FOREWORD

A folk saying dating to the fifteenth century calls the duty of a physician “to cure sometimes, to relieve often, to comfort always.” The modern oncologist has the tools to cure approximately 50% of all individuals who develop cancer, although virtually every cancer patient sometime during the course of the disease and treatment has the need for relief from symptoms and comfort from anxieties. The physical symptoms associated with cancer and its treatment, as well as the emotional burdens on patients and their families, profoundly impact the quality of life of cancer patients.

The scope of information in modern oncology ranges from understanding the single nucleotide base changes in oncogenes that can result in malignant transformation to understanding the emotional needs of a patient with metastatic cancer in the last hours of life. The practicing oncologist faces the daunting challenge of translating a vast array of new clinical and scientific information to benefit the care of individual cancer patients.

Most modern textbooks of oncology as well as the majority of articles in peer-reviewed journals deal predominantly with the pathogenesis of disease and attempts to develop curative treatments. Coordinated information dealing with the supportive aspects of cancer care designed to relieve symptoms and to comfort anxieties has often been difficult to find. Only recently have major institutions organized separate services concentrating on cancer care staffed by health care professionals whose training is concentrated on the palliative and supportive care needs of cancer patients.

The information needed by all health care providers to “relieve often, to comfort always” all cancer patients, whether curable or not, is found in these pages of the comprehensive second edition of *Principles and Practice of Palliative Care and Supportive Oncology*. The editors have provided a comprehensive guide to dealing with the severe physical and emotional impact of the cancer itself, as well as the side effects of the treatments administered.

The contents of this text provide the practicing oncologist with the base of information needed to deal with this extraordinarily important aspect of modern oncology.

Steven A. Rosenberg, M.D., Ph.D.
Chief of Surgery, National Cancer Institute
National Institutes of Health
Bethesda, Maryland

PREFACE FROM THE FIRST EDITION

The term *supportive oncology* refers to those aspects of medical care concerned with the physical, psychosocial, and spiritual issues faced by persons with cancer, their families, their communities, and their health care providers. In this context, supportive oncology describes both those interventions used to support patients who experience adverse effects caused by antineoplastic therapies and those interventions now considered under the broad rubric of palliative care. The term *palliative* is derived from the Latin *pallium*: to cloak or cover. At its core, palliative care is concerned with providing the maximum quality of life to the patient-family unit.

In 1990, the World Health Organization (WHO) published a landmark document, *Cancer Pain Relief and Palliative Care*, which clearly defined the international barriers and needs for improved pain and symptom control in the cancer patient.

The WHO definition of palliative care is (1)

> The active total care of patients whose disease is not responsive to curative treatment. Control of pain, of other symptoms, and of psychological, social, and spiritual problems is paramount. The goal of palliative care is achievement of the best quality of life for patients and their families. Many aspects of palliative care are also applicable earlier in the course of the illness in conjunction with anti-cancer treatment.

In 1995, the Canadian Palliative Care Association chose a somewhat broader definition that emphasizes a more expanded role of palliative care (2):

> Palliative care, as a philosophy of care, is the combination of active and compassionate therapies intended to comfort and support individuals and families who are living with a life-threatening illness. During periods of illness and bereavement, palliative care strives to meet physical, psychological, social, and spiritual expectations and needs, while remaining sensitive to personal, cultural, and religious values, beliefs, and practices. Palliative care may be combined with therapies aimed at reducing or curing the illness, or it may be the total focus of care.

In developing this textbook, the editors have brought together those elements of palliative care that are most applicable to the health care professional caring for cancer patients, and have combined this perspective with a detailed description of related therapies used to support patients in active treatment. The editors view these interventions as a necessary and vital aspect of medical care for all cancer patients, from the time of diagnosis until death. Indeed, most patients will have a significant physical symptom requiring treatment at the time of their cancer diagnosis.

Even when cancer can be effectively treated and a cure or life prolongation is achieved, there are always physical, psychosocial, or spiritual concerns that must be addressed to maintain function and optimize the quality of life. For patients whose cancer cannot be effectively treated, palliative care must be the dominant mode, and one must focus intensively on the control of distressing symptoms. Planning for the end of life and ensuring that death occurs with a minimum of suffering and in a manner consistent with the values and desires of the patient and family are fundamental elements of this care. Palliative care, as a desired approach to comprehensive cancer care, is appropriate for all health care settings, including the clinic, acute care hospital, long-term care facility, or home hospice.

Palliative care and the broader concept of supportive care involve the collaborative efforts of an interdisciplinary team. This team must include the cancer patient and his or her family, care givers, and involved health care providers. Integral to effective palliative care is the opportunity and support necessary for both care givers and health care providers to work through their own emotions related to the care they are providing.

In organizing this textbook, the editors have recognized the important contributions of medical research and clinical care that have emerged from the disciplines of hospice and palliative medicine; medical, radiation, and surgical oncology; nursing; neurology and neuro-oncology; anesthesiology; psychiatry and psychology; pharmacology; and many others. The text includes chapters focusing on the common physical symptoms experienced by the cancer patient; a review of specific supportive treatment modalities, such as blood products, nutritional support, hydration, palliative chemotherapy, radiotherapy, and surgery; and, finally, a review of more specialized topics, including survivorship issues, medical ethics, spiritual care, quality of life, and supportive care in elderly, pediatric, and AIDS patients.

There are many promising new cancer treatments on the horizon. No matter what these new treatments will offer in terms of curing the disease or prolonging life, cancer will remain a devastating illness, not only for the affected patients, but for their families, community, and health care providers. Providing excellent, supportive care will continue to be a goal for all health care providers.

The authors would like to thank our many contributors for their efforts. We are also grateful to our publisher and secretaries, whose oversight and gentle prodding were essential to our success. Finally, we want to express our gratitude to our families and colleagues, who accommodated our needs in bringing the volume to fruition and provided the support we needed throughout the process.

Ann M. Berger, R.N., M.S.N., M.D.
Russell K. Portenoy, M.D.
David E. Weissman, M.D.

PREFACE

> You matter because you are you. You matter to the last moment of your life, and we will do all that we can not only to help you die peacefully, but also to live until you die.
>
> —Dame Cicely Saunders

We offer this second edition as a contribution to the changes that have taken place in palliative medicine in the past 4 years. Palliative medicine is an art and a science of patient-focused, family-oriented, relationship-centered care, from the onset of a serious life-challenging illness throughout the trajectory of illness, aimed at enhancing quality of life and minimizing suffering.

Clearly, palliative care has developed into a recognized discipline. In the United States, palliative care is rapidly evolving in parallel with a well-established hospice model. The U.S. version of hospice remains a critically important part of this broader approach to palliative care, which attempts to help patients and their families deal with quality-of-life issues throughout the trajectory of illness, even when treatment has curative intent.

In this second edition, we have added several new chapters, including hiccups, physiatric approaches, bone pain, management of hypercoagulable states and coagulopathy, management of advanced heart failure, cross-cultural issues, models of palliative care, ethics and the law, music and art therapy, and complementary and alternative approaches.

As before, when we edited our first edition, there are many new medical treatments on the horizon that cure disease. But equally important is providing excellent palliative care aimed at relieving suffering.

Ann M. Berger, R.N., M.S.N., M.D.
Russell K. Portenoy, M.D.
David E. Weissman, M.D.

ACKNOWLEDGMENTS

We would like to thank all of the contributors for their tireless efforts. We are also grateful to Zia Raven, whose oversight, gentle prodding, and years of experience were essential to the success of the book. We would like to thank Stuart Freeman, whose vision many years ago helped us bring the first text to fruition and begin the second edition. Finally, we want to express our gratitude to our families and colleagues for their unstinting support for all our efforts.

Russell K. Portenoy, M.D.
David E. Weissman, M.D.

1

CANCER PAIN: PRINCIPLES OF ASSESSMENT AND SYNDROMES

NATHAN I. CHERNY

Surveys indicate that pain is experienced by 30–60% of cancer patients during active therapy and more than two-thirds of those with advanced disease (1). This has been corroborated in a series of recent studies which identified a pain prevalence of 28% among patients with newly diagnosed cancer (2), 50–70% among patients receiving active anticancer therapy (3,4), and 64–80% among patients with far advanced disease (5,6,7 and 8). Unrelieved pain is incapacitating. It precludes a satisfying quality of life. It interferes with physical functioning and social interaction. It is strongly associated with heightened psychological distress (9,10). Persistent pain interferes with the ability to eat (11), sleep (12,13), think, interact with others (10,14), and is correlated with fatigue in cancer patients (15).

