of the spinal cord). Patients may have very subtle loss of bowel and bladder function such as overflow incontinence, constipation, and difficulty voiding or defecating.

The clinician must carefully query the patient with a history of cancer and bone pain. When suspicious, the clinician has a variety of imaging modalities to use, including plain radiographs, technetium bone scans, computerized tomography scans, and MRI scans.

Plain radiographs are the most useful of radiographical studies. Plain radiographs should be obtained in both anteroposterior and lateral projections of long bones. When evaluating potential pelvic and lumbosacral spine lesions, an anteroposterior view of the pelvis and anteroposterior and lateral views of the lumbosacral spine should be obtained. It may be very difficult to localize the site of a pelvic or lumbar spine lesion. The radiographs should be carefully inspected for sites of cortical bone destruction. The findings may be subtle, so the clinician should carefully study every cortex.

If the plain radiographs are normal or only show degenerative changes, the clinician must search further. Normal plain radiographs in a patient with a history of cancer and bone pain are not sufficient to exclude the possible presence of metastatic bone disease. Up to 30–50% of “bone stock” may be destroyed before the appearance of obvious roentgenographic findings. The technetium bone scan is an excellent modality to search for an unknown location of metastatic bone disease or to evaluate the entire skeletal system for bone metastases. The sensitivity is extremely high (well over 90%) but the specificity is low. False-negative technetium bone scans may occur in patients with multiple myeloma, very early metastatic bone disease, malignant melanoma, metastatic squamous cell carcinoma, and in very rapidly destructive lesions such as lung and renal cancer. Patients may have increased uptake at sites of degenerative disease in the spine, shoulders, and knees, or in areas of previous trauma such as the ribs or extremities. Patients should never be told that they have diffuse bone metastases based on the technetium bone scan alone. Plain radiographs of areas of increased uptake are obtained and correlated with these nuclear medicine studies. With these two modalities, one can often make the correct diagnosis and plan treatment.

MRI is an excellent modality to characterize the bone marrow in a patient with increased uptake on the technetium bone scan and no or equivocal findings on the plain radiographs. The most useful imaging sequences are the coronal T1 and inversion recovery images. Metastatic lesions typically have low signal intensity on T1 weighted images and high signal intensity on T2 weighted images. When the clinician reviews the images with the radiologist, he or she should know the age of the patient, whether the patient is a smoker, and whether the patient has had chemotherapy. With a high-quality MRI scan, one can usually make the definitive diagnosis of metastatic disease. Computerized tomography scans are less useful in establishing the diagnosis of metastatic disease, as the marrow cannot be adequately studied. However, computerized tomography scans can be very useful for surgical planning in the spine and pelvis as very accurate determinations of cortical bone destruction can be made. Due to its excellent osseous detail, this modality is often of great value in ruling out subtle fractures.

TREATMENT OF METASTATIC BONE DISEASE

There are four principles in the treatment of patients with metastatic bone disease: (a) provide analgesia, (b) prevent progression of bone destruction, (c) prevent or treat fractures, and (d) maintain independence of the patient. The first two principles are intimately linked together. The pain in metastatic bone disease is usually caused by the bone destruction. When the clinician identifies the site of involvement, then treatment should begin. External beam irradiation and opioid analgesics are very effective in halting the bone destruction and controlling pain. Patients should also be evaluated by their medical oncologist for consideration of systemic treatment. Systemic treatment with hormones, cytotoxic chemotherapy, or a bisphosphonate may halt the bone destruction. Patients with breast carcinoma and multiple myeloma may have significant reconstitution of the skeleton with a combination of chemotherapy and bisphosphonate treatment.

SURGICAL TREATMENT

Surgery plays a valuable role in patients with metastases to bone. Prophylactic stabilization as part of the treatment of long bone lesions and decompression with stabilization of the spine are among the most common procedures performed. Operative management can immediately improve pain, allow mobilization, and increase independence and quality of life. Operative management can be conveniently divided into three groups: treatments of long bone lesions, pelvic lesions, and spine lesions. The goals of treatment at each of these sites are the same—pain relief and mobilization, achieved through immediate rigid fixation for stabilization and postoperative external beam irradiation to prevent progression.

The most common sites that require fixation are the femur and humerus. Other long bones that occasionally require operative intervention include the tibia, ulna, and radius. Clinicians are often required to assess a particular long bone lesion as to the need for prophylactic fixation. When studying the radiographs, one must decide whether the bone can withstand physiological loading with an acceptable risk of fracture. When one judges that the bone is too weak to withstand normal loading, then one makes the diagnosis of “impending fracture” and begins an assessment of the patient for prophylactic fixation.

Criteria for Impending Fracture

The criteria for impending fracture are far from absolute. There are a number of useful criteria in the literature (1,4,5,7,9). Clinicians use a combination of variables to predict fracture and often individualize the recommendation for each patient. The most important variables are the amount of cortical bone destruction, the pattern of bone metastasis, the location of the lesion and the location's stress concentration with activities of daily living, and the presence or absence of weight-bearing pain. It is also important to know if the patient has previously had a course of irradiation to that bony site.

Amount of Bone Destruction

The percentage of cortical bone destruction is the most important variable considered. When the amount of bone destruction exceeds 50%, the risk of fracture is significant. The amount of involved bone is determined by estimating the amount of cortical bone destroyed on both the anteroposterior and lateral radiographs (four specific cortices are thus measured and their involvement summed). Fidler has shown that fractures are unlikely to occur (2.3%) when less than 50% of the cortex is involved and very likely (80%) to occur when greater than 75% of the cortex is destroyed (4).

Pattern of Bone Destruction

Lesions may be sclerotic (blastic), mixed lytic-sclerotic, or purely lytic. Prostate, bladder, medulloblastoma, and bronchial carcinoid are the most likely carcinomas to have purely blastic metastases to bone. Blastic lesions are the least likely to fracture and the most likely to heal after internal fixation of a fracture when one does occur. In contrast, purely lytic lesions are most often seen in metastatic disease secondary to kidney, lung, thyroid, uterine, adrenal, melanoma, and gastrointestinal cancers. Lytic lesions are the most likely to fracture and the least likely to heal. Mixed metastatic lesions, often seen in breast, ovarian, testicular, lymphoma, and cervical cancers, have an intermediate risk of fracture.

Location of Lesion

There are a number of sites that are very prone to fracture; these sites are called “high stress sites.” The subtrochanteric region, femoral diaphysis, and distal femoral dia-metaphyseal regions are particularly prone to fracture as up to eight times body weight can stress some of these regions during stair climbing. When extensive disease exists, fracture may ensue with minor trauma; the bone may even fail spontaneously. The humeral diaphysis and distal dia-metaphyseal areas are also high stress sites, especially in patients using crutches or a walker. In these patients, the humerus becomes a weight-bearing bone. The femoral neck is another anatomical region that is subjected to high stresses, but less so than the subtrochanteric region.

Weight-Bearing Pain

Weight-bearing pain is an extremely important variable. When patients experience pain with every step, structural insufficiency is likely present with normal physiological loading. If the patient has significant weight-bearing pain and bone destruction greater than 30–40% associated with purely lytic bone destruction, one should consider these variables as potentiating each other and should strongly consider prophylactic fixation. If bone pain is present in a small blastic metastasis and is painful at night and at rest, then this pain may be more consistent with pain due to local periosteal or nerve stimulation, tumor biology rather than structural insufficiency of the bone.

Prior External Beam Irradiation

Significant pain after external beam irradiation may indicate either tumor progression or structural insufficiency. If significant bone destruction is present (30–40%), internal fixation to rigidly stabilize the bone and a second course of irradiation can be considered.

There are no absolutes in predicting fracture risk and surgical candidates. The criteria that have just been presented provide consistent and helpful guidelines for decision making, but the clinician must use judgment in making recommendations. Medical comorbidities and surgical risk stratification of patients certainly influence the recommendation to proceed with surgical intervention. Life expectancy and activity level before diagnosis are important variables in determining appropriateness of surgery, as well as in choosing a specific implant design for reconstruction. Additionally, serial radiographs, when appropriate and available, provide much greater insight into the biology of the lesion than does a single picture. Radiographs should certainly be followed over time in those patients considered appropriate for nonoperative management.

Specific Treatments

Long bone lesions can be treated with either internal fixation or prosthetic devices. Internal fixation devices (intramedullary rods and plates) are most commonly used. They are the treatment of choice when rigid and durable fixation can be achieved. Prosthetic devices are chosen when rigid internal fixation cannot be achieved or the joint surfaces have been compromised.

Intramedullary Devices

Locked intramedullary rods are excellent devices to achieve rigid fixation of lesions in the femur (Fig. 52-1), humerus (Fig. 52-2), and tibia. These rods are best suited for fixation of diaphyseal and dia-metaphyseal lesions. The closer the lesion is to the metaphysis, the less rigid the fixation of the locked intramedullary nail. The femoral nail has been modified so that a large screw can be placed close to the articular surface to achieve rigid fixation in the metaphysis and epiphysis (also called the *reconstruction* or *third generation femoral* nail). As the neutral axis of the nail and the femur are almost the same, the moment arm about the implant, and therefore the transmission of torque, is small. This confers excellent long-term implant survival even in the face of full weight bearing.

FIGURE 52-2. A: Anteroposterior left humerus showing pathological fracture of the humerus secondary to metastatic hypernephroma. **B:** After internal fixation with intermedullary nail.

Plate Devices

Plates are very useful for fixation of metaphyseal and epiphyseal lesions. There are two major prerequisites for successful plate fixation. First the joint surface must be completely intact so that the patient has a functional range of motion without pain. Second, there must be sufficient intact bone stock that rigid fixation is achieved and the patient is allowed to bear full weight after the procedure. To achieve rigid fixation such that full physiological loading is possible, at least one cortex must be almost completely intact. The plate is contoured to replace the destroyed cortex. Methyl methacrylate cement augmentation is used to supplement plate fixation in virtually all cases.

Prosthetic Devices

Prostheses are used for reconstruction of large destructive lesions and periarticular areas not amenable to internal fixation. Additionally, these devices are often used for salvage of failed internal fixation or for cases in which radiation therapy cannot be used postoperatively and therefore internal fixation would be likely to fail due to disease progression. Prosthetic devices are most commonly used in the proximal femur for femoral neck fractures and intertrochanteric lesions. Standard femoral prostheses are used for femoral neck and head lesions, whereas head and neck prosthetic devices are used for large lesions in the intertrochanteric region when there is significant bone destruction. The femoral endoprostheses are very versatile, allowing the surgeon to choose different-length stems to achieve varying levels of fixation within the femoral shaft. However, most devices are unable to extend all the way into the distal femoral metaphysis. Custom modular devices have played an important role in patients with large lesions that have been resistant to rigid fixation with standard devices, as well as when progressive disease necessitates the resection of large segments of the involved bone (11).

SPECIFIC ANATOMICAL SITES

Lower Extremity

Femur

The most commonly involved region is the proximal femur, followed by the femoral shaft and, least commonly, the distal dia-metaphyseal region. When evaluating and treating patients with femoral lesions, one should carefully image the entire femur with plain radiographs to ensure that there are not multiple areas of cortical bone destruction. If an internal fixation device ends short of an area of bone destruction, a “stress riser” is then created and the area becomes very prone to subsequent fracture at this location. Marrow replacement with no cortical bone destruction generally does not need to be bypassed by the fixation device. However, the patient must be treated with external beam irradiation postoperatively to control disease progression, which might result in cortical bone destruction.

Femoral Neck/Head

Patients with femoral neck and head metastases present with groin pain and difficulty ambulating. A careful history and examination are paramount, as these symptoms may mimic arthritis. The femoral neck is subjected to high forces during ambulating and twisting movements. Femoral neck and head lesions are treated with bipolar hemiarthroplasty after fracture or when there is an impending fracture. Smaller lesions can be effectively treated with external beam irradiation.

Subtrochanteric and Intertrochanteric Lesions

The intertrochanteric and subtrochanteric regions are common sites for femoral destruction. The reconstruction nail is an excellent fixation device for this region as the femoral neck, subtrochanteric region, and shaft can be protected with a single device. In addition the nail is easy to insert, with low morbidity (16). Only small incisions are used, and patients can bear full weight immediately after surgery. When there is a large amount of bone destruction, such that rigid internal fixation cannot be achieved, prosthetic devices are the best method of reconstruction. Head and neck endoprostheses (Fig. 52-3) can be chosen such that the intertrochanteric bone loss is replaced with the metal body of the prosthesis. Very large destructive lesions can be completely removed and reconstructed with custom modular prostheses (Fig. 52-4). The intramedullary stems of these devices are fixed with cement so that immediate full weight bearing is usually permitted.

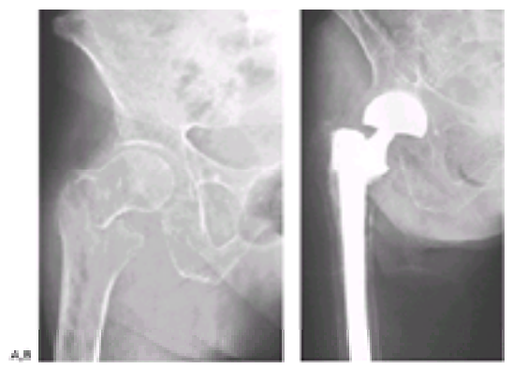

FIGURE 52-3. A: Anteroposterior right proximal femur showing pathological peritrochanteric fracture. **B:** Prosthetic replacement using a head and neck prosthesis.

FIGURE 52-4. A: Anteroposterior left proximal femur showing metastatic lesion with extensive bone destruction. **B:** After resection and replacement with

megaprosthesis.

Femoral Shaft

Femoral shaft lesions are common and very prone to fracture. Standard interlocking intramedullary nails (Fig. 52-1) are often chosen because a wide selection of rod diameters are available. The largest appropriately sized nail should be chosen to minimize the risk of nail fatigue failure. When the bone destruction is extensive, having a large nail is very advantageous, as it may take a long time for the bone to reconstitute after external beam irradiation. Unlike standard nails, most reconstruction nails have the disadvantage of a fixed diameter through the shaft portion of the nail (e.g., 11 mm). It may not be feasible with such a design to use a larger nail, e.g., a 12-, 13-, or 14-mm nail; the larger nail is more resistant to fatigue failure.

Distal Femoral Dia-Metaphyseal Region

The distal dia-metaphyseal region can be treated with either a plate device or a retrograde nail. The closer the lesion is to the joint surface, the less rigid fixation will be with the retrograde nail. For this reason, plate fixation is often chosen over nail fixation for distal femoral lesions. Plate fixation is augmented with methyl methacrylate cement. The cement provides immediate rigidity and is very effective in structurally replacing the destroyed bone.

Tibia

The tibia is not commonly destroyed. When bone destruction does occur it is usually in the proximal metaphysis or the diaphysis. The exact same principles are applied as in the femur, with plate fixation often used for proximal lesions and rod fixation commonly used for lesions of the shaft.

Pelvis

Pelvic lesions may occur in the sacrum, ilium, periacetabular region, or the ischium. Fortunately, pelvic fractures secondary to metastatic bone disease are very uncommon. Patients become symptomatic early in the disease so that treatment can begin before significant bone destruction and fracture have occurred. Acetabular lesions pose the greatest challenge to orthopaedic surgeons and oncologists. Many acetabular lesions can be treated nonoperatively with external beam irradiation and protected weight bearing until the weakened area has healed. If fracture has occurred into the weight-bearing dome of the hip joint, then nonoperative treatment is unlikely to provide lasting pain relief with good function. If the joint is compromised or the bone destruction is so significant that healing is unlikely, then acetabular reconstruction is necessary. Acetabular reconstruction is generally done with cemented acetabular components. The surgeon must decide whether to augment the reconstruction with an acetabular ring or to cement the component in a standard fashion. Augmented reconstruction with rings should be performed whenever there is significant medial wall destruction (Fig. 52-5).

FIGURE 52-5. A: Anteroposterior pelvis showing extensive destructive lesion secondary to metastatic breast cancer. **B:** After total hip arthroplasty with acetabular reconstruction with antiprotrusio cage with Steinmann pins and methyl methacrylate augmentation used to reinforce the acetabulum.

Upper Extremity

Humeral shaft lesions are best treated with intramedullary nails. If the lesion is of moderate size, excellent fixation can be achieved by locking the nail proximally and distally without opening the fracture to augment the lesion with cement. In contrast, if the lesion is large (greater than 60– 80% cortical bone destruction), cement augmentation plays a prominent role in achieving rigid fixation. In the same manner, if a fracture has occurred and there is 50% bone destruction, cement augmentation is often necessary to achieve rigid fixation. Proximal lesions are common, and if the joint surfaces have been compromised, prosthetic arthroplasty (Fig. 52-6) is an excellent modality to achieve rigid fixation and good pain-free function.

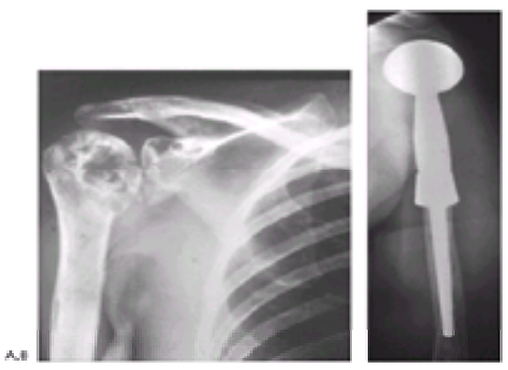

FIGURE 52-6. A: Anteroposterior right proximal humerus showing large metastatic disease involving the humeral head. **B:** After resection and reconstruction with megaprosthesis.

POSTOPERATIVE CARE

Postoperative care is an important component of the overall care of the patient. Attention to detail is important to prevent cardiopulmonary, skin, and urinary tract complications. Thrombosis is common in patients who have cancer. A specific plan to prevent thromboembolism should be carried forward in the immediate postoperative period. However, one must be cautious—especially in patients who have brain metastases, as they are prone to cerebrovascular bleeding while anticoagulated. Skin decubiti can develop quickly; prevention is the best measure. Patients should be mobilized from bed on the first postoperative day and careful attention paid to their heels (especially if they have had lower extremity surgery). Urinary tract infections are also common and should be treated to prevent seeding of the prosthetic joint or internal fixation devices. Nutritional status is of paramount importance in patients with metastatic disease. Evaluation and repletion of nutritional deficiencies, including those of protein or calorie malnutrition, must be aggressive to minimize cachexia, wound complications, immunosuppression, and anemia of chronic disease.

Hypercalcemia can be a significant problem (13). Patients should be evaluated for hypercalcemia if they develop any of the early signs, such as anorexia, fatigue, nausea, or neurological changes. The serum calcium level should be checked in the early postoperative period if the patient has a history of previous hypercalcemia; ionized calcium should be checked directly or should be calculated by the clinician.

PROGNOSIS

Unfortunately, virtually all patients with metastatic bone disease eventually succumb to the disease, with median survivals from 6 to 48 months. It is difficult to predict prognosis for the individual patient. In general, patients with breast and prostate carcinoma live for longer periods than patients with lung carcinoma. Patients with renal cell carcinoma have a variable life expectancy, with some living for long periods whereas others succumb rapidly.

Yamashita studied a group of 82 patients with metastatic breast carcinoma; the median survival was 35 months (14). In a multivariate analysis, the distribution of bone metastases and the presence of blastic metastases had a significant impact on survival. On the basis of the technetium bone scan, patients were divided into two groups, those with a cranial distribution (above the lumbosacral junction) and those with a caudal distribution (below the lumbosacral junction). Patients with a cranial distribution had a 5-year survival rate of 36% compared to 16% in the caudal group (p = .0194). Patients with blastic metastases also had a better 5-year survival compared to lytic metastases (42% vs. 23%, p = .0031). The authors noted the following favorable prognostic variables in patients with metastatic breast cancer: (a) no extraosseous metastases, (b) cranial bone metastases, (c) presence of radiographical osteosclerosis in metastatic bone lesions, and (d) no evidence of hypercalcemia. Coleman also reported additional organ involvement as a poor prognostic sign in patients with metastatic breast carcinoma to bone (3). Favorable prognostic factors included estrogen receptor positivity, a long disease-free interval (>3 years), and premenopausal status. Rana, in a study of 169 patients with metastatic prostate carcinoma, found that the number of metastatic sites had a significant effect on survival (10). Patients with either pelvis only or thoracic vertebrae only had the best prognosis (median survival 1578 and 1250 days, respectively) compared to patients with sternum and elsewhere, and skull and elsewhere who had the worst prognosis (321 and 281 days, respectively).

POSTOPERATIVE RADIATION TREATMENT

External beam irradiation is used postoperatively to arrest tumor growth and control pain. The use of external beam irradiation after surgery has been associated with a decrease in the need for second surgical procedures and improved functional status of patients with previously unirradiated long bone and acetabular lesions (12). In Townsend's retrospective study, 15% of patients treated with surgery alone required a second surgical orthopaedic procedure because of increasing pain and loss of fixation of the internal fixation device. In patients treated with postoperative irradiation, only 3% required a second procedure. If surgical intervention is deemed appropriate, then external beam irradiation should be done postoperatively to prevent delay in stabilization of an impending fracture.

External beam irradiation is generally initiated 2–4 weeks after surgery. Three thousand centiGray (cGy) in 10 fractions is commonly given to fields that encompass the original site of disease as well as the length of the prosthesis. The British Association of Surgical Oncology Guidelines from the United Kingdom recommend 2000 cGy in 5 fractions as an appropriate dose in the postoperative setting (2). Patients with renal cell carcinoma receive higher doses to control their disease (4500 cGy in 180 cGy fractions) (17).

It is critical in the treatment of these complex patients that a multidisciplinary approach among surgeons, radiation and medical oncologists, radiologists, physiatrists, therapists, and pain clinicians be used to maximize the patient's quality of life and to coordinate care in an expeditious and logical manner.

PALLIATIVE ENDOSCOPIC AND INTERVENTIONAL RADIOLOGIC PROCEDURES

JANAK N. SHAH
MICHAEL C. SOULEN
MICHAEL L. KOCHMAN

Palliation of symptoms associated with advanced cancer can be accomplished through less invasive and more cost-efficient endoscopic and radiologic methods when compared with standard open surgical procedures. Specialization in oncologic procedures by gastroenterologists and interventional radiologists has spared many patients additional loss of time and postoperative pain associated with aggressive surgical interventions (1,2 and 3). Technological advances and refinements in endoscopic and interventional radiologic procedures have eliminated the need for extensive surgeries and possibly lengthy recuperation in these ill patients, and have decreased the risks of complications. Patency of the gastrointestinal (GI) tract affected by cancerous tumor growth or strictures caused by radiotherapy can be restored with minimal discomfort and without significant threat to the patient's well-being. Internal and external drainage systems can be placed to relieve organ obstruction pain and inanition, and to prevent life-threatening end-organ dysfunction. Table 53-1outlines palliative endoscopic and interventional procedures.

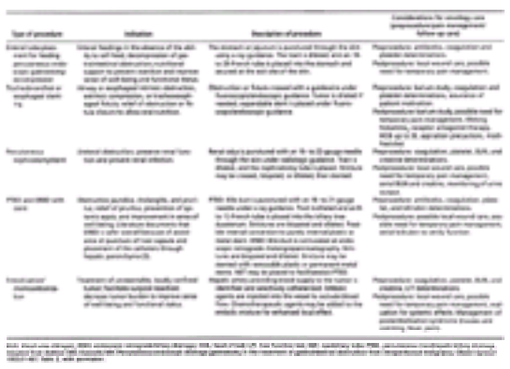

TABLE 53-1. COMMON ENDOSCOPIC AND INTERVENTIONAL PROCEDURES FOR ONCOLOGY PATIENTS

GASTROINTESTINAL TUBES FOR DECOMPRESSION AND NUTRITION

Nearly half of all patients undergoing gastrostomy and jejunostomy have cancer. Although the majority require GI tubes for enteral nutrition, gastrostomies and jejunostomies are inserted in a select group of patients for the purposes of decompression and drainage of intestinal obstructions. Approximately 40% of patients with ovarian cancer and as many as 28% of patients with colorectal cancer are at risk for developing bowel obstruction (4). Isolated malignant foci or widespread carcinomatosis of the abdomen causing external compression of GI structures are common causes of obstruction. Occlusion of the gastric outlet or intestine by tumor and adhesions from prior surgery, radiotherapy, and intraperitoneal chemotherapy are other mechanisms for gastric and intestinal blockages. Cramping and intestinal distention may be transiently relieved by vomiting, belching, flatus, and defecation; however, the unremitting cycle of these symptoms is often physically and emotionally intolerable. When initial management with aggressive pharmacotherapy, bowel rest, and temporary nasogastric decompression fails, GI decompression should be considered. Intolerable pain, fecal vomitus, intractable nausea or emesis, and esophageal ulceration are clear indications for venting gastrostomies or jejunostomies (5,6and7).

Gastrostomy and jejunostomy, whether intended for venting purposes or for feeding, can be accomplished through surgical, radiologic, or endoscopic techniques. In a meta-analysis of the efficacy and safety of each technique (8), the 30-day mortality rate (8%) was the same for both radiologic and percutaneous endoscopic approaches. Statistical analyses revealed significantly fewer complications (p <.001) and decreased mortality (p <.001) with radiologic techniques compared to surgery and percutaneous endoscopic gastrostomy (PEG). These data must be interpreted cautiously, as subset analyses were not performed.

Techniques for Gastrostomy and Jejunostomy Placement

Endoscopic Placement

Both percutaneous radiologic and endoscopic placement of gastrostomy tubes (G-tubes) and jejunostomy tubes (J-tubes) for decompression and feeding provide an acceptable alternative to the uncomfortable presence of nasogastric tubes, and eliminate the need for operative procedures. (6,9). Insertion of PEG involves a standard upper endoscopy with conscious sedation. After endoscopic examination of the stomach and duodenum to exclude significant ulcerations, the anterior gastric body or antrum is transilluminated and the gastric body is fully insufflated. Using the endoscopic light source, a suitable area on the anterior abdominal wall is transilluminated and the suitability of the site for a percutaneous tract is confirmed by gentle external compression at the potential entry site. These maneuvers allow for the determination of a safe site with the absence of any intervening viscera or major blood vessels. With some exceptions, dependent on the type of G- tube to be inserted and operator preference, a needle or trocar is passed into the gastric lumen and a guidewire is then threaded through the hollow needle and retrieved endoscopically (Fig. 53-1). The guidewire is then pulled up to the patient's oropharynx and the G-tube is passed over the wire into the stomach and out of the anterior abdominal wall. Firm traction is applied to ensure passage of the internal bolster through the esophagus and to allow a traction seal and apposition of the gastric and abdominal walls to minimize leakage of gastric contents or feedings.

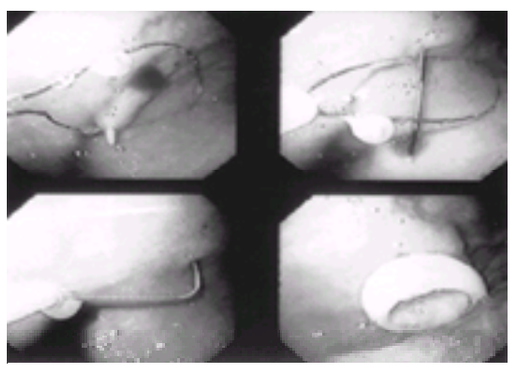

FIGURE 53-1. Endoscopic placement of gastrostomy tube. Initial introduction of trocar into gastric lumen (upper left). Guidewire passed through trocar and grasped by endoscopy snare (upper right). Guidewire fed into stomach and withdrawn to allow per os introduction of feeding tube (lower left).Appearance of gastrostomy after placement (lower right).

Recently, endoscopic ultrasound (US) has been used as an adjunct to aid in the placement of endoscopically placed G-tubes when the transillumination and indentation are not optimal (10). The advantage of this technique is that it may be performed in formerly complicated situations, including previously operated abdomens and in postpartial gastrectomy patients. The use of endoscopic US imaging significantly improves visualization of the bowel and gastric viscera, which might otherwise be impeded by the formation of adhesions, presence of taut peritoneum or ascites, or diffuse intraabdominal metastases. As a result, risks for inadvertent perforation of bowel, other organs, and metastatic foci are minimized. Studies show promising results over conventional procedures in facilitating ease of insertion and decreasing morbidity associated with the procedure (5).

Radiologic Placement

Radiologic gastrostomy is performed using fluoroscopic guidance under local anesthetic, with conscious sedation if needed. If swallowing function is intact and there is no GI obstruction, the patient is given oral contrast the night before to opacify the transverse colon and splenic flexure the next day. A nasogastric tube is placed and the stomach insufflated with air. US is used to mark the left lobe of the liver if it crosses over the stomach. The anterior wall of the stomach is then punctured through the abdominal wall under fluoroscopy, avoiding both the colon and the liver. Aspiration of air and injection of contrast confirm that the needle tip is within the stomach. One or more “T-anchors” are placed for gastropexy, then the puncture tract is dilated over a guidewire and the tube placed. In patients with aspiration risk, the pylorus is crossed and a gastrojejunostomy catheter is placed with the tip beyond the ligament of Treitz. Single- or doublelumen catheters are available, with the second lumen allowing decompression of the stomach as well as jejunal feeding. The catheter is left to external drainage for 24 hours, and the patient is monitored for peritoneal signs. If the tube is to be used for feeding, an enteral cap is placed and feeds begun with water or dextrose solution at 30 cc per hour, which is advanced as tolerated. Peritoneal leakage, procedure-induced ileus, or bowel dysmotility may limit advancement of feeds.

Complications

Technical difficulties encountered during insertion tend to be relatively low, ranging from 4% to 8% (5,7,9,11,12). The inability to implant G-tubes has been attributed to tumor invasion of anterior gastric wall, anatomical anomalies, and massive ascites (9,13,14). Overall, such difficulties seem to be noted more frequently with PEG placement than for radiologic guidance (8). Complication rates for both procedures vary from study to study, and must be cautiously interpreted in view of different methods of placement, operator experience, and diversity of patients. Procedure-related deaths, typically defined as mortality within 30 days of the procedure, have been reported (8). However, mortality rates within 30 days of the procedure may reflect consequences of the underlying disease and the overall poor status of the patients rather than direct causation from the procedure. Significant risks for complications include urinary tract infection, previous aspiration, and age >75 years (15).

Intestinal (colonic) perforation, peritonitis, and gastric hemorrhage are among the most serious complications. Isolated occurrences of mechanical intraabdominal seeding of tumor (16) and stomal seeding (17) have been reported. Although the diameter of the lumen might be expected to increase adverse effects, Cannizzaro et al. found no appreciable differences in symptomatic relief and placement-related complications between patients who received 15- and 20- French lumen catheters (5). Prophylactic use of preprocedure and postprocedure antibiotic administration has been used to reduce the incidence of infection. The data are not clear, but it appears that the preprocedure use of antibiotics reduces the postprocedure incidence of tube site cellulitis and fasciitis. Meticulous cleansing of the tube site with an iodine prep or antibacterial soap and application of a sterile gauze dressing minimizes early wound infections. Once the sutures are removed (if used) and the subcutaneous tract has sealed (in approximately 3 weeks), no additional care to the site is generally required.

Jejunostomy Tube Placement

Radiologic and endoscopic placement of jejunostomies are valuable techniques associated with low risks while avoiding the need for surgery. Tubes can be placed into the jejunum indirectly via a gastric puncture site, such as a double-lumen gastrojejunostomy tube or a J-tube threaded through a G-tube (14,18). Alternatively, direct endoscopic jejunostomy is placed using methods similar to PEG placement with good success rates, low complication rates, and high patient satisfaction (19). The tubes are inserted distal to the ligament of Treitz under conscious sedation. The advantage of this technique is the relative stability of the direct J-tube placement in comparison with a J-tube threaded through a G-tube. Insertion of percutaneous jejunostomy catheters are more easily accomplished when a J-tube has previously been present because the small bowel is adherent to the abdominal wall, creating a secure tract. The bowel loop can be punctured under fluoroscopic or endoscopic guidance, the tract dilated, and a new tube placed. The absence of a wellestablished access site makes the initial percutaneous procedure technically more difficult because of bowel mobility. In these circumstances, a gastrojejunostomy catheter may be needed. Magnetic technology, which allows for transient fixation of otherwise mobile bowel segments against the anterior abdominal wall, may allow for easier endoscopic placement of J-tubes. This has been studied in a swine model, and holds promise for direct endoscopic enteral tube placement using minimally invasive techniques (20).

Considerations with Gastrointestinal Tube Placement

Several factors must be taken into account to select the best method and site of GI tube insertion. Both radiologic and endoscopic methods have similar procedural success rates, 30-day mortality rates, and types of complications (8,14). Local expertise and patient factors should be considered in selecting the appropriate method of placement. For instance, in patients with severe pharyngeal or esophageal strictures that prevent the passage of an endoscope, radiologic guidance may be preferred (14). In other patients, who need visual investigation of the upper GI tract, endoscopic guidance is favored.

Other factors are considered in selecting the appropriate site of GI tube placement (gastric versus jejunal). Feeding gastrostomies are preferred over jejunostomies for patients who may require skilled nursing placement, as J-tubes tend to fall out and clog more frequently. Venting gastrostomies are indicated for patients with high upper intestinal or gastric outlet obstructions, whereas venting jejunostomies are more effective for decompression of intestinal obstructions that are more distal. Patients at risk for aspiration via emesis, as opposed to oropharyngeal dysphagia, are better candidates for jejunostomy feeding tubes. Through the use of a dual-lumen gastrojejunostomy tube, an artificial GI bypass can be constructed with a venting gastrostomy above the obstruction, enabling enteral feedings via a jejunostomy below the obstruction (21).

Lumen size appears to be more of an issue for patients who require intermittent or continuous decompression and wish to ingest soft food and fluids. Modifications in the contour of the tube and outflow portion, rather than lumen size, seem to be most critical in maximizing the flow of GI secretions mixed with semisolid foods and liquids (11). It is necessary to ensure that the tube selected for any patient is appropriate for its intended purpose. Some tubes now have one-way valves, which decrease the likelihood of patients expelling gastric contents if the end seal is loose, but these tubes are not suitable for gastric decompression. Most tubes are now designed in such a manner that they may be removed via firm traction and do not require repeat surgery or endoscopic procedure. Replacement button devices and stomal tubes are available.

Above all, patient and family acceptance, motivation, and ability to care for the tube or administer feedings are critically important in the successful management of GI intubation. Patients and families are instructed to (a) care for the tube exit site, (b) observe the site for any peristomal redness, ulceration, or drainage, and (c) flush, cap, and connect the tube to the appropriate devices. The tube can be anchored to the abdomen with special securing devices (Fig. 53-2). Arrangements for home health care are coordinated if patients are immediately discharged to home after tube placement, require nutritional support (enteral or total parenteral) or fluid replacement, or need additional teaching after hospitalization. This is necessary to assure proper monitoring as feeds are initiated and advanced, as well as to assist the patient and family with wound care and help them select an appropriate drainage container and operate suction devices for venting tubes.

FIGURE 53-2. The Dale gastrostomy tube holder (Dale Medical Products, Inc., Plainville, MA) allows patients requiring enteral feeding greater mobility and security, and the ability to enjoy a more active, comfortable lifestyle. The tube holder secures percutaneous endoscopic gastrostomy tubes and other abdominal feeding tubes without the discomfort and irritation caused by tape and other adhesive-backed holders.

Costs associated with the procedure must also be considered. Endoscopically and radiologically placed tubes can avoid the use of the operating room and general anesthesia, and their attendant costs and risks. Charges for PEG placement have been assessed around $2400 and radiologic placement at $4500 (8). Estimated reimbursement for professional fees remains similar, and for inpatients, the hospital reimbursement for the procedure is generally embedded into the fixed rate established for the diagnostic category.

PALLIATIVE MANAGEMENT OF GASTROINTESTINAL AND BILIARY OBSTRUCTION

Malignant intrinsic obstructions or extrinsic compressions of GI structures can be relieved through the placement of endoprostheses made from materials that restore both patency and function of the esophagus, colon, rectum, and biliary and pancreatic ducts. Over the past decade a dramatic improvement in the materials, design, and delivery systems has served to make these procedures both widely disseminated and less dangerous.

Esophageal Stenting

Indications

Esophageal endoprosthetic intubation is used to treat esophageal compression from locally advanced esophageal, mediastinal, or tracheobronchial malignancies, as well as strictures that may have resulted from prior radiotherapy. Endoprostheses (stents) also allow for the palliation and occlusion of tracheoesophageal (TE) fistula, permitting oral intake. The insertion of an artificial tube restores patency of the esophagus and can provide relief from dysphagia, pain, and the inability to swallow or effectively clear oral secretions.

Relative contraindications for the placement of esophageal stents include extensive circumferential tumor growth that occludes the lumen and interferes with passage of a guidewire and dilators, necrotic lesions that may hemorrhage, friable tissues that increase the chance for perforation, anticipated discomfort associated with the presence of the stent, and lack of patient acceptance or compliance with dietary modifications and follow-up care. The stents may leave a patient with a persistent globus sensation if placed within 2 cm of the upper esophageal sphincter. The placement of a stent into a fibrotic (posttherapy) stricture or one resistant to dilatation may result in mediastinal pain, as the pressure exerted by the stent in its attempt to deploy continues until full expansion.

Types of Stents

A variety of rigid and metal self-expandable stents are available as endoprosthetic devices. Selection of stents is dependent on several factors, including life expectancy, pattern of tumor growth (e.g., location, orientation of tumor invasion, extent of invasion, size), anticipated complications, and desired treatment outcomes (Table 53-2). Rigid stents have been manufactured from several materials, including polyvinyl tubing, silicone with metal reinforcements (Wilson-Cook, Wilson-Cook, Inc., Winston-Salem, NC), radiopaque silicone with metal reinforcements (Atkinson tube, Key-Med, Inc., Essex, UK). Promising results have been reported using cuffed rigid stents in managing life-threatening sequelae associated with TE fistulas (22,23). Patients with TE fistulas tend to be poor surgical candidates because of respiratory distress, malnutrition, and debilitation from advanced stages of cancer. Mortality rates as high as 36% have been documented with attempts to surgically repair this type of fistula; however, peroral intubation using a cuffed rigid stent to seal off the fistula has reduced mortality to 24% (22). Expandable cuffs attached to rigid endoprostheses have been successful in occluding fistulas with less patient discomfort and reduced hospitalization compared to surgery, and without the risk of pressure necrosis (23).

Situation	Rigid stents	Expandable metal stents
Cancer within 2 cm of upper esophageal sphincter	--	--
Airway compression by tube	--	+
Limited life expectancy	--	--
Lack of patient motivation	--	--
Luminal obstruction preventing passage of a guidewire	--	--
Noncircumferential tumors preventing anchoring of the stent	--	+
Soft or necrotic lesions with poor anchoring qualities	--	+
Profusely bleeding lesions	-	-
Horizontal orientation of the malignant lumen	+	+
Acutely angulated, complex lesions	+	+

+, preferred; -, suboptimal; --, to be avoided if possible.

TABLE 53-2. RELATIVE INDICATIONS FOR RIGID AND EXPANDABLE METAL ENDOPROSTHESES

The introduction of metal self-expanding esophageal stents, patterned after biliary and vascular stents, has minimized problems associated with the rigid polymeric stents and their fixed lumen diameters (Fig. 53-3). Although selfexpanding metal stents are approximately ten times more expensive, their advantages of larger lumen size, ease of insertion, decreased complication rates, and greater success with more stenotic lesions often outweigh any cost expenditures. All of the metal stents share an ability to be placed into a narrow lumen on a small-bore delivery device and then allowed to expand once in correct anatomical position. Technical success rates for deployment are reported to be greater than 95%, with significant improvement in dysphagia and tolerability of oral intake (24,25,26 and 27). A variety of self-expanding metallic stents are available that differ in design, elasticity, and resistance to angulation (28). Some metallic self-expanding stents are covered with a polymeric sheet to inhibit tumor ingrowth and to facilitate occlusion of TE fistula tracts (27). Others are designed with an artificial sleeve to ideally help decrease reflux symptoms after placement for tumors near the gastroesophageal junction. Knowledge of their physical properties and tumor characteristics/anatomy can help in selecting the appropriate stent for a particular patient. Unlike rigid stents that can be taken out, metal self-expanding tubes are virtually impossible to remove short of an open surgical procedure, due to the expandable nature of the device.

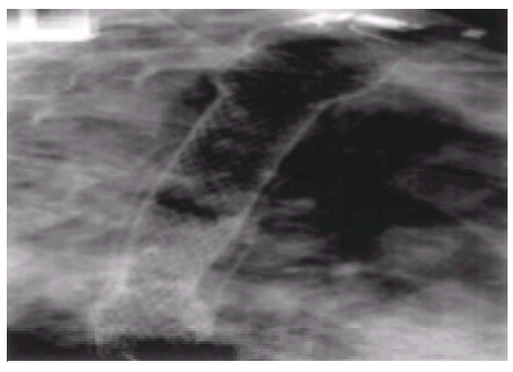

FIGURE 53-3. Fluoroscopic view of Schneider-covered esophageal prosthesis (Boston Scientific, Natick, MA) at the time of deployment.

Complications

Perforation, stent migration, pain, and hemorrhage are among the most common complications of esophageal stents. Perforation is the most serious complication and

occurs with a frequency of approximately 6–8% with the rigid endoprostheses (29,30). The rate of perforation is <3% with the metallic self-expandable stents (24,26,27,31). Perforation may occur as a result of the endoscopy, esophageal dilatation, or the endoprosthetic placement. Factors associated with a higher incidence of perforation include prior radiotherapy and surgical intervention, sharp angulation from tortuous tumor involvement, and preexisting kyphoscoliosis. In the majority of cases, perforations are identified at the time of stent placement by careful endoscopic inspection of the esophagus and pharynx, the physical examination findings of subcutaneous emphysema or crepitation of air, and radiographic detection of extraluminal air in the chest and neck areas. The exact location of a leak can be detected by the use of water-soluble contrast media.

Perforation always carries a risk for accompanying mediastinitis. Once identified, the use of acid-suppressive agents and i.v. antibiotics are the mainstays of therapy; the stent itself may seal off the site of the perforation. Consideration for the placement of an additional endoprosthetic or surgical repair needs to be entertained for open communicating tracts.

Stent migration and dislodgement may complicate metallic stent placement in up to 5% of patients (27). Some stents are designed to decrease migration (26), but further studies ascertaining their effectiveness for this complication are needed. Barium studies postprocedure document location and function of the stent, and provide a baseline should migration be suspected in the future. Tumor ingrowth occludes stents in approximately 10–60% of cases, depending on the type of endoprosthesis used, and occurs a mean of 7 weeks postprocedure (24,27).

Bleeding related to expandable metallic stent placement occurs in <5% of cases (25,27). This is often insignificant, but more serious hemorrhage requiring transfusions has been reported (25). Aspiration may occur either during the placement of the endoprosthetic or subsequently, due to reflux of gastric contents. It is important to instruct patients that they should not lie supine or prone after placement; this is especially important when the endoprosthetic bridges the gastroesophageal junction.

A persistent globus sensation may occur if the stent is placed in the proximal esophagus, within 2 cm of the upper esophageal sphincter. Mediastinal pain may occur in 5–15% of patients (24,27,31).

It is useful to have a preprocedure barium study to assess for sharp angulations, unsuspected perforations, distance from the upper esophageal sphincter, and presence of fistulas. Despite concerns over complications of esophageal endoprosthetic placement, this procedure is relatively safe and offers considerable benefits for optimizing oral nutrition and improving quality of life. Patients are advised to gradually increase the consistency of their food but to avoid solid meats, breads, and baked products.

Colorectal Endoprostheses or Stenting

Indications

The introduction of colorectal stents, designed similarly to esophageal prostheses, has successfully relieved colorectal stenosis from obstructing tumors. In some cases, endoprosthetic devices have been implanted for acute management of intestinal obstruction to allow for luminal decompression before palliative and definitive surgical resection (33,34). In other cases, colorectal stenting has been advocated as a primary palliative treatment (35). De Gregorio et al. reported survival after colorectal stents ranging from 4 to 22 months (35), and others have determined that the time to reobstruction varies from 45 to 91 days (36).

Types of Rectal Stents

Endoprostheses used to restore and maintain colorectal patency are similar to the metal self-expanding tubes inserted to alleviate esophageal compression. They are placed under endoscopic or fluoroscopic guidance. The Wallstent (Boston Scientific, Natick, MA) is a popular stent, with models constructed with diameters of 18–22 mm and deployed lengths of 60–90 mm. Plastic stents have been used; however, one study comparing this technology to metal self-expanding stents found a higher incidence of placement failure due to iatrogenic perforation and temporary incontinence with plastic material (37).

Complications

Mild rectal bleeding may occur with colorectal stent procedures. More serious complications such as perforation seem to be more prevalent among patients with local tumor necrosis. Stent placement failures tend to be related to technical malfunctions or the inability to intubate the obstructed area due to extensive tumor involvement and luminal compromise.

In a manner analogous to the placement of the esophageal endoprostheses, we have found it beneficial to obtain a preprocedure barium study, if possible, to rule out acute angulation. After colorectal stent placement, patients are advised to report signs and symptoms of increased pain, rectal bleeding, inability to defecate, abdominal distention, or stent protrusion through the anal opening. Consistent use of laxatives and stool softeners as well as dietary modifications aids in maintaining bowel regularity.

Enteral Endoprostheses or Stenting

Malignant gastric-outlet, duodenal, and small bowel obstructions may be caused by occlusion of the lumen by intrinsic tumor mass or extrinsic compression. Until recently, surgical procedures were the only palliative option for these patients. Enteral stents can replace the need for palliative surgery by providing patients relief from symptoms and allowing maintenance of oral intake (38,39 and 40).

The types of endoprostheses are similar to the colorectal stents. One of the more popular models (Wallstent-Enteral, Boston Scientific, Natick, MA) is available in lengths of 60 and 90 mm, and in diameters of 18, 20, and 22 mm. They are usually placed under endoscopic and fluoroscopic guidance. Contrast studies and abdominal computed tomography (CT) scans are helpful in defining anatomy and guiding appropriate placement. Types and rates of complications appear similar to those of esophageal and colorectal stenting, and include perforation and hemorrhage; large datasets are not yet published.

Biliary Stenting and Drainage Procedures

Indications

Palliative management of biliary obstruction or stenosis in patients with unresectable hepatic metastases, cholangiocarcinoma, and pancreatic carcinomas may improve quality of life (41,42,43 and 44). A measurable effect on psychosocial outcomes with placement of biliary stents has been observed (43).

Therapy of malignant biliary obstruction can be approached in a variety of ways. Surgical resection offers the possibility for cure, but is only possible in 10–15% of cases. Palliation can be achieved by surgical bypass or by endoscopic or percutaneous stenting combined with adjuvant radiation and chemotherapy. Comparative trials have shown no advantage between surgical versus nonsurgical palliation of the obstruction in survival (43a). Some surgeons prefer that all patients undergo preoperative biliary drainage, although a clear benefit from preoperative drainage has not been proven.

Methods of Placement

Endoscopic therapy requires retrograde cannulation of the common bile duct, performance of a sphincterotomy, and placement of a 7- to 11-French plastic endoprosthesis. A successful diagnostic endoscopic retrograde cholangiopancreatography is accomplished in 75–90% of patients, after which the technical success rate for performing a sphincterotomy is very high. For low strictures, such as pancreatic carcinoma, stent placement after successful cannulation of the duct is achieved in 95%, with a morbidity of 10% and a mortality of approximately 3% (45). Success rates for hilar strictures decline significantly to the 40–60% range, with an increase in morbidity and mortality to 18% and 8%, respectively (46,47). Higher success rates can be obtained using a rendezvous procedure, in which an interventional radiologist passes a guidewire percutaneously through the biliary tree into the duodenum, and is met by the endoscopist who pulls the guidewire out through the mouth. With this throughand-through approach, an endoprosthesis can be passed retrograde without creating a large transhepatic track. Use of the rendezvous technique increases the success rate for retrograde stenting of hilar strictures to almost 90% (48).

Percutaneous biliary drainage is successful 95–100% of the time but suffers from an acute, serious complication rate of 15%. Once internal drainage has been achieved, conversion to an endoprosthesis is almost always possible with little added morbidity (49). Advantages of retrograde endoscopic stenting are its lower morbidity and the ability to change a clogged endoprosthesis. However, the endoscopic approach to the bile duct has a lower technical success rate than the percutaneous approach. Endoscopically placed plastic stents are usually smaller than those placed percutaneously, but metal stents are of the same size. It is not possible to administer intracavitary radiation without percutaneous access. Percutaneous internal–external drainage can almost always be accomplished regardless of the level of obstruction; this allows for larger tubes, which can be easily changed. Access is maintained for brachytherapy or for later interventions as the disease

progresses.

Types of Stents

Technologic advancements in the perfection of metallic self-expanding implantable stents have maximized the efficiency of stents, but stent malfunction as a result of tumor ingrowth and overgrowth is a significant problem. Percutaneous or endoscopic deployment of metal stents has been associated with less pain during placement than plastic stents (47). The main advantage of metal stents appears to be a slightly longer duration of patency, 9–12 months.

Complications

Chronic internal–external drainage is associated with complications in up to 50% of patients, including cholangitis, skin infection, bleeding, leakage of bile and ascites, rib erosion, osteomyelitis, catheter fracture or dislodgement, and seeding of tumor cells along the track. The tubes require regular flushing and dressing. Even with optimal care, routine tube changes are necessary at 8- to 12-week intervals to avoid occlusion. For some, the distortion of their body image is psychologically distressing. Insertion of an endoprosthesis avoids many of the complications of having a chronic percutaneous catheter, but repeat drainage is required if the stent becomes obstructed.

Long-term patency rates are difficult to measure because of the high mortality in this population, but are in the range of 68–94% at a follow-up of 4–5 months (47,50,51,52 and 53). Occlusion of plastic stents occurs due to a sequence of bacterial adherence, glycoprotein deposition, and encrustation with bile salts. Newer series, employing longer stents made from smooth-surfaced polymers or antibacterial coatings, show patencies at the higher end of this range, with median patencies of approximately 6.5 months (51,54).Long-term complications are common, with cholangitis in 20% and an average occlusion rate of 11%. Stents fracture or dislodge in 3–6% of cases. Average survival with malignant biliary obstruction is only 3–5 months. In the subset of patients with more indolent cholangiocarcinomas, stent placement can significantly increase survival.

Several studies have evaluated the efficacy of metal selfexpanding stents in the treatment of neoplastic-related biliary obstruction by percutaneous insertion. Nicholson et al., who placed metal self-expanding stents percutaneously in 77 patients with inoperable biliary obstruction with no evidence of metastatic spread, found serum bilirubin levels returned to normal within 7 days of stent placement in 98.7% of patients (42). Use of metal stents may prove advantageous in patients with cholangiocarcinoma when intraductal radiation is administered via an iridium wire before stent placement, which can deliver 2000–3000 rads within a 1-cm radius. This can be supplemented by external beam therapy and chemotherapy with 5-fluorouracil. This combined modality approach can yield a mean survival of close to 2 years, with mean stent patency of 19.5 months (55). Intraductal brachytherapy does not appear to improve patency in patients with biliary obstruction from other types of tumors. In another series, successful placement and catheter longevity were noted for patients with cholangiocarcinoma (N = 31; mean survival 14 months), yet 77% of patients with sclerosing cholangitis from intraarterial chemotherapy (N = 11) experienced catheter occlusions (41).

After catheter or stent placement, patients are followed with an anticipated reduction in serum bilirubin levels and resolution of pruritus over the first 7–10 days. Signs and symptoms of pain, fever, jaundice, or leakage at the tube site at any time may be a signal of stent occlusion or dislocation. Local care to the catheter exit site with a sterile dressing is done every day for the first few days, then every 3–4 days. Patients and family members are given instructions for catheter care and when to notify the physician or nurse regarding unusual findings. The site and dressing are continually observed for signs of bile leakage. The catheter is initially placed to straight drainage, with the output measured daily. Temperature is taken at least once a day for approximately 1 week after insertion. Internal–external catheters can be capped after 24 hours to move the internal flow of bile into the duodenum. Biliary tubes require flushing thrice weekly whether capped or to external drainage. Patients with longterm external drainage systems are periodically monitored for electrolyte and bicarbonate depletion. Electrolyte loss can be avoided by reingestion of the bile.

TUMOR ABLATION TECHNIQUES

Endoscopic Ablative Palliation

Palliation of symptoms of GI malignancies may be achieved through the use of tumor ablative techniques (3). These methods may be applied endoscopically and include thermal debulking techniques (bipolar cautery, monopolar cautery, laser), tissue destruction (alcohol, chemotherapeutic agents, photodynamic therapy), and radiotherapy (after loading techniques, seed implantation). The use of any of these methods is dependent on the local expertise and resources available, as well as a multidisciplinary approach to the overall care of the patient.

Esophagus

The maintenance of esophageal luminal patency is a goal for the palliation of nutritional support and the prevention of the aspiration of saliva, as well as for allowing the patient to obtain oral gratification. Many different techniques have been used. The most commonly applied in the past was bipolar cautery, but this has fallen out of favor due to concerns over full-thickness injury, stricture formation, the need for a circumferential tumor, and technical difficulties. This technique uses a rigid bipolar probe that is inserted into the tumor; serial applications of current are made as the probe is withdrawn under radiographic or direct visual guidance.

Nd:YAG laser treatment has been the mainstay of the obliterative techniques used recently by gastroenterologists. The technique is relatively fast and inexpensive if the cost of the laser power source is spread over several specialties. Numerous difficulties, including perforation, may be encountered in its application, although careful patient selection may ameliorate these risks (56). Direct ethanol injection into tumor masses has been used with success to debulk lesions, improve dysphagia, salvage endoprostheses when overgrowth has occurred, and maintain luminal patency. Scant data are available on which to base recommendations regarding its efficacy and safety. Use of chemotherapeutic agents for intratumoral injection is in clinical trials.

Another technique is photodynamic therapy, a modality that is currently approved by the U.S. Food and Drug Administration for the palliation and restoration of luminal patency in esophageal cancer (57). Photodynamic therapy involves a two-stage process in which a photosensitizing agent is intravenously administered 1–3 days before endoscopic illumination. Several studies have shown significant improvement in dysphagia in patients with inoperable, obstructing esophageal cancer (58,59 and 60). Complications with this procedure may include perforation, stricture formation, esophagitis, and skin photosensitivity (59). Further bench and clinical research will likely lead to better hematoporphyrin derivatives, better techniques, and additional applications. Local radiotherapy (brachytherapy) may be directed and aided by endoscopic techniques, including endoscopic US. Brachytherapy markers and delivery tubes may be placed endoscopically and location of the tumor precisely determined to allow for the accurate delivery of intraluminal and external beam therapy.

Rectum

The mainstay of endoscopic debulking of colorectal neoplasms has been the use of thermal ablation techniques. Large sessile or pedunculated lesions may be effectively debulked to allow for the passage of stool or for the preparation of the colon for a resection or stent placement. These techniques are relatively easily applied in the rectum below the peritoneal reflection, without much concern for the complication of free peritoneal perforation. The use of monopolar cautery snare resection coupled with saline injection is a technique that can be readily mastered and does not require a large investment in capital expenditures. Lesions that are commonly found in the rectum (and higher in the colon) tend to be circumferential and are not easily managed by application of cautery. The majority of lesions require the use of endoscopic laser therapy, most commonly performed with Nd:YAG. The KTP laser (532 nm) is just coming into clinical use, and we have found it to be quite effective. The laser energy may be applied via a free fiber and allowed to vaporize tissue to open the lumen, or it may be used with contact-type probes to allow for precise delivery of energy and, theoretically, more controlled depth of penetration. There is a paucity of data comparing this technique with others, although data that are published support its safety and efficacy when used by those experienced with the equipment and technique.

Percutaneous Ablation of Liver Tumors

In situ destruction of liver tumors has been performed with a variety of chemical and thermal techniques. Chemical ablation is most often performed with ethanol. Acetic acid has also been used. Thermal techniques include cryosurgery, hot saline injection, radiofrequency (RF), microwave, laser, and high-intensity focused US.

Patient Selection

The best candidates for percutaneous tumor ablation are those with small tumors, and with cancers that are confined to the liver but are nonetheless unresectable due to the distribution of disease, severity of underlying cirrhosis, or other comorbid diseases. Tumors must be accessible under imaging guidance. Patients with three or fewer lesions that are no more than 3 cm in diameter are excellent candidates for percutaneous treatment. Ablating lesions between 3–5 cm is more difficult, and above 5 cm the local failure rate increases dramatically.

Chemical Ablation

Chemical ablation with ethanol causes cell death due to cellular dehydration and protein denaturation. These processes, combined with small vessel thrombosis, lead to coagulative necrosis of tissue. Intravenous access is required for sedation and analgesia. Prophylactic antibiotics are not necessary. After localization of the tumor under CT guidance or US, the skin is prepped and draped and local anesthesia administered from the skin through the liver capsule. The lesion is then punctured with a 20–22 G diamond-tip, multi-side-hole needle (e.g., Bernadino needle, Wilson-Cook, Inc., Winston-Salem, NC), passing the needle to the back wall of the tumor. Absolute alcohol is injected slowly while rotating the needle, preferably during real-time US monitoring. Alcohol is brilliantly echogenic on US, jet-black on CT. The needle is gradually withdrawn toward the proximal edge of the tumor. Injection is stopped and the needle repositioned if alcohol is observed to flow into a blood vessel, bile duct, or into the liver outside of the tumor. After completing the injection, the needle is left in place for 1–2 minutes to allow the alcohol to diffuse, then the needle is aspirated firmly during withdrawal to minimize leakage. Additional passes may be required to treat the entire tumor volume.

Lesions up to 3 cm are easily treated in a single session.Because the toxic dose of ethanol is 0.8–1.0 cc/kg, lesions 4 cm or larger usually require multiple treatment sessions. Patients can be brought back at weekly intervals for this simple outpatient procedure until the entire tumor has been treated. Pain and nausea are common during the procedure, and can be managed with medication. Patients will become intoxicated if sufficient alcohol is injected, particularly Asians with alcohol dehydrogenase deficiency. Fever and transient liver function test elevation typically occur in the days after the procedure, and do not require specific therapy. Patients can be discharged after a few hours of observation. Complications occur in 1–14% of procedures. Vasovagal episodes can occur; intraperitoneal bleeding and pleural effusion are each reported after 0.5% of procedures. Rarer complications include pneumothorax, ascites, cholangitis, abscess, hepatic infarct, biliary stricture, and tumor seeding.

Successful chemical ablation causes an area of necrosis in the liver that is larger than the index lesion. Hence the apparent size of the lesion increases on follow-up imaging. It is essential to obtain “functional” imaging that is sensitive to cellular viability. At a minimum, CT or magnetic resonance imaging scans should be obtained using dynamic scanning during the arterial phase of contrast enhancement. Positron emission tomography and spectroscopy are more sophisticated techniques for assessing tumor viability. Serum tumor markers should be followed, if elevated at baseline. Fine-needle aspiration biopsy can be performed to evaluate regions suspicious for residual or recurrent tumor.

Over 1000 cases of hepatoma treated with percutaneous ethanol injection (PEI) have been reported (61,62 and 63). Among resected specimens, complete necrosis was observed in 67–80%. Local recurrence at the treated site occurred in up to 15%. Unfortunately, regional failure is high, with 64–98% of patients developing new liver tumors within 5 years. Survival rates at 5 years are reported to be 30–50%. Although these figures are remarkably high compared to most series reporting other therapies for hepatoma, it must be remembered that PEI patients are a highly selected group with very small tumor burden.

PEI does not work as well for metastatic lesions. Because metastases tend to be less vascular and are harder than the surrounding liver, the liquid alcohol tends to follow the path of least resistance back along the needle and on to infiltrate the liver, rather than diffusing through the tumor nodule. Complete necrosis is achieved in less than half of lesions, usually in tumors <2 cm in size.

PEI has been used extensively for treatment of focal hepatomas in patients with hepatic cirrhosis. However, it is being replaced by thermal ablation in many institutions. Livraghi and colleagues reported their comparative experience with the two techniques (64). These were not prospective or randomized trials. Among 84 patients/121 lesions treated with PEI and 96 patients/106 lesions treated with RF ablation, it took over four sessions of PEI on average to ablate the entire tumor, versus only 1.2 sessions for RF. Complete success as judged by imaging studies was similar for both modalities, but the local recurrence rate was 13% after PEI versus 2% for RF. There was one complication in the PEI group, five in the RF group. The conclusion was that RF is more efficient and effective than ethanol in ablating hepatomas.

Acetic Acid

Acetic acid was first proposed as an ablation agent by Ohnishi and colleagues, who reasoned that acetic acid, used in vitro to dissolve lipids and extract collagen from various tissues (including cirrhotic liver), may have applications in percutaneous ablation (65). Ohnishi initially demonstrated acetic acid to be superior to ethanol in cell kill in a rat model with a higher degree of necrosis and more homogenous diffusion. The cytotoxic mechanisms of acetic acid are similar to those of ethanol, including protein denaturation and dissolution of basement membrane and interstitial collagen resulting in coagulative necrosis of tumor cells. Dose– response studies in a rat model have shown the cytotoxic effects of acetic acid plateau at a concentration of 50% (approximately 8 mol/l). Acetic acid has an advantage of infiltrating the septae and capsule of tumors, whereas ethanol does not cross tumor septae. As a result, a smaller volume is required to achieve the same degree of cell kill with fewer treatment sessions.

These characteristics may account for the differences observed by Ohnishi and coworkers in the only prospective, randomized trial comparing ethanol ablation with acetic acid ablation for small (<3 cm) hepatocellular carcinomas (66). A total of 31 patients underwent acetic acid ablation and 29 patients underwent ethanol ablation of one to four discrete tumors. The groups were well matched in terms of age, sex, underlying liver disease, Child-Pugh score, and tumor burden (size, number, and histological grade). All patients underwent acetic acid or ethanol ablation by the same operator, using US guidance and a 22-G needle. The number of treatment sessions and total volume injected for all sessions was less with patients treated with acetic acid compared to those treated with ethanol. A significant and substantial difference was observed in cancer-free and overall survival. The 1- and 2-year cancer-free survival rates were 83% and 63% in the acetic acid group and 59% and 33% in the ethanol group. The 1- and 2-year overall survival rates were 100% and 92% in the acetic acid group and 83% and 63% in the ethanol group. No major complications occurred in either group; the minor postablation effects of pain and fever were seen in both groups.

Large-volume injections of acetic acid (greater than 20 cc) should be avoided because of the potential for metabolic acidosis and direct renal toxicity of acetic acid. Preliminary observations indicate that acetic acid may be especially useful when treating hepatic metastases, which are notoriously difficult to treat with ethanol due to their hard, firm consistency. Acetic acid appears to infiltrate through firm lesions more homogenously than ethanol.Acetic acid may also hold promise in the treatment of nonhepatic neoplasms.