The relationship between pain and psychological well-being is complex and reciprocal. Mood disturbance and beliefs about the meaning of pain in relation to illness can exacerbate perceived pain intensity. The presence of pain is a major determinant of function and mood. The affective dimension of pain includes sensations of unpleasantness and emotions associated with future implications. The affective component of the pain experience is related to a central network of brain structures, including spinal pathways to limbic structures and medial thalamic nuclei, spinal pathways to somatosensory thalamic, and a cortico-limbic pathway to cortical areas. This cortico-limbic pathway integrates nociceptive input with contextual information and memory to provide cognitive mediation of pain affect (16).

The presence of pain can provoke or exacerbate existential distress (17), disturb normal processes of coping and adjustment (18,19 and 20), and augment a sense of vulnerability, contributing to a preoccupation with the potential for catastrophic outcomes (10,18).

The high prevalence of acute and chronic pain among cancer patients and the profound psychological and physical burdens engendered by this symptom oblige all treating clinicians to be skilled in pain management (21). Relief of pain in cancer patients is an ethical imperative. It is incumbent on clinicians to maximize the knowledge, skill, and diligence needed to attend to this task.

The undertreatment of cancer pain, which continues to be common (22,23), has many causes, among the most important of which is inadequate assessment (24,25). In a study to evaluate the correlation between patient and clinician evaluation of pain severity, Grossman et al. (25) found that when patients rated their pain as moderate to severe, oncology fellows failed to appreciate the severity of the problem in 73% of cases. In studies of pain relief among cancer patients in the United States (26) and in France (27), the discrepancy between patient and physician evaluation of the severity of the pain problem was a major predictor of inadequate relief. Surveys indicate that oncology clinicians recognize that suboptimal assessment is one of the most important causes of inadequate pain relief in cancer patients (24,28,29).

APPROACH TO CANCER PAIN ASSESSMENT

Assessment is an ongoing and dynamic process that includes evaluation of presenting problems, elucidation of pain syndromes and pathophysiology, and formulation of a comprehensive plan for continuing care. The objectives of cancer pain assessment include (a) the accurate characterization of the pain, including the pain syndrome and inferred pathophysiology, and (b) the evaluation of the impact of the pain and the role it plays in the overall suffering of the patient.

This assessment is predicated on the establishment of a trusting relationship with the patient in which the clinician emphasizes the relief of pain and suffering as central to the goal of therapy, and encourages open communication about symptoms. Clinicians should not be cavalier about the potential for symptom underreporting. Symptoms are frequently described as complaints and there is a common perception that the “good patient” refrains from complaining (30). The prevalence of pain is so great that an open-ended question about the presence of pain should be included at each patient visit in routine oncological practice. If the patient is either unable or unwilling to describe the pain, a family member may need to be questioned to assess the distress or disability of the patient.

Pain Syndromes

Cancer pain syndromes are defined by the association of particular pain characteristics and physical signs with specific consequences of the underlying disease or its treatment. Syndromes are associated with distinct etiologies and pathophysiologies, and have important prognostic and therapeutic implications. Pain syndromes associated with cancer can be either acute (Table 1-1) or chronic (Table 1-2). Whereas acute pains experienced by cancer patients are usually related to diagnostic and therapeutic interventions, chronic pains are most commonly caused by direct tumor effects. Adverse consequences of cancer therapy, including surgery, chemotherapy, and radiation therapy, account for 15–25% of chronic cancer pain problems. A small proportion of the chronic pains experienced by cancer patients are caused by pathology unrelated to either the cancer or the cancer therapy.

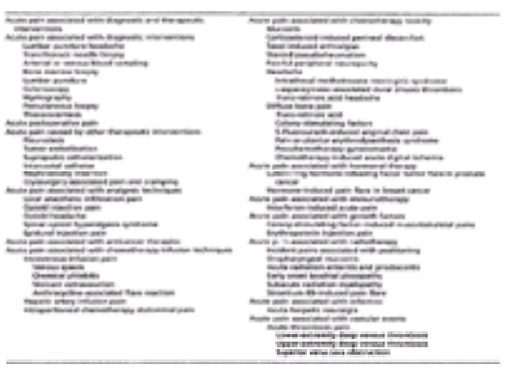

TABLE 1-1. CANCER-RELATED ACUTE PAIN SYNDROMES

TABLE 1-2. CANCER-RELATED CHRONIC PAIN SYNDROMES

Pain Characteristics

The evaluation of pain characteristics provides some of the data essential for syndrome identification. These characteristics include intensity, quality, distribution, and temporal relationships.

Intensity

The evaluation of pain intensity is pivotal to therapeutic decision-making (31,32). It indicates the urgency with which relief is needed and influences the selection of analgesic drug, route of administration, and rate of dose titration (31). Furthermore, the assessment of pain intensity may help characterize the pain mechanism and underlying syndrome. For example, the pain associated with radiation-induced nerve injury is rarely severe; the occurrence of severe pain in a previously irradiated region therefore suggests the existence of recurrent neoplasm or a radiation-induced second primary neoplasm.

Quality

The quality of the pain often suggests its pathophysiology. Somatic nociceptive pains are usually well localized and described as sharp, aching, throbbing, or pressurelike. Visceral nociceptive pains are generally diffuse and may be gnawing or crampy when due to obstruction of a hollow viscus, or aching, sharp, or throbbing when due to involvement of organ capsules or mesentery. Neuropathic pains may be described as burning, tingling, or shocklike (lancinating).

Distribution

Patients with cancer pain commonly experience pain at more than one site (3,4,33). The distinction between focal, multifocal, and generalized pain may be important in the selection of therapy, such as nerve blocks, radiotherapy, or surgical approaches. The term *focal pain*, which is used to denote a single site, has also been used to depict pain that is experienced in the region of the underlying lesion. Focal pains can be distinguished from those that are referred to a site remote from the lesion. Familiarity with pain referral patterns is essential to target appropriate diagnostic and therapeutic maneuvers (34,35) (Table 1-3). For example, a patient who develops progressive shoulder pain and has no evidence of focal pathology needs to undergo evaluation of the region above and below the diaphragm to exclude the possibility of referred pain from diaphragmatic irritation.

Pain mechanism	Site of lesion	Referral site
Visceral	Diaphragmatic irritation	Shoulder
	Urothelial tract	Inguinal region and genitalia
Somatic	C7-T1 vertebrae	Interscapular
	L1-2	Sacroiliac joint and hip
	Hip joint	Knee
	Pharynx	Ipsilateral ear
Neuropathic	Nerve or plexus	Anywhere in the distribution of a peripheral nerve
	Nerve root	Anywhere in the corresponding dermatome
	Central nervous system	Anywhere in the region of the body innervated by the damaged structure

TABLE 1-3. COMMON PATTERNS OF PAIN REFERRAL

Temporal Relationships

Cancer-related pain may be acute or chronic. Acute pain is defined by a recent onset and a natural history characterized by transience. The pain is often associated with overt pain behaviors (such as moaning, grimacing, and splinting), anxiety, or signs of generalized sympathetic hyperactivity, including diaphoresis, hypertension, and tachycardia. Chronic pain has been defined by persistence for 3 months or more beyond the usual course of an acute illness or injury, a pattern of recurrence at intervals over months or years, or by association with a chronic pathological process (1). Chronic, tumor-related pain is usually insidious in onset, often increases progressively with tumor growth, and may regress with tumor shrinkage. Overt pain behaviors and sympathetic hyperactivity are often absent, and the pain may be associated with affective disturbances (anxiety and/or depression) and vegetative symptoms, such as asthenia, anorexia, and sleep disturbance (36).

Transitory exacerbations of severe pain, over a baseline of moderate pain, may be described as “breakthrough pain” (37). Breakthrough pains are common in both acute or chronic pain states. These exacerbations may be precipitated by volitional actions of the patient (so-called incident pains), such as movement, micturition, cough or defecation, or by nonvolitional events such as bowel distention. Spontaneous fluctuations in pain intensity can also occur without an identifiable precipitant.

Inferred Pain Mechanisms

Inferences about the mechanisms that may be responsible for the pain are helpful in the evaluation of the pain syndrome and in the management of cancer pain. The assessment process usually provides the clinical data necessary to infer a predominant pathophysiology.

Nociceptive Pain

Nociceptive pain describes pain that is perceived to be commensurate with tissue damage associated with an identifiable somatic or visceral lesion. The persistence of pain is thought to be related to ongoing activation of nociceptors. Nociceptive pain that originates from somatic structures (somatic pain) is usually well localized and described as sharp, aching, burning, or throbbing. As previously described, pain that arises from visceral structures (visceral pain) is generally diffuse; pain characteristics may differ depending on the involved structures. From the clinical perspective, nociceptive pains (particularly somatic pains) usually respond to opioid analgesics (38,39 and 40) or to interventions that ameliorate or denervate the peripheral lesion.