Thermal Ablation

Temperatures above 60°C cause cell death within minutes. This can be accomplished with various energy sources, including RF, microwave, laser, or high-intensity US. Of these, only RF electrocautery is commercially available in the United States. Heating has advantages over chemical ablation, in that it does not depend on direct contact with the cells. Energy is dispersed fairly evenly across the treatment volume, and is not limited by septations or areas of necrosis or fibrosis within the tumor. RF ablation works by inducing ionic agitation in the surrounding tissues. This results in localized frictional heating. Lesion size is proportional to the power of energy delivered (Watts), time, and size of the probe. Reliable thermal lesions up to 3.5 cm can be created using a radial or multiprobe array.

The ablation technique is similar to PEI. IV access is essential, as pain is a significant side effect of the procedure, and deep sedation or anesthesia may be required. Access to the lesion is obtained under imaging guidance, using local anesthesia. If necessary, multiple overlapping burns are performed to treat the entire tumor volume. Each burn takes 10–30 minutes, so the procedure is more time-consuming than PEI.

Immediate results of RF ablation based on follow-up imaging indicate absence of any enhancing tumor in 60–90% of tumors, with lesion size being the major determinant of success (67,68). Local recurrence rates have been reported to be from as low as 2% to as high as 40% within 1 year. As with any local approach, new lesions are the predominant mode of failure, occurring in up to 65% of patients within 1 year. Complications occur in approximately 2.4% of cases.

Combined Regional and Local Therapy

Chemoembolization (see section Chemoembolization), although treating a large volume, is limited in its ability to induce complete tumor necrosis. Conversely, RF ablation causes thorough tissue necrosis within a small volume, primarily limited by blood flow. Hence, combining the two techniques is an appealing approach to intermediate size lesions. Occlusion of the hepatic artery or portal vein during RF ablation results in substantially larger burn volumes. This is routinely done during intraoperative ablation, using the Pringle maneuver to temporarily reduce hepatic blood flow. Temporary balloon occlusion, embolization, or chemoembolization to devascularize the tumor allows effective RF ablation of tumors up to 8 cm in diameter. Blood flow to the surrounding liver is still preserved via the portal vein, so a “surgical” margin is not achieved. Experience with this combined modality therapy is still preliminary, so long-term follow-up for recurrence is not available.

Chemoembolization

Malignancies in the liver present one of the most challenging problems in clinical oncology. Other tumors that are less common but frequently develop fatal hepatic metastases despite a resectable primary include ocular melanoma, neuroendocrine tumors, and the rare GI sarcomas. Response rates of hepatoma and metastatic colorectal cancer to a variety of systemic chemotherapeutic agents are no better than 20–40%, and a significant survival benefit has not been demonstrated. Intraarterial chemotherapy using continuous infusion of 5-fluorodeoxyuridine and steroids delivered by percutaneous catheters or by surgically implanted pumps has

remained a popular regional approach to hepatic malignancies and colorectal metastases to the liver, although none of the phase III trials comparing intraarterial to i.v. chemotherapy for metastatic colorectal cancer has shown a long-term survival benefit for intraarterial infusions (69,70,71 and 72). Response rates of hepatoma to intraarterial chemotherapy are 50–60%, with an increase in survival to 20–60% at 1 year (73,74).

Embolization of the hepatic artery has proven effective for palliation of liver metastases from carcinoid and islet cell tumors, with response rates of 80–90% (75,76). Hepatoma has a more modest response to embolization (50–60%), with some increase in short-term survival (77,78). The efficacy of embolization is limited by the liver's ability to develop collateral blood supply when the hepatic artery is occluded. For this reason, benefits from hepatic artery embolization tend to be transient. Embolization has not been shown to extend survival for patients with colorectal metastases (79,80). Chemoembolization combines hepatic artery embolization with simultaneous infusion of a concentrated dose of chemotherapeutic drugs. Theoretical advantages of this technique include the following: (a) embolization renders the tumor ischemic, depriving it of nutrients and oxygen and decreasing drug resistance; (b) tumor drug concentrations are orders of magnitude higher than those achieved by infusion alone (81,82); (c) blood flow is arrested, prolonging the dwelling time of the chemotherapy with measurable drug levels present as long as a month later (83,84); and (d) most of the drug is retained in the liver, minimizing systemic toxicity. A variety of chemotherapeutic drugs and embolic agents are used around the world. Doxorubicin, in doses of 40–80 mg, is proably the most commonly used single agent. Often it is combined with cisplatinum (100–150 mg) or mitomycin-C (10–20 mg).These drugs can be dissolved in their powdered form directly in radiographic contrast. This solution can be injected directly, or emulsified with iodized oil (Ethiodol, Savage Laboratories, Melville, NY) before injection. Embolization is completed with small particles of gelatin sponge or polyvinyl alcohol sponge.

Critical to the selection of patients for regional therapy is tumor confinement to the liver. Patients with minimal or indolent extrahepatic disease may be candidates if the liver disease is considered to be the dominant source of morbidity and mortality. Tumors that typically meet these criteria include hepatoma, intrahepatic cholangiocarcinoma, and metastases from colorectal cancer, ocular melanoma, neuroendocrine tumors, and sarcomas. When the parenchyma is diseased, the liver becomes more dependent on the hepatic artery for its blood supply. Subgroups of patients have been identified who are at high risk of acute hepatic failure after hepatic artery embolization. They typically have >50% of the liver volume replaced by tumor, lactate dehydrogenase >425 IU/l, aspartate aminotransferase (AST) >100 IU/l, and total bilirubin >2 mg/dl (85). The presence of hepatic encephalopathy or jaundice is an absolute contraindication to embolization. Biliary obstruction is also a contraindication. Even with a normal serum bilirubin, the presence of dilated intrahepatic bile ducts places the patient at high risk for biliary necrosis in the obstructed segment(s) of the liver.

Evaluation for chemoembolization includes a tissue diagnosis, cross-sectional imaging of the liver, exclusion of extrahepatic disease, and laboratory studies. Given the significant discomforts, hazards, and expense of this treatment, its palliative role should be clearly understood. After hydration and premedication with antibiotics and antiemetics, diagnostic visceral arteriography is performed to determine the arterial supply to the liver and confirm patency of the portal vein. The origins of vessels supplying the gut, particularly the right gastric and supraduodenal arteries, are carefully noted to avoid embolization of the stomach or small bowel. Once the arterial anatomy is clearly understood, a catheter is advanced superselectively into the right or left hepatic artery, depending on which lobe holds the most tumor, and chemoembolization is performed. The patient receives intraarterial lidocaine and i.v. fentanyl or morphine sulfate to alleviate pain during the embolization. After the procedure, vigorous hydration, i.v. antibiotics, and antiemetic therapy are continued. Opioids, prochlorperazine, and acetaminophen are liberally supplied for control of pain, nausea, and fever. The patient is discharged as soon as oral intake is adequate and parenteral narcotics are not required for pain control. Approximately one-half of patients are discharged in 1 day, and most of the rest within 2 days. Oral antibiotics are continued for another 5 days, and antiemetics and opioids are continued as needed. Follow-up includes return for a second procedure directed at the other lobe of the liver 3–4 weeks later. Depending on the arterial anatomy, two to four procedures are required to treat the entire liver, after which response is assessed by repeat imaging studies and tumor markers. Eighty to ninety percent of patients suffer a postembolization syndrome, characterized by pain, fever, and nausea and vomiting. The severity of these symptoms varies tremendously from patient to patient, and they can last from a few hours to several days. Serious complications occur in up to 5%of procedures.

Major complications of hepatic embolization include hepatic insufficiency or infarction, hepatic abscess, biliary necrosis, and nontarget embolization to the gut. With careful patient selection and scrupulous technique, the incidence of these serious events collectively is 3–4%. Other complications include renal insufficiency and anemia requiring transfusion, with incidences of <1% each. Thirty day mortality ranges from 1% to 4%.

Among combined series of 800 patients with unresectable hepatocellular carcinoma treated with chemoembolization in Asia, Europe, and the United States, response rates as measured by decreased tumor volume and decreased serum a-fetoprotein levels were 60–83% (83,86,87). Cumulative probability of survival ranged from 54% to 88% at 1 year, 33% to 64% at 2 years, and 18% to 51% at 3 years. Survival varies inversely with tumor volume, stage, and Childs class. Despite the large volume of single-institution experiences with chemoembolization of hepatoma published over the past decade, few controlled trials have been reported. A multicenter European trial comparing cisplatin/Lipiodol gelfoam chemoembolization to no therapy in 100 patients with relatively small tumor burdens (90% stage I) found 1-year survivals of 62% and 43%, respectively, and 2-year survivals of 38% and 26% (88). A French multicenter trial of 127 patients with more advanced disease (62% stage II or III) showed almost identical survival rates in the chemoembolization arm (64% and 38% at 1 and 2 years), with survival in the control arm of only 18% and 6%, respectively (p<.0001) (89). Several reports of chemoembolization for liver metastases from colon cancer have been reported (90,91). These consistently show a response in two-thirds of patients, and median survivals on the order of 2 years, which is approximately double that seen with systemic chemotherapy alone. A phase III randomized trial is now under way to evaluate the benefit of chemoembolization in addition to standard chemotherapy in this disease.

REGIONAL ANALGESIA

Interventional radiologists, to a limited extent, perform regional anesthetic techniques such as intercostal and pleural analgesia that can provide superior temporary analgesia during many thoracic and upper abdominal procedures. Intercostal access to the liver and kidney can be extremely painful due to irritation of the pleura and adjacent rib periosteum, especially if a temporary drain remains in place after the procedure. Interpleural analgesia and pleural blocks are especially helpful in controlling pain during procedures that involve the chest wall (i.e., pleural biopsy, thoracentesis, pleural sclerosing) (92), liver and biliary tree (i.e., liver biopsy, percutaneous biliary drainage, and stenting), and kidneys (i.e., renal biopsy, percutaneous nephrostomy), as well as providing long-term relief of intractable pain in the thorax and upper abdomen. Temporary pleural blocks may also be considered for patients undergoing radiologic placement of drainage catheters for difficult-to-localize empyemas, and more permanent neurolytic blocks for thoracic and lumbosacral pain (93). Interpleural analgesia has demonstrated safety and efficacy in the treatment of both postoperative and diffuse thoracic cancer pain (94,95).

Celiac plexus blocks (CPBs) with local anesthetics have been used to temporarily control pain associated with percutaneous biliary drainage, which is performed to gain access to the intrahepatic and extrahepatic tree for the purpose of biopsy, biliary endoscopy, and stent placement (96). This technique has significant advantages in relieving severe visceral pain that arises from biliary tract dilation and manipulation, which can be difficult to manage with sedating agents and opioids alone. Most studies document positive outcomes with CPB during procedures; however, investigators have recently proved that CPB was no better than midazolam hydrochloride and fentanyl in reducing pain (96). The mean elevation in heart rate in this study was significantly lower in the CPB group, favoring this form of regional analgesia to i.v. opioids for patients with cardiac disease. For more information on regional analgesic techniques, refer to Table 53-3. CPB using a neurolytic agent such as alcohol or phenol can be performed by anesthesiologists, surgeons, interventional radiologists, and gastroenterologists (guided by endoscopic US) to gain long-term control of pain from hepatic metastases and pancreatic carcinomas (Fig. 53-4).

TABLE 53-3. REGIONAL ANALGESIA

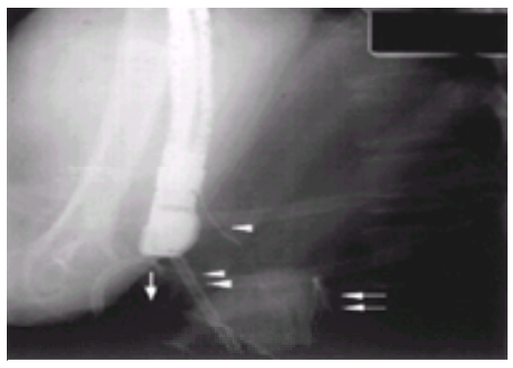

FIGURE 53-4. Radiograph demonstrating complete nonsurgical palliation from unresectable pancreatic cancer causing biliary and duodenal obstruction and with accompanying hypercoagulable state with deep venous thrombosis and visceral pain. Needle exiting Pentax endoscopic endoscope at time of celiac axis neurolysis (arrowhead). Percutaneously placed internal biliary drain (double arrowhead). Schneider-uncovered endoprosthetic in duodenum restoring patency after obstruction (percutaneously placed and endoscopically dilated to full diameter) (arrow). Percutaneously placed vena cava filter (double arrow).

CONSCIOUS SEDATION AND ANALGESIA

Interventional techniques for palliation are aimed at relieving pain and improving symptoms. However, in some circumstances these procedures may transiently worsen pain, exacerbate other symptoms, and sometimes, create new temporary sources for pain. The need for pain control before, during, and after procedures cannot be overestimated. Uncontrolled pain leads to a release of catecholamines that stimulates the sympathetic nervous system, which can stress the cardiovascular system, resulting in tachycardia, cardiac arrhythmias, or cardiac ischemia (97). It can also result in elevated blood pressure, which in turn may increase the risk of stroke and potential for hemorrhage at the procedural site (98). Nausea, vomiting, and bradycardia, which are parasympathetic responses, can accompany severe pain originating from the viscera or peritoneum as the result of an invasive procedure.

As areas of the body are manipulated, nociceptors (free nerve endings) are activated, giving rise to various painful sensations that may or may not be similar to the pain of cancer. A painful stimulus to viscera or organ structures, such as inflammation, that is sustained over time increases the vulnerability of visceral nociceptors to stimuli that would not normally evoke pain (99). The slightest manipulation of visceral structures affected by cancer pain can provoke significant pain. Moreover, ischemic pain caused by embolization procedures or damage to vasculature is so severe that adequate pain control during and after remains a clinical priority (100,101).

To some extent, the perception of pain can be diminished by percutaneous and intravascular local anesthetics, regional blocks, and liberal use of systemic opioid analgesics and sedating agents. Nonpharmacologic methods, such as relaxation techniques, can reduce the need for opioids and sedating agents, enhance amnesia, and improve the patient's overall well-being and outlook on the procedure (98). The level of complexity and duration of the procedure have warranted more liberal use of sedating agents and intensive monitoring in endoscopic and interventional radiology procedure units. Specific details are beyond the scope of this chapter and the following recommendations.for the selection of sedating agents and opioids to manage procedural pain and anxiety that accompany interventional procedures for cancer (9,102,103 and 104).

CONCLUSION

Decisions for endoscopic and interventional radiologic techniques must be based on available data and sound judgments, balancing potential risks and benefits. The ability to perform some palliative interventions is largely the result of local expertise and the availability of clinical resources. All possible comfort and supportive care measures should be considered or attempted before the undertaking of invasive interventions. Moral, ethical, and social issues arise if patients are subjected to these procedures only to prolong intense pain and suffering when life expectancy is very limited. On the other hand, withholding therapeutic options for palliation of intolerable and unmanageable symptoms takes hope away from patients for a better quality of life for the remaining weeks or months of life.

Gastroenterologists and interventional radiologists may overlap in areas of expertise and perform similar procedures; however, each offers unique aspects to the technical performance of the procedure. Careful patient selection and knowledge of the local expertise and areas of interest of each specialist leads to a multidisciplinary effort and more options and opinions in regard to the therapy for the individual patient. Differences in how each specialty approaches an individual clinical situation may be readily evident, but despite these differences, the indications for treatment and the intended outcomes for treatment remain similar.

PSYCHOSOCIAL CONSEQUENCES OF ADVANCED CANCER

JAMES R. ZABORA
MATTHEW J. LOSCALZO

Despite significant progress in research and treatments, the diagnosis of cancer creates fear and turmoil in the lives of every patient and family. In many respects cancer generates a greater sense of dread than other life-threatening illnesses with similar prognoses (1). Some studies have found that cancer patients are sicker and have more symptoms than noncancer patients in the year prior to death, and most often, it is easier to predict the course of the illness (2).

Frequently, the greatest concern of cancer patients is not death, pain, or physical symptoms, but rather the impact of the disease on their families (3). According to the World Health Organization (4), family refers to those individuals who are either relatives or other significant people as defined by the patient. Health care professionals must acknowledge the role of the family to maximize treatment outcomes. If the family is actively incorporated into patient care, the health care team gains valuable allies and resources. Families are the primary source of support and also provide the caregiving roles for persons with cancer. Of note, women comprise the majority of individuals who serve in these caregiving roles (5,6).

Although access to ongoing palliative care could potentially provide needed support for both patient and family, resources for palliative care are consistently limited. In the United States most palliative care is invested in hospice programs, but only one-third of all cancer patients receive formal hospice care, often only in the final days of life (7,8). Furthermore, a discussion concerning a referral to hospice can seem quite sudden and to the patient and family may be experienced as rejection. Despite the sobering survival statistics for many cancers, relatively few hospitals have developed a continuum of cancer care which informs patients and families that most antineoplastic therapy is palliative and not curative. This is particularly significant given that the majority of cancer patients overestimate the probability of long-term survival (9). The transition from a period of primary therapy to a period without such therapy can be very difficult and it may be surmised that the situation is worse for other chronic life-threatening diseases. At present, patients and family members enter hospice care, which is the primary deliverer of comprehensive palliative care services, and attempt to accept that prolongation of life is no longer the goal of care. In addition to the shift in the focus from cure to care, the patient and family experience the loss of the health care team with whom trust has been imbued over months and sometimes many years. The loss occurs simultaneously at multiple levels. Although palliative care at the end of life should be a time of refocusing and resolution, the referral process may cause an iatrogenic crisis rather than comfort.

PSYCHOLOGICAL RESPONSES TO ADVANCED CANCER

The psychological impact of advanced cancer and its management is directly influenced by the interactions among the degree of physical disability, internal resources of the patient, the intensity of the treatment, side effects, and other adverse reactions, and the relationship with the health care team.

Adaptation to this phase of the illness begins with an appraisal of the extent of harm, loss, threat, and challenge that this experience generates. In many respects this appraisal is linked to the intensity and quality of the patient's emotional response. Overall, this primary appraisal and definition of the meaning of advanced cancer results in an assessment of the extent of the potential harm, which then requires a secondary appraisal to occur. In this secondary level, patients must assess their personal (internal) and social (external) resources necessary to begin to address the demands and problems associated with advanced cancer (10).

In addition, two salient timelines or continua related to patient and family adaptation must be considered. The level of psychological distress forms the first continuum and the second consists of the predictable and transitional phases of the disease process. Patients with a preexisting high level of psychological distress can experience significant difficulty with any attempt to adapt to the stressors associated with a cancer diagnosis. Although most patients experience significant distress at the time of their diagnosis, the majority of patients gradually adjust during the following 6 months (11). Evidence indicates that the best predictor of positive adaptation is the psychological state of the cancer patient prior to the initiation of any therapeutic regimens (12).

Figure 54-1 details potential interventions along the disease and distress continua. The level of psychological vulnerability also falls along a continuum from low to high distress and should guide this selection of interventions. In addition, problem-solving interventions have been demonstrated to reduce distress among cancer patients as well as among family members (13,14 and 15). Prevalence studies demonstrate that one of every three newly diagnosed patients (regardless of prognosis) need psychosocial or psychiatric intervention (16,17,18 and 19). As disease advances, a positive relationship exists between the increase in the occurrence and severity of physiological symptoms and the patient's level of emotional distress and overall quality of life. For example, a study of 268 cancer patients with recurrent disease observed that patients with higher symptomatology, greater financial concerns, and a pessimistic outlook experience higher levels of psychological distress and lower levels of general wellbeing (20).

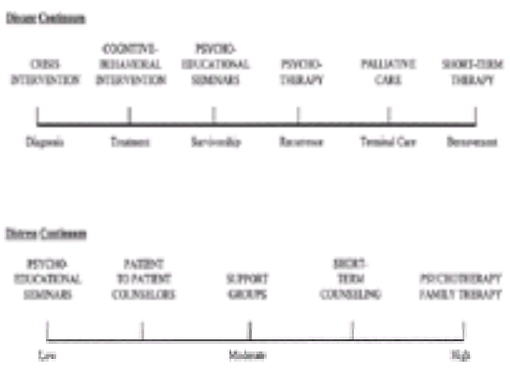

FIGURE 54-1. Continuums of care for cancer patients and their families.

If distress levels can be identified through techniques such as psychosocial screening (21), patients can then be introduced into supportive care systems earlier in the treatment or palliative care process. Accordingly, any attempt to identify vulnerable patients and families in a prospective manner is worthwhile. Screening techniques are available through the use of standardized instruments which are able to prospectively identify patients and families that may be more vulnerable to the cancer experience. Preexisting psychosocial resources are critical in any predictive or screening process. In one approach, Weisman et al. (22) delineated key psychosocial variables in the format of a structured interview accompanied by a self-report measure (Table 54-1). However, in hospitals, clinics, or community agencies which provide care to a high volume of patients and family members, a structured interview by a psychosocial provider is seldom feasible. Consequently, brief and rapid methods of screening are necessary. Brief screening techniques that examine components of distress, such as anxiety or depression, can be incorporated into the routine clinical care of the patient. Early psychosocial interventions may be less stigmatizing to the patient, and more readily accepted by patients, families, and staff if

screening identifies the management of distress as one component of comprehensive care (23). Screening is also a costeffective technique for case identification in comparison to an assessment of all new patients (24).

Social support	History	Current concerns	Other variables
Marital status	Substance abuse	Health	Education
Living arrangements	Depression	Religion	Employment
Number of family members and relatives in vicinity	Mental health	Work Finance	Physical symptoms
Church attendance	Major illness	Family	Anatomical staging
	Past regrets	Friends	
	Optimism versus pessimism	Existential	
		Self-appraisal

TABLE 54-1. VARIABLES ASSOCIATED WITH PSYCHOSOCIAL ADAPTATION

Standardized measures of psychological distress can differentiate patients into low, moderate, or high degree of vulnerability. Patients with a low level of distress may benefit from a psychoeducational program which can enhance adaptive capabilities and problem-solving skills; high distress patients may possess psychosocial needs that require individual psychotherapy or family therapy along with psychotropic drug therapy for the patient. For some patients ongoing mental health services are essential, whereas other patients may require assistance only at critical transition points. Clinical practice suggests that virtually all patients could benefit from some type of psychosocial intervention at some point along the disease continuum, especially at the end of life. Psychosocial interventions include educational programs, support groups, cognitive-behavioral techniques, and psychotherapy (25). To further facilitate the process of screening, the Brief Symptom Inventory-18 was developed to create greater ease with administration and scoring and to identify gender-based norms (26,27).

The second continuum relates to the predictable phases of the disease process. This disease continuum extends from the point of diagnosis to cancer therapies and beyond. As patients move across this continuum, they may acquire experiences, knowledge, and skills that enable them to respond to the demands of their disease. The needs of a newly diagnosed patient with intractable symptoms differ significantly from a patient who has advanced disease and no further options for curative treatments.

The patient and family may be supported throughout the illness process and the family requires continuing support following the death of the patient. At times families are overwhelmed by the illness, and as a result are unable to effectively respond. For some families a death may represent a loss of the family's identity and may paralyze the family's coping and problem-solving responses. Failure to respond and problem-solve leads to a lack of control and may generate a significant potential for a chronic grief reaction (28). Although the disease continuum consists of specific points, Table 54-2 identifies a series of predictable and relevant crisis events and psychosocial challenges that occur as patients and families confront advanced disease.

TABLE 54-2. ADVANCING DISEASE AND PSYCHOSOCIAL TREATMENT

FAMILY ADAPTABILITY AND COHESION

The Circumplex Model of Family Functioning, as developed by Olson et al. (29), categorizes families in a manner that explains the variation in their behavior. Although not specifically developed for cancer, this model conceptualizes families' responses to stressful events based on two constructs, adaptability and cohesion. End-of-life care simultaneously generates significant stressors for both patients and families, especially in issues related to power, structure, and role assignments. Adaptability reflects the capability of a family to reorganize internal roles, rules, and power structure in response to a significant stressor. Given the impact of advancing cancer on the total family unit, families must frequently reassign roles, alter rules for daily living, and revise long-held methods for problem-solving. Dysfunction in the family can relate to either low adaptability (rigidity) or excessively high adaptability (chaotic). A family characterized as rigid in its adaptability persists in the use of specific coping behaviors even when they are ineffective. Those that exhibit high adaptability create a chaotic response within the power structure, roles, and rules of the family; such families lack structure in their responses and attempt different coping strategies with every new stress. Although the majority of families are in the more functional category of “structured adaptability,” 30% are rigid or chaotic. These latter families are likely to exhibit problematic behaviors such as excessive demands of staff time or interference with the delivery of medical care that the health care team may find difficult to manage (30).

The second construct of Olson and colleagues— cohesion—is indicative of the family's ability to provide adequate support. Cohesion is the level of emotional bonding that exists among family members, and is also conceptualized on a continuum from low to high. Low cohesion (disengagement) suggests little or no connectedness among family members. A commitment to care for other family members is not evident and, as a result, these families are frequently unavailable to the medical staff for support of the patient or in the decision-making process. At the other extreme, high cohesion (enmeshment) blurs the boundaries among family members. This results in the perception by health care providers that some family members seem to be just as affected by the diagnosis or treatment, or by each symptom, as the patient. Enmeshed families may demand excessive amounts of time from the health care team and be incapable of following simple medical directives. These families are not able to objectively receive and comprehend information which may be in the best interest of the patient. Also these families may assume an overprotective position in relation to the patient and may speak for the patient even when the patient's self-expression could be encouraged.

When engaging families, it is necessary to gain an appreciation for the rules and regulations of particular families. Each family has its own rules, regulations, and communication styles. In gaining an understanding of the role of the patient in the family, it is helpful to ask the patient to describe the specific responsibilities he or she performs in the family, especially during a crisis. Generalities are less informative than descriptions of the specific experiences and duties of each family member during a crisis. These queries enable the patient to openly communicate and objectively evaluate his or her role and importance in the family system and provide a clinical opportunity to assess ongoing progress or deterioration. Patients and families can usually tolerate even the worst news or the most dire prognosis as long as it is framed within a context in which the patient and family know how they are expected to respond and that the health care team will not abandon them.

IMPACT OF PHYSICAL AND PSYCHOLOGICAL SYMPTOMS

Patients with advanced illness experience pain, dyspnea, fatigue, nausea, anxiety, depression, sleeplessness, and many other symptoms that impair quality of life. These noxious symptoms also compromise cognition, concentration, and memory (31), and override the underlying mental schema of patients. For the person in pain or acute physical distress, perception is confined to only the most immediate and essential elements of his or her sensory experience, and there is only a distant remnant of a past or future. The immediate need and goal is to stop or minimize the noxious experience. In some sense, pain and other symptoms absorb the limited psychic energy of the patient, and valuable energy can only be made available if physical distress is effectively managed. The psychic life is subservient and dependent to the bodily experience.

Moderate to severe pain is reported by 30–45% of patients undergoing (32) cancer treatments and 75–90% of patients with advanced disease (33). Pain seems to

stand alone in its ability to gain the active attention of others while dramatically demonstrating a sense of being alone and vulnerable. This is especially true of patients with advanced disease, and their families. While a patient is experiencing pain, another person only inches away is incapable of truly understanding what is so central and undeniable to the patient. This invisible and almost palpable boundary between the person in pain and his or her caregivers has significant implications for the quality and effectiveness of the therapeutic relationship (34).

Given that cancer pain can be adequately managed in almost all circumstances, its deleterious and at times lifethreatening impact on the physical, psychological, and spiritual resources of both the patient and family are not only unnecessary but are evil. There is no known benefit to unrelieved pain. There are many known negative consequences. For example, Chochinov et al. (35) found that the desire for death was correlated with ratings of pain and low family support but most significantly with depression. Given the relationship between pain and depression, the importance of adequate pain management can hardly be overstated. Recently Cobb et al. (36), in their comprehensive review of the delirium literature, found that poor pain control was identified as the number one cause or contributor for delirium. Given the obvious importance and prevalence of delirium as an indicator of quality of life at the end of life, this is very important information.

Serlin et al. (37) were able to demonstrate that there is a positive correlation between pain intensity and function. As expected, low levels of pain intensity cause low levels of interference with life, while moderate to high levels of pain make it virtually impossible to have meaningful interactions with others and to feel part of a larger whole. Clinical experience consistently demonstrates that people with physical illness accompanied by high levels of pain intensity experience acute isolation and are unable to advocate for themselves and are at very high risk to be badly cared for even in the best medical centers. Family and health care providers can be sensitive, caring, supportive, and concerned, but if pain is not adequately managed, the person confronting death has little possibility to think clearly, express his or her concerns, make a contribution and to have anything resembling a peaceful death.

It is generally accepted that pain is poorly managed despite the availability of effective therapies (38,39 and 40). Patients, families, and professional staff may share a reluctance to use opioid analgesics even when life expectancy is quite limited. A primordial evolutionary process continues to exist which enables patients to accept suffering and allows the health care team to permit the unnecessary pain to occur. This type of response represents an adaptive, but “dark side” of human nature. Although most cancer patients are psychologically healthy (16,41), inadequately managed cancer pain and other symptoms can produce a variety of “pseudopsychiatric” syndromes which are anxiety-provoking and confusing to patients, families, and clinicians. Cancer patients with pain are also more likely to develop psychiatric disorders than cancer patients without significant pain (42). In the short-term, pain provokes anxiety; over the longterm, it generates depression and demoralization.

The differences between depression and demoralization as clinical constructs have yet to be empirically explored. Depression is significantly related to higher levels of cancer. pain and pain is likely to play a causal role related to depression. Overall depression rates for cancer patients are 20–25% (42) and estimates as high as 50–70% have been applied to populations with advanced disease (43). Demoralized patients are disheartened or discouraged by their circumstances but not in a pathological sense. There is a significant correlation between affective disorders and pain and among the negative emotional states associated with pain (dysphoria, hopelessness, guilt, suicidal ideation, etc.). Anecdotal clinical experience consistently demonstrates that once pain and related distressing physical symptoms are relieved, and suffering, anxiety, depression, demoralization, and suicidal ideation are ameliorated, the impact on the family is equally significant (44).

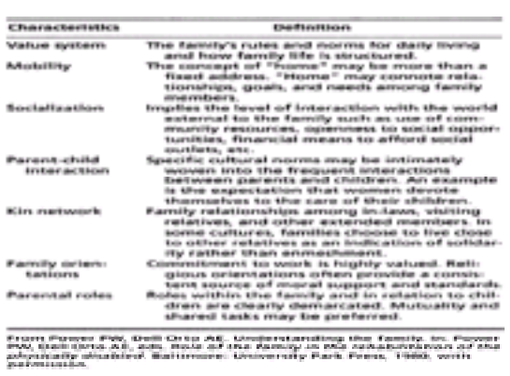
Depressed patients distort reality and grossly minimize their perceived abilities in managing the demands of the illness and its treatment. Furthermore depressed cancer patients with inadequately controlled pain are at increased risk of suicide (35,45). For the depressed patient, acute sensitivity to physical sensations may lead to or exaggerate preexisting morbid or catastrophizing thoughts. The complex and interactive associations among physical sensations (neutral or noxious sensations), mentation (personal meaning given to the sensations), and behaviors (attempts to minimize threat and regain control) are all negatively influenced by depression. The destructive synergy of unrelieved pain and depression may lead to overwhelming suffering in patients and families and to a shared sense of hopelessness and helplessness (46). Consequently a patient or family may develop the faulty perception that suicide is their only remaining vestige of control. From this perspective, the value of a multimodality approach that combines pharmacology, supportive psychotherapy, and cognitive-behavioral skills training is clear (47). From a psychological perspective promotion of compliance with medical regimens, correction of distorted cognitive perceptions, acquisition of coping skills to manage physical tension, stress and pain, and the effective use of valuable physical energy to maximize engagement of life become the focus of care.

SOCIOCULTURAL INFLUENCES ON PATIENT AND FAMILY ADAPTATION

Perceptions of illness and death can be conceptualized as experiences with both conscious and unconscious associations. These perceptions include concerns and fears that are beyond the limits of objective knowledge. Sociocultural beliefs may soothe anxiety or fear by providing comfort when a vacuum exists due to a lack of experience in the management of a chronic illness. Sociocultural attitudes also exert considerable influence as patients approach the ends of their lives (48,49). These beliefs and attitudes are evident in direct observations of how the family cares for the patient, views of an afterlife, or rituals related to how the corpse is to be managed.

Koenig and Gates-Williams (50) offer a framework to assess cultural responses relevant to palliative care. This framework, which is consistent with a comprehensive psychosocial assessment, posits that “culture is only meaningful when interpreted in the context of a patient's unique history, family constellation, and socioeconomic status. . . Dangers exist in creating negative stereotypes—in simply supplying clinicians with an atlas or map of 'cultural traits' common among particular ethnic groups.”

Patients and their families can simply not be adequately understood without knowledge of their sociocultural backgrounds (Table 54-3) (51). Patients and families vary according to interests, beliefs, values, and attitudes. Individuals learn attitudes or values through family interactions and these patterns influence how patients respond to the health care team. Although the health care team represents expertise, safety, and authority, it is also an external and foreign force, which only through necessity has gained influence and power within the family system. In stressful situations the patient and family may project their own perceptions about themselves onto the health care team.



Characteristics	Definition
Value system	The family's rules and norms for daily living and how family life is structured.
Mobility	The concept of "home" may be more than a fixed address. "Home" may connote relationships, goals, and needs among family members.
Socialization	Implies the level of interaction with the world external to the family such as use of community resources, openness to social opportunities, financial means to afford social outlets, etc.
Parent-child interaction	Specific cultural norms may be intimately woven into the frequent interactions between parents and children. An example is the expectation that women devote themselves to the care of their children.
Kin network	Family relationships among in-laws, visiting relatives, and other extended members. In some cultures, families choose to live close to other relatives as an indication of solidarity rather than enmeshment.
Family orientations	Commitment to work is highly valued. Religious orientations often provide a consistent source of moral support and standards.
Parental roles	Roles within the family and in relation to children are clearly demarcated. Mutuality and shared tasks may be preferred.

From Power PW, Dell Orto AE. Understanding the family. In: Power PW, Dell Orto AE, eds. Role of the family in the rehabilitation of the physically disabled. Baltimore: University Park Press, 1988, with permission.

TABLE 54-3. FAMILY CHARACTERISTICS SUSCEPTIBLE TO CULTURAL INFLUENCES

Although cultural characteristics are important these influences often diminish over time as families are assimilated into the predominant culture. Second-generation families are more similar to the host country than the country of origin. First-generation immigrants may possess oldworld attitudes and values about authority and illness, whereas the perspectives of their offspring will be more consistent with the health care team.

Given the many and complex demands already made on health care professionals and the rapidly increasing diversity of institutions, is it reasonable to expect that staff to be informed about the myriad of cultures represented in such a pluralistic environment? For example, it is estimated that there are over 150 different languages spoken among the native Americans, with each tribe having its own rituals around end of life (52). One can only imagine trying to provide bereavement services to a group that demands that the name of the deceased never be mentioned again? Or that even mentioning the word death will cause the event to happen? These barriers to effective and open communication, so respected by health care professionals in the United States, are not unique to native Americans (53). Furthermore, evidence exists that African-Americans are far less likely to discuss end-of-life issues due to a belief that these discussions may result in less care being delivered (54).

Although there is no formula to making a connection with another person when he or she is ill, there are some areas that can be explored together that can be mutually enriching. The health care provider needs to specifically ask the patient and family about them as a system patient, family, tribe, group, etc. Some examples are

- Since everyone is different, can you teach me how to help you get the information you need about your illness?
- How would you like me to share information with you about your illness?
- How much information, if any, would you like me to share with your family and others?
- Is there a particular person you would like me to include when you and I talk about serious matters?

- Would you like me to give you an overview of what is happening to you each time we meet or would you like me to simply answer your specific questions?
- What is your understanding of your health right now?
- What kinds of information would you like me to tell you?
- You have a very serious illness. Some people want to know what they have to prepare for in the near future. Is there anything that you would like to know?
- Is there anything you think we need to share with your family and others that may be helpful to them and you?
- Is there anything we can do together to make this time meaningful for you and your family?
- Would you feel comfortable contacting me if you have any questions?

Ultimately, a relationship is always between two people at a time. Opening up one's self to be taught by the patient and family about who they are and how they want to manage the illness is the perfect counterpoint to the awesome power held by the health care professional.

PRINCIPLES OF EFFECTIVE PATIENT AND FAMILY MANAGEMENT

The family, as defined by the patient, is virtually always the primary supportive structure for the patient. The family serves as a supportive environment, which provides instrumental assistance, psychological support, and consistent encouragement, so that the patient seeks the best available medical care. Early in the diagnostic and treatment planning phases, a family's primary functions are to instill hope and facilitate communication. For the patient whose disease is beyond life-prolonging therapy, caregiving becomes the primary focus for the family. In the latter situation, families must prepare psychologically and financially for the experience of life without the patient (anticipatory grief). Cancer and its treatments are always a crisis and an assault on the family system. As an uninvited intruder, cancer challenges the viability of the family structure to tolerate and integrate a harsh and threatening reality which cannot be overcome by force, denial, or even joint action. Joint action can be successful in terms of adaptation, and if the goals are clearly defined, there is an ongoing plan that promotes the optimal opportunity for successful goal attainment.

The health care team can guide the family in developing a problem-solving approach to the demands of the illness. The plan must be clearly communicated because it delineates each individual's responsibility so that the potential for goal-attainment is maximized. For many families with histories of effective functioning, the cancer experience represents the first time that their joint action may not overcome an external threat. Consequently, the cancer experience must be reframed into more realistic terms so that the threat can be perceived as manageable rather than destructive. If this is not achieved, the family can manifest anger, avoidance, displacement, or other forms of regressive behavior. For the family with a history of multiple defeats and failures, the cancer experience may be perceived as more evidence that they are incapable of managing the demands of an overwhelming world. The cancer experience temporarily alters the family structure, but it also has the potential to inflict permanent change. The health care team can significantly influence how these changes are interpreted and integrated into family life.

Patients often identify the effect on the family as the most upsetting repercussion of the cancer (3). Therefore, any effective intervention must include the patient, the family, and other social support networks. When patients consider their families, they may experience guilt, shame, anger, frustration, and fear of abandonment. Family members may experience anger, fear, powerlessness, survivor guilt, and confusion as they attempt to care for the patient. Family members may demonstrate the defense mechanism of displacement, transferring emotion from one person or situation to another and potentially confusing health care professionals. This confusion can create tension for family members and providers at a time when clarity and effective interactions are essential.

With little exception, assessment of the primary players in the family system is a rather straightforward process. The patient can be asked directly the following:

- Who do you rely on most to assist you in relation to the practical needs of your illness (e.g., transportation, insurance company negotiations)?
- When you get scared or confused, with whom in your family are you most able to talk?
- Who in your family most concerns you?
- Is anyone in your family overwhelmed with your ongoing medical and practical needs?
- Who in your family is coping least well with your illness?
- Is anyone in your family openly angry with you because of your illness?
- Are you particularly worried about how a specific person in your family is coping?
- Are you ever concerned that the demands of your illness will be too much for your family?
- Who is most dependent on you in your family?
- For what are they dependent on you?
- What would happen to your family if you were unable to maintain your present level of functioning?

The answers to these questions communicate to the patient and family that it is appropriate and necessary to gauge the impact of the cancer and its treatment on their lives and also provide the groundwork for the coordination of patient and family functions. In addition, role-modeling of open communication provides an environment of emotional support, flexibility in roles, and the implied and spoken promise never to abandon each other. This cannot be achieved unless the patient and family accept that some treatment effects and life events are beyond their control and there are limits to what is possible. The medical team has the responsibility to manage the physical aspects of the disease while the patient and family actively strive to integrate change, maintain normalcy, and accept the reality of the illness. The course of the illness—including death— must be identified as one of the potentially uncontrollable issues so the patient and family can focus on areas that are amenable to their influence.

Financial resources are virtually always a major concern of patients and families. When discussions of money and resources occurs within the family system, shame and guilt are common. These emotions are frequently alluded to but not openly discussed. This can be a barrier to open communication and can lead to patient fears and fantasies of abandonment. This is especially true for patients with advancing disease. Simultaneously the family may have concerns about life goals after the patient's acute need is past or death occurs. The expected range of emotional reactions within the family include anger, fear, guilt, anxiety, frustration, powerlessness, and confusion. Cancer confronts people with the reality of limitations.

In addition to the increasing costs of health insurance and home care, there are a wide variety of nonreimbursable, illness-related costs that can be financially devastating to patients and families. Transportation, nutritional supplements, temporary housing, child care, and lost work days are but a few examples of costs borne almost totally by patients and families for which there is seldom any form of reimbursement (55). Schulz et al. (56) found that respondents spent more than $200 per month on health-related expenses and reported significant negative effects on amount of time worked. Other studies have confirmed the negative financial impact of advanced cancer (57,58).

Money is almost always a metaphor for value, control, and power (59). How patients and family members communicate about money can be an indication of their perceptions of whether treatment is progressing or not. Thus interchanges about financial matters can actively represent latent communications about the perceived but unexpressed value of care and its potential outcome. For example, the patient and family may at the beginning of treatment state that money is no object and all resources must be expended so that the patient survives. By the end of treatment, however, a much more sober and realistic view concerning valuable and vanishing resources may become evident, and a greater discussion of investment and return may ensue. At this point in time, both patient and family may be actually talking about their ability to persevere. Concerns about money may then be an expression of exhaustion, diminishing hope, or anger. It is important that this metaphorical communication be seen as inadequate for open and direct communication. A metaphor is a signal and cue that indicate the need for open discussion. Openness is essential for the patient and family to discuss both their common and increasingly diverging needs. Patients and families must discuss their physical and spiritual fatigue, as well as specific financial concerns related to diminishing resources as a result of their struggle with cancer. The following clinical example illustrates a number of these points.

A 54-year-old married woman with three adolescent daughters expressed concern to the medical team about the ongoing cost of care for her terminally ill husband. The team felt that she was selfish and that it was unethical for them to consider the financial impact on the family in caring for the patient. Sensing their resistance to her plight, she felt rejected and became irate. A meeting with the patient, family, and relevant staff was organized by the social worker to openly address her financial concerns. The family had existing financial debts due to past medical treatments and consequently had ample reason for its concern related to the additional costs of care. Once this meeting resolved concerns over additional unneeded expenditures, the focus shifted to the much more emotionally laden issues related to the slow deterioration of the patient and the family's intense grief over the impending loss. It became evident that money for the family represented the loss of “everything.”

In some cases, the family may begin to perceive the dying patient as already being deceased. Anticipatory grief and premature emotional withdrawal from the dying patient creates confusion and a sense of terror in the patient. As a result, the family experiences guilt and shame because they are prepared for the loss but the patient is still alive.

SPECIFIC PROBLEMATIC PATIENT AND FAMILY BEHAVIORS

Physicians almost always identify “difficult families” as one of the most challenging tasks as a medical provider. Within the context of the family milieu, conflicts with staff may be unavoidable. It is the management of these conflicts that will determine the quality of the relationship between the patient, family, and professional staff. Conflicts may result if a family cannot follow simple guidelines or is intolerant of any physical discomfort that the patient may experience. Families that frequently criticize staff may be held to more rigid standards of behavior. Unit guidelines become laws, and the struggle for control results in fear and mistrust. Conversely,

patients and families who endear themselves to staff through verbal praise of the quality of care often receive warmth and flexibility, and, as a result, unit guidelines, such as visiting hours or number of visitors, may be relaxed.

The professional staff must be flexible in their communication styles or they may be perceived as violating family boundaries. This type of interaction can devolve into a battle for power and control. Conflicts that remain at the level of power and control make it virtually impossible to work with the patient and family to develop action-oriented, problem-solving strategies which unite all in a common set of values and goals. Effective symptom management is essential to engage the patient, family, and the staff toward a common goal. Poor management can lead to estrangement and abandonment (60). Open communication can establish goals within the context of the family and significantly reduce the strain. However health care providers must accept that at times any approach may be ineffective because the family structure cannot tolerate the influence of external forces. When this occurs continued attempts at open communication is the only alternative that can achieve some sense of mutual understanding and trust.

Families can exhibit a range of behaviors that the health care team defines as problematic and can potentially interfere with the delivery of medical care. Families can delay or prevent the completion of a procedure, verbally abuse the staff, or divide the team. Families may demand excessive amounts of staff time, repeatedly demanding sessions to review the same information. Confusion may reflect intense anxiety and the overwhelming nature of this experience for caregivers. Some families have unrealistic expectations and compare the responses of staff members searching for inconsistencies. Others fail to follow unit guidelines, consistently arriving well before visiting hours or delaying their departure from the hospital at the end of the day. Families may encourage patients to refuse medical recommendations or directives. Family members at times may speak for the patient and encourage the patient to withdraw and regress. Families may also possess unrealistic expectations of staff. Family members may perceive the staff as their own medical providers and seek personal care from the team.

Family functions include facilitation of medical decision making, reduction of stress, initiation of effective problem solving, and provision of comfort to the patient. If the family cannot provide these functions or is unavailable to the patient and staff, the staff may need to assume and fulfill these roles. At times, the staff may be resentful when families are unavailable or withdraw from participation. The burden on staff to care for these patients can be dramatically increased.

SPECIAL PATIENT AND FAMILY ISSUES

Children in the Home

Children of adult cancer patients may be an unseen and forgotten population. In acute care settings, children are not observed due to the patients' daytime appointments or policies that prohibit visits to inpatient units. Within the palliative setting, however, children and grandchildren are often present and may play an active role in the caregiving process.

Although salient developmental differences exist among children of different ages, those 3 years or older are able to verbally communicate their concerns so that an ongoing dialogue can occur. Highly sensitive to emotional and physical changes, children benefit most from an environment where they are continually given information in a manner that they can understand and are then encouraged to ask questions. Adults should be prepared for questions to be rather concrete and egocentric, centered around the immediate needs of the child and any potential change in the immediate family. Children are specifically concerned about the continued presence of parents and their own safety. Questions from children usually come one or two at a time. Children often need time to interpret and integrate the adult responses before returning for additional information, which may occur days or weeks later.

Methods to deliver medical information or relieve distress must vary according to each child's developmental stage. Children have fantasies about the etiology, meaning, and duration of a parent's illness. Young children need consistent information about the chronic nature of the disease so that they can anticipate changes and incorporate an understanding of these medical events into their world. Young children cannot fully appreciate the concept of permanence. The permanence of death or abstract terms, such as “forever,” are beyond their ability to integrate. Children need consistent support, measured doses of information, and an environment that can respond to their questions.

Developmentally, adolescence is the time for resolution of conflicts with parents as well as a quickened pace to individuation from the family. These processes can be delayed or significantly complicated by the family's focus on a loved one who is slowly deteriorating and dying. Competitiveness, sexuality, aggression, and peer relationships may compound and confuse attempts to cope with a loss and the end of a specific relationship.

Familial roles can be disrupted or confused during a parent's illness, and, as a result, adolescents may be required to assume adult responsibilities. There is a danger in treating an adolescent as an adult. The demands of adolescence under normal circumstances generate numerous stressors for the family, and a chronic illness at this point in the life cycle can significantly exacerbate the family's level of distress. Of particular concern, adolescents may be “parentified.” Physical maturity should not be equated with emotional, intellectual, or spiritual development. Adolescents can easily be overwhelmed with guilt and shame when their normal sense of power and grandiosity cannot control symptoms or death. This may have a long-term negative effect on the ability to tolerate emotional relationships. If the death of a parent or grandparent is to occur in the home, children must be carefully assessed, and appropriate interventions and support should be offered.

Psychiatric Illness

Histories of psychiatric disorders present further challenges in the effective management of patients and families. Psychiatric symptoms must be assessed and appropriately managed if the patient is to truly benefit from supportive care interventions. For example, symptoms, such as severe depression, may dramatically influence a patient's perception of pain and the ability of the health care team to control it. Furthermore, psychiatric symptoms of a family member can also cause a significant concern given the health care team's expectations concerning caregiving in the home by family members. Frequently expectations of family members as caregivers are relatively uniform despite the significant variation that exists in each family's level of functioning. Families must be assessed not only for their availability but also for their ability to provide adequate supportive care.

Patients or family members with a history of physical or sexual abuse may exhibit significant difficulty in the ability to develop a trusting relationship with the health care team and may require psychiatric management. Families with a history of abuse may try to withhold information related to the abuse and any attempt to assess the patient or family as an intrusion. Trust can only be developed over time as the health care team consistently verbalize their concern for patient and family as well as their availability for support and intervention. Families with severe dysfunction isolate and protect themselves from the outside world with rigid outer boundaries. Health care providers may define such a family as problematic when initial offers of assistance are refused. The team may experience frustration and rejection, which is inevitably communicated directly to the patient and family. Consequently, the family is lost as an ally and resource and as a result their isolation is increased. Although few in number, timely psychiatric referrals for these patients and family members are essential.

Addictions

A current or past history of substance abuse or an active addiction within the patient or the family creates a sense of alarm within the health care team. For example, the patient with a history of substance abuse may not be trusted by health care providers. The patient's behavior may be viewed as manipulative and if pain is a problem, there may be reticence to prescribe higher opioid doses if the patient is in pain, or even when dying.

Patients should not needlessly suffer as a result of a prior history of opioid abuse or their current treatment in a methadone clinic. Patients with a history of opioid addiction that is remote or has been effectively managed in a drug treatment program may be at much greater risk for the undertreatment of cancer pain. Consultation with a drug treatment facility may be necessary to plan effective management strategies.

Family members of a substance abuser can negatively influence or reinforce the patient's drug-seeking behavior.These families frequently possess a high level of cohesion, which can be characterized as enmeshed. Within this type of family, boundaries between family members are nebulous, and, as a result, family members may appear to be equally affected by the status of the patient. The care provided the patient may be sporadic or inconsistent because the family may be overwhelmed by the severity of the illness. Careful medical and psychosocial coordination between patient, family, staff, and, when appropriate, a drug treatment center, is necessary to maximize cooperation and to maintain quality care. Despite the level of frustration associated with this group of patients, dignified care is possible and attainable.

Intimacy and Sexuality

Advanced disease always affects sexuality and sexual functioning. Notwithstanding, the lack of libido and impaired sexual functioning are frequently overlooked or ignored as a concern of the patient. Open discussion of intimacy and sexuality with the team can actually result in enhancement of emotional vitality. In fact, an increase in intimacy can evolve as closeness is redefined and openly discussed. Patients' needs for intimacy and sexual activity must be examined and supported. A couple's expression of intimacy, even during terminal care, can create a sense of normalcy and relief in the midst of a highly traumatic course of medical events. As patients enter the terminal phase, these discussions require a high level of sensitivity. Most patients long to be touched and held, and it is not uncommon for spouses

or children to lie in bed with a dying patient to provide comfort and experience closeness or intimacy.

Dying at Home

While many patients and families describe a preference for death to occur in the comfort of their homes, this goal is not always attainable. Approximately 76–80% of patient deaths occur in medical institutions; only 10–14% of patients die in hospices, and the remaining 5–10% die in nursing homes or in patients' homes (61,62 and 63). The return to home, nursing homes, or hospices as the chosen places of death continues to increase, primarily as a result of the Medicare Hospice Benefit (64) and physician availability for home visits (65). A number of key psychosocial variables (table 54-2) may inhibit or prevent the occurrence of death in the home even with the highest level of supportive care or hospice services. Families must be carefully assessed and prepared for the death event. Key family members can be specifically questioned concerning their level of comfort or toleration for stressful events within the home. Preparations, including advance directives, wills, and do-not-resuscitate orders, should begin as early as possible to resolve all questions and informational needs that the family may possess. Typically, hospice services are only available in the home for a fraction of each day. Consequently, the patient's death will probably occur when the family is alone.

A family that wants to maintain a dying member at home despite complex needs may suddenly request that the patient die in the hospital. Reasons for rapid changes may be obvious and practical or may be irrational and unconscious. Either way, the resources and limitations of the family must be assessed and supported. Many terminally ill patients possess acute care needs (e.g., pain control, mental status changes, etc.), and admission may be warranted to provide brief respite for the family or to actually manage the death event.

When the Patient Dies

The final hours of the patient's life have significant meaning for the family and offer an opportunity for closure. The ritualistic need to be present at the exact moment of death can be very powerful for family members. The desire to be present for the death event is common, and for family members who are absent, significant regrets may result (66). Unexpected deaths occur in about 30% of patients; attempts to notify the family of the impending event is possible in 70% of cases (67).

Family members may require objective information concerning the cause of death, especially if the death was unexpected. Despite the terminal prognosis, many families need to understand why the patient died when he or she did. This information can mitigate the high level of distress and address any irrational concerns and fears associated with the death as it is happening.

Interactions with staff that occur immediately following the death can have a long-term effect. Emotional reactions of family members are expected, and crying, sobbing, and wailing are common. The therapeutic demands associated with the provision of terminal care challenges the health care professional to communicate with empathy while facilitating the initiation of essential tasks such as removal of the body and funeral arrangements. Families vary in their ability to receive information and emotional support during this time. The relationship between the family and the health care team influences how much of these preparations can be made prior to the death event and how much clinical intervention the family requires and can tolerate. Generally, families elect a spokesperson to provide and receive information but care must be taken to assess other members of the family. A follow-up meeting with the family by a social worker or nurse in the home can be very helpful to identify any family member who may be at risk for an abnormal grief response (68).

CONCLUSIONS

All patients and families possess a personal meaning of disease, prolonged illness, and death. These meanings are influenced over time by numerous factors. A clear understanding of these meanings, associated emotions, and their antecedents enhances the health care team's ability to provide care and anticipate potential problems. Information and education must be consistently available as the patient and family move across the disease continuum toward and post the death event (69).

Variables, such as cohesion, describe the quality and intensity of relationships within the family. High cohesion or enmeshed families lose more than a family member when the patient dies. For these families, part of their identity is also lost. Given their extreme level of dependence, these families may experience the death as catastrophic, which prevents the effective resolution of the loss. Chronic grief can exacerbate current psychological symptoms and influence health care practices. Bereavement follow-up among high-risk families is essential as a means to develop psychosocial prevention programs. The psychosocial obligation to the family does not end with the patient's death, and some families may require followup beyond the customary 1-year period. Given the intensity of the loss and the family's level of risk, grief must be monitored and resolved.

Ultimately, the role of the health care team is to create an environment with exquisite symptom management and honest and open communication (70). If these components are present, the opportunity exists to provide meaning to the death event. If this occurs, a sense of growth is possible for dying patients and family survivors.

DISORDERS OF SEXUALITY AND REPRODUCTION

URSULA S. OFMAN

The medical treatment of cancer patients has become increasingly effective during the past decades, extending lives and increasing survival. As a result the emotional and physical side effects of cancer treatment have gained increasing importance. Although the long-term, sexual side effects of cancer treatments have received considerable attention in clinical research during the past decade, potential infertility and its emotional cost have not been documented as thoroughly, perhaps in part because until recently there was no large cohort of long-term cancer survivors concerned with their own reproductive potential. Therefore, this newly emerging area of interest is to some extent a sign of more effective cancer treatments in younger populations.

After active treatment, survivors attempt to return to their previous daily routines. The challenge this represents for many cancer survivors is not trivial. Sexuality is one of the most complicated areas of functioning to regain. A diagnosis of cancer means having to face one's own mortality, possibly for the first time. The treatments are often painful, frightening, and intrusive and have the potential to erode one's sense of body integrity and body image. Memories of the illness and treatment together with their emotional aftereffects present a disruptive mix for sexual interest and functioning. These effects may continue long after active treatment is over and are “stirred” again at every routine follow-up visit.

Many cancer treatments interfere physiologically with some aspect of physical functioning, which also may impede an easy return to pretreatment life. These disruptive, long-term effects are not only those that directly affect sexual organs or gonads but also include other aspects of functioning that may interfere with the patient's sexual self-image, such as scars, a change in physique as a result of hormone treatment, ostomies, disfiguring surgery, and so on. Any change in appearance or functioning and any long-term treatment side effect can be a reminder of the illness and its treatment and may interfere with a sensuous, virile, and confident sexual self-image.

Changes in gender-role behavior resulting from the physical and emotional side effects of cancer surgery or treatment not only may impair the patient's sexual interest, but also affect the partner's perception of the patient as a sexual object. For both the patient and the patient's partner, it may be difficult to view each other from the same perspective that had previously drawn them to each other sexually. The patient may have become physically and emotionally dependent on the partner, who in return may have had to assume a nurturing, parenting role. After treatment ends, it may be impossible to return to the previous role distribution in the relationship. Both partners also are faced with the varying reactions of extended family, friends, and colleagues to the illness and subsequent difficulties. These reactions may range from affectionate support to angry withdrawal, adding to the psychosocial difficulty of the posttreatment period. Worries about the possibility of a recurrence, together with uncertainty about the future, heightened anxiety and depression, a sense of personal inadequacy, and diminished sense of control in either or both partners also can interfere seriously with the resumption of a sexual life (1,2 and 3).

Despite the consistently documented negative effects of cancer and cancer treatments on sexual functioning, cancer survivors' experiences with their bodies continue to be sexual in nature. Little has been done to identify the richness of patients' attempts to integrate their cancer experiences into a new sexual self-concept. Research in this area has been hampered, among other factors, by methodological issues including the need for innovative approaches to solicit and measure responses (4,5).

The psychosexual issues regarding the prospect of infertility in this population appear to be undocumented at this time. To face death and at the same time to surrender one's chance of living on in one's offspring must present a depressing, noxious combination for many of the young, childless patients beginning treatment. On a marital level, the issue of possible infertility undoubtedly has a long-term negative effect on the stability of the relationship as well as the need to renegotiate aspects of the implicit relationship contract. Unattached patients may not worry about possible loss of fertility in the early stages of diagnoses and treatment but still may feel damaged and limited in their capacity as a potential mate. Research in this area is urgently needed to alert the medical community to this issue and to develop strategies for helping these patients cope with this immense psychosocial stressor.

Although psychosocial causes are responsible for much of the sexual and procreative difficulty that survivors experience, physical causes are to some extent more easily researched and identified. Therefore, the vast majority of studies in this area focus on medically caused sexual and reproductive dysfunction. In the following sections, this literature is reviewed by disease site and systemic treatments.

SEXUAL AND REPRODUCTIVE SIDE EFFECTS OF CANCER TREATMENT IN WOMEN

Breast Cancer

Breast cancer patients may be the best researched group in terms of the sexual impact of treatment on sexual functioning. Partly because radical mastectomy had been the treatment of choice for all breast cancer patients, the effects of breast loss on women's sexual experience and life were researched early. In recent years, it has been widely accepted that comparable survival rates may be obtained in early breast cancer patients treated either with traditional surgical procedures (modified radical mastectomy) or with breast-conserving techniques combined with radiation and, increasingly, chemotherapy. The psychological and psychosexual outcomes of these two approaches have been compared in a number of studies. Although some studies report a tendency toward better preservation of body image and sexual functioning in patients who elect breast-conserving treatment (6,7,8,9 and 10), there is no conclusive evidence that these women also have better overall adjustment. Schover (11) questioned the frequently assumed connection between mutilating breast surgery and poor sexual adjustment posttreatment. She suggested that a woman's overall psychological health, relationship satisfaction, and premorbid sexual life appear to be far stronger predictors of postcancer sexual satisfaction than the extent of the damage to the breast and that even a less damaged sense of desirability and better preserved body image may have only a subtle impact on actual sexual functioning after surgery. It is also possible that age at the time of treatment plays a significant role in these patients' perception of quality of life. Wenzel et al. (12) found that immediately after treatment for breast cancer, younger women (younger than or equal to 50 years) reported significantly worse overall quality of life than the older women in their study. No significant differences in sexual dysfunction or body image were noted in this study.

In an effort to clarify the nature of women's response to lumpectomy, McCormick and coworkers (13) studied 74 women following lumpectomy and radiation and reported that 39% of the sexually active patients avoided the treated breast, 20% stated that their partner avoided it, and 48% noted breast discomfort during sexual activity; still, 90% indicated a high level of satisfaction with the results of their treatment.

The implications of breast reconstruction for the psychological adjustment of the mastectomy population is also beginning to receive attention. Rowland et al. (14) studied 83 women who had undergone reconstruction after modified radical mastectomy for early stage breast cancer and reported that these patients generally returned to premorbid levels of sexual satisfaction and comfort. The timing of the reconstructive surgery may be a relevant factor for these women. In a retrospective study of women who had undergone immediate breast reconstruction after breast cancer surgery, and women who had delayed breast reconstruction, Al-Ghazal et al.

(15) found significantly superior outcomes for women who had undergone breast reconstruction at the time of their initial surgery.

Although there is now a growing body of research dealing with the emotional and sexual consequences of surgery for early stage breast cancer, little is known about the effects of systemic regimens for breast cancer on sexual functioning. In a survey of 1098 women who had been diagnosed with breast cancer 1–5 years earlier and who had been treated with different adjuvant regimens, Ganz et al. (16) found that patients who had received chemotherapy seemed to experience a higher incidence of vaginal dryness and pain during intercourse, whereas women treated with tamoxifen reported a higher incidence of hot flashes, night sweats, and vaginal discharge. In a large survey of breast cancer survivors Meyerowitz et al. (17) found no significant differences between their subjects and age-matched healthy women on a standard measure of sexuality. However, women who were most likely to have reported negative impact on their sexuality from cancer treatment included women who had experienced changes in their hormonal status.

A further concern is posed by the large number of women now receiving hormonal treatment, especially tamoxifen, for long periods. The long-term side effects of these treatments are only now emerging slowly and require more research in the future. Research to date suggests that tamoxifen actually may produce estrogenic changes in the vaginal mucosa of postmenopausal women (18,19). However, its impact on symptomatic vaginal atrophy in these women is unknown (20).

Cancer of the Female Reproductive Organs

The incidence of sexual problems in women after gynecological cancer treatment ranges in various reports from 0% to virtually 100% (21). This reflects both the many methodologic difficulties of assessment in this field and the varied treatments for gynecological malignancies. These treatments range from laser surgery for cervical carcinoma *in situ* to total pelvic exenteration and vigorous chemotherapies for advanced gynecological tumors. The gynecological malignancies, with their obvious significance for sexual function, deserve comprehensive study to help women recover sexually as fully as possible (22). As Van de Wiel et al. (23) point out in their review of sexual function after cervical cancer treatment, many studies use frequency of intercourse as the sole indicator of the quality of sexual relations. This sheds little light on the true sexual status of the gynecological cancer survivor. Further refinements in research instruments and methodology hopefully will benefit this population. A review of the research in this area is also available in Berek and Andersen (24) and McCartney and Auchincloss (25).