Neuropathic Pain

The term *neuropathic pain* is applied when pain is due to injury to, or diseases of, the peripheral or central neural structures or is perceived to be sustained by aberrant somatosensory processing at these sites (41). It is most strongly suggested when a dysesthesia occurs in a region of motor, sensory, or autonomic dysfunction that is attributable to a discrete neurological lesion. The diagnosis can be challenging, however, and is often inferred solely from the distribution of the pain and identification of a lesion in neural structures that innervate this region.

Although neuropathic pains can be described in terms of the pain characteristics (continuous or lancinating) or site of injury (for example, neuronopathy or plexopathy), it is useful to distinguish these syndromes according to the presumed site of the aberrant neural activity ("generator") that sustains the pain (42). Peripheral neuropathic pain is caused by injury to a peripheral nerve or nerve root and is presumably sustained by aberrant processes originating in the nerve root, plexus, or nerve. Neuropathic pains believed to be sustained by a central "generator" include sympathetically maintained pain [also known as *reflex sympathetic dystrophy* (RSD) or *causalgia*] and a group of syndromes traditionally known as the *deafferentation pains* (e.g., phantom pain). Sympathetically maintained pain may occur following injury to soft tissue, peripheral nerve, viscera, or central nervous system, and is characterized by focal autonomic dysregulation in a painful region (e.g., vasomotor or pilomotor changes, swelling, or sweating abnormalities) or trophic changes (43). Understanding of "RSD" and "causalgia" and sympathetically maintained pain have undergone considerable review. The International Association for the Study of Pain has suggested classification of these syndromes as Complex Regional Pain Syndromes types I and II, indicating that sympathetically maintained pain is a frequent but variable component of these syndromes. Type I corresponds to RSD and occurs without a definable nerve lesion. Type II, formerly called *causalgia*, refers to cases where a definable nerve lesion is present (44,45).

The pain of peripheral neuropathies may be generated by several pathophysiological mechanisms in both the peripheral and central nervous system: (a) pathologically active or sensitized nociceptors can induce spinal cord hyperexcitability that causes input from mechanoreceptive A-b-fibers (light touching) to be perceived as pain; (b) nociceptor function may be selectively impaired within the allodynic skin such that pain and temperature sensation are impaired but light moving mechanical stimuli can often produce severe pain (dynamic mechanical allodynia); (c) inflammatory reactions of the nerve trunk, mediated by the cytokine tumor necrosis factor-a, can induce ectopic activity in primary afferent nociceptors and thus generate spontaneous pain and allodynia; (d) injury can alter sympathetic nervous system interaction with afferent neurons such that sympathetic fibers can induce further activity in sensitized nociceptors (46).

The diagnosis of neuropathic pain has important clinical implications. The response of neuropathic pains to opioid analgesics is less predictable and generally less dramatic than the response of nociceptive pains. Optimal treatment may depend on the use of so-called adjuvant analgesics (47,48 and 49) or other specific approaches such as somatic or sympathetic nerve block (35).

Idiopathic Pain

Pain that is perceived to be excessive for the extent of identifiable organic pathology can be termed *idiopathic* unless the patient presents with affective and behavioral disturbances that are severe enough to infer a predominating psychological pathogenesis, in which case a specific psychiatric diagnosis (e.g., somatoform disorder) can be applied (50,51). When the inference of a somatoform disorder cannot be made, however, the label *idiopathic* should be retained and assessments should be repeated at appropriate intervals. Idiopathic pain in general, and pain related to a psychiatric disorder specifically, are uncommon in the cancer population, notwithstanding the importance of psychological factors in quality of life.

Stepwise Approach to the Evaluation of Cancer Pain

A practical approach to cancer pain assessment incorporates a stepwise approach that begins with data collection and ends with a clinically relevant formulation.

Data Collection

History

A careful review of past medical history and the chronology of the cancer are important to place the pain complaint in context. The pain-related history must elucidate the relevant pain characteristics, as well as the responses of the patient to previous disease-modifying and analgesic therapies. The presence of multiple pain problems is common. If more than one is reported, each must be assessed independently. The use of validated pain assessment instruments can provide a format for communication between the patient and health care professionals and can also be used to monitor the adequacy of therapy (see the section Pain Measures in Routine Clinical Management).

The clinician should assess the consequences of the pain, including impairment in activities of daily living; psychological, familial, and professional dysfunction; disturbed sleep, appetite, and vitality; and financial concerns. The patient's psychological status, including current level of anxiety or depression, suicidal ideation, and the perceived meaning of the pain, is similarly relevant. Pervasive dysfunctional attitudes, such as pessimism, idiosyncratic interpretation of pain, self-blame, catastrophizing, and perceived loss of personal control, can usually be detected through careful questioning. It is important to assess the patient-family interaction and to note both the kind and frequency of pain behaviors and the nature of the family response.

Most patients with cancer pain have multiple other symptoms (52,53,54,55 and 56). The clinician must evaluate the severity and distress caused by each of these symptoms. Symptom checklists and quality of life measures may contribute to this comprehensive evaluation (57,58).

Examination

A physical examination, including a neurological evaluation, is a necessary part of the initial pain assessment. The need for a thorough neurological assessment is justified by the high prevalence of painful neurological conditions in this population (59,60). The physical examination should attempt to identify the underlying etiology of the pain problem, clarify the extent of the underlying disease, and discern the relationship of the pain complaint to the disease.

Review of Previous Investigations

Careful review of previous laboratory and imaging studies can provide important information about the cause of the pain and the extent of the underlying disease.

Provisional Assessment

The information derived from these data provides the basis for a provisional pain diagnosis, an understanding of the disease status, and the identification of other concurrent concerns. This provisional diagnosis includes inferences about the pathophysiology of the pain and an assessment of the pain syndrome.

Additional investigations are often required to clarify areas of uncertainty in the provisional assessment (59). The extent of diagnostic investigation must be appropriate to the patient's general status and the overall goals of care. For some patients, comprehensive evaluation may require numerous investigations, some targeted at the specific pain problem and others needed to clarify extent of disease or concurrent symptoms. In specific situations, algorithms have been developed to facilitate an efficient evaluation. This is well illustrated by established clinical algorithms for the investigation of back pain in the cancer patient (61,62), which provide a straightforward approach for those patients at highest risk for epidural cord (see the section Algorithm for the Investigation of Cancer Patients with Back Pain).

The lack of a definitive finding on an investigation should not be used to override a compelling clinical diagnosis. In the assessment of bone pain, for example, plain radiographs provide only crude assessment of bony lesions and further investigation with bone scintigrams, computed tomography (CT), or magnetic resonance imaging (MRI) may be indicated. To minimize the risk of error, the physician ordering the diagnostic procedures should personally review them with the radiologist to correlate pathological changes with the clinical findings.

Pain should be managed during the diagnostic evaluation. Comfort will improve compliance and reduce the distress associated with procedures. No patient should be inadequately evaluated because of poorly controlled pain.

The comprehensive assessment may also require evaluation of other physical or psychosocial problems identified during the initial assessment. Expert assistance from other physicians, nurses, social workers, or others may be essential.

Formulation and Therapeutic Planning

The evaluation should enable the clinician to appreciate the nature of the pain, its impact, and concurrent concerns that further undermine quality of life. The findings of this evaluation should be reviewed with the patient. Through candid discussion, current problems can be prioritized to reflect their importance to the patient. This evaluation may also identify potential outcomes that would benefit from contingency planning. Examples include evaluation of resources for home care, prebereavement interventions with the family, and the provision of assistive devices in anticipation of compromised ambulation.

Measurement of Pain and Its Impact on Patient Well-Being

Although pain measurement has generally been used by clinical investigators to determine the impact of analgesic therapies, it has become clear that it has an important role in the routine monitoring of cancer patients in treatment settings (63,64 and 65). Because observer ratings of symptom severity correlate poorly with patient ratings and are generally an inadequate substitute for patient reporting (25), patient self-report is the primary source of information for the measurement of pain.

Pain Measures in Routine Clinical Management

Recent guidelines from the Agency for Health Care Policy and Research (66), American Pain Society (64), and the Joint Commission on Accreditation of Healthcare Organizations (67) recommend the regular use of pain rating scales to assess pain severity and relief in all patients who commence or change treatments. These recommendations also suggest that clinicians teach patients and families to use assessment tools in the home to promote continuity of pain management in all settings. The two most commonly used scales for adults are a verbal descriptor scale (i.e., “Which word best describes your pain: none, mild, moderate, severe, or excruciating?”), or a numerical scale (i.e., “On a scale from 0 to 10, where 0 indicates no pain and 10 indicates the worst pain you can imagine, how would you rate your pain?”) (66,67).

A recent study demonstrated that the use of a simple verbal pain assessment tool improved the caregiver's understanding of pain status in hospitalized patients (65). Regular pain measurement, using a pain scale attached to the bedside chart (Fig. 1-1), has been incorporated into a continuous quality improvement strategy at a cancer center (68) and preliminary data suggest that nursing knowledge and attitudes regarding the assessment and management of cancer pain have improved as a result. In addition to focusing staff attention on symptom assessment, such measures may be used as a means of reviewing the quality of patient care and ascertaining situation-specific barriers to symptom control (69,70).

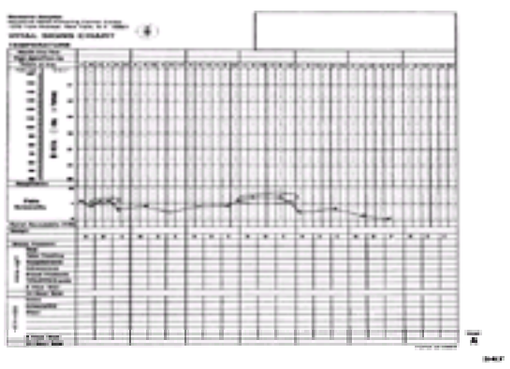

FIGURE 1-1. The patient observation chart from the Memorial Sloan-Kettering Cancer Institute. Incorporated into the chart is a 10-point pain scale and an item regarding the adequacy of pain control.

Instruments for the Measurement of Pain in Research Settings

Pain can be measured using a unidimensional or multidimensional scales. Unidimensional scales generally address intensity or relief using visual analogue, numerical, and categorical scales. Multidimensional instruments include the Memorial Pain Assessment Card (MPAC), the McGill Pain Questionnaire (MPQ), and the Brief Pain Inventory (BPI).

Memorial Pain Assessment Card (MPAC)

The MPAC (71) is a brief, validated measure that uses 100-mm visual analogue scales to characterize pain intensity, pain relief, and mood, and an eight-point verbal rating scale to further characterize pain intensity (Fig. 1-2). The mood scale, which is correlated with measures of global psychological distress, depression, and anxiety, is considered to be a brief measure of global symptom distress (71). Although this instrument does not provide detailed descriptors of pain, its brevity and simplicity may facilitate the collection of useful information while minimizing patient burden and encouraging compliance.

FIGURE 1-2. The Memorial Pain Assessment Card. (Reproduced with permission.)

Brief Pain Inventory (BPI)

The BPI (Fig. 1-3) (72) is a simple and easily administered tool that provides information about pain history, intensity, location, and quality. Numeric scales (range, 1–10) indicate the intensity of pain in general, at its worst, at its least, and right now. A percentage scale quantifies relief from current therapies. A figure representing the body is provided for the patient to shade the area corresponding to his or her pain. Seven questions determine the degree to which pain interferes with function, mood, and enjoyment of life. The BPI is self-administered and easily understood, and has been translated into several languages (73,74 and 75). It is suitable for ongoing evaluation of pain over time.

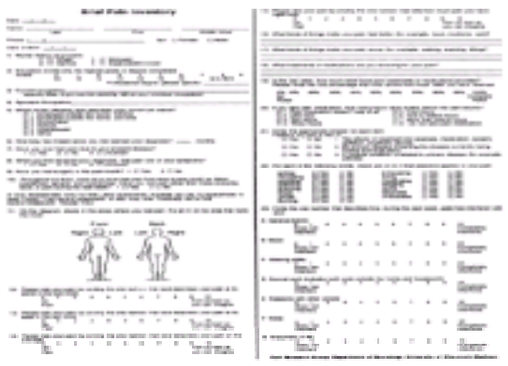

FIGURE 1-3. The Brief Pain Inventory. (Reproduced with permission of the Pain Research Group, Department of Neurology, University of Wisconsin-Madison.)

McGill Pain Questionnaire (MPQ)

The MPQ (76,77) is a self-administered questionnaire that provides global scores and subscale scores that reflect the sensory, affective, and evaluative dimensions of pain. The scores are derived from ratings of pain descriptors selected by the patient. A 5-point verbal categorical scale characterizes the intensity of pain. A pain drawing localizes the pain. Further information is collected about the impact of medications and other therapies. The impact of pain on function is not assessed. Although the MPQ has been extensively evaluated in chronic-pain patients, the utility of the subscale scores has not been demonstrated for cancer pain (78). A short form of the MPQ was developed for use in research settings and has been validated in a palliative care setting (79).

ACUTE PAIN SYNDROMES

Cancer-related acute pain syndromes are most commonly due to diagnostic or therapeutic interventions (80) (Table 1-1). They generally pose little diagnostic difficulty. Although some tumor-related pains have an acute onset (such as pain from a pathological fracture), most of these will persist unless effective treatment for the underlying lesion is provided. A comprehensive pain assessment in such patients is usually valuable, potentially yielding important information about the extent of disease or concurrent issues relevant to therapy.

Acute Pain Associated with Diagnostic and Therapeutic Interventions

Many investigations and treatments are associated with predictable, transient pain. For those patients with a preexisting pain syndrome, otherwise innocuous manipulations can also precipitate an incident pain.

Acute Pain Associated with Diagnostic Interventions

Lumbar Puncture Headache

Lumbar puncture (LP) headache is the best characterized acute pain syndrome associated with a diagnostic intervention. This syndrome is characterized by the delayed development of a positional headache, which is precipitated or markedly exacerbated by upright posture. The pain is believed to be related to reduction in cerebrospinal fluid (CSF) volume, due to ongoing leakage through the defect in the dural sheath, and compensatory expansion of the pain-sensitive intracerebral veins (81,82). The incidence of headache is related to the caliber of the LP needle (0–2% with 27–29-gauge, 0.5–7% with 25–26-gauge, 5–8% with 22-gauge, 10–15% with 20-gauge, and 20–30% with 18-gauge needles) (83,84 and 85). Using a regular bevelled needle, the overall incidence can be reduced by the use of a small-gauge needle and by longitudinal insertion of the needle bevel, which presumably induces less trauma to the longitudinal elastic fibers in the dura (86). Recent evidence suggests that the use of a nontraumatic, conical-tipped needle with a lateral opening spreads the dural fibers and is associated with a substantially lesser risk of post-LP headaches than regular cannulae (84,87,88 and 89). The evidence that recumbency after LP reduces the incidence of this syndrome is controversial (90).

LP headache, which usually develops hours to several days after the procedure, is typically described as a dull occipital discomfort that may radiate to the frontal region or to the shoulders (81,83,91,92 and 93). Pain is commonly associated with nausea and dizziness (91). When severe, the pain may be associated with diaphoresis and vomiting (91,94). The duration of the headache is usually 1–7 days (94,95), and routine management relies on rest, hydration, and analgesics (92). Persistent headache may necessitate application of an epidural blood patch (92). Although a recent controlled study suggested that prophylactic administration of a blood patch may reduce this complication (96), the incidence and severity of the syndrome do not warrant this treatment. Severe headache has also been reported to respond to treatment with intravenous or oral caffeine (81).

Transthoracic Needle Biopsy

Transthoracic fine-needle aspiration of intrathoracic mass is generally a nonnoxious procedure. Severe pain has, however, been associated with this procedure when the underlying diagnosis was a neurogenic tumor (97).

Transrectal Prostatic Biopsy

Transrectal, ultrasound-guided prostate biopsy is an essential procedure in the diagnosis and management of prostate cancer. In a prospective study, 16% of the patients reported pain of moderate or greater severity (PAS PI ³5) and 19% would not agree to undergo the procedure again without anesthesia (98). Transrectal, ultrasound-guided prostatic nerve blockade is effective in relieving discomfort associated with this procedure (99).

Mammography Pain

Breast compression associated with mammography can cause moderate and, rarely, severe pain (100,101). Unless patients are adequately counseled and treated, occasional patients will refuse repeat mammograms because of pain (100).

Acute Pain Associated with Therapeutic Interventions

Postoperative Pain

Acute postoperative pain is universal unless adequately treated. Undertreatment is endemic despite the availability of adequate analgesic and anesthetic techniques (102,103 and 104). Guidelines for management have been reviewed (103,105). Postoperative pain that exceeds the normal duration or severity should prompt a careful evaluation for the possibility of infection or other complications.

Cryosurgery-Associated Pain and Cramping

Cryosurgery of the cervix in the treatment of intraepithelial neoplasm commonly produces an acute cramping pain syndrome. The severity of the pain is related to the duration of the freeze period and it is not diminished by the administration of prophylactic nonsteroidal anti-inflammatory drugs (106).

Other Interventions

Invasive interventions other than surgery are commonly used in cancer therapy and may also result in predictable acute pain syndromes. Examples include the pains associated with tumor embolization techniques (107) and chemical pleurodesis (108).