Cervical Cancer

Cervical cancer is the fourth most common neoplasm in women, with 13,000 new cases of invasive disease diagnosed annually in the United States. Excluding *in situ* lesions, treatment consists of radical hysterectomy, radiation therapy, or a combination of both approaches. For almost two decades, researchers explored and compared the relative incidence of sexual dysfunction in women with cervical cancer after surgery or radiation (26,27 and 28). These studies indicate that at 6 months posttreatment, both surgery and radiation patients reported no significant changes in sexual functioning. At 1 year posttreatment, however, both populations reported decreased sexual interest and radiation patients reported significantly diminished sexual functioning with severe dyspareunia, postcoital bleeding, and pain on penetration. These studies highlight the difficulties posed for sexual recovery by pelvic irradiation for gynecological cancer. The sequelae of fibrosis, vaginal stenosis, and decreased lubrication (29) are likely to interfere with sexual function unless treated appropriately, promptly, and continuously with vaginal dilators, effective vaginal lubricants (e.g., Astroglide and others) and, in some cases, a hormonefree vaginal moisturizer such as Replens.

Total pelvic exenteration is a surgical procedure occasionally performed to excise advanced pelvic tumors *en bloc* in the absence of distant metastases. The surgery entails removal of the bladder, urethra, vagina, uterus, ovaries, and rectum; two ostomies are created. The treatment is such a serious challenge to both physical and emotional recovery that early clinical reports explored whether postoperative quality of life justified the continued use of so radical an approach (30,31). Some researchers have reported that construction of a neovagina combined with special support and counseling efforts offers an improved chance for sexual rehabilitation after surgery (32,33 and 34). At present, however, many questions remain regarding vaginal reconstruction. The long-term advantage to patient adjustment and satisfaction must be weighed against the risk of these procedures. The psychological and practical adjustments required by exenteration, which include body image, ostomy, and mortality concerns, also merit continued further study.

The impact of gynecological cancer on a woman's sexual self-esteem or sense of worth as a sexual partner remains an intuitively powerful yet little-studied factor in postcancer distress. Van de Wiel et al. (23) compared 11 women treated for cervical carcinoma with a group of nonpatient controls and found that although the frequency of sexual activity did not differ between the groups, the patients with cervical cancer valued sexual interactions significantly less and had a lower self-appraisal of themselves as sexual partners. Although the small populations studied and the retrospective nature of the work limit conclusions, this report marks a valuable effort to illuminate the subtler but far-reaching consequences of gynecological cancer for sexual well-being.

Endometrial and Ovarian Cancer

Endometrial cancer presents most commonly in postmenopausal women. Treatment consists of surgery, radiation therapy, chemotherapy, or a combination of modalities. Ovarian cancer presents in premenopausal and postmenopausal women; surgical evaluation and debulking are ordinarily the first step in treatment, followed by a chemotherapy regimen with a combination of agents. Only with the advent of chemotherapy for ovarian cancer has the previously dismal prognosis for this tumor improved markedly. Studies of the long-term implications of this illness for the survivor's sexual function have begun to appear (21,35,36). Compared with healthy controls, women with these cancers report lower frequency of sexual behaviors, lower levels of arousal, increased incidence of dyspareunia, and problems with body image.

The ovarian cancer patient faces the serial trauma of a serious cancer diagnosis, major pelvic surgery with resultant changes to the vagina, a demanding chemotherapy regimen, treatment-related onset of menopause in the premenopausal patient, and complete loss of fertility. The psychological, physical, and hormonal impact on sexual function in this population merits further careful study.

The endometrial cancer patient must often contend with radiation changes to the vagina and pelvis (37). Vaginal changes include fibrosis with resultant shortening and narrowing; reduced elasticity of the vaginal wall; and diminished lubrication, creating high risk of dyspareunia. As mentioned earlier, the consequences of radiation to the vagina may be avoided or alleviated by the regular use of vaginal dilators and sexual comfort can be improved by the use of appropriate lubricants, vaginal moisturizers, and intercourse positions. An important area for future inquiry is the implementation of patient support and education plans for women facing pelvic radiation, which may increase contact with health care providers and encourage crucial patient compliance with these strategies during the demanding months of treatment, especially during the first year posttreatment, as radiation changes evolve and produce physical and relationship distress.

Vulvar Cancer

Vulvar carcinoma is a rare tumor arising primarily in older women. In early stage disease, treatment may consist of wide local excision. In more advanced disease, the lesions are often multicentric and radical vulvectomy is performed, which entails removal of clitoris, labia minora and majora, and bilateral inguinal lymph node dissection. Postoperatively, patients may experience a high degree of complications, including wound infections and lymphedema of the lower extremities as well as introital stricture. Research attention has begun to focus on this population in recent years (31,38,39) and reports document that sexual dysfunction posttreatment for vulvar cancer is common and affects all phases of the sexual response cycle.

Sexual and Reproductive Implications of Systemic Cancer Treatments in Women

Sexual and reproductive consequences of surgery are obvious, occur at the time of treatment, and are usually permanent. In contrast, the side effects of radiation and chemotherapy may accumulate over time and may not be permanent. Premature menopause, which is a frequent longterm side effect of systemic cancer treatments, such as chemotherapy, hormone therapy, and pelvic irradiation, have implications for both sexual and reproductive functioning. Ovarian failure secondary to single-agent and combination chemotherapy has been documented (40). Alkylating agents appear to be the most notorious cause of ovarian failure in older women (aged 40 and older). Resulting symptoms include amenorrhea and menopausal symptoms, such as hot flashes, irritability, vaginal dryness, and atrophy of the vaginal epithelium. The treatment increases the likelihood of vaginitis, dyspareunia, and decreased sexual interest. Although some women recover normal ovarian functioning after treatment, premature menopause is the long-term outcome for many women. Aside from the specific drug regimen used, age is an important variable in this context, with older women more prone to loss of fertility and early menopause, particularly after treatment with larger, cumulative drug doses. In a study of women who received high dose chemotherapy for breast cancer with autologous bone marrow support, Winer et al. (41) found that even though overall quality of life after treatment was relatively high in this population 1 or more years after completion of treatment, problems with sexual functioning were common.

Gonadal dysfunction and infertility after radiation therapy are difficult to predict. The central location of the ovaries within the pelvis, close to major nodal areas, makes damage from radiation scatter and leakage likely. As with chemotherapy, radiation damage is dose-related, cumulative, and age-dependent. Loescher et al. (42) found that permanent infertility after 25 treatments of 500 Gy occurred in 60% of women aged 15–40 years and in 100% in women aged over 40. Because pelvic radiation interferes with the vasocongestive processes of female sexual arousal, vaginal lubrication also may be impaired, and dyspareunia and vaginitis may develop. Therefore, pelvic radiation may result in long-term adverse effects on female sexual functioning (43).

Radiation treatment is often combined with chemotherapy regimens. In such cases it is difficult to differentiate between toxicity incurred from radiation versus that due to the chemotherapeutic agent(s). Data from women who received combined radiation and chemotherapy for Hodgkin disease suggest that these combination treatments result in additive ovarian toxicity (44).

CANCER OF THE MALE REPRODUCTIVE ORGANS

Prostate Cancer

Prostate cancer is the most commonly diagnosed cancer in men. It affects mostly older men; 80% of all diagnoses are made in men aged 65 years and older. Men and their partners in this age group are often at a developmental stage dominated by losses: retirement, death of peers, and separation from adult children who move away. These losses may include diminished sexual activity secondary to sexual dysfunction that precedes the cancer diagnosis. Changes in sexual functioning due to normal aging are often compounded by age-related chronic diseases, such as hypertension, and their treatment. In a prospective study of 22 men with stage B or C prostate cancer, Schover and von Eschenbach (45) found that 23% reported painful ejaculation prior to therapy and 40% reported erectile difficulties. More recently, Zinreich et al. (46) reported that 63% of 43 patients (mean age, 67.7 years) with varying stages of prostate cancer had erectile dysfunction before undergoing any cancer treatment. Of these, 44% were never able to obtain an erection and 56% reported difficulty maintaining erections during intercourse. For many elderly couples, the man's erectile difficulty results in a complete cessation of sexual activity.

Treatment for early stage disease commonly consists of surgery or radiation therapy. In early stage prostate cancer, the advances in medical technology have meant gains for sexual functioning posttreatment. Quinlan et al. (47), in a case series of 500 men, reported an incidence of erectile dysfunction of 32% with nerve-sparing surgery techniques compared with 85% after radical prostatectomy. Recovery of erectile functioning is often slow, however, and may exceed 6 months in some patients (48)

Traditional radiation regimens for prostate cancer also may produce erectile dysfunction as a long-term side effect. Schover (49) found in a review of the literature that the generally estimated 50% of erectile dysfunction after definitive radiotherapy may be inflated. The actual incidence may lie between 14% and 46% of all cases. The mechanism believed to be responsible for the development of erectile dysfunction in radiation patients is vascular scarring, which may develop 6 months posttreatment or later. Helgason et al. (50) confirmed the general observation of increased incidence of erectile dysfunction in men treated with radical prostatectomy compared to men treated with external beam radiation.

Advanced-stage prostate cancer is commonly treated with testosterone deprivation, accomplished by bilateral orchiectomy or the administration of estrogen, flutamide, or luteinizing hormone-releasing hormone analogues. All these interventions produce sexual side effects, including loss of desire for sexual activity and impaired erectile functioning. Men undergoing hormone treatments also are confronted with body image issues, reduced energy levels, and hot flashes, which may contribute to the development of sexual problems.

Testicular Cancer

Unlike prostate cancer, testicular cancer typically affects young men. It is the most common cancer in men aged 17 to 34 in the United States. These men are confronted with a life-threatening disease at a life stage in which they are supposed to separate from their families of origin and find their own identity as an adult. The demands of the illness interfere with the developmental goals of this population and interfere with the young man's concept of himself as an independent, strong, and virile person.

In the past, treatment routinely included unilateral orchiectomy, retroperitoneal lymphadenectomy, and either chemotherapy for nonseminomatous tumors or radiation for seminomas (51). Men with metastatic seminomas may receive chemotherapy in addition to radiation. Despite the traumatic aspects of treatment for testicular cancer and the psychosocial issues faced by this group, survivors of the disease fare quite well as far as their long-term sexual outcomes are concerned. Studies document levels of decreased levels of sexual desire and erectile difficulties that are not significantly different from age-matched controls. Fertility issues due to retrograde ejaculation as a result of surgical damage to paraaortic sympathetic nervous system pathways are a prominent concern for men after retroperitoneal lymphadenectomy (52). Rieker et al. (53) found in a retrospective study of 223 testicular cancer survivors who were more than 1 year postdiagnosis that 30% experienced overall performance distress, 10% had erectile difficulties, and 6% were anorgasmic. Fossa et al. (54) surveyed 31 men postbilateral orchiectomy and found that despite difficulties in dosing androgen replacement therapies, most patients were psychologically and sexually well adjusted to their situation. More evidence that sexual outcomes in this population are strongly influenced by psychosexual factors comes from Arai et al. (55), who found in a study that included patients who had been on a surveillance protocol post surgery that these men reported the same extent and nature of sexual difficulty as men who had also been treated with chemotherapy or radiation.

Thus, fertility concerns relating to retrograde ejaculation and chemotherapy appear to be the most common sexual side effects of testicular cancer and may impair sexual quality of life for these patients (56,57). Despite the relative low incidence of reported sexual dysfunction in this group posttreatment sexual support seems to be warranted in this young population. They may experience problematic relationships because of persisting low-grade sexual dysfunction, which is treatable (58).

Sexual and Reproductive Implications of Systemic Cancer Treatments in Men

Testicular function in adult men is particularly susceptible to injury by chemotherapeutic agents. Affected are the germinal epithelium, the Leydig cells responsible for steroidogenesis (59), and the hypothalamic-pituitary-testicular axis (60). Dysfunction of the testis occurs shortly after initiation of treatment and can persist for months or years after function has returned to other tissues. Manifestations of toxicity are reduction in testicular volume, severe oligospermia or azoospermia, and infertility (61). The effects of the alkylating agents have been particularly well documented. For example, doses of chlorambucil below 400 mg cause reversible oligospermia, and cumulative doses in excess of 400 mg result in azoospermia and germinal aplasia (62). Low sperm count and elevated follicle-stimulating hormone levels are physiological indicators of germinal aplasia. The Sertoli cells are more resistant to chemotherapeutic agents and consequently, testosterone levels may remain within the normal range during and after treatment.

Combination chemotherapy regimens may have an even more disruptive effect on the germinal epithelium than treatment with a single agent. MOPP (nitrogen mustard, vincristine, procarbazine, and prednisone) results in irreversible germinal dysfunction in male lymphoma patients. However, other regimens that are equally efficacious cause germ cell aplasia in fewer patients many of whom experience the return of spermatogenesis with time (40). Chemotherapeutic agents are not known to affect the male sexual response cycle directly.

In contrast to the consequences of chemotherapeutic regimens on male reproductive capacity, which have been established for a number of antineoplastic agents, the effects of radiation therapy on sexual functioning and fertility have received little attention to date (43). The testis and both the germinal epithelium and the Leydig cells are very radiosensitive. Damage and recovery appear to be dose dependent. Doses as low as 150 cGy may result in a marked, if transient, suppression of sperm production. Disruption of sperm production increases with accelerating doses; at 2000 to 3000 cGy, recovery may take 3 years; at 4000 to 6000 cGy, approximately 5 years; and above 6000 cGy, sterility seems permanent (40). By affecting the vasocongestive mechanisms necessary for erectile functioning, pelvic radiation also may cause erectile dysfunction in men.

CANCER SITES IN BOTH SEXES

Bladder Cancer

Bladder cancer arises primarily in older men and women, who already may have experienced age-related changes in sexuality. Whereas treatment in the United States previously consisted of cystectomy for lesions of any stage, early bladder carcinoma *in situ* without infiltration may now be treated with local excision and bacille Calmette-Guérin.

In patients with invasive bladder cancer, cystectomy is still the treatment of choice. Recent advances in the development of nerve sparing cystectomies in men and women promise improved sexual functioning outcomes in both sexes (63). A common sexual side effect for men after radical cystectomy is erectile dysfunction resulting from transection of the nerves governing erection (64) and loss of ejaculation secondary to excision of the prostate at the time of surgery. Changes in the sensation of orgasm may ensue. Patient response to this loss is not well documented.

In women, cystectomy may result in a narrowed or shortened vagina, scarring, and numbness or loss of sensation, all of which may impair the excitement response. Further-more, removal of both ovaries during surgery causes premature menopause in premenopausal patients, which may lead to reduced vaginal lubrication and desire. The simultaneous creation of a stoma and external diversion of urine generates concerns about body image, odor, leakage, and spills and thus may contribute

to sexual avoidance and other difficulties (65). In recent years, continent cutaneous urinary diversion and orthotopic bladder substitution have become clinically accepted alternatives to ileal conduit diversion. The a priori assumption had been that postoperative quality of life would be better following these types of continent cutaneous diversions. However, although studies on the validity of this assumption have been hampered by a lack of consensus regarding methodology, follow-up studies do not seem to confirm any advantage in quality of life or sexual functioning in these patients (66).

Colorectal Cancer

Cancer of the colon and rectum is the second most common cancer in the United States; approximately 140,000 new cases are diagnosed annually, primarily in older men and women. Surgery remains the mainstay of treatment; resection of the tumor with pelvic lymphadenectomy may be followed by radiation, chemotherapy, or both. Pelvic lymphadenectomy may result in damage to the parasympathetic nervous system, causing erectile dysfunction, and to the sympathetic nervous system, causing retrograde or diminished ejaculation. Past studies have reported a varying incidence of these side effects after treatment (67,68 and 69). More recently Havenga and Welvaart (70) studied 26 men with rectosigmoid carcinoma, nine of whom were treated with abdominoperineal resection and 17 of whom were treated with low anterior resection. Only two of the patients with abdominoperineal resection returned to sexual activity, five had erectile dysfunction, and seven were anorgasmic. Patients who had low anterior resection reported less sexual dysfunction after surgery; 12 maintained sexual activity, and four reported either erectile dysfunction or anorgasmia. Further evidence that abdominoperineal resection produces significant sexual dysfunction was reported by Koukouras et al. (71), who studied 60 sexually active male patients with colorectal cancer who were treated with high anterior resection, low anterior resection, or abdominoperineal resection. Patients with the abdominoperineal resection had the highest incidence of sexual dysfunction; 65% became sexually inactive, 45% lost all erectile ability, and 50% reported absence of ejaculation. New surgery techniques to address primary rectal cancer promises to improve sexual outcomes for some of these patients. In a prospective study, Maas et al. (72) evaluated the sexual outcomes of operative procedures that combine pelvic nerve-preserving techniques with radical tumor resection to ensure optimal local tumor control with minimal bladder and sexual dysfunction. They found that the nerve-preserving technique results in low morbidity and good functional outcome. Impotence was related to sacrifice of the inferior hypogastric plexus and preservation of the superior hypogastric plexus was crucial for ejaculation.

Hojo et al. (73) described the use of a nerve-sparing approach to pelvic lymphadenectomy in 134 patients with advanced disease. They found that although bladder dysfunction was best prevented with a nerve-sparing procedure, preservation of sexual function in men is more difficult and requires a high degree of nerve preservation. This approach is therefore not advisable for patients with locally extensive disease.

In patients with early stage rectal cancer who are treated by amputation of the rectum alone, erectile dysfunction appears to be less prevalent, but problems with the orgasm phase persist (74). There is a glaring shortage of studies focusing on the sexual side effects of treatment for colorectal neoplasms in women.

After the creation of a colostomy, both men and women must contend with issues of changed body image and sensitivity about cleanliness, odor, and fear of accidents. Sutherland and coworkers' early studies (75) have remained clinically on target; they found that the sexual impact of the ostomy far exceeds the extent of physical handicap. Depression, anger, and fear of being repugnant are common emotional reactions postoperatively and may contribute to a pattern of sexual avoidance. The medical staff must anticipate these issues and offer support to patients, whose challenges include self-care of the ostomy, overcoming fears concerning changed appearance, and regaining physical self-esteem. Other patients who are farther along in this process may provide invaluable help to the recovering colorectal patient in this regard. Overall adjustment to the colostomy may take more than 1 year, as documented by Hurny and Holland (76).

Sexual response after colorectal surgery remains an insufficiently understood area, particularly in view of the current high prevalence of this tumor. For women particularly, the issues of sexual recovery after colorectal and bladder cancer remain too little explored. Nonetheless the impact of pelvic surgeries on the female excitement and orgasm responses, as well as the impact of the ostomy issues on desire, may be surmised to be great. The value of treatment interventions for sexual dysfunction in this population, including both penile prosthesis implantation and sexual counseling for the patient or couple, is also an appropriate area of study.

Other Cancers

Patients with less common tumors and those with common tumors that do not directly affect the organs of sexual response have received little or no research attention with regard to the sexual sequelae of their treatment. The diagnosis and treatment of all cancers have far-reaching psychological implications for the patient and family that lie beyond the scope of this review. These matters are covered comprehensively elsewhere (77). Some cancer treatments pose a particularly severe challenge to the recovery of normal selfesteem and restored body image; treatments involving limb amputations, marked facial and other appearance changes, or loss of normal phonation are examples. In a rare study of the sexual outcomes of patients with head and neck cancer, Monga et al. (78) found that although the majority of patients studied continued to be interested in sex, only 49% were satisfied with their sexual functioning after treatment. Older patients (65 years and older) reported more satisfaction with their sexual partner and current sexual functioning than younger patients, who also tended to have more advanced disease and lower performance status, and significantly poorer sexual functioning.

The simple passage of time does not heal all wounds. In the area of sexuality, it is not uncommon for problems to become more severe with time (79). The adjustment to cancer and its elements of disfigurement is by nature a slow process, and problems with adjustment and recovery, including those in the sexual and relationship arena, may often be more accessible to counseling by oncology mental health professionals during the first and second posttreatment year than at a later stage in cancer survivorship.

Cancers that require systemic treatment with chemotherapy, whole body irradiation, or bone marrow transplantation challenge the patient physically and emotionally more than most surgeries or radiation regimens. Treatments may be lengthy and arduous, depleting the patient of energy and causing severe side effects. Sexual functioning is clearly affected by many of these regimens. In recent years, the sexual concerns of female bone marrow transplant patients have received some research attention. Ovarian failure secondary to conditioning treatment with melphalan or cyclophosphamide and total body irradiation is associated with profound effects on sexual functioning, most commonly vaginal dryness, loss of desire for sexual activity, and difficulties with sexual intercourse (80). Ostroff et al. (81) found that standard regimens of hormone replacement therapy did not alleviate all sexual impairment experienced by women with treatment-related ovarian failure. In a study comparing bone marrow transplant survivors and a matched sample undergoing maintenance chemotherapy, Altmaier et al. (82) found that bone marrow transplant patients reported a higher incidence of sexual difficulties. Ostroff and Lesko (43) confirmed the prevalence of sexual dysfunction in bone marrow transplant survivors. Clearly, this population is at increased risk for sexual dysfunction and would benefit from further research attention.

Patients with Hodgkin's disease are now often successfully treated with aggressive chemotherapy. Treatment is associated with a high degree of infertility in both men (80–90%) and in women (50%) (82). The interrelationship in young cancer survivors between cancer treatment, loss of desire and sexual dysfunction, lost or impaired fertility, and relationship distress remains clinically inescapable but very little studied.

A group that also has received very little attention concerning the sexual and fertility related sequelae of cancer and its treatment are survivors of childhood cancers. Relander et al. (83) surveyed 77 adult male survivors of childhood malignancies. One-third of them had been treated for hematological cancers, one-third for central nervous system tumors, and one-third for other malignancies. They found that patients treated for tumors in the hypothalamic-pituitary region, with testicular irradiation, and those treated with high doses of alkylating agents suffered from severe gonadal and sexual dysfunction as adults. Puukko et al. (84) found in a survey of 31 survivors of childhood leukemia that although they did not differ from healthy, age-matched controls with regard to the frequency of sexual intercourse, their sexual identity was less well developed and they had more restrictive attitudes about sexuality and sexual pleasure. More research is needed to assess the long-term physical and emotional outcomes of these young patients with cancer.

PREVENTION AND MANAGEMENT OF SEXUAL AND REPRODUCTIVE DYSFUNCTION IN CANCER PATIENTS

Medical Strategies to Prevent and Manage Sexual and Reproductive Dysfunction

Efforts have been made to reduce sexual and reproductive morbidity by refining surgical and radiation therapies. Examples include the development of nerve-sparing surgical techniques to preserve erectile function after prostatectomy (85) and nerve-sparing retroperitoneal lymph node dissection (RPLND) for men with clinical stage I nonseminomatous testicular cancer to preserve emission and ejaculation. In some cases the effort to preserve ejaculatory function and avoid other treatment side effects in men with nonseminomatous tumors who do not evidence metastatic spread led to the use of unilateral orchiectomy followed by careful observation. A further example of the attempt to preserve quality of life is the strategy of offering observation as a treatment for nonmetastatic seminomatous testicular cancer instead of immediately proceeding with chemotherapy post-RPLND, thus preserving gonadal functioning. New, nerve-sparing techniques that involve preservation of the superior hypogastric plexus also may contribute to the preservation of ejaculatory functioning (86) in these men.

Similar attempts have been made to preserve sexual functioning in some treatments used for cancers in women. For example, wide local excision for vulvar cancer (38) and lumpectomy of breast tumors mark efforts on the part of surgeons to preserve sexual function and body image as much as possible without compromising treatment efficacy.

In both men and women, efforts to keep pelvic radiation doses to a therapeutically efficacious minimum may reduce the incidence of radiation-induced sterility and allow recovery of gonadal function. Radiation damage to gonads in men now may be reduced drastically by employing a new testicular shield that reduces scatter to about 10% of the patient's prescription dose. In women, oophoropexy (the surgical transposition of the ovaries to a midline position behind the uterus) reduces the ovarian exposure of women receiving pelvic radiation in about 50% of patients (87). These developments reflect the growing willingness of the oncology world to try to preserve and maintain sexual and reproductive function while providing appropriately aggressive cancer therapy.

Medical treatments for iatrogenic sexual dysfunction and infertility also have begun to be developed. Loss of emission and ejaculation is a frequent side effect of RPLND in men. Because most men undergoing this procedure are young (17 to 34), this loss is a serious concern. For men with adequate sperm production before sterilizing cancer treatment, cryobanking is usually advised. However, many patients present with suboptimal sperm before treatment. To secure a postthaw sample adequate for spousal insemination, more than 20 million sperm per milliliter with at least 40% progressive motility is generally required (40). Multiple ejaculates, if time permits, can increase the total of viable sperm for storage. For men after RPLND, antegrade ejaculation may return with time and, in some men, sympathomimetic drugs such as ephedrine or anticholinergic drugs, such as diphenhydramine or imipramine, may help to facilitate normal ejaculation. Electroejaculation is possible to harvest sperm in men who do not recover ejaculatory function (88). Recently, there have also been some encouraging medical developments to help patients overcome sexual difficulties. Particularly notable in this context is pharmacologic injection therapy for erectile dysfunction and ongoing research exploring the use of topical agents to promote erections in men with organic impotence.

Other interventions to help cancer patients overcome iatrogenic gonadal and sexual dysfunction focus on hormonal intervention. Hall and others (89) treated nine women with acquired hypogonadotropic hypogonadism after therapy for cranial tumors using a physiological replacement regimen of exogenous gonadotrophin-releasing hormone. This restored ovulation and fertility in 78% of the participants. Although the technology does not yet exist for the safe thawing of frozen ova, cryobanking of fertilized eggs (i.e., embryos) is possible. Several fertility centers now offer this option. Bone marrow transplant patients may be stimulated with hormonal therapy at the end of chemotherapy to stimulate ova for collection. The fertilized ova are frozen until later implantation in the patient or a surrogate mother. This procedure is experimental and controversial (43) and carries the potential burden for the father to decide how to proceed if the spouse's therapy is not successful.

Women who undergo premature menopause after cancer treatment need medical intervention to alleviate menopausal symptoms and prevent atherosclerosis, hypertension, cardiovascular accidents, and osteoporosis. Unless an estrogen-sensitive tumor was involved, hormonal replacement should be considered (90). Wren (91) argued that hormone replacement may be feasible in most women after genital tract cancer. In his view, estrogen/progestogen regimens will not affect malignant cell growth in vulvar and vaginal cancer as well as squamous cell carcinoma of the cervix. Although the endometrium and the ovary contain hormone receptors that may respond to estrogen by increased growth factor production, a large number of women with these cancers were cured by the initial treatment and would benefit from hormone replacement without risk of stimulating cancer growth. Women who were not cured may benefit from treatment with progestogens alone or estrogen and progesterone in combination to relieve any discomfort caused by estrogen deficiency.

Aside from estrogen replacement therapy, nonhormonal medications, such as clonidine, methyldopa, and betablockers, may be used to control hot flashes (92). Emotional instability also may be addressed with serotonin selective reuptake inhibitors such as fluoxetine or sertraline. Topical solutions to counteract reduced lubrication and changes of the vaginal lining include Replens, vitamin E oil, Chaste berry, 1–2% testosterone cream, and limited doses of estrogen cream or Vagifem (93). Androgen treatment may be indicated in women with reduced bioavailable androgen levels after chemotherapy (94) and may improve sexual interest.

Psychosocial Prevention and Intervention for Sexual Difficulties

Although efforts are under way to prevent and alleviate adverse sexual and reproductive side effects of cancer treatments medically, severe physical and emotional damage can occur nonetheless. Even patients whose treatments did not affect sexual end organs report being impaired in their sexual enjoyment after cancer treatment. Indeed, impaired sexual functioning during or after cancer treatment can occur regardless of the specific physiological changes that have taken place. The sexual response cycle (desire, arousal, and orgasm) is a complex process that may be disrupted by a wide range of factors both physiological and psychological.

Sexual response during and after cancer treatment is vulnerable to the impact of the cancer itself, medical treatment side effects, other medical problems, medications, pain, depression, anxiety, partner response, and subtler psychological effects, such as changed body image and belief in cancer myths. Cancer patients must face their own mortality, undergo uncomfortable, sometimes lengthy, or disfiguring treatments, and deal with the effect of their illness on spouse, family, and work. An understandable consequence of this process can be loss of sexual desire and impaired sexual response. Von Eschenbach and Schover (95) found that the most frequent sexual side effect reported by men with cancer is erectile dysfunction, whereas women are more likely to lose interest in sex altogether. Loss or impairment of sexual desire may be triggered by the trauma of diagnosis and treatment, which interferes with the patient's perception of himself or herself as a sexual person. There may be concerns about one's attractiveness and the partner's reaction that contribute to an overall withdrawal from sexual activity. Concerns about sexual functioning may contribute to sexual avoidance even if sexual desire per se is not impaired.

Although inhibited sexual desire, sexual avoidance, and erectile dysfunction may be the most frequently observed sexual difficulties in this context, any sexual dysfunction may be caused by the patient's and the partner of the patient's reaction to the trauma of the experience. Little has been reported on how ethnic differences in sexual socialization and attitudes affect sexual outcomes of cancer treatments. Most populations studied at major cancer centers are predominantly white, and there often are not enough members of different backgrounds to enable researchers to compare subgroups along these lines. Wyatt et al. (96) compared 147 African-American and white breast cancer survivors and found that even though both groups in their study were from very similar sociodemographic backgrounds, African-American women were significantly less likely to be comfortable with and practice oral sex and any self-touching/masturbation than their white counterparts. Also white women were much more likely to report that breast cancer had a negative impact on their sex lives. Ethnic differences in survivor groups deserve much more attention to enable treatment providers to deliver psychosexual support in an optimal fashion to all patient groups.

The medical team often fails to help prevent development of sexual dysfunction by not addressing the topic with the patient. This may be due to a number of factors such as discomfort with the topic or a concern about appearing intrusive or presumptuous. When the patients are elderly, young, single, widowed, or homosexual, sexual concerns appear to be particularly difficult to address (58). All too often, sexuality is viewed as being a concern only for men and women who are sexually active within a committed relationship. Every patient, regardless of current level of sexual activity, has a perception of himself or herself as a sexual being and is invested in knowing that he or she can function sexually even if not pursuing any sexual relationships at the moment. Often, the medical staff waits for the patient to open the topic and concludes that there is no interest in sexual issues if the patient remains silent. Vincent et al. (26) found that 80% of patients receiving cancer treatment were interested in more information about sex, although 75% said they would not initiate conversation about it with their doctor. Cancer patients often feel they should be glad to be alive. Asking about sexual concerns may seem ungrateful and frivolous. If physicians and nurses initiate communication about sexual side effects of proposed treatments at the time of treatment decisions, they signal to the patient that sexual functioning is a legitimate concern that can be addressed.

Privacy and confidentiality are crucial prerequisites for discussing sexual concerns with patients. Sexual matters cannot be discussed productively during rounds, when several staff members are present or when a roommate is within earshot. Under such conditions, the clinician is likely to encounter vague responses and little enthusiasm for the topic. Assessment of the patient's sexual status and history at the time of treatment decision provides the crucial basis for members of the medical team to give appropriate support and information about the possible impact of treatment options on sexual functioning. It also signals to the patient that sexual concerns are understood to be an integral component of patients' quality of life. The time of diagnosis and treatment decision is a stressful one for the patient and his or her partner, and sexual concerns are not likely to be in the forefront of their minds. However, sexual functioning needs to be addressed from the start to support the patient in the struggle to adjust to the impact of cancer treatment on self-image and functioning. Clear and detailed information enables patients and their partners to anticipate problems and prepare for them. The nursing staff in particular can be instrumental in helping patients and their partners deal with both emotional and physical side effects by explaining the physiology involved, normalizing the experience, and giving pragmatic advice and coping strategies. The timing of these interventions is determined by the situation. Certainly in emotional or medical crisis situations, such as when a relapse of the cancer is discovered, it is not helpful for the patient to be asked about sexual matters. Sexual advice is best received when it specifically addresses the problems with which the patient and his or her partner are currently struggling.