Acute Pain Associated with Analgesic Techniques

Local Anesthetic Infiltration Pain

Intradermal and subcutaneous infiltration of lidocaine produces a transient burning sensation before the onset of analgesia. This can be modified with the use of buffered solutions (109). Other maneuvers, including warming of the solution (110) or slowing rate of injection (111), do not diminish injection pain.

Opioid Injection Pain

Intramuscular and subcutaneous injections are painful. When repetitive dosing is required, the intramuscular route of administration is not recommended (66,103). The pain associated with subcutaneous injection is influenced by the volume injected and the chemical characteristics of the injectant. Subcutaneous injection of opioids can produce a painful subdermal reaction. This is infrequently observed with morphine or hydromorphone (112) but common with methadone (113). For this reason, the subcutaneous infusion of methadone is not recommended. There is some data to suggest that the addition of a low concentration of dexamethasone may reduce the likelihood of local irritation (114).

Opioid Headache

Rarely patients develop a reproducible generalized headache after opioid administration. Although its cause is not known, speculation suggests that it may be caused by opioid-induced histamine release.

Spinal Opioid Hyperalgesia Syndrome

Intrathecal and epidural injection of high opioid doses is occasionally complicated by pain (typically perineal, buttock, or leg), hyperalgesia, and associated manifestations, including segmental myoclonus, piloerection, and priapism. This is an uncommon phenomenon that remits after discontinuation of the infusion (115,116 and 117).

Epidural Injection Pain

Back, pelvic, or leg pain may be precipitated by epidural injection or infusion. The incidence of this problem has been estimated at approximately 20% (118). It is speculated that it may be caused by the compression of an adjacent nerve root by the injected fluid (118).

Acute Pain Associated with Anticancer Therapies

Acute Pain Associated with Chemotherapy Infusion Techniques

Intravenous Infusion Pain

Pain at the site of cytotoxic infusion is a common problem. Four pain syndromes related to intravenous infusion of chemotherapeutic agents are recognized: venous spasm, chemical phlebitis, vesicant extravasation, and anthracycline-associated flare. Venous spasm causes pain that is not associated with inflammation or phlebitis, and which may be modified by application of a warm compress or reduction of the rate of infusion. Chemical phlebitis can be caused by cytotoxic medications including amasarcine, dacarbazine, carmustine (119,120), and vinorelbine (121), as well as the infusion of potassium chloride and hyperosmolar solutions (122). The pain and linear erythema associated with chemical phlebitis must be distinguished from the more serious complication of a vesicant cytotoxic extravasation (Table 1-4) (123,124). Vesicant extravasation may produce intense pain followed by desquamation and ulceration (123,124). Finally, a brief venous flare reaction is often associated with intravenous administration of the anthracycline, doxorubicin. The flare is typically associated with local urticaria and occasionally patients report pain or stinging (125,126).

Amasarcine	Mitomycin-C
BCNU	Mitoxantrone
Cis-platinum	Streptozotocin
Dacarbazine	Teniposide
Daunorubicin	Vinblastine
Doxorubicin	Vincristine
Etoposide	Vindesine

BCNU, bischloroethyl-nitrosurea (carmustine).

TABLE 1-4. COMMONLY USED TISSUE VESICANT CYTOTOXIC DRUGS

Hepatic Artery Infusion Pain

Cytotoxic infusions into the hepatic artery (for patients with hepatic metastases) are often associated with the development of a diffuse abdominal pain (127). Continuous infusions can lead to persistent pain. In some patients, the pain is due to the development of gastric ulceration or erosions (128), or cholangitis (129). If the latter complications do not occur, the pain usually resolves with discontinuation of the infusion. A dose relationship is suggested by the observation that some patients will comfortably tolerate reinitiating of the infusion at a lower dose (130).

Intraperitoneal Chemotherapy Pain

Abdominal pain is a common complication of intraperitoneal chemotherapy. A transient mild abdominal pain, associated with sensations of fullness or bloating, is reported by approximately 25% of patients (131). A further 25% of patients reports moderate or severe pain, necessitating opioid analgesia or discontinuation of therapy (131). Moderate or severe pain is usually caused by chemical serositis or infection (132). Drug selection may be a factor in the incidence of chemical serositis. It is a common complication of intraperitoneal use of the anthracycline agents mitoxantrone and doxorubicin and with paclitaxel (Taxol), but it is relatively infrequent with 5-fluorouracil (5-FU) or cisplatinum. Abdominal pain associated with fever and leukocytosis in blood and peritoneal fluid is suggestive of infectious peritonitis (133).

Intravesical Chemotherapy or Immunotherapy

Intravesical bacillus Calmette-Guérin therapy for transitional cell carcinoma of the urinary bladder usually causes a transient bladder irritability syndrome characterized by frequency and/or micturition pain (134). Rarely treatment may trigger a painful polyarthritis (135). Similarly intravesical doxorubicin often causes a painful chemical cystitis (136).

Acute Pain Associated with Chemotherapy Toxicity

Mucositis

Severe mucositis is an almost invariable consequence of the myeloablative chemotherapy and radiotherapy that precedes bone marrow transplantation, but it is less common with standard intensity therapy (137,138 and 139). Although the clinical syndrome usually involves the oral cavity and pharynx, the underlying pathology commonly extends to other gastrointestinal mucosal surfaces. Symptoms may occur as a result of involvement of the esophagus, stomach, or intestine (e.g., odynophagia, dyspepsia, or diarrhea). Damaged mucosal surfaces may become superinfected with microorganisms such as *Candida albicans* and herpes simplex. The latter complication is most likely in neutropenic patients, who are also predisposed to systemic sepsis arising from local invasion by aerobic and anaerobic oral

flora.

Corticosteroid-Induced Perineal Discomfort

A transient burning sensation in the perineum is described by some patients following rapid infusion of large doses (20–100 mg) of dexamethasone (140). Patients need to be warned that such symptoms may occur. Clinical experience suggests that this syndrome is prevented by slow infusion.

Steroid Pseudorheumatism

The withdrawal of corticosteroids may produce a pain syndrome that manifests as diffuse myalgias, arthralgias, and tenderness of muscles and joints. These symptoms occur with rapid or slow withdrawal and may occur in patients taking these drugs for long or short periods of time. The pathogenesis of this syndrome is poorly understood, but it has been speculated that steroid withdrawal may sensitize joint and muscle mechanoreceptors (141). Treatment consists of reinstituting the steroids at a higher dose and withdrawing them more slowly (141).

Painful Peripheral Neuropathy

Chemotherapy-induced painful peripheral neuropathy, which is usually associated with vinca alkaloids, cisplatinum and paclitaxel, can have an acute course. The vinca alkaloids (particularly vincristine) are also associated with other, presumably neuropathic, acute pain syndromes, including pain in the jaw, legs, arms, or abdomen, that may last from hours to days (142,143 and 144). Vincristine-induced orofacial pain in the distribution of the trigeminal and glossopharyngeal nerves occurs in approximately 50% of patients at the onset of vincristine treatment (144). The pain, which is severe in approximately half of those affected, generally begins 2–3 days after vincristine administration and lasts for 1–3 days. It is usually self-limiting and if recurrence occurs, it is usually mild (144). The neuropathy associated with paclitaxel neuropathy is dose related and is generally subacute in onset with a tendency to resolution after the completion of therapy (145).

Headache

Intrathecal methotrexate in the treatment of leukemia or leptomeningeal metastases produces an acute meningitic syndrome in 5–50% of patients (146). Headache is the prominent symptom and may be associated with vomiting, nuchal rigidity, fever, irritability, and lethargy. Symptoms usually begin hours after intrathecal treatment and persist for several days. CSF examination reveals a pleocytosis that may mimic bacterial meningitis. Patients at increased risk for the development of this syndrome include those who have received multiple intrathecal injections and those patients undergoing treatment for proven leptomeningeal metastases (146). The syndrome tends not to recur with subsequent injections.

Systemic administration of L-asparaginase for the treatment of acute lymphoblastic leukemia produces thrombosis of cerebral veins or dural sinuses in 1–2% of patients (147). This complication typically occurs after a few weeks of therapy, but its onset may be delayed until after the completion of treatment. It occurs as a result of depletion of asparagine, which, in turn, leads to the reduction of plasma proteins involved in coagulation and fibrinolysis. Headache is the most common initial symptom, and seizures, hemiparesis, delirium, vomiting, or cranial nerve palsies may also occur. The diagnosis may be established by angiography or by gradient echo sequences on MRI scan (148).

Trans-retinoic acid therapy, which may be used in the treatment of acute promyelocytic leukemia, can cause a transient severe headache (149). The mechanism may be related to pseudotumor cerebri induced by hypervitaminosis A.

Diffuse Bone Pain

Trans-retinoic acid therapy in patients with acute promyelocytic leukemia often produces a syndrome of diffuse bone pain (150,151). The pain is generalized, of variable intensity, and closely associated with a transient neutrophilia. The latter observation suggests that the pain may be due to marrow expansion, a phenomenon that may underlie a similar pain syndrome that occurs following the administration of colony-stimulating factors (152).

Taxol-Induced Arthralgia and Myalgia

Administration of paclitaxel generates a syndrome of diffuse arthralgias and myalgia in 10–20% of patients (153,154). Diffuse joint and muscle pains generally appear 1–4 days after drug administration and persist for 3–7 days. The pathophysiology of this phenomenon has not been well evaluated.

5-Fluorouracil–Induced Anginal Chest Pain

Patients receiving continuous infusions of 5-FU may develop ischemic chest pain (155). Continuous ambulatory electrocardiographic monitoring of patients undergoing 5-FU infusion demonstrated a near three-fold increase in ischemic episodes over pretreatment recordings (156). These electrocardiographic changes were more common among patients with known coronary artery disease. It is widely speculated that coronary vasospasm may be the underlying mechanism (155,156 and 157).

Palmar-Plantar Erythrodysesthesia Syndrome

Protracted infusion of 5-FU can be complicated by the development of a tingling or burning sensation in the palms and soles followed by the development of an erythematous rash. The rash is characterized by a painful, sharply demarcated, intense erythema of the palms and/or soles followed by bulla formation, desquamation, and healing. Continuous low-dose 5-FU infusion (200–300 mg/m^2/day) will produce this palmar-plantar erythrodysesthesia syndrome in 40–90% of patients (158,159). It occurs rarely with patients undergoing 96- to 120-hour infusions (160). The pathogenesis is unknown. The eruption is self-limiting in nature and it does not usually require discontinuation of therapy. Symptomatic measures are often required (160) and treatment with pyridoxine has been reported to induce resolution of the lesions (161). Palmar-plantar erythrodysesthesia is also commonly observed among patients treated with the orally administered 5-FU prodrug, capecitabine, when it may warrant discontinuation of therapy if severe (162).

A similar syndrome has recently been reported with liposomal doxorubicin, which is thought to be relatively sequestered in skin (163). As with 5-FU, this is also a dose-related adverse effect related to repeated dosing. Uncommonly palmar-plantar erythrodysesthesia has been observed with paclitaxel (164).

Postchemotherapy Gynecomastia

Painful gynecomastia can occur as a delayed complication of chemotherapy. Testis cancer is the most common underlying disorder (165) but it has been reported after therapy for other cancers as well (166,167). Gynecomastia typically develops after a latency of 2–9 months and resolves spontaneously within a few months. Persistent gynecomastia is occasionally observed (167). Cytotoxic-induced disturbance of androgen secretion is the probable cause of this syndrome (165). In the patient with testicular cancer, this syndrome must be differentiated from tumor-related gynecomastia, which may be associated with early recurrence (see the section Tumor-Related Gynecomastia) (168,169).

Chemotherapy-Induced Acute Digital Ischemia

Raynaud's phenomenon or transient ischemia of the toes is a common complication of bleomycin, vinblastine, and cisplatin treatment for testicular cancer (170). Rarely, irreversible digital ischemia leading to gangrene has been reported after bleomycin (171).

Chemotherapy-Induced Tumor Pain

Pain at the site of tumor is reported to occur in some patients (7%) after treatment with vinorelbine. Typically, pain begins within a few minutes of the vinorelbine infusion, is moderate to severe in intensity, and requires analgesic therapy. Premedication with ketorolac may prevent recurrence in some cases (172,173 and 174).

Acute Pain Associated with Hormonal Therapy

Luteinizing Hormone-Releasing Factor Tumor Flare in Prostate Cancer

Initiation of luteinizing hormone-releasing factor (LRF) hormonal therapy for prostate cancer produces a transient symptom flare in 5–25% of cases (175,176). The flare is presumably caused by an initial stimulation of luteinizing hormone release before suppression is achieved. The syndrome typically presents as an exacerbation of

bone pain or urinary retention; spinal cord compression and sudden death have been reported (177). Symptom flare is usually observed within the first week of therapy, and lasts 1–3 weeks in the absence of androgen antagonist therapy. Coadministration of an androgen antagonist during the initiation of LRF agonist therapy can prevent this phenomenon (178). Among patients with prostate cancer that is refractory to first-line hormonal therapy, transient tumor flares have been observed with androstenedione (179,180) and medroxyprogesterone (181).

Hormone-Induced Pain Flare in Breast Cancer

Any hormonal therapy for metastatic breast cancer can be complicated by a sudden onset of diffuse musculoskeletal pain commencing within hours to weeks of the initiation of therapy (182). Other manifestations of this syndrome include erythema around cutaneous metastases, changes in liver function studies, and hypercalcemia. Although the underlying mechanism is not understood, this does not appear to be caused by tumor stimulation, and it is speculated that it may reflect normal tissue response (183).

Acute Pain Associated with Immunotherapy

Virtually all patients treated with interferon (IFN) experience an acute syndrome consisting of fever, chills, myalgias, arthralgias, and headache (184). The syndrome usually begins shortly after initial dosing and frequently improves with continued administration of the drug (184). The severity of symptoms is related to type of IFN, route of administration, schedule, and dose. Doses of 1–9 million units of IFN-a are usually well tolerated, but doses greater than or equal to 18 million units usually produce moderate to severe toxicity (184). Acetaminophen pretreatment is often useful in ameliorating these symptoms.

Acute Pain Associated with Bisphosphonates

Bisphosphonates are widely used in the care of patients with bony metastases, especially among patients with breast cancer and myeloma (185). Infusion of bisphosphonates is sometimes associated with the development of multifocal bone pain and/or myalgia. Typically, pain occurs within 24 hours of infusion and may last up to 3 days. Pain intensity is variable and may be severe. The condition is self-limiting but may require analgesic therapy (186).

Acute Pain Associated with Growth Factors

Colony-stimulating factors are hematopoietic growth hormones that stimulate the production, maturation, and function of white blood cells. Granulocyte-macrophage colony-stimulating factors and granulocyte colony-stimulating factors and interleukin-3 commonly produce mild to moderate bone pain and constitutional symptoms such as fever, headache, and myalgias during the period of administration (187,188).

Subcutaneous administration of recombinant human erythropoietin a (r-HuEPO-a) is associated with pain at the injection site in approximately 40% of cases (189). Subcutaneous injection of r-HuEPO-a is more painful than r-HuEPO-b (190). Alpha erythropoietin injection pain can be reduced by dilution of the vehicle with benzyl alcohol saline, reduction of the volume of the vehicle to 1.0–0.1 ml (191), or addition of lidocaine (192).

Acute Pain Associated with Radiotherapy

Incident pains can be precipitated by transport and positioning of the patient for radiotherapy. Other pains can be caused by acute radiation toxicity, which is most commonly associated with inflammation and ulceration of skin or mucous membranes within the radiation port. The syndrome produced is dependent upon the involved field: Head and neck irradiation can cause a stomatitis or pharyngitis (139), treatment of the chest and esophagus can cause an esophagitis (193), and pelvic therapy can cause a proctitis, cystitis-urethritis, vaginal ulceration, or radiation dermatitis.

Oropharyngeal Mucositis

Radiotherapy-induced mucositis is invariable with doses above 1000 cGy, and ulceration is common at doses above 4000 cGy. Although the severity of the associated pain is variable, it is often severe enough to interfere with oral alimentation. Painful mucositis can persist for several weeks after the completion of the treatment (139,194).

Acute Radiation Enteritis and Proctocolitis

Acute radiation enteritis occurs in as many as 50% of patients receiving abdominal or pelvic radiotherapy. Involvement of the small intestine can present with cramping abdominal pain associated with nausea and diarrhea (195). Pelvic radiotherapy can cause a painful proctocolitis, with tenesmic pain associated with diarrhea, mucous discharge, and bleeding (196). These complications typically resolve shortly after completion of therapy, but may have a slow resolution over 2–6 months (195,196 and 197). Acute enteritis is associated with an increased risk of late onset radiation enteritis (see the section Chronic Radiation Enteritis and Proctitis).

Early Onset Brachial Plexopathy

A transient brachial plexopathy has been described in breast cancer patients immediately following radiotherapy to the chest wall and adjacent nodal areas. In retrospective studies, the incidence of this phenomenon has been variably estimated as 1.4–20.0% (198,199); clinical experience suggests that lower estimates are more accurate. The median latency to the development of symptoms was 4.5 months (3–14 months) in one survey (198). Paresthesias are the most common presenting symptom, and pain and weakness occur less frequently. The syndrome is self-limiting and does not predispose to the subsequent development of delayed onset, progressive plexopathy.