At the time of treatment decision, the patient needs to know about the sexual and reproductive issues that may arise as a result of the treatment. Patients also need reassurance that help is available should sexual difficulties occur. As treatment proceeds and patients are seen for follow-up visits, the sexual status should be assessed by asking openended questions like, “How are things going in your relationship?” and “How are things sexually?” As patients express difficulty, it is easy for the caregiver to normalize the experience of the patient and to offer specific advice on how to improve matters sexually.

Because any change in appearance and functioning may have sexual consequences, the medical staff should consider the potential sexual implications of all treatments offered to the patient and address them with all patients. A good resource for both staff and patients is a pair of booklets published by the American Cancer Society that address sexual concerns of male and female patients after cancer treatment. The booklets are lucid, practical, and informative about both sexual side effects and strategies to deal with them (97). If patients continue to experience sexual difficulty after cancer treatment, referral to a sex therapist for careful evaluation and treatment is indicated.

Often, a short course of sexual counseling suffices to facilitate better adaptation and functioning, particularly for patients who had a satisfactory sex life before the cancer diagnosis. Sex therapy with cancer patients is geared to address the specific difficulty expressed by the patient and the patient's partner. Sexual attitudes and fears are explored, and frequently physical exercises are prescribed to do at home. These exercises are designed to reintroduce sexual activity slowly. Usually these exercises follow a graded approach, beginning with general physical pleasuring and gradually becoming more sexually focused. This approach is particularly helpful to patients who have a great deal of performance anxiety, who avoid sexual activity for fear of being unable to complete it, whose confidence in their ability to function is shaken, and who feel unattractive and shy about how their bodies were affected by cancer treatment. Similarly, partners can be traumatized by the experiences they had in the course of the treatment and also may benefit from such exercises.

SUMMARY

The focus of the available literature is primarily on the incidence of sexual and gonadal dysfunction after cancer treatment. Very few authors compare their population with normal age-matched controls. Considering the high incidence of sexual difficulty in the general population (98), such comparisons might reveal how very successfully many cancer survivors are able to integrate sexual side effects and continue some sexual life despite the impairing physical and emotional side effects of their treatments. New medical strategies aim at prevention and amelioration of sexual side effects and infertility. Comprehensive psychosexual support during and after treatment promises to further aid patients and their partners in minimizing negative sexual outcomes. Sexual side effects in particular can be addressed in brief sexual counseling or therapy. Informing the patient of possible side effects before treatment makes early intervention of psychosexual difficulties possible. Psychosocial aspects of fertility concerns of the cancer patient during active treatment and as a survivor have received little attention so far, possibly because of previous experience, when long-term survival of young patients was rare. With advancing technology in cancer treatment, this cohort of long-term survivors is likely to grow and requires an adequate response to these medical and psychosocial needs.

HOME CARE

BETTY R. FERRELL
BARBARA A. HASTIE

INTENSIVE CARE OF HOME CARE

Since the mid-1980s, there has been a major shift in home health care. In the United States this shift was caused originally by the prospective system; it has been sustained by current trends toward managed care. Long hospital stays have been replaced by early discharges and the shifting of the burden of care to the home. The intensity of care for these home care patients has also changed because of the demographics of both patients and caregivers. Home care nurses and family caregivers have been charged with managing patients with complex and highly technical treatment plans. Home care is characterized by intensive management of symptoms and by needs for supportive care of both the patient and the family caregivers who assume the burdens of cancer and its treatment (1,2,3,4,5,6 and 7).

Complexities of Home Care in the 1990s

Until recently the study of symptom management has been largely confined to major symptoms, such as cancer pain, and to acute care settings. Recent studies have focused on the special needs of patients in other settings, including the nursing home (8,9,10,11,12 and 13), the hospice (14,15,16,17,18 and 19), and the home (2,20,21 and 22). Several factors can influence pain management in these settings. Heavy reliance on family members, access to diagnostic facilities, and, often, limited pharmacy services can influence the effectiveness of pain and symptom management at home.

It may be assumed that comfort is enhanced in home care, as the home environment has been considered preferable to institutional settings. Indeed, patients, families, and health care professionals often elect care at home because they assume that patients are more comfortable there. Research has not confirmed this perspective—at least in the case of pain management—and has demonstrated that treatment may not be substantially better at home (20,23). As researchers have extended studies into the home care setting, barriers have been described that actually hinder pain management in the home, including patient's and family's fears of addiction, failure of the patient to report pain, and limited access to needed services (24,25,26,27,28,29 and 30). These facts emphasize that fulfilling the patient's preference to be at home may not necessarily result in effective symptom management.

Symptom management is different at home than in the hospital or other institutional setting (20). Hospitals typically provide technical equipment and services for acutely ill patients. For patients with complex problems, inpatient care often includes a variety of aggressive or invasive strategies for diagnosis and definitive treatment of the underlying conditions. Home care, by contrast, relies heavily on low-tech strategies, concentrating mostly on symptom management. The overall effectiveness of these different strategies at home in comparison with hospitals remains difficult to analyze.

Cancer as a Family Experience

Cancer and other life-threatening illnesses, such as AIDS, are generally recognized as affecting the entire family unit rather than a single individual. The recent shift in health care, with movement toward home care as the predominant setting, emphasizes the importance of family involvement in the total care needs of the patient. It is indeed remarkable that care which only a decade ago was reserved for intensive care units by specially trained registered nurses is now delegated to family caregivers in the home environment who have had little or no preparation to assume both the physical and emotional demands of illness (31,32,33,34,35,36,37,38,39,40,41 and 42). Home care has advanced from low-tech care, focused on follow-up for patients discharged from hospitals, into its current status as the setting for active treatments, including chemotherapy, intravenous fluid administration, blood transfusion, complex wound care, and many other technical procedures. Recent literature has acknowledged the intense demands of family caregiving at home largely in the areas of technical care, acquisition of skills, and provision of intense, 24-hour physical caregiving. Less emphasis has been placed on the emotional burdens of assuming responsibilities for the patient's well-being or peaceful death in the home (43,44,45 and 46).

The home environment can be viewed as a delicate balance. At one end of the spectrum are the many demands that the home care environment offers that, if out of balance, can result in intense burdens for family caregivers and compromised care for patients. At the other end are the many benefits of home care. The home care environment potentially can offer the patient improved physical comfort, the psychological comfort of familiar surroundings, an opportunity for healing of relationships, and the ability for patients and families to benefit from the compassion of giving and receiving comfort care and a shared transition from life to death (15,45,47,48).

Another significant trend has been the use of home as the setting of care. In the late 1970s and early 1980s, health care professionals generally made the decision whether to discharge a patient to the home or to offer an extended stay in an inpatient setting based on patient or family preferences. The decade of the 1990s transformed home care as the primary setting of active treatment as well as palliative care. Very important, however, has been the diminished choice on the part of patients and families primarily due to changes in the health care system (38,49,50). Although some patients and families have volitionally chosen home care, others have had care relegated to the home setting due to health care system or hospital determinants.

The potential benefits of home care also have been threatened in the United States by the managed care movement. It is now common practice for patients to be discharged from acute care stays with a limited number or duration of home care visits, often limited to only a few nursing visits or a duration of care of only a few weeks. Subsequent care then is provided only by the patient and family with no professional support.

The outcomes of home care may often be best evaluated by the effects on family caregivers following the death of the patient and during bereavement. Hospice providers have long recognized that positive experiences with caregiving in the home result in positive bereavement and adaptation by family members after the patient's death. Feelings of inadequacy in providing home care, patient complications, and deaths that are less optimal than anticipated can result not only in the patient's diminished quality of life or quality of death, but also in long-term consequences for the family. Home care then is best viewed as not merely care provided to a single individual in the home environment but rather as a family experience in which every aspect of care provided to the patient or the provision of care by the family caregiver will impact the others (51,52,53,54 and 55).

Public Denial of Death and Influence on Care

Much literature has addressed the social need to deny death and the reluctance of individuals in society to accept death and dying amidst a health care system focused on cure. Efforts by the hospice movement, the social influences of AIDS, the prevalence of cancer, and other factors have in many ways made our society confront the reality of death in recent years. In an effort to diminish societal denial of death and heighten awareness of the growing end-of-life movement, the well-known documentary reporter Bill Moyers produced a 4-part series for public television that aired in fall 2000. Through his years of work in preparing “On Our Own Terms: Dying in America,” Moyers sought to address myriad aspects of how individuals, families, and the health care systems view and manage death in the United States. This was the first time in modern U.S. history that such a well-known media personality devoted such substantial effort to examining the societal views toward end-of-life. For professionals in the end-of-life movement, this represented a major coup in overcoming societal silence, denial, and aversion to such a critical stage in life.

In the 1990s, several other programs were developed in the United States to address the need for increased research, professional education, and advocacy in end-of-life care, including aspects of home care, hospice, and community involvement. The Project on Death in America was established by the Open Society Institute through a grant from the Soros Foundation, one of the wealthiest philanthropic foundations in the United States. Interestingly enough, the benefactor recognized the incredible dearth of resources and training in caring for those at the end of life. Therefore, a major portion of the budget is appropriated toward Project on Death in America programs addressing aspects of end-of-life care in various professional fields, including medicine, nursing, social work, chaplaincy, and other social service fields. Efforts in training and research are intended to encompass a wide breadth of topics, including home care and caregiver issues, factors influencing care, and neglected areas such as how correctional systems manage pain and symptoms in incarcerated terminally ill persons.

Another organization emerged in the 1990s with the expressed purpose of addressing public policy and advocacy issues related to end-of-life care, including home care. Americans for Better Care of the Dying (ABCD), based in Washington, D.C., is involved in policy analysis, lobbying, and educating lawmakers as to the under-allocation of funds for necessary services for those entering the final stages of life. Ironically, the growing crisis in home care funding and services actually spawned the creation of organizations such as ABCD. At the end of the twentieth century, lawmakers were beginning to take notice while society as a whole seemed to maintain its denial of the staggering impact of caregiving and death on families and society.

These efforts at examining the end of life as a natural life stage have been balanced by intense media attention on new potentially curative therapies, such as gene therapy, biomedical engineering, and advanced technologies. This attention encourages continuation of the death-denying society. Health care providers should recognize that for many family caregivers and patients, the death that they are now witnessing is perhaps their first personal encounter with the termination of life. Family caregivers struggle with the sanctity of life and denial of death just as do health care professionals and society at large. However, the profound experience of dying, or of caring for a loved one who is dying, transcends all aspects of home care. This experience has been described as an all-encompassing aspect of the clinical care of the terminally ill patient at home (38,56,57 and 58).

Physical and Psychosocial Issues

The needs of patients and family caregivers in home care span the domains of quality of life, as depicted in Figure 56-1. Home care needs most often involve physical needs, such as management of pain and other symptoms, and treatment of the side effects associated with treatment of the disease. Nutritional needs, sleep disturbance, fatigue, incontinence, and other physical aspects of disease and treatment are common priorities of home care. In fact the area of physical well-being and symptom management has been the focus of home care and also is the area with the greatest scientific basis for the practice of care in the home (59).

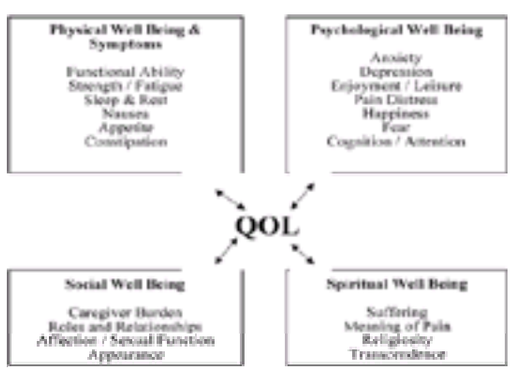

FIGURE 56-1. Dimensions of quality of life (QOL).

Psychological well-being is predicated on pharmacological management of symptoms, such as anxiety and depression, as well as counseling to address issues such as fears, loss of control, and the many other psychological demands of lifethreatening illness (60,61,62,63 and 64). Similar to psychological needs are the patient's social needs, such as the ability to maintain appearance and normal roles and relationships, and family issues such as financial concerns. The ability to meet psychological and social needs is more difficult outside palliative care programs, in which there is limited access to social workers, clinical psychologists, and other support personnel (65,66,67,68 and 69).

Spiritual well-being presents perhaps the greatest challenge in home care. In the institutional setting, such as the inpatient hospital, chaplaincy services may be more available. Yet it is during the advanced stages of illness, when care takes place in the home, that spiritual needs, like psychosocial needs, may become more prominent (70,71 and 72). This issue emphasizes the importance of psychosocial and spiritual assessment to determine unmet needs.

Innovative home care programs have begun to incorporate volunteer programs in order to meet the demands that simply will not be addressed in traditional home care services or those for which reimbursement is not possible. As a model example, the City of Hope National Medical Center has recently instituted a program in cooperation with the community Interfaith Council of Churches to begin providing intensive volunteer support for respite care and other services in order to enhance the current services provided in home care.

In addition, in recognition of the importance of community and volunteer involvement in home care and end-of-life care, the Robert Wood Johnson Foundation developed a funding program in 1999 through the Mid-west Bioethics Center to support partnerships that comprise community-based organizations and state government agencies aimed at enhancing collaborative efforts in the area of end-of-life care. Several of the recipients of the Community-State Partnership grants created innovative programs to incorporate faith-based organizations in training community and family members in home care aspects. The programs were established to coincide with the efforts of the Moyers series, “On Our Own Terms.” The longitudinal effect of the Moyers program coupled with the nationwide Robert Wood Johnson Foundation projects will remain to be seen. However, initial results of such efforts have evidenced a steady increase in the professional and societal end-of-life movement, with increased attention to the importance of home care, the needs of caregivers, and the lack of funding allocation for much needed services.

CHALLENGES TO SYMPTOM MANAGEMENT AT HOME

There are at present many uncertainties about the future of the health care system in the United States and in virtually all countries. A certainty, however, is that care continues to shift into the outpatient and home care environment. Thus it is patients and families who will assume the majority of care in the future. One of the greatest challenges in this area derives from demographical and social influences such as the impact of a steadily aging population of patients with multiple chronic illnesses. Care of the cancer patient at home becomes far more difficult when the patient is 80 years old and also has concomitant illnesses such as cardiac disease, hypertension, and diabetes, with their associated medications and treatments (73,74,75,76 and 77). There is still limited attention focused on the special care needs of the geriatric population at home and that of their caregivers, who are often elderly children (54). Expanded efforts in attending to complex needs of the aging will need to be adopted, especially given the growing percentage of population over the age of 65.

An equal challenge rests in the demographics of family caregivers in the home. Research has revealed that approximately 70% of caregiving is provided by elderly spouses in the home and an additional 20% is provided by daughters or daughters-in-law, who are often balancing full-time employment as well as the demands of their own families while providing intensive care to their loved ones (38,78,79,80,81 and 82).

One of the most challenging aspects of home care will be the future impact of managed care and similar factors influencing the types and extent of care to be provided

in the home. Factors, such as limitations in the types of services available, the frequencies of visits, and the duration for which this care can continue, will make home care extremely challenging. In essence, as the intensity of needs is increasing, the available resources in home care are diminishing.

Involvement of Family Caregivers in Medications

A primary task of home care related to cancer and other terminal illness is management of medications. It is enlightening to realize that home care nurses and other professionals assume similar responsibilities in other settings only after formal courses in pharmacology and with support available from colleagues, pharmacists, and physicians reached by direct access. This is particularly true in oncology, where symptom management is often either accomplished on an as-needed basis for symptoms, such as nausea or anxiety, or with necessary titration of around-the-clock dosing of medication such as analgesics (58,83).

Management of medications is important not only to preserve the patient's comfort but also to diminish the burden on the family and avoid costly complications such as repeat hospitalizations when medications are not effectively used (84). Patients and family caregivers often do not have the necessary knowledge to judge indications for administration of medications or the delicate issues involved with titration or the side effects of medications. Health care providers can make a valuable contribution to the care of patients at home by insuring that medication schedules are made as simple as possible using single agents rather than multiple drugs, and maintaining the simplest possible routes of administration and dosage schedules. Patients require assistance with important decisions regarding the use and titration of medications and practical techniques such as written dosage schedules, use of self-care logs, and provision of guidelines to help in medication choices. Table 56-1 includes examples of the types of decisions patients and families have reported in the use of pain medications at home. This illustrates the practical dosing decisions and the intense dilemmas patients and families may face in trying to seek relief of symptoms while avoiding the hazards of overmedication. Patients and families require information as well as support in their decisions regarding medications and treatments.

Deciding what to give "I am the 'pill pusher.' I have to assess intensity, mix meds, and try to find the right combo." Deciding when to give "Totally, I regulate it. I can tell by the look on her face when she needs more pain medicine." "I wonder about the time—whether to give it sooner or later." Night duty "I set my alarm to get up and get his meds." "Dad gives Mom the medications she's taking. He sets the alarm during the night." Reminding/encouraging "She doesn't like to take them, so I encourage her." "My mother has been reluctant to get involved in taking drugs for pain. I have tried to encourage her to take the drugs." "My role has been more of an emotional support rather than one of dispensing any drugs." Keeping records "I write down what time it is and how many pills I give." Fear of addiction "I try to control pills. He's popping them before it's time. He's angry . . . was he liking them too much? The prescription said every 4 hours, but I would try to hold off if he was crying at 3 hours for 15 minutes. I kept them in my drawer after I found he was popping them." "I know he needs the controlled drugs, but I hate to see him take them. So I don't remind him. He knows when he has pain. The only time I talk to him is when I think he has had too much medication." Doing everything "I do everything for her—give her the medications, et cetera." "I administer the pills. I do everything for him."

TABLE 56-1. THE CAREGIVER'S ROLE IN THE ADMINISTRATION OF PAIN MEDICATIONS

Other Concerns of Family Caregivers

An exploratory study investigated the experience of managing pain in the home from the perspectives of the patient, the primary family caregiver, and the home care nurse (83). In particular, the decisions and ethical conflicts encountered by members of ten patient-caregiver-nurse triads were studied. The subjects reported that the use of medications prompted the majority of the decisions and provoked most of the conflicts. However, decisions related to assessment, the future, and how to live with pain were identified as well. The subjects also identified other areas that created conflict such as spiritual and theological issues, determining when to tell the truth, and interpersonal relationships. Similar findings emphasizing the importance of information and support for family caregivers have been reported by other investigators (32,33,43,44,45,50,85,86).

An additional burden of family caregiving, often neglected, is the costs assumed by patients and family caregivers themselves related to pain management and home care (84,85,86,87,88 and 89). Families incur significant expenses related to home care in advanced disease, much of which is not reimbursed. Costs include direct expenses, such as medications, as well as extensive indirect costs such as loss of wages (38,39,88). Most of the cost savings to third-party payors have resulted in increased costs assumed by patients and families.

Cultural Considerations of Home Care

The increase in multiculturalism in the United States has added another dimension to the complexity of health care provision as well as coverage. Language barriers, cultural traditions, and religious beliefs create the need for increased sensitivity and knowledge on the part of health care professionals. No longer is health care—or home care—merely for English-speaking, Anglo-Saxon, Judeo-Christian patients and families (90). These facts present additional challenges when considering assessment of pain and symptoms as well as issues related to beliefs about death in various cultures (91,92). Assessment and treatment are complicated by cultural factors, and health care providers along with researchers seek ways to understand and accomplish a nonbiased medium from which to practice (93,94). Likewise, health care providers may be caught by the demands for individualized care in the midst of a growing multicultural society (95).

Some researchers argue that efforts to make all care and assessments standard without considerations of multicultural factors may actually increase health care costs (93). By taking into account these issues, health care providers assess the patient holistically. This approach may incorporate family and community resources as aids to planning culturally sensitive and appropriate care (96). While this may seem like a logical necessity, it has the risk of presenting even more demands and obstacles to an already overburdened home care system.

Notably, in many non-Anglo communities, it is tacitly acknowledged as a “duty” in the culture that the burden of much health care automatically shifts to the extended family. In theory this increases the number of caregivers, but it does not increase the certainty of training, understanding or efficacy of home care. In such environments, familiarity with one's ethnic, religious, or cultural beliefs—especially with respect to terminal care—is best appropriated within a person's respective community. Not only is this true for the patient but also for the surviving family and community. It may justify transcultural home care.

Benefits of Care at Home

A primary benefit of home care—its cost—has led to its growth. Care at home can significantly decrease the costs of care throughout the entire illness, from outpatient diagnostic procedures to active treatments, such as the administration of chemotherapy or blood products, to terminal care. Work at the City of Hope National Medical Center has demonstrated the significant cost reductions in comparing inpatient costs with those of home care (87). In this setting the potential cost savings of effective home care was shown to partly involve a reduction in unnecessary readmission for controlled symptoms. Work by Grant and Ferrell initially documented a cost of $5.1 million for the years 1989 to 1990 related to admissions for uncontrolled pain by this institution. Follow-up analysis for the subsequent years of 1991 to 1993 has demonstrated initial cost savings to the institution of $2.7 million in reduced admissions costs because of efforts to improve the quality of pain management (84).

Home Care of Children

Most literature regarding home care has focused on the care of adults. The care of children is often perceived to be less demanding or even normal as families are usually expected to provide such pediatric home care. On the contrary such care is quite demanding because of the characteristics of the ill child, the parents, the siblings, and the extended family. Recent studies have explored the experience of parents in caring for a child with pain. These studies added a dimension to the previous research related to families and pain and also described the decisions and conflicts in pain management for children (97,98,99 and 100).

Parents of pediatric cancer patients in pain often reported that their health care team did not take their child's pain seriously and did not provide adequate analgesia to relieve the pain (97). This is consistent with recent literature describing the inadequate assessment and management of pediatric cancer pain (101). However, when specialized pain teams were involved, they were better able to relieve not only the child's pain but the parents' emotional suffering as well. The parents' role in decision making varied from allowing the child to have control whenever possible regarding his or her treatment to personally administering nondrug methods of pain relief that temporarily alleviated both the child's pain and the parents' feelings of helplessness.

SUPPORTING FAMILY CAREGIVERS IN HOME CARE

The literature consistently supports the importance of family members during advanced illness. The caregiver's own health, attitudes, and knowledge have a profound

effect on the successful management of the patient's symptoms. This is especially important in the care of terminal cancer patients at home (102,103).

The control of chronic pain remains a perplexing problem that may have important implications for stress experienced by the caregiver. Increased anxiety, depression, marital and family conflicts, embarrassment, guilt, resentment, low morale, and severe emotional and physical exhaustion are commonly reported by distressed caregivers (33,42,43,44 and 45,50,104,105 and 106). Studies have revealed an overall marked decrease in dimensions of caregiver quality of life, which are particularly prevalent when the patient has unmanaged pain and symptoms (107). Indeed pain management may present caregivers with unique kinds of stress. For example, pain management often requires drugs that must be monitored carefully to achieve maximum pain control safely with minimum side effects. Newer, high-tech pain strategies, such as infusion pumps and chronic spinal infusions, also require the caregivers to have special knowledge and skills. The areas of greatest burden for caregivers in the management of pain include demands on time, emotional adjustment, distressing symptoms, work adjustment, sleep adjustment, and family and relationship adjustments.

Studies of family factors influencing pain management among cancer patients at home, made by this author and colleagues, suggest that caregivers need education and support to cope with many of these issues (20,23,37,53,54). These unanswered questions may lead to increased anxiety, stress, and overall burden on the caregiver that in turn may translate into inadequate pain management. The need for education and support for caregivers cannot be overemphasized in the management of pain in the home. Other researchers have asserted that identification of psychological needs of caregivers early in the home care process helps to form the basis for interventions to improve the long-term psychological outcome and bereavement after the death of their loved one (55).

As an advocate of the ethical issues facing family caregivers, Callahan (66) has been a champion of family caregivers and the struggles they face. Callahan has questioned the obligations of family caregivers when heroic, extraordinary care is needed. Improved social support from government agencies as well as a sensitive, responsive society that rewards the heroic efforts of family caregiving is required given the current demands on families. Yet such social recognition and value is often not present (66).

Jennings and colleagues (32) have discussed the ethical challenges the individual, family members, and society as a whole face as a result of the homebound chronically ill. Management of the chronically ill in the home results in social withdrawal and isolation, transformation of family relationships and roles, and the placing of new burdens on both the patient and family caregivers. Altilio and Rigoglioso (108) argued that payers and providers have moral and ethical responsibilities toward caregivers. Such responsibilities range from viewing the caregiver as a member of the health care team and involving them in all aspects of care planning to providing ongoing support, after-care, and bereavement care. Their plan includes the provision of improved insurance coverage for both the ill family member and the caregivers. Altilio and Rigoglioso noted that increased involvement in the care team may help caregivers feel more prepared to manage the huge challenge of home care. Conversely they also mention that there are dangers in incorporating caregivers as members of the treatment team because professionals may feel the right to abdicate their own responsibilities to the overburdened caregiver. Essentially, Altilio and Rigoglioso call for a paradigm shift in viewing caregivers. They assert that health care providers should be major advocates for caregivers in order to improve discharge planning to home care, provide ongoing education, skills training, and support, and simplify insurance coverage policies. This latter point is especially important because it would allow families to know exactly what to expect and how to safeguard against failure for lack of knowledge or understanding.

Assessment of Symptoms

Assessment of both acute and chronic symptoms can be difficult in the home. In the absence of diagnostic facilities and multidisciplinary specialists, care must be taken to avoid attributing symptoms to preexisting illness. Underreporting of symptoms may be common for a variety of reasons. Cancer patients may not report pain because they fear the social implications of opioid analgesics. Elderly patients are often stoic and dread additional diagnostic tests, hospitalization, and new medications (73,74). Although home care nurses and family caregivers may be extremely helpful, most patients require careful evaluation of significant new complaints as well as continued assessment for the management of chronic or persistent symptoms.

Patients with chronic pain should be evaluated for psychological problems. Functional assessment, including ambulation and a broad variety of activities, may represent important indicators of overall physical well-being. Most patients with chronic pain also have significant anxiety or depression at some time. The need to identify and manage anxiety and depression cannot be overemphasized in the adjunctive management of chronic pain, because ongoing symptoms have been shown to significantly affect general emotional well-being, adjustment to illness, cognition, pain perception, and overall treatment outcome (109,110,111 and 112). Formal assessment screening instruments for functional and psychological impairments are helpful in this evaluation and minimize the possibility that detectable problems will be missed (75,113,114,115 and 116).

Nondrug Treatments

In addition to the extensive responsibilities related to the pharmacological management of pain, patients and family caregivers use many nondrug strategies for pain relief at home. The home care environment offers the benefit of access to nondrug pain relief methods, and patients and families often feel more comfortable with these alternative methods at home. Previous research has demonstrated that patients and family caregivers infrequently receive formal information or guidance regarding nondrug strategies but rather rely on their own attempts to discover methods that may add to the patient's comfort (23,45,58).

Since 1991, our program of research at the City of Hope has evaluated a structured program for introducing nondrug pain methods at home. These interventions include both physical and cognitive methods. Physical means of pain relief include such interventions as heat, cold, and massage, and cognitive strategies include relaxation, imagery, and a variety of distraction techniques (117,118). Studies have demonstrated a marked decrease in anxiety and depression, especially at the end of life, when such nonpharmacological techniques are incorporated into traditional treatment regimens (119,120 and 121). Given the increase in attention to complementary therapies, the National Institutes of Health conducted an extensive study evaluating the efficacy of various nontraditional modalities. Their conclusion confirmed the benefits of certain types of complementary medicine on treating cancer pain (122).

Our experience has also demonstrated that patients and families are very eager to add nondrug interventions to their overall pain management (117,118). These provide great benefit to the patient by not only enhancing physical relief but also alleviating anxiety and giving the patient a better sense of control. We have also demonstrated that family caregivers have found nondrug comfort measures to be extremely valuable in reducing their sense of helplessness. Families are very eager to learn skills that will add to the patient's comfort. It is these family interventions that are often recalled during bereavement as positive memories of their ability to provide greater comfort during terminal illness.

Other more structured interventions can also be incorporated by referral to health care professionals such as clinical psychologists, psychiatrists, social workers, and others who can offer many other treatments that might assist in the patient's comfort at home.

EDUCATING CAREGIVERS

Although there is much evidence demonstrating the need for educating caregivers, few programs have been developed to address the intricate components and complex issues related to providing care to chronically or terminally ill in the home.

Cancer Pain Education for Patients and the Public

Beginning in the early 1990s structured pain education interventions were offered by the City of Hope investigators to assist patients and families at home (123). In 1994, the researchers extended such training into communities. The research was divided into two phases. In phase I (1994–96), the intervention was transferred to home care nurses to integrate pain education in their home care visits. Essentially, phase I focused on issues related to the integration of pain education into routine home care services. From 1996 to 1998, phase II focused on the evaluation of effectiveness of intervention implemented by the home care clinicians.

From those initial programs evolved a larger, more comprehensive effort to extend such training nationwide. In this effort to address the needs of caregivers and to improve patient and public education, Ferrell and colleagues at the City of Hope National Medical Center in Duarte, California, developed and implemented educational programs targeted toward staff from hospitals, ambulatory care, hospices, home care settings, and consumer groups. Thus, the Cancer Pain Education for Patients and the Public (CPEPP) program is designed as a “train the trainers” model to educate staff working directly with patients and the public. Following such training participants return to their communities and offer training to patients and the public, essentially caregivers. Although CPEPP is designated for cancer pain patients, its principles can be applied to other disease-specific groups. The general training guidelines of caregiving education can be standardized for preparing lay members of the community. The CPEPP program will offer three national programs of training with follow-up. The long-term evaluation of influencing patients, the public, and family caregivers, will be forthcoming. It is the hope of the investigators that such a model will be the beginning of a trend to meet the training needs of caregivers and the health care professionals with whom they interface.

In other studies Ferrell and colleagues recognized the limitations and challenges that health care professionals face in attempting to train patients and their caregivers (124). They asserted that the health care field must explore innovative methods of training, such as trained volunteers or peer educators, while overcoming significant

barriers of time and limited resources to achieve such goals. Key to any strategy developed will be the incorporation of the principles of effective teaching and learning.

Other Efforts of Preparing Family Caregivers

In a review of literature from 1975 to 1999, Pasacreta and McCorkle (86) found a dearth of data-based literature and limited number of well-designed training programs for caregivers. The limited programs that were discovered represented three broad categories: (a) educational, (b) counseling/psychotherapeutic, and (c) hospice/palliative home care. Of those dimensions of training, most interventions were aimed at individuals or families, typically were located at one facility, and often represented selection bias in well-adjusted caregivers. Nonetheless the disparate and limited attempts at training caregivers further highlights the extent of the need. Pasacreta and colleagues discovered that a 6-hour psychoeducation program for cancer caregivers had a positive influence on several factors (85,86). For instance, caregivers relayed an improved sense of confidence in providing care as well as improved perception of their own health. The focus on skills and application of principles was particularly noteworthy as the training addressed symptom management, psychosocial support, and resource identification.

In an effort to increase communication and collaboration between health care professionals and family caregivers, the Children's Hospital in Philadelphia, Pennsylvania, developed a unique training program that placed family members as faculty (125). The “Family Faculty” trains parents of children with special health needs to present classes on family-centered care to physicians, nurses, and other hospital staff. The underpinnings of the Family Faculty program is based on the philosophy of family-centered care and the belief that health care professionals will learn firsthand the hardships and challenges encountered by family caregivers. Such increase in insight is expected to enhance understanding that would lead to better treatment planning and coordination between providers and families.