Subacute Radiation Myelopathy

Subacute radiation myelopathy is an uncommon phenomenon that may occur following radiotherapy of extraspinal tumors (200,201). It is most frequently observed involving the cervical cord after radiation treatment of head and neck cancers and Hodgkin's disease. In the latter case, patients develop painful, shock-like pains in the neck that are precipitated by neck flexion (Lhermitte's sign). These pains may radiate down the spine and into one or more extremities. The syndrome usually begins weeks to months after the completion of radiotherapy, and typically resolves over a period of 3–6 months (200).

Radiopharmaceutical-Induced Pain Flare

Strontium-89, Rhenium-186 hydroxyethylidene diphosphonate, and Samarium-153 are systemically administered beta-emitting calcium analogues that are taken up by bone in areas of osteoblastic activity and which may help relieve pain caused by blastic bony metastases (202). A “flare” response, characterized by transient worsening of pain 1–2 days after administration, occurs in 15–20% of patients (203). This flare usually resolves after 3–5 days and most affected patients subsequently develop a good analgesic response (203).

Acute Pain Associated with Infection

A significantly increased incidence of acute herpetic neuralgia occurs among cancer patients, especially those with hematological or lymphoproliferative malignancies and those receiving immunosuppressive therapies (204,205). Pain or itch usually precedes the development of the rash by several days and may occasionally occur without the development of skin eruption (205,206). The pain, which may be continuous or lancinating, usually resolves within 2 months (206). Pain persisting beyond this interval is referred to as *postherpetic neuralgia* (see the section Postherpetic Neuralgia). Patients with active tumor are more likely to have a disseminated infection (204). In those predisposed by chemotherapy, the infection usually develops less than 1 month after the completion of treatment. The dermatomal location of the infection is often associated with the site of the malignancy (204): Patients with primary tumors of gynecological and genitourinary origin have a predilection to lumbar and sacral involvement, and those with breast or lung carcinomas tend to present with thoracic involvement; patients with hematological tumors appear to be predisposed to cervical lesions. The infection also occurs twice as frequently in previously irradiated dermatomes as nonradiated areas.

Acute Pain Associated with Vascular Events

Acute Thrombosis Pain

Thrombosis is the most frequent complication and the second cause of death in patients with overt malignant disease (207). Thrombotic episodes may precede the diagnosis of cancer by months or years and represent a potential marker for occult malignancy (208). Postoperative deep vein thrombosis is more frequent in patients

operated on for malignant diseases than for other disorders, and both chemotherapy and hormone therapy are associated with an increased thrombotic risk (208).

Possible prothrombic factors in cancer include the capacity of tumor cells and their products to interact with platelets, clotting and fibrinolytic systems, endothelial cells, and tumor-associated macrophages. Cytokine release, acute phase reaction, and neovascularization may contribute to in vivo clotting activation (207,208). Patients with pelvic tumors (209), pancreatic cancer (210), gastric cancer, advanced breast cancer (211), and brain tumors (212) are at greatest risk.

Lower-Extremity Deep Venous Thrombosis

Pain and swelling are the most common presenting features of lower-extremity deep vein thrombosis (213). The pain is variable in severity and it is often mild. It is commonly described as a dull cramp, or diffuse heaviness. The pain most commonly affects the calf but may involve the sole of the foot, the heel, the thigh, the groin, or pelvis. Pain usually increases on standing and walking. On examination, suggestive features include swelling, warmth, dilatation of superficial veins, tenderness along venous tracts, and pain induced by stretching (213).

Rarely, patients may develop tissue ischemia or frank gangrene, even without arterial or capillary occlusion. This syndrome is called *phlegmasia cerulea dolens*. It is most commonly seen in patients with underlying neoplasm (214,215) and is characterized by severe pain, extensive edema, and cyanosis of the legs. Gangrene can occur unless the venous obstruction is relieved. When possible, optimal therapy is anticoagulation and thrombectomy (216). The mortality rate for ischemic venous thrombosis is approximately 40%, the cause of death usually being the underlying disease or pulmonary emboli (215).

Upper-Extremity Deep Venous Thrombosis

Only 2% of all cases of deep venous thrombosis involve the upper extremity, and the incidence of pulmonary embolism related to thrombosis in this location is approximately 12% (217). The three major clinical features of upper-extremity venous thrombosis are edema, dilated collateral circulation, and pain (218). Approximately two-thirds of patients have arm pain. Among patients with cancer, the most common causes are central venous catheterization and extrinsic compression by tumor (218). Although thrombosis secondary to intrinsic damage usually responded well to anticoagulation alone and rarely causes persistent symptoms, when extrinsic obstruction is the cause, persistent arm swelling and pain are commonplace (219).

Superior Vena Cava Obstruction

Superior vena cava (SVC) obstruction is most commonly caused by extrinsic compression by enlarged mediastinal lymph nodes (220). In contemporary series lung cancer and lymphomas are the most commonly associated conditions. Increasingly, thrombosis of the SVC is caused by intravascular devices (221), particularly with left-sided ports and when the catheter tip lies in the upper part of the vena (222). Patients usually present with facial swelling and dilated neck and chest wall veins. Chest pain, headache, and mastalgia are less common presentations.

Acute Mesenteric Vein Thrombosis

Acute mesenteric vein thrombosis is most commonly associated with hypercoagulability states. Rarely, it has been associated with extrinsic venous compression by malignant lymphadenopathy (223), extension of venous thrombosis (224), or as a result of iatrogenic hypercoagulable state (225).

CHRONIC PAIN SYNDROMES

Most chronic cancer-related pains are caused directly by the tumor (Table 1-2). Data from the largest prospective survey of cancer pain syndromes revealed that almost one-fourth of the patients experienced two or more pains. Over 90% of the patients had one or more tumor-related pains and 21% had one or more pains caused by cancer therapies. Somatic pains (71%) were more common than neuropathic (39%) or visceral pains (34%) (8). Bone pain and compression of neural structures are the two most common causes (33,226,227,228 and 229).

Bone Pain

Bone metastases are the most common cause of chronic pain in cancer patients (33,226,227,228 and 229). Cancers of the lung, breast, and prostate most often metastasize to bone, but any tumor type may be complicated by painful bony lesions. Although bone pain is usually associated with direct tumor invasion of bony structures, more than 25% of patients with bony metastases are pain-free (230), and patients with multiple bony metastases typically report pain in only a few sites. The factors that convert a painless lesion to a painful one are unknown. Bone metastases could potentially cause pain by any of multiple mechanisms, including endosteal or periosteal nociceptor activation (by mechanical distortion or release of chemical mediators) or tumor growth into adjacent soft tissues and nerves (231). Recent studies have demonstrated that tumor osteolysis may be mediated by a cascade involving the secretion of tumor-produced parathyroid hormone-related protein, which stimulates osteoclastic bone resorption, thus releasing transforming growth factor b, which is abundant in bone matrix. The released transforming growth factor b further promotes osteolysis by stimulating tumor-produced parathyroid hormone-related protein production by tumor cells (232).

Bone pain due to metastatic tumor needs to be differentiated from less common causes. Nonneoplastic causes in this population include osteoporotic fractures (including those associated with multiple myeloma), focal osteonecrosis, which may be idiopathic or related to chemotherapy, corticosteroids (233), or radiotherapy (see the section Osteoradionecrosis) (234).

Multifocal or Generalized Bone Pain

Bone pain may be focal, multifocal, or generalized. Multifocal bone pains are most commonly experienced by patients with multiple bony metastases. A generalized pain syndrome, which is well recognized in patients with multiple bony metastases, is also rarely produced by replacement of bone marrow (235,236). This bone marrow replacement syndrome has been observed in hematogenous malignancies (237,238) and, less commonly, solid tumors (236). This syndrome can occur in the absence of abnormalities on bone scintigraphy or radiography, increasing the difficulty of diagnosis. Rarely, a paraneoplastic osteomalacia can mimic multiple metastases (234).

Vertebral Syndromes

The vertebrae are the most common sites of bony metastases. More than two-thirds of vertebral metastases are located in the thoracic spine; lumbosacral and cervical metastases account for approximately 20% and 10%, respectively (239,240). Multiple level involvement is common, occurring in greater than 85% of patients (241). The early recognition of pain syndromes due to tumor invasion of vertebral bodies is essential, because pain usually precedes compression of adjacent neural structures and prompt treatment of the lesion may prevent the subsequent development of neurological deficits. Several factors often confound accurate diagnosis; referral of pain is common, and the associated symptoms and signs can mimic a variety of other disorders, both malignant (e.g., paraspinal masses) and nonmalignant.