Resources for Caregivers

Since the middle 1990s, researchers and clinicians have recognized the need to develop resources specifically aimed at family caregivers. Stetz, McDonald, and Compton (126) discovered five major categories of informational needs of family caregivers: (a) preparing the caregiver, (b) managing the care, (c) facing challenges, (d) developing supportive strategies, and (e) discovering unanticipated rewards and benefits. These researchers asserted that health care professionals have a responsibility to prepare family members with educational strategies that include skill development, access to and use of resources, home care management, decision-making, and self-care.

Levine (38) has highlighted projects that were developed in the 1990s to create “step-by-step” guides on home care principles for lay caregivers. For instance, the Visiting Nurses Association (127) published the *Caregiver's Hand-book: A Complete Guide to Home Health Care* as a reference tool for lay family members as well as to assist new professionals in the field. Other such guides are available for caregivers including a fully illustrated book entitled *The Comfort of Home: An Illustrated Step-by-Step Guide for Care-givers* (128). Many other such resources have become available for family members who find themselves in the throes of having to manage the home care of their loved one. While such informational materials can be enormously helpful, the caregiver is met with the challenge of finding sufficient time to study the techniques and principles they offer.

Within the context of caregiver preparation, it is important to highlight nongovernmental, nonprofit organizations that have burgeoned in the latter part of the twentieth century. For instance, the American Cancer Society has an extensive network of resources and highly defined materials for caregivers as well as for patients. The Wellness Community also serves an important function in providing group support for patients and their families. Cancer Care, a New York-based group, is another organization established exclusively to develop and offer resources to patients and caregivers. Yet these organizations do not offer practical training in caregiving skills.

Just as the technology boom has advanced medical treatments, it has also allowed greater access to resources for caregivers. If a family is fortunate enough to own a computer and have access to the Internet, a wealth of information is available. Moreover, many treatment centers have created “information centers” that allow access to the World Wide Web. Although such an environment can offer volumes of material, caregivers will have to be cautious not to become further inundated and to find the time and energy to pursue such resources. The fact that such items are available within moments represents a step forward in trying to prepare caregivers for their “other full-time job” of managing the home treatment of their loved ones.

Public Policy Implications

To examine trends in end-of-life care across generations, Byock initiated a 10-year longitudinal study in Missoula, Montana (15). That project seemed to bring national attention to end-of-life care, and it seemed to propel new efforts in advocacy and public policy in that field. Despite the increase in advocacy efforts to enhance federal allocation of funding for home care efforts and the needs of caregivers, little has been done at the federal level to lessen the burden. At the outset of the twenty-first century, home care continues to face enormous and increasing challenges with decreased funding. The burden on health care professionals as well as on families has increased exponentially in the past decade. With the expanding aging populations, home care will likely take on a different look in the new millennium (21,129).

In the late 1990s several U.S. senators attempted to pass legislation that would increase resources and rights for endof-life care, including aspects of home care. Such legislation never passed Congress. As a result efforts increased to pursue federal legislation that would include special benefits for caregivers. In early 2001, a new program was launched that offers $113 million in grants to states under a new National Family Caregiver Support Program. In November 2000 Congress created the new caregiver program as part of the Older Americans Act Amendments. The central element of the program consists of grants to states distributed through a congressionally mandated formula. Other components include innovative, competitive grants and a new Native American Caregiver support program. Ideally the funds allocated will allow programs at the state level to provide critical support, such as home and community-based services, including information, assistance, training, counseling, support, and respite opportunities for caregivers. Essentially the programs are aimed at allowing families to maintain their caregiver roles.

This is particularly relevant when considering the cost of caregiving. In 1997, the national economic value of informal caregiving—care provided by an untrained family member—was $196 billion, dwarfing the national expenditures of $32 billion for formal home health care and $83 billion for nursing home care. Notably the estimated economic value of informal caregiving represents approximately 18% of the total national health care expenditures (38). Although the outcome of the new $113 million caregiver program remains to be seen, at least there seems to be some recognition of the value and important role of family caregivers as well as the tremendous toll that providing such care takes on an individual and whole family systems.

In addition to governmental factors, other policy experts have attempted to influence whole systems of care. In the late 1990s, Lynn, founder of the Center to Improve Care of the Dying as well as the advocacy group, ABCD, proposed a comprehensive system of managed care of endof-life care. Her program, Medicaring, is based on the notion that capitated or salaried managed care systems offer important opportunities to provide high-quality, costeffective care for seriously ill individuals nearing the end of life (130,131). Despite the fact that managed care systems for the most part have largely ignored the need for end-of-life care, Lynn argues that such systems inherently offer certain advantages that include coordinated care across delivery systems, interdisciplinary teams, integrated services, service arrays, utilization controls, and accountability for care standards. Capitated or salaried managed care systems may be well positioned to achieve marked change in end of life if they were to broaden their current focus to include end-of-life care and if payment reimbursements were revised to encourage such programming. The focus of managed care systems on prevention, patient education, cost efficiency, service coordination, integrated provider networks, and such organizational structures could potentially support real change in end-of-life care. Indeed some managed care organizations have expanded services to hospices, albeit with extensive limits. Lynn asserts that her “Medicaring” proposal encompasses the best components of palliative care within a structured managed care system. Such a program would be comprehensive and supportive and would offer community-based services to meet personal and medical needs with a focus on patient preferences, symptom management, family counseling, and support (131). Home care would be profoundly influenced if such a program became the standard of care in community-based managed care organizations. It is a larger system and societal change that needs to occur before such programs are institutionalized.

ENHANCING PROFESSIONAL TRAINING IN HOME CARE

Home Care Outreach for Palliative Care Education

Although palliative care principles are prevalent in hospice programs, such elements have not necessarily extended into other health care systems such as home care. This dearth of training exists despite the fact that home care agencies provide extensive care to patients and families facing physical and psychosocial demands at the end of life. Even though nonhospice home care agencies are technically not intended for terminally ill, palliative care education is important to support home care providers given the challenges of the health care system in general and the greater demands on home care, essentially making it the primary setting of care (132).

Beginning in the middle 1990s, Ferrell and colleagues developed and implemented the Home Care Outreach for Palliative Care (HOPE) project to: (a) assess current practices within select nonhospice home care agencies regarding care of the dying, (b) design the HOPE educational program to include relevant content for realistic implementation in home care agencies, (c) implement the HOPE project in select home care agencies, and (d) assess outcomes of the project and plan for future dissemination to home care agencies and organizations.

The HOPE curriculum is organized into five modules. The first module presents a general overview of palliative care and end-of-life issues. The second and third modules address various aspects of pain and symptom management, respectively. The fourth component focuses on communication, family caregivers, and

spirituality. The last module, entitled “the good death,” covers important elements of the last days of life. Key aspects of the modules are the attention given to psychosocial dimensions of care at home, cultural considerations, and the special care required at the time of death. In early 2001, the HOPE project was extended to a national training group with planned followup studies and additional programs scheduled. The first of its kind in a “train the trainers” format for palliative care education of home care providers, the HOPE project is aimed at changing the landscape of end-of-life care in the home care setting (4,132,133).

Communication Training

Of interest, the retrospective assessment provided by caregivers after the death of their family member is in large part influenced by how they viewed the relationship and communication with the health care professional (134). Missing components of “model” treatment programs can be overlooked if the caregiver feels sufficiently supported by the health care community (135). However in palliative care and home care studies, patients and their families are often dissatisfied with their interactions with health professionals (136). That may come as no surprise when one considers that ironically medical professionals spend up to 70% of their working time communicating but have virtually no education in that aspect of their work (134). Yet communication behaviors seem to play an important role in meeting the cognitive and affective needs of patients with cancer as well as the needs of their caregivers (137). Moreover, communication skills are particularly imperative in home care settings with its myriad of family dynamics, along with cultural, ethnic, and religious nuances of the home. Such issues have prompted researchers to develop training in communication skills for health care professionals (137,138). Adding another component of training to an already overburdened health care professional may not be a welcome endeavor. However some studies have demonstrated that such training has actually helped to reduce the intensity of the emotionally laden interactions and increase the professional's sense of confidence to adequately address the affective components of life-threatening illness and care (136,137).

Cultural Competency

Health care providers must be prepared to manage diverse, multicultural patient populations in various health care settings while working collaboratively with coworkers who also represent various cultural backgrounds (90). Home care presents a greater challenge in that the health care provider is essentially being immersed into the microculture of the family and the macrocosm of the community. Health care educators have recognized this changing demography of our culture, and some have developed programs in cultural competency for their workers (90). Of note, cultural competency does not necessitate that health care providers know and understand all the traditions and practices of the numerous ethnic groups. Rather the intent is to have managers, administrators, and front-line employees work collectively to increase their knowledge of cultural diversity, share that knowledge, and combine efforts to promote cultural awareness and sensitivity in practice settings (90).

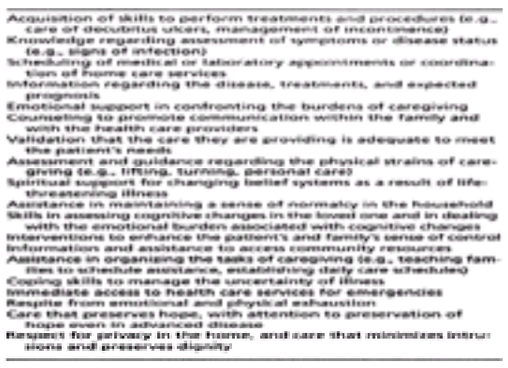
Patient education efforts also have developed in the past few decades (96), and researchers advocate that health care professionals must consistently exercise heightened cultural sensitivity through their approach to patients as well as in information provided (90,139). Failing to do so runs the risk of necessitating more time and resources (93).

Davis (140) asserts that health care professionals traditionally have established a portrait of the “ideal dying patient,” which implicitly places expectations on terminally ill patients with whom they come in contact. Such tacit anticipation runs the risk of causing a chasm between the health care provider and the patient and family. This may further heighten emotionally laden situations and make care and treatment even more complicated. In addition, lack of recognition of cultural factors may cause further difficulties in communication and understanding with regard to informed consent and truth-telling about diagnosis, prognosis, and treatment options (141).

As a result of the potential dangers associated with lack of recognition and training in multicultural care, Lister (142) presented a taxonomy for developing cultural competence among health care providers. Of interest, some policy advocates have argued for licensing boards to require cultural competency as a provision of licensure. Rather than adding more demands to the taxed home care system, De Savorgnani and Haring (143) assert that the impact of cultural issues on home care has the potential to serve as the impetus for development of “comprehensive diversity programs” that would enhance the lives of patients and staff in home care. Consistently in the past decade, researchers have demonstrated the benefits of a culturally sensitive staff as patients and their families have reported that they view their homes as the milieu that allows for continuity of lifestyle, family relationships, and cultural values (144,145). Many professional organizations now view transcultural training as a necessity given the changing demographics in the United States and in home care.

CONCLUSION

The home care environment can best be described as the intensive care unit of the future. Home care is complex as a result of changing patient and family caregiver characteristics. The home environment is rich with benefits to enhance patient comfort, but it also provides challenges in providing optimum physical, psychosocial, and spiritual care. The literature has addressed many interventions that are helpful in assisting families in home care (Table 56-2). These interventions include a range of suggestions about physical care, including the transferring of information about physical caregiving back to families, offering validation and support to families for their efforts at home care, and interventions to improve communication.



Acquisition of skills to perform treatments and procedures (e.g., care of decubitus ulcers, management of incontinence)
Knowledge regarding assessment of symptoms or disease status (e.g., signs of infection)
Scheduling of medical or laboratory appointments or coordination of home care services
Information regarding the disease, treatments, and expected prognosis
Emotional support in confronting the burdens of caregiving
Counseling to promote communication within the family and with the health care providers
Validation that the care they are providing is adequate to meet the patient's needs
Assessment and guidance regarding the physical strains of caregiving (e.g., lifting, turning, personal care)
Spiritual support for changing belief systems as a result of life-threatening illness
Assistance in maintaining a sense of normalcy in the household
Skills in assessing cognitive changes in the loved one and in dealing with the emotional burden associated with cognitive changes
Interventions to enhance the patient's and family's sense of control
Information and assistance to access community resources
Assitance in organizing the tasks of caregiving (e.g., teaching families to schedule assistance, establishing daily care schedules)
Coping skills to manage the uncertainty of illness
Immediate access to health care services for emergencies
Respite from emotional and physical exhaustion
Care that preserves hope, with attention to preservation of hope even in advanced disease
Respect for privacy in the home, and care that minimizes intrusions and preserves dignity

TABLE 56-2. INTERVENTIONS FOR ASSISTING FAMILIES IN HOME CARE

There is a tremendous need for continuity of care as patients are increasingly cared for across many settings. It is essential that issues of care in the home are communicated to those involved in ambulatory care, inpatient care, and other areas of care. Expert care for patients at home, similar to all aspects of palliative care, begins with a thorough assessment of the patient's needs. Organized care based on a comprehensive perspective, which recognizes the physical, psychological, social, and spiritual needs during advanced illness, is best accomplished by empowering families to provide excellent care for patients at home.

MANAGEMENT OF SYMPTOMS IN THE ACTIVELY DYING PATIENT

PAUL ROUSSEAU

The obligation of physicians to relieve suffering is universal, particularly when death is imminent and the indignities of illness consume patients' final days and hours of life. This honored encumbrance transcends all other duties accorded physicians and is fundamental to a death free of interminable symptoms and a satisfactory bereavement for surviving family members (1). Lamentably, the dying process can be a time of untold loss and suffering, and although spiritual and psychosocial concerns are basic domains in the inherent makeup of an individual, unrelieved physical suffering can detract from attention to important spiritual and psychosocial issues at the end of life. Accordingly, physicians must be competent in relieving physical distress and in so doing maintaining patient dignity and familial equanimity (2).

During the last days of life, there are characteristic symptoms that commonly occur, including dyspnea and noisy, gurgling respirations frequently referred to as the “death rattle,” anxiety, restlessness, delirium, nausea and vomiting (NV), and pain (2,3,4,5,6,7,8 and 9). Although such symptoms are often multifactorial in etiology, treatment is usually empiric and palliative. Diagnostic evaluation is limited in recognition of the short life expectancy and impending death. Nevertheless empiric treatment strategies do not suggest or encourage clinical indifference but rather mandate ongoing clinical assessment of therapeutic interventions in a continual effort to allay suffering. From time to time terminal symptoms are refractory and unresponsive to aggressive and exhaustive interventions. In such cases palliative sedation (PS) is an ethically and morally appropriate option that may be utilized to afford a more peaceful and tranquil death and a satisfactory grieving process for remaining family members.

DYSPNEA AND THE DEATH RATTLE

Dyspnea

Dyspnea occurs in 29–90% of terminally ill patients and is frequently the most common severe symptom as death approaches (9,10,11,12 and 13). Although it is more common in patients with pulmonary disorders, 23.9% of dyspneic patients in the National Hospice Study did not exhibit cardiac or pulmonary disease (11). Dyspnea in terminally ill patients derives from five primary causes: (a) existing disease [i.e., chronic obstructive pulmonary disease (COPD) and congestive heart failure], (b) acute superimposed illness (i.e., pneumonia, pulmonary embolus), (c) cancer-related complications (i.e., pleural effusion, lymphangitis carcino-matosis, tumor-induced bronchial obstruction, ascites), (d) effects of cancer therapy (i.e., radiation and chemotherapy-induced pulmonary fibrosis), and (e) miscellaneous causes (i.e., anemia, uremia, anxiety) (9,13,14).

As with any symptom, the treatment of dyspnea should address any easily correctable underlying cause, all the while recognizing and considering the limited life expectancy of the imminently dying patient and the invasiveness and discomfort of proposed therapeutic interventions. Consequently for most patients near death, opioids, benzo-diazepines, phenothiazines, and corticosteroids are the mainstays of therapy (2,7,8 and 9,12,13,14 and 15).

Opioids purportedly relieve dyspnea by altering the perception of breathlessness (10,16), decreasing ventilatory response to hypoxia and hypercapnia (10,17), and reducing oxygen consumption at rest and with exercise (10,18). Controlled trials and anecdotal case reports on the use of systemic opioids in the treatment of malignant and COPD-associated dyspnea have generally demonstrated a reduction in dyspnea, with many patients in the various studies already receiving opioids for pain control (10,15,19,20,21,22 and 2323). Although morphine preparations are generally utilized, any opioid potentially should alleviate dyspnea (Table 57-1). Opioids can be administered orally, rectally, sublingually, subcutaneously, intravenously, and by inhalation, but during the final hours of life when the ability to swallow declines and consciousness wanes, rectal, subcutaneous, and intravenous routes are more commonly used.

TABLE 57-1. PHARMACOLOGICAL TREATMENT OF TERMINAL DYSPNEA

Inhalation of opioids is a unique and innovative approach to drug delivery. Controlled trials have revealed conflicting results (15,19,23,24,25,26 and 27), but anecdotal reports have generally been favorable (13,28,29 and 30). It is postulated that inhaled opioids exert their effect by means of opioid receptors that have been identified in the bronchial mucosa, as pharmacokinetic studies suggest that systemic bioavailability of nebulized morphine is extremely poor, varying from 4% to 8% (19,27,31). However, opioids also may stimulate histamine release from pulmonary mast cells and precipitate bronchospasm, worsening terminal dyspnea. Because this complication is usually a first-dose effect, careful observation should occur during initial administration. Contrary to many clinicians' belief that the use of preservative-free opioid preparations prevents histamine release, bronchospasm may still occur (27). Although studies are contradictory and further research is unquestionably warranted, in the dyspneic patient near death, nebulized opioids may be efficacious and worth a trial in an attempt to reduce breathlessness and assuage the horrific fear of suffocation.

Benzodiazepines have been frequently utilized in dyspnea primarily when a component of anxiety is involved. Studies and anecdotal reports are contradictory (15), with no well-designed controlled trials evident in cancer patients (24). Nevertheless benzodiazepines are frequently beneficial in reducing dyspnea, particularly during the final days of life (32) and are increasingly used in hospice and palliative care programs. Buspirone, a popular nonbenzodiazepine anxiolytic and serotonin agonist, has been shown to relieve dyspnea in patients with anxiety and COPD at a dose of 15 mg to 45 mg daily (33). Because of its delayed onset of action, it may be of limited use in actively dying patients. Although not a benzodiazepine, the neuroleptic chlorpromazine has been used in dyspnea refractory to other medications. It appears to reduce air hunger and anxiety with minimal side effects (primarily sedation and hypotension) and has been efficacious in patients near death (9,34,35).

Although corticosteroids are useful when bronchospasm is associated with inflammation, most studies suggest that only 20% to 30% of patients with COPD improve with corticosteroid therapy. In the final days of life corticosteroids are most useful when prescribed for dyspnea associated with airway obstruction, lymphangitis carcinomatosis, radiation pneumonitis, and superior vena cava syndrome (9,14). Corticosteroids can be administered orally, rectally, subcutaneously, intravenously, and by inhalation. Although side effects are of concern during chronic use, such concerns are negated by short-term use in dying patients.

Other medications also are available to attenuate dyspnea in the dying patient. These include diuretics, bronchodilators, and inhaled anesthetics. Diuretics are useful when pulmonary edema and ascites contribute to dyspnea. Although bronchodilators are best utilized in patients with a bronchospastic component to dyspnea (i.e., asthma, COPD with reactive airways), these drugs frequently are used when there is little-to-no evidence of bronchospasm and appear to provide subjective reduction of dyspnea in many patients. The use of adrenergic agonist bronchodilators, such as albuterol and metaproterenol, should be tempered by the possibility of resultant agitation, tremor, and heightened anxiety, potentially aggravating terminal dyspnea (9).

Nebulized anesthetics have been used infrequently for dyspnea in dying patients. In a study comparing nebulized saline and lidocaine, saline exerted a greater effect on the reduction of breathlessness (27,36). However nebulized anesthetics have been useful for cough and may be considered when persistent coughing contributes to or aggravates dyspnea (27).

Nonpharmacological interventions that are useful for terminal dyspnea include oxygen, a bedside fan, thoracentesis for pleural effusion, and paracentesis for ascites. The role of oxygen therapy in reducing dyspnea in patients near the end of life is somewhat controversial. In hypoxemic patients with disorders such as COPD, congestive heart failure, or pulmonary fibrosis, most studies suggest that there is significant symptomatic improvement (19,24,37). In patients without hypoxemia, however, its use is more contentious. Even so, oxygen therapy may alleviate dyspnea by way of a placebo effect and should be considered in actively dying patients (a nasal cannula is better tolerated than a mask) (9). Moreover oxygen therapy may provide many family members with the symbolic solace that “something is being done” to help their loved one in spite of the fact that oxygen may actually provide little therapeutic benefit.

A bedside fan may also be useful in alleviating dyspnea by reportedly stimulating thermal and mechanical receptors of the trigeminal nerve in the cheek and nasopharynx, altering the perception of breathlessness (9,38,39). The fan should be placed at the bedside, set on a low speed, and directed at the patient's face (9).

Thoracentesis and paracentesis may be useful when pleural effusion and ascites contribute to dyspnea (particularly if previous drainage has reduced dyspnea). In the final days of life, however, other strategies generally should be utilized unless noninterventional approaches have failed and breathlessness aggravates suffering.

Death Rattle

In the last 24–48 hours of life, most patients retain secretions in the back of the throat that produces a gurgling type of respiration frequently referred to as the death rattle (9,40). Fortunately, the patient is usually unaware of the noise. It can, however, be very disturbing to family members. Oropharyngeal suctioning is usually provided, but gagging and coughing may generate patient discomfort and further distress for relatives and caregivers. Instead, treatment with anticholinergic drugs is recommended to desiccate bronchial secretions and abolish the need for suctioning. Suggested medications include atropine, glycopyrrolate, scopolamine, and hyoscyamine (Table 57-2) (9,14). These antisialagogues do not dry up secretions already present, and they should therefore be used at the first sign of noisy respirations (7). In addition, placing patients in a lateral recumbent position with the head slightly elevated may help reduce the pooling of secretions and diminish noisy respirations (2).

Drug	Dose
Scopolamine	0.4–0.6 mg s.q. q2–4h; 0.8–2.0 mg CSI q24h; 1–3 transdermal patches q3d
Hyoscyamine	0.125–0.250 mg s.l. q2–4h; 0.25–0.5 mg s.q. q2–4h; 1–2 mg CSI q24h
Glycopyrrolate	0.2 mg s.l., s.q. q2–4h
Atropine	0.4 mg s.q. q2–4h; may give 2 mg of atropine, 2.5–5.0 mg of morphine, and 2 mg of dexamethasone q2–4h via nebulizer

CSI, continuous subcutaneous infusion.

TABLE 57-2. PHARMACOLOGICAL TREATMENT OF THE DEATH RATTLE

ANXIETY, RESTLESSNESS, AND DELIRIUM

Anxiety

Anxiety is one of the most common psychological problems in terminally ill patients and like many symptoms can have numerous etiologies (41,42,43,44 and 45). Anxiety can be a component of a preexisting anxiety disorder or, more commonly in actively dying patients, accompany medical disorders and complications of illness and medications (42,44). Medical disorders that can cause anxiety include hyperthyroidism, pheochromocytoma, and primary and metastatic brain tumors. Medical complications and medications that can precipitate anxiety include hypoxia, sepsis, unrelieved pain, dyspnea, and medications such as corticosteroids, bronchodilators, and antiemetics that cause akathisia (41,42,43 and 44). In addition, withdrawal states from benzodiazepines and opioids can result in anxiety and may occur inadvertently when medications are suddenly discontinued after admission to a hospital or long-term care facility (43).

The treatment of anxiety in the terminally ill often depends on etiology but generally involves nondrug maneuvers, specific interventions, and pharmacotherapy. Nondrug measures include meditation, biofeedback, progressive relaxation, and psychotherapy (43). In actively dying patients these nondrug methods are of little value. In some cases specific interventions can be of benefit and include such measures as oxygen and opioids for dyspnea, opioids and other analgesics for pain, and discontinuing medications that cause akathisia.

The principal therapy for anxiety includes the judicious use of benzodiazepines, neuroleptics, and antihistamines (41,42,43 and 44). Benzodiazepines are the mainstay of treatment in the terminally ill patient, with the shorter-acting agents, such as lorazepam and oxazepam, preferred in the patient with advanced disease (Table 57-3). These drugs are metabolized by conjugation in the liver and are safest when hepatic disease is present (41,42,44). This is in contrast to alprazolam and other benzodiazepines which are metabolized through oxidative pathways and may accumulate in debilitated patients (46). Midazolam, a water-soluble benzodiazepine, may be infused intravenously or subcutaneously and is very useful in controlling anxiety in the terminal phase of illness. The cost of midazolam may limit its use (41,42,43 and 44,47), particularly in managed care and capitated health systems. Diazepam, an older but efficacious benzodiazepine, may be used rectally when no other route is available and cost is of concern, with recommended dosages equivalent to oral regimens. Clonazepam, a longacting benzodiazepine used for seizure disorders and myoclonus, is useful in patients who experience end-of-dose recurrence of anxiety on shorter-acting benzodiazepine medications (41,42,43 and 44).

Drug	Dose[a]
Benzodiazepines	
Lorazepam	0.5–2.0 mg p.o., s.l., i.m., i.v., s.q. q1–4h
Midazolam	0.5–5.0 mg i.v., s.q. q1–4h; 10–30 mg CSI q24h
Diazepam	2.5–10.0 mg p.o., i.m., i.v., p.r. q1–4h
Clonazepam	0.5–2.0 mg p.o. b.i.d.–q.i.d.
Oxazepam	15 mg p.o. t.i.d.–q.i.d.
Neuroleptics	
Haloperidol	0.5–1.0 mg p.o., i.m., i.v., s.c. q1–6h
Chlorpromazine	10–25 mg p.o., i.m., i.v., p.r. q4–6h
Thioridazine	10–75 mg p.o. t.i.d.–q.i.d.
Antihistamines	
Hydroxyzine	10–50 mg p.o., i.m., i.v., s.q. q2–4h

CSI, continuous subcutaneous infusion.
[a]Suggested starting doses, may need to be clinically titrated; older frail patients may need doses adjusted appropriately, may be difficult for actively dying patients to take oral medications.

TABLE 57-3. PHARMACOLOGICAL TREATMENT OF ANXIETY

Other nonbenzodiazepine medications useful for anxiety include the neuroleptics chlorpromazine, thioridazine, and haloperidol, and the antihistamine hydroxyzine

(Table 57-3). Neuroleptics may be used when benzodiazepines fail to relieve anxiety, when psychotic symptoms accompany anxiety, or when there is concern regarding the respiratory depressant effects of benzodiazepines (48). Hydroxyzine, an effective antihistaminic anxiolytic, may have coanalgesic effects (49) and may be a particularly useful alternative to benzodiazepines when pain accompanies or exacerbates anxiety, or when benzodiazepines and neuroleptics are contraindicated (i.e., allergy, respiratory depression, akathisia).

Restlessness

Restlessness is commonly observed during the last hours of life. Although it has multiple causes (and may overlap with delirium), specific treatment may not be possible (7). Restless patients may have diverse symptoms, including impaired consciousness, intermittent sleepiness, tossing and turning, moaning, grunting, crying out, and agitation and muscle spasms or twitching (2). Restlessness may be caused by spiritual conflicts, physical discomfort, such as a distended urinary bladder or bladder spasms, fecal impaction, unrelieved pain, and pressure ulcers, or by nausea, dyspnea, pruritus, hypoxia, extreme weakness, corticosteroids, and sudden withdrawal from benzodiazepines. Treatment involves identifying and managing the underlying cause or, if that is not possible, providing spiritual support, verbal and tactile reassurance, and utilizing a benzodiazepine, such as midazolam, or a neuroleptic, such as chlorpromazine (Table 57-3) (2,7).

Delirium

Delirium is a nonspecific global disorder of cognition and attention that occurs in 8% to 75% of hospitalized cancer patients (43,44,50,51) and in 62% of patients just prior to death (52,53). It is a significant sign of physiological disturbance and, analogous to anxiety, may be secondary to multiple etiologies, including primary or metastatic brain tumors, infection, organ failure, metabolic disturbances, vascular complications, nutritional deficiencies, medication side effects, and a paraneoplastic syndrome (52). In contrast to dementia, delirium is considered a reversible disorder with rapid onset; in the last 24 to 48 hours of life, however, it may be irreversible. According to the Diagnostic and Statistical Manual of the American Psychiatric Association (54), delirium is characterized by

- Disturbance of consciousness (reduced awareness of the environment) with reduced ability to focus, sustain, or shift attention,
- Change in cognition (memory deficit, disorientation, perceptual disturbances such as hallucinations, illusions, delusions) that is not related to a preexisting dementia,
- Development over a short period of time, with usual fluctuation throughout the day, and
- Evidence from the history, physical examination, or laboratory tests of a general medical condition judged to be etiologically related to the causation of delirium.

The assessment of delirium must take into consideration the life expectancy of the patient and the patient's goals for care. Most palliative care clinicians would undertake a diagnostic workup only when a clinically suspected cause can be easily identified and treated effectively with simple interventions that carry a minimal burden or risk of causing further distress (i.e., hypodermoclysis for dehydration). Most often, the cause of delirium in the actively dying patient is multifactorial and irreversible, and treatment is usually empiric (52). Similar to anxiety, nondrug supportive measures are of limited value (other than the presence of family members, a well-lit room, and familiar sounds and music). Consequently pharmacological interventions are the primary methods for treating delirium in patients near death.

Neuroleptic medications are the preferred pharmacological agents and are particularly safe and efficacious in reducing disturbing cognitive symptoms in dying patients (Table 57-4) (14,41,42,43 and 44,50,52). Haloperidol is the usual drug of choice and may be given orally, intravenously, and subcutaneously. However clinicians should be aware that parenteral doses are approximately twice as potent as oral doses (50,52). It is the drug of choice because of its short half-life, lack of active metabolites, and minimal anticholingeric and cardiovascular side effects. It is also less likely to cause sedation or paradoxical delirium (55). Unfortunately, extrapyramidal symptoms and movement disorders may occur with the use of haloperidol and other neuroleptics and require the use of antiparkinsonian drugs, such as diphenhydramine, benztropine, and trihexyphenidyl, and beta blockers, such as propranolol, for akathisic movements.

Drug	Dose[a]
Neuroleptics	
Haloperidol	0.5–1.0 mg p.o., i.m., i.v., s.c. q1–6h; 5–15 mg CSI q24h; in acute situations, 0.5–1.0 mg i.v., s.q. q45–60 min until symptoms controlled
Chlorpromazine	10–25 mg p.o., i.m., i.v., p.r. q4–6h
Risperidone	0.5–1.0 mg p.o. b.i.d.
Benzodiazepines	
Lorazepam	0.5–2.0 mg p.o., s.l., i.m., i.v., s.q. q1–4h
Midazolam	0.5–5.0 mg i.v., s.q. q1–4h; 10–30 mg CSI q24h

CSI, continuous subcutaneous infusion.
[a]Suggested starting doses, may need to be clinically titrated; older frail patients may need doses adjusted appropriately; may be difficult for actively dying patients to take oral medications if the patient is taking an opioid; rotating to another opioid with no active metabolites (i.e., hydromorphone) may help lessen delirium if the delirium is opioid-induced; severe agitated delirium may require palliative sedation.

TABLE 57-4. PHARMACOLOGICAL TREATMENT OF DELIRIUM

A short-acting benzodiazepine can be added if the patient is overly agitated, even though benzodiazepines alone are not indicated in the treatment of delirium. In fact, benzodiazepines may actually exacerbate the delirious state and should be used cautiously and discontinued if delirium worsens. When delirium is difficult to control in the last days of life, PS to the point of unconsciousness may be needed (6,56). In such situations a benzodiazepine, such as lorazepam or midazolam, is the drug of choice, either alone or in conjunction with a neuroleptic.

NAUSEA AND VOMITING

Nausea and vomiting occur in 62% of terminal cancer patients. Although the prevalence is 40–46% during the last 6 weeks of life (57), it rarely develops as a new symptom during the last days of life (8). NV is observed more frequently in women, persons younger than 65 years of age, and patients with stomach and breast cancer (57).

The etiology of NV in terminal illness varies and is frequently multifactorial (9), particularly as death approaches. Although diagnostic evaluation can be done, in the actively dying patient, treatment usually involves the empirical use of nonpharmacological measures and antiemetics. However, if the clinician, patient, or family insists on an evaluation, simple tests, such as measurement of electrolytes, blood urea nitrogen, creatinine, calcium, albumin, glucose, and digoxin or anticonvulsant drug levels, are recommended and may readily disclose a reversible cause.

Nonpharmacological measures used to treat NV include dietary manipulations (Table 57-5), elimination of emetogenic medications [i.e., nonsteroidal anti-inflammatories, digoxin, iron (59)], and the limited use of nasogastric suctioning, particularly for high gastrointestinal bowel obstruction. Nasogastric tubes can be uncomfortable and difficult to place, especially in the home environment, but intermittent use may be considered for severe and intractable vomiting refractory to antiemetic therapy. A percutaneous venting gastrostomy is useful if placed prior to the active dying process. However its placement in the patient near death is usually not practical.

Minimize unpleasant odors
Sounds and smells of food preparation should be excluded
Avoid foods known to precipitate nausea and vomiting
Clear liquid diet may be best tolerated
Cold foods may be preferred
Sour foods, such as lemons, and rinsing of the mouth with weak lemon juice may reduce nausea
Utilize frequent small feedings if the patient wants to eat

Adapted from Lichter I. Nausea and vomiting in patients with cancer. *Hematol Oncol Clin North Am* 1996;10:207–220, with permission.

TABLE 57-5. DIETARY MANIPULATIONS FOR NAUSEA AND VOMITING

Nine types of antiemetics are utilized in the treatment of terminal NV: dopamine antagonists, metoclopramide, anticholinergics, antihistamines, corticosteroids, serotonin antagonists, octreotide, cannabinoids, and benzodiazepines (Table 57-6) (9,59,60 and 61). Dopamine antagonists include haloperidol and prochlorperazine and are the usual firstline antiemetics chosen by most clinicians. Haloperidol is an excellent antiemetic and is particularly useful for delirious patients with NV because both symptoms may be improved with a single medication. As mentioned earlier (see the section Delirium), parenteral doses are twice as potent as oral doses, and there is a reported ceiling effect at approximately 30 mg a day. Prochlorperazine is also efficacious and a favorite of many clinicians, and while promethazine and chlorpromazine are also prescribed, there is probably little advantage to using them over prochlorperazine (59). Although combination therapy for NV is common in the terminally ill, two or more dopamine antagonists should not be prescribed concurrently as the potential for adverse extrapyramidal reactions is increased without additional antiemetic benefit.

Drug	Dose[a]
Dopamine antagonists	
Haloperidol	0.5–2.5 mg p.o., i.m., i.v., s.q. q4–6h; 5–15 mg CSI q24h
Prochlorperazine	5–20 mg p.o., i.m., i.v. q4–6h; 25 mg p.r. q8h
Droperidol	2.5–5.0 mg i.v. q4–6h
Promazine	25 mg p.o., p.r. q4–6h; 12.5–25.0 mg i.v. q4–6h
Substituted benzamide	
Metoclopramide[b]	5–20 mg p.o., i.m., i.v., s.q. q6h; 20–40 mg CSI q24h
Anticholinergics	
Scopolamine	0.3–0.8 mg p.o., s.q. q4–6h; 1–2 transdermal patches q3d, 0.4–2.0 mg CSI q24h
Hyoscyamine	0.125–0.250 mg p.o., s.l. q4h; 0.25–0.50 mg s.q. q4–6h; 1.2 mg CSI q24h
Antihistamines	
Buclizine	50 mg p.o. q4–6h
Meclizine	25–50 mg p.o. q4–6h
Diphenhydramine	25–50 mg p.o., i.m., i.v. q4–6h
Corticosteroids	
Dexamethasone	1–4 mg p.o., i.v., s.q. q6h; 2–12 mg CSI q24h
Serotonin antagonists	
Ondansetron	8 mg p.o., i.v., s.q. q8h; 8–24 mg CSI q24h
Granisetron	0.5–1.0 mg p.o., i.v., s.q. q12h
Somatostatin analogue	
Octreotide	150 µg s.q. t.i.d.; 0.2–0.9 µg CSI q24h
Cannabinoid	
Dronabinol	2.5–7.5 mg p.o. b.i.d.–t.i.d.
Benzodiazepines	
Lorazepam	0.5–2.0 mg p.o., s.l., i.m., i.v., s.q. q4h
Compounded medication[c]	
ABHR, ABHRD, ABHRDC	1 p.r. q4–6h

[a] Available as a topical patch, to convert from an oral opioid, convert the opioid to a morphine equivalent dose, then divide the morphine dose by 2 to get the approximate strength of the fentanyl patch. From Storey P, Knight EP, UNMC Hice. assessment and treatment of pain in the terminally ill. Asheville, FL: American Academy of Hospice and Palliative Medicine, 1996, with permission.
[b] Also available as a suppository; hydromorphone also available as a suppository.
[c] Morphine can be compounded into a gel for topical use, bioavailability is unknown.
[d] 1–3 mg/kg bolus; 100 mg/l i.v. over 20–30 min or s.q. over 30–60 min. If pain relieved, start an infusion either i.v. or s.q. at 0.5–2 mg/kg/h; serum levels may be monitored. See Ferrini R. Parenteral ketorolac for severe intractable pain in six hospice patients controlled at home. J Pain Symptom Manage 2000; 19:174–182.
[e] Can be administered by a continuous subcutaneous infusion, 60 mg q24h.
[f] Crush the tablets, put in a gelatin capsule, and place rectally.

TABLE 57-6. PHARMACOLOGICAL TREATMENT OF NAUSEA AND VOMITING

Metoclopramide is both a dopamine antagonist and a serotonin (5-HT4) agonist, but at doses greater than 120 mg a day, it becomes a serotonin (5-HT3) antagonist (62). It is very useful as an antiemetic and a prokinetic agent for gastroparesis-induced vomiting but caution must be exercised with older patients as it may cause extrapyramidal reactions that may not be dose dependent (59).

Anticholinergic medications are most efficacious in NV related to colic and mechanical bowel obstruction (58,59). They include scopolamine, hyoscyamine, and glycopyrrolate. Antihistamines are effective in motion sickness, mechanical bowel obstruction, and increased intracranial pressure. These drugs comprise buclizine, meclizine, and diphenhydramine.

Corticosteroids have a synergistic effect with metoclopramide and the serotonin antagonists (59) but are rarely useful as single agents (although they may reduce peritumor edema of gastrointestinal malignancies and brain metastases, and in so doing, lessen emetic episodes). Dexamethasone is the favored agent due to the small pill size, minimal mineralocorticoid activity, and availability of intravenous and subcutaneous administration. Serotonin antagonists are relatively new and expensive agents. Although quite useful in chemotherapy-induced emesis, their value in terminal NV is unknown. Nevertheless, they are frequently utilized in dying patients and are reportedly quite effective in reducing emesis, particularly NV associated with radiation, bowel obstruction, and renal failure (59,63).

Octreotide is a somatostatin analogue that is useful in reducing NV associated with intestinal obstruction. This drug decreases gastrointestinal secretions, stimulates absorption of water and electrolytes, and inhibits intestinal peristalsis (64).

Dronabinol is the only commercially available cannabinoid available in the United States. It is rarely used in terminal NV. It exhibits antikinetic properties in the stomach and small bowel (59) and may be most useful in emesis related to small bowel obstruction. It may, however, potentially worsen gastroparetic conditions.

The benzodiazepines have little role as singular antiemetics in the actively dying patient unless anxiety is a dominant component. They are best utilized as adjuncts to other antiemetics through their amnesic, anxiolytic, and sedative properties (65).

Many hospice programs utilize compounding pharmacists to prepare diverse and innovative medications and delivery systems for symptom control in dying patients. A compounding pharmacist can prepare a topical gel and/or suppository variously known as ABHR, ABHRD, or ABHRDC that contain commercially available antiemetics, including Ativan, Benadryl, or Dramamine, Reglan, Haldol, Decadron, and Cogentin. These drugs are combined in various dosages (i.e., Ativan, 1.0 mg; Benadryl, 12.5–25.0 mg or Dramamine, 25–50 mg; Haldol, 0.5–1.0 mg; Reglan, 5–10 mg; Decadron, 10 mg; and Cogentin, 1 mg). The suppositories have been quite useful in refractory NV and may be very effective in patients near death. Although there have been no studies that assess the varied combinations, they appear to benefit some patients because of both antiemetic and sedative effects.

PAIN

As death approaches, pain may become less problematic because the patient becomes bedbound and experiences less movement-related pain. Nevertheless, opioids must not be stopped abruptly, and clinicians should be cognizant that patients may be disturbed by pain even when comatose (7). Assessment of pain may become difficult and, in the final hours of life, patients may appear to show signs of pain when turned or repositioned, even when unconscious. Such pain may be due to an underlying medical disorder or joint stiffness secondary to bed rest and minimal body movement (66).

Assessing pain in confused or demented patients may be problematic. Such patients frequently exhibit pain by facial grimacing, resistance to turning or repositioning, agitation, and a reduction in functional abilities. Conversely, signs of apparent discomfort may be noted when a patient that is hearing or visually impaired or confused is touched without forewarning. Such response may not in fact be pain but rather the result of a startled response from tactile stimulation without prior warning.

In the final hours of life, patients may be unable to swallow, and sublingual/buccal, transdermal, rectal, intravenous, or subcutaneous administration of analgesics may be necessary (Table 57-7). Although rectal administration of sustained-release opioids is not approved by the U.S. Food and Drug Administration, studies suggest that rectal absorption is similar to oral administration. In addition, suppositories are available for nonsteroidal anti-inflammatory drugs, the tricyclic antidepressant doxepin, and the corticosteroid dexamethasone. The antiepileptics carbamazepine and valproic acid are frequently administered rectally by placing them in gelatin capsules.

Opioids that can be delivered subcutaneously	
Morphine	
Hydromorphone	
Methadone	
Fentanyl	
Opioids that can be delivered topically	
Fentanyl[a]	
Morphine[b]	
Oral opioids that can be delivered rectally	
Morphine[c]	
Oxycodone	
Anesthetics that can be delivered subcutaneously	
Lidocaine[d]	
Adjuvant medications and alternative routes of delivery	
Dexamethasone	s.q., i.m., i.v., p.r.
Indomethacin	p.r.
Diclofenac	p.r.
Ketorolac[e]	s.q.
Carbamazepine[f]	p.r.
Valproic acid	p.r.
Doxepin	p.r.

[a] Available as a topical patch, to convert from an oral opioid, convert the opioid to a morphine equivalent dose, then divide the morphine dose by 2 to get the approximate strength of the fentanyl patch. From Storey P, Knight EP, UNMC Hice. assessment and treatment of pain in the terminally ill. Asheville, FL: American Academy of Hospice and Palliative Medicine, 1996, with permission.
[b] Also available as a suppository; hydromorphone also available as a suppository.
[c] Morphine can be compounded into a gel for topical use, bioavailability is unknown.
[d] 1–3 mg/kg bolus; 100 mg/l i.v. over 20–30 min or s.q. over 30–60 min. If pain relieved, start an infusion either i.v. or s.q. at 0.5–2 mg/kg/h; serum levels may be monitored. See Ferrini R. Parenteral ketorolac for severe intractable pain in six hospice patients controlled at home. J Pain Symptom Manage 2000; 19:174–182.
[e] Can be administered by a continuous subcutaneous infusion, 60 mg q24h.
[f] Crush the tablets, put in a gelatin capsule, and place rectally.

TABLE 57-7. ALTERNATIVE ROUTES OF DELIVERY FOR PHARMACOLOGICAL TREATMENT OF PAIN

Unfortunately many patients and family members are reluctant to utilize the rectal route for administration of medications, especially if pain is not controlled and frequent supplementary doses of analgesics are required. In such cases, subcutaneous infusions are appropriate and well tolerated. Opioids; the nonsteroidal

anti-inflammatory ketorolac (67); the anticholinergics scopolamine, atropine, hyoscyamine, and glycopyrrolate; and the corticosteroid dexamethasone can all be given by means of the subcutaneous route in an effort to maintain or improve pain control. Epidural and other invasive analgesic interventions are rarely utilized when the patient is near death and should ideally be considered for use earlier in the disease process.

PALLIATIVE SEDATION

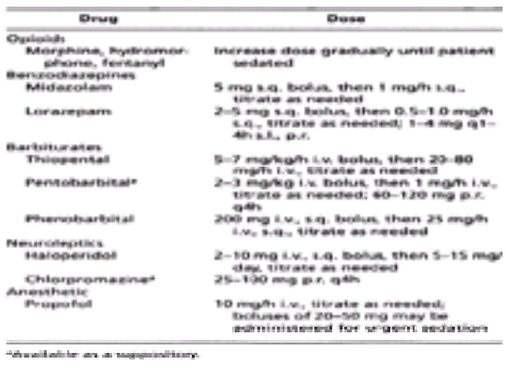
Palliative sedation, also referred to as terminal sedation, is the intentional use of pharmacological agents to induce and maintain a deep sleep, but not deliberately cause death, in specific clinical circumstances complicated by refractory symptoms (68). The incidence of PS varies from 5% to 52% (69). This variation is attributable to diverse definitions of PS, the retrospective nature of studies, and cultural and ethnic diversity. A refractory symptom is at times subjective and nonspecific and includes physical as well as psychological symptoms (70). Cherny and Portenoy clarify the boundaries of a refractory symptom by offering three criteria that suggests a symptom is refractory: (a) it cannot be controlled adequately despite aggressive efforts to identify a tolerable therapy that does not compromise consciousness, (b) additional invasive and noninvasive interventions are incapable of providing adequate relief, and (c) the therapy directed at the symptom is associated with excessive and intolerable acute or chronic morbidity and is unlikely to provide relief within a tolerable time frame (68).

The ethical validity of PS derives from the doctrine of double effect, a doctrine that is applied to situations in which it is impossible for a person to avoid all harmful actions, and the precept of informed consent. The traditional formulations of the doctrine of double effect involves four basic conditions: (a) the nature of the act must be good or morally neutral and not in a category that is absolutely prohibited and intrinsically wrong, (b) the intent of the clinician must be good, and the good effect, not the bad effect, must be intended, (c) the demarcation between the means and effects must be acceptable, in other words, the bad effect must not be the means to the good effect, and (d) proportionality, whereby the good effect must exceed or balance the bad effect (71).

Contentious issues with PS revolve around the use of tube feedings and eventual dehydration, and PS's relationship to physician-assisted suicide and euthanasia. Opponents of PS claim that the sedated patient dies of malnutrition and/or dehydration, not the underlying disease, although most patients have stopped eating and drinking prior to the initiation of PS, negating the argument of clinician-induced food and fluid deprivation. Nevertheless, if patients or surrogate family members wish to continue tube feedings, most clinicians discuss the futility of nutritional support but acquiesce to such requests and initiate PS.

Opponents of PS also contend that PS is nothing more than slow euthanasia. As proffered by the doctrine of double effect, however, the intent of the clinician must be considered. In the case of refractory symptoms, the intent is to alleviate suffering, not assist in suicide or euthanasia, even though PS may undeniably hasten death. Auspiciously, the U.S. Supreme Court fundamentally sanctioned PS in its decision opposing the constitutional right to physicianassisted suicide in 1997 (72,73), and in so doing, helped establish its value in the palliative armamentarium.

If PS is employed in a dying patient, informed consent must be obtained, as it is intimately integrated with autonomy and self-determination, and allows a reasonable person or surrogate to make independent and noncoerced treatment decisions. The reason for PS should be documented, as should the people present during the discussion, and if required by institutional or corporate policy, a completed consent form placed in the patient's chart. The choice of medications for PS is practitioner-dependent; clinicians should choose the drugs they are most familiar with, considering efficacy, cost, and clinical circumstance. Drugs frequently used for PS include opioids, benzodiazepines, barbiturates, neuroleptics, and propofol (Table 57-8).



Drug	Dose
Opioids	
Morphine, hydromorphone, fentanyl	Increase dose gradually until patient sedated
Benzodiazepines	
Midazolam	5 mg s.q. bolus, then 1 mg/h s.q., titrate as needed
Lorazepam	2–5 mg s.q. bolus, then 0.5–1.0 mg/h s.q., titrate as needed; 1–4 mg q1–4h s.l., p.r.
Barbiturates	
Thiopental	5–7 mg/kg/h i.v. bolus, then 20–80 mg/h i.v., titrate as needed
Pentobarbital*	2–3 mg/kg i.v. bolus, then 1 mg/h i.v., titrate as needed; 40–120 mg p.r. q4h
Phenobarbital	200 mg i.v., s.q. bolus, then 25 mg/h i.v., s.q., titrate as needed
Neuroleptics	
Haloperidol	2–10 mg i.v., s.q. bolus, then 5–15 mg/day, titrate as needed
Chlorpromazine*	25–100 mg p.r. q4h
Anesthetic	
Propofol	10 mg/h i.v., titrate as needed; boluses of 20–50 mg may be administered for urgent sedation

*Unavailable as a suppository.

TABLE 57-8. MEDICATIONS FOR PALLIATIVE SEDATION

FAMILY VIGIL

As death nears, family members tend to gather for comfort, solace, and support of themselves and their dying loved one. Emotions may become capricious and volatile, and aggressive treatments may be requested in an attempt to delay or preclude death. A “long-lost” family member may also suddenly appear and precipitate dissension among family members. Such disruption can distract health care providers as well as family members from providing the care and sustenance the dying patient needs. The clinician must keep in mind that such actions are often a manifestation of grief and fear, a desire to control an uncontrollable situation, or apprehension regarding one's own predestined death. It is important to maintain open communication with family members and reaffirm the goal of comfort care. Social work, nursing, and chaplain involvement can help direct family members in accepting the inevitable death of their loved one and provide reassurance that they will be there during this final journey.

Involving family members in the plan of care for the patient will enhance cooperation and a sense of contribution. They should be encouraged to assist in care by swabbing the oral mucosa, applying cool compresses to the eyes, performing gentle range of motion, and holding the hand of their loved one. The signs and events of the dying process should be reinforced, and personal, cultural, and religious beliefs and rituals honored (74,75). Family members may also be encouraged to convey the five affirmations recommended by Ira Byock: I forgive you, forgive me, I love you, thank you, and good-bye (76). Facilitating and supporting the opportunity for resolution and closure, personal and spiritual growth, and emotional healing is cardinal to a constructive death and bereavement, and should be provided for and encouraged.

To preclude confusion and turmoil during a home death, family members should be advised not to call “911.” Specific instructions should be given about whom to call (i.e., hospice nurse, social worker, chaplain, or physician). Family members should also be instructed about the physiological events that occur as the patient dies [e.g., the heart stops beating, breathing stops, pupils may dilate, eyes may remain open, urine and stool may be released, jaw may drop open (74)] and offered sufficient time to ask questions. Once death occurs, there is no immediacy to deliver the body to the morgue or funeral home, and family members should be allowed private time with their deceased loved one. Intravenous lines and catheters should be removed and, if desired by the spouse or children, the deceased bathed by family members; the latter can facilitate closure and allow expressions of immediate grief in a supportive setting (75). Finally, if the clinician is present to pronounce the patient, forthright and candid respect should be shown to the patient and family. Words such as, “I'm sorry, he/she has died,” and “My deepest condolences” are appropriate. However, silence, touch, and mere presence can be the greatest forms of communication and compassion at the time of death.

SPIRITUALITY

CHRISTINA M. PUCHALSKI

Dying is a normal part of life. In today's society, however, dying is still treated as an illness. All too often, people die in hospitals or nursing homes, alone and burdened with unnecessary treatment. In many cases, treatments would be refused if patients were given the chance to talk about their choices with their physicians long before the deathbed scene. Dying people are not always listened to … their wishes, their dreams, their fears go unheeded. They want to share those with us.

At the turn of the century, an average American's life expectancy was 50 years (1). Now, 73% of deaths are among people at least 65 years old, and 24% of deaths are among those at least 85 years old. The leading causes of deaths in 1900 were influenza, tuberculosis, diphtheria, heart disease, cancer, and stroke. Today, heart disease is the number one cause of death, followed by cancer and stroke. Modern med-icine has granted more people an old age, but it also slows the process of dying. The end of life can last several years.

Because the end of life can last so long, the question arises as to how to live with dying. Some people choose to live fighting their illness to the end, with much of their focus on the fight. Others focus their attention on other aspects of their lives, such as work, family, and hobbies. Still others pursue a mix of these approaches. Each person's way of handling his or her dying is reflective of who that person is, what is important to him or her, and how he/she faces crisis. One needs to remember that there is no set map for living with dying. Each individual patient creates his or her own path and approach.

Illness and the prospect of dying can call into question the very meaning and purpose of a person's life. Illness can also cause people to suffer deeply. Victor Frankl wrote that man is not destroyed by suffering; he is destroyed by suffer-ing without meaning (2). Writing about concentration camp victims, he noted that survival itself might depend on seeking and finding meaning. Harold Kushner also noted that pain may be the reason, and out of pain and suffering may come the answer (3). In my own clinical experience, I have found that people may cope with their suffering by finding meaning in it. Illness can present people with the opportunity to find meaning in their lives. Many patients say that out of their despair they were able to realize an entirely new and more fulfilling meaning in their lives. Rabbi Cohen wrote:

> When my mother died, I inherited her needlepoint tapestries. When I was a little boy, I used to sit at her feet as she worked on them. Have you ever seen needlepoint from underneath? All I could see was chaos; strands of thread all over with no seeming purpose. As I grew, I was able to see her work from above. I came to appreciate the patterns, the need for the dark threads as well as the light and gaily colored ones. Life is like that. From our human perspective, we cannot see the whole picture, but we should not despair or feel that there is no purpose. There is meaning and purpose even for the dark threads, but we cannot see that right away. (4)

Spirituality helps people find hope in the midst of despair. As caregivers, we need to engage our patients on that spiritual level (5). This is where spirituality plays such a critical role—the relationship with a transcendent being or concept can give meaning and purpose to people's lives, to their joys and to their sufferings. Spirituality is concerned with a transcendental or existential way to live one's life at a deeper level, “with the person as human being” (6). All people seek meaning and purpose in life; this search may be intensified when someone is facing death.

Downey defined spirituality as “an awareness that there are levels of reality not immediately apparent and that there is a quest for personal integration in the face of forces of fragmentation and depersonalization” (7). Spirituality is that aspect of human beings that seeks to heal or be whole. Foglio and Brody wrote:

> For many people religion [spirituality] forms a basis of mean-ing and purpose in life. The profoundly disturbing effects of illness can call into question a person's purpose in life and work; responsibilities to spouse, children, and parents … Healing, the restoration of wholeness (as opposed to merely technical healing) requires answers to these questions. (8)

Healing, then, is not synonymous with recovery. Indeed, healing may occur at any time, independent of recovery from illness. In dying, for example, restoration of wholeness may be manifested by a transcendent set of meaningful experiences while very ill. It may be reflected by a peaceful death. In chronic illness, healing may be experienced as the acceptance of limitations (5). A person may look to medical care to alleviate his or her suffering, and when the medical system fails to do so, begin to look toward spirituality for meaning, purpose, and understanding. As people are faced with serious illness or the prospect of dying, questions often arise (9):

- Why did this happen to me?
- What will happen to me after I die?
- Why would God allow me to suffer this way?
- Will I be remembered?
- Will I be missed?

These questions can cause people to undergo a life review whereby they analyze their lives, accomplishments, relationships, and perceived failings (10). This questioning can result in fears, anxieties, and unresolved feelings, which in turn can result in despair and suffering as people face themselves and their eventual mortality. Cassell wrote: “Since in suffering, disruption of the whole person is the dominant theme, we know of the losses and their meaning by what we know of others out of compassion for their suffering” (11). Compassion is essential in the care of all patients, particularly those who are dealing with chronic and serious illnesses and are dying. Two Latin words form the root of the word compassion: “cum,” meaning “with,” and “passio,” meaning “suffering with” (12). What compassionate care asks us to do is to suffer with our patients, i.e., to be present to them fully as they suffer and to partner with them in the midst of their pain.

Medicine has enjoyed tremendous technological advances that have helped treat illness and prolong lives. These advances have shaped medical care in the Western world. Although this is very positive, it has tended to focus care on the technological and curative aspects, diminishing the importance of the humanitarian and compassionate aspects of care. As Doka wrote, “Efforts to humanize patient care are essential if the integrity of the human being is not to be obscured by the system” (6).

Dying is a natural occurrence in life. However, the Western medical and social culture still treats dying as if it were just a biological occurrence. Dying should be as natural an experience as birth. It should be a meaningful experience for dying persons, a time in which they find meaning in their suffering and have all the dimensions of their experience addressed by their caregiver. These dimensions are the physical, psychological, social, and spiritual (Table 58-1).

Physical	Pain and other symptom management
Psychological	Anxiety and depression
Social	Social isolation, economic issues
Spiritual	Purpose and meaning, relationships with the transcendent, search for ultimate meaning, hope, reconciliation, despair

TABLE 58-1. THE DIMENSIONS OF THE DYING EXPERIENCE

Patients encounter all types of suffering—spiritual as well as physical. Cecily Saunders, the founder of St. Christopher's Hospice in London and of the Hospice movement, stated that one of the aims of hospice is that there be relief of “total pain,” including the physical, emotional, psychological, social, and spiritua1 (13). It should be the obligation of all physicians and other caregivers to respond to, as well as attempt to relieve, all suffering if possible. Because people may cope with suffering using their spiritual resources, physicians should be able to communicate with their patients about spiritual issues. They should recognize the spiritual as well as physical dimensions of suffering and make resources available for those patients who wish them. Physicians have the responsibility to listen to people as they struggle with their dying. We *need* to be willing to listen to their anxieties, their fears, their unresolved conflicts, their hopes, and their despairs. If people are stuck in despair, they will suffer deeply. It is through their spirituality that people become unstuck from despair.

SPIRITUALITY IN CLINICAL PRACTICE

Medical professionals are recognizing that there are inadequacies in the health care system in terms of care of the dying. The American College of Physicians convened an end-of-life consensus panel, which concluded that physicians should extend their care for those with serious medical illness by attentiveness to psychosocial, existential, or spiritual suffering (14). Other national organizations have also supported the inclusion of spirituality in the clinical setting. The Joint Commission on Accreditation of Healthcare Organizations has a policy that states: Pastoral counseling and other spiritual services are often an integral part of the patient's daily life. When requested, the hospital provides, or provides for, pastoral counseling services (15).

The interest in spirituality in medicine among medical educators has been growing exponentially. Medical schools are now teaching courses in end-of-life care and in spirituality and medicine. Only one school had a formal course in spirituality and medicine in 1992. Now, over 70 medical schools are teaching such courses (16,17). The key elements of these courses have to do with listening to what is important to patients, respecting their spiritual beliefs, and being able to communicate effectively with them about these spiritual beliefs, as well about their preferences at the end of life.

In 1998, the Association of American Medical Colleges (AAMC), responding to concerns by the medical professional community that young doctors lacked these humanitarian skills, undertook a major initiative—The Medical School Objectives Project (MSOP)—to assist medical schools in their efforts to respond to these concerns. The report notes that “Physicians must be compassionate and empathetic in caring for patients … they must act with integrity, honesty, respect for patients' privacy and respect for the dignity of patients as persons. In all of their interactions with patients they must seek to understand the meaning of the patients' stories in the context of the patients', and family and cultural values” (18). In recognition of the importance of teaching students how to respect patients' beliefs, AAMC has supported the development of courses in spirituality and medicine.

In 1999, a consensus conference with AAMC was convened to determine learning objectives and methods of teaching courses on spirituality, cultural issues, and end-of- life care. The findings of the conference were published as Report III of the MSOP. This report included a clinically relevant definition of spirituality: Spirituality is recognized as a factor that contributes to health in many persons. The concept of spirituality is found in all cultures and societies. It is expressed in an individual's search for ultimate meaning through participation in religion and/or belief in God, family, naturalism, rationalism, humanism, and the arts. All of these factors can influence how patients and health care professionals perceive health and illness and how they interact with one another (19).

Spirituality, that which gives us meaning, can be expressed in many ways. When approaching patients' spiritual issues, it is important to recognize that the definition of spirituality is broad and all-encompassing. It is critical to allow the patient to inform the physician and other care providers what spirituality means to that patient. The outcome goals stated in MSOP III are that students will

- Be aware that spirituality, as well as cultural beliefs and practices, are important elements of the health and wellbeing of many patients
- Be aware of the need to incorporate awareness of spirituality, and cultural beliefs and practices, into the care of patients in a variety of clinical contexts
- Recognize that their own spirituality, and cultural beliefs and practices, might affect the ways they relate to, and provide care to, patients
- Be aware of the range of end-of-life care issues and when such issues have or should become a focus for the patient, the patient's family, and members of the health care team involved in the care of the patient
- Be aware of the need to respond not only to the physical needs that occur at the end of life, but also to the emotional, sociocultural, and spiritual needs that occur (19)

More than half of U.S. medical schools have courses in spirituality and medicine, many of which are required and integrated into the curriculum. The response to these courses has been positive. Students and practicing physicians find their relationships with their patients are warmer, more meaningful, and deeper once they talk with their patients about their spiritual beliefs. Medical students and residents are finding it easier to address end-of-life issues in the context of a spiritual history (20). Doctors who felt burned out by the hectic schedules of managed care now feel a way to reconnect with their patients and bring compassionate care giving back into the practice of medicine. Most important, the patients are happier because their whole person is treated—body, mind, and spirit—and not just their illness.

In these courses, future doctors learn how to communicate with patients about the patients' spiritual beliefs. A spiritual history is really nothing more than listening to the patient—to the patient's fears, hopes, and beliefs (21). When talking with someone about spiritual beliefs, it is natural to bring up issues of advance directives. Advance directives may be obtained through forms or brief questions in a history, which can be sterile and out of context. Discussions about the way people want to die should be done in the context of a person's values and beliefs. A spiritual history is an ideal place for centering discussions around advance directives (21).

DATA DEMONSTRATING PATIENT NEED

That spirituality is central to the dying person is well recognized by many experts, the most important of which are our patients. Several other national surveys have documented patients' desire to have spiritual concerns addressed by their physicians. A 1990 Gallup poll showed that religion, one expression of spirituality, plays a central role in the lives of many Americans (22). A more recent Gallup survey showed that 94% of Americans surveyed espouse a belief in God or a higher power, six out of ten Americans say that religion is very important in their life, and another three out of ten say it is fairly important. Approximately two-thirds of Americans claim to be a member of a church or synagogue. Additionally, when asked to state their religious preference, only 9% of the public says “none” (23).