Atlantoaxial Destruction and Odontoid Fracture

Nuchal or occipital pain is the typical presentation of destruction of the atlas or fracture of the odontoid process. Pain often radiates over the posterior aspect of the skull to the vertex and is exacerbated by movement of the neck, particularly flexion (242). Pathological fracture may result in secondary subluxation with compression of the spinal cord at the cervicomedullary junction. This complication is usually insidious and may begin with symptoms or signs in one or more extremity. Typically, there is early involvement of the upper extremities and the occasional appearance of so-called “pseudo-levels” suggestive of more caudal spinal lesions; these deficits can slowly progress to involve sensory and motor function (243). MRI is probably the best method for imaging this region of the spine (244), but clinical experience suggests that CT is also sensitive. Plain radiography, tomography, and bone scintigraphy should be viewed as ancillary procedures.

C7-T1 Syndrome

Invasion of the C7 or T1 vertebra can result in pain referred to the interscapular region. These lesions may be missed if radiographical evaluation is mistakenly targeted to the painful area caudal to the site of damage. Additionally, visualization of the appropriate region on routine radiographs may be inadequate due to obscuration by overlying bone and mediastinal shadows. Patients with interscapular pain should therefore undergo radiography of both the cervical and the thoracic spine. Bone scintigraphy may assist in targeting additional diagnostic imaging procedures such as CT or MRI. The latter procedures can be useful in assessing the possibility that pain is referred from an extraspinal site such as the paraspinal gutter.

T12-L1 Syndrome

A T12 or L1 vertebral lesion can refer pain to the ipsilateral iliac crest or the sacroiliac joint. Imaging procedures directed at pelvic bones can miss the source of the pain.

Sacral Syndrome

Severe focal pain radiating to buttocks, perineum, or posterior thighs may accompany destruction of the sacrum (245,246 and 247). The pain is often exacerbated by sitting or lying and is relieved by standing or walking. The neoplasm can spread laterally to involve muscles that rotate the hip (e.g., the pyriformis muscle). This may produce severe incident pain induced by motion of the hip, or a malignant “pyriformis syndrome” characterized by buttock or posterior leg pain that is exacerbated by internal rotation of the hip. Local extension of the tumor mass may also involve the sacral plexus (see the section Lumbosacral Plexopathy).

Imaging Investigations of Bone Pain

The two most important imaging modalities for the evaluation of bone pain are plain radiography and nuclear bone scan. In general, CT and MRI scans are reserved for situations when the diagnosis cannot be discerned from clinical information and these baseline tests or when there are specific diagnostic issues to be resolved that require special techniques.

Plain Radiography

Radiography should be the first test ordered in the evaluation of bone pain and to confirm findings of other imaging studies. There are three radiographical patterns of metastatic disease: osteolytic, osteoblastic, and mixed. Osteoblastic areas correspond to the reaction of the host bone to the metastases. This reactive bone forms in a random pattern lacking normal bone structure and it often lacks mechanical strength despite its sclerotic, radiopaque appearance. Lytic lesions with little or no reactive bone formation indicate bone destruction in excess of bone formation. Periosteal thickening or elevation is commonly seen with primary bone neoplasms, rapidly growing tumor, or a stress fracture through the underlying bone.

When examining bone radiographs of long bones, it is important to evaluate the extent of cortical destruction. The risk of pathological fracture is high if 50% or more of the cortex is destroyed by tumor (248,249 and 250). Vertebral bodies must be carefully examined for collapse of the vertebral bodies (best viewed on a lateral radiograph) and pedicle erosion (viewed on an anterior/posterior radiograph) because both of these findings are associated with enhanced risk of epidural encroachment by tumor.

Bone Scan

Technetium bisphosphonate bone scans are valuable in evaluating patients with multifocal pain and in identifying the extent of bony secondaries (251). Three patterns of uptake may indicate bony metastases. Most commonly, the radioisotope accumulates in the reactive new bone giving rise to a “hot spot.” Less frequently metastases give rise to cold spots due to the complete absence of reactive bone or poor blood flow (252) or to a pattern of diffuse accumulation of tracer throughout the skeleton (super scan) in the setting of disseminated skeletal disease.

There are several problems associated with bone scans:

1. Bone scans are characterized by high sensitivity and low specificity. Uptake may occur at any skeletal site with an elevated rate of bone turnover such as trauma (even remote trauma), infection, arthropathy, or even acute osteopenia of disuse (251,253,254 and 255). Whereas a scan showing multiple lesions strongly suggests metastases, only 50% of solitary foci represent metastases and, in such cases, radiographical correlation is essential.
2. Because bone scans do not evaluate the structural integrity of the bone, positive findings that correspond to painful sites should be further evaluated by plain radiographs, CT scan, or both.
3. There are some situations in which bone scans are notoriously unreliable. Cancers, such as melanoma and multiple myeloma, may evoke little reactive bone formation, leading to false-negative scans (256,257 and 258). In these situations, plain radiography is the preferred initial examination.

Other radionucleotide bone scanning techniques are occasionally used. Single-photon-emission CT scanning is a bone scanning technique with improved sensitivity and specificity over conventional bone scanning techniques (251,259). In patients with diffuse tracer uptake, bone marrow scanning using tracer linked to antigranulocyte antibody can be helpful in distinguishing a normal scan from a super-scan caused by diffuse marrow infiltration (260). Gallium scanning is useful for detecting otherwise undetected bone metastases from lymphomas and soft-tissue sarcomas (261).

Computed Tomography

CT is a second-tier investigation technique in the evaluation of bony secondaries. It is very effective in evaluating the three-dimensional integrity of bone and to better visualize abnormal lesions identified on bone scan (262). It may be useful in confirming suspicions raised by bone scans and more clearly illustrating the extent of bone destruction. It is particularly helpful in the evaluation of patients with pain in the regions of the pelvic and shoulder girdles and base of skull who have equivocal or nondiagnostic findings on plain radiography. Spine lesions can also be well visualized by CT. With contemporary CT equipment and techniques the additional yield from MRI is usually very limited.

When confirmation of histological diagnosis is required, CT-guided biopsy or fine-needle aspiration is usually diagnostic (263,264 and 265). When the lesion is osteolytic, CT-guided needle biopsy is usually satisfactory (diagnostic accuracy, 80%). When the lesion is osteoblastic or there is a thick overlying cortical rim, it is extremely difficult to insert a needle and obtain an adequate tissue sample. Such cases may necessitate open surgical biopsy.

Magnetic Resonance Imaging

This imaging technique is generally reserved for three clinical situations: (a) to arbitrate suspicious lesions that remain ill-defined despite plain radiography and CT, (b) when bone marrow infiltration is suspected, and (c) in the evaluation of spinal cord compression.

MRI is an excellent method to evaluate bone marrow involvement in disease such as leukemia, lymphoma, and multiple myeloma that replace the marrow space. Because bone marrow (including hematopoietic or “red” marrow) contains a high percentage of fat, T1-weighted MRI scans generally reveal metastases as focal areas of low signal intensity (266). This approach has also been shown to be very sensitive in solid tumors that metastasize to bone marrow such as breast and lung cancer (267,268 and 269).

It is often difficult to distinguish between changes caused by treatment, fracture, and tumor. Indeed, noncontrast MRI cannot reliably distinguish among these changes. In one study the false-positive tumor detection rate was as high as 50% (270). More recent data suggests that gadolinium-enhanced bone imaging can be helpful in this situation; tumor commonly demonstrates high or inhomogeneous signal intensity after gadolinium injection that is not seen in fractures or postoperative changes (271).

Back Pain and Epidural Compression

Epidural compression (EC) of the spinal cord or cauda equina is the second most common neurological complication of cancer, occurring in up to 10% of patients (62). In the community setting, EC is often the first recognized manifestation of malignancy (272); at a cancer hospital it is the presenting syndrome in only 8% of cases (62). Most EC is caused by posterior extension of vertebral body metastasis to the epidural space (Fig. 1-4). Occasionally, EC is caused by tumor extension from the posterior arch of the vertebra or infiltration of a paravertebral tumor through the intervertebral foramen (Fig. 1-5).

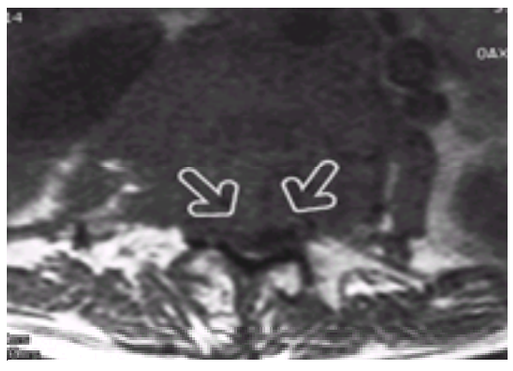

FIGURE 1-4. Axial magnetic resonance imaging scan of the lumbar spine in a 56-year-old woman with carcinoma of the colon who presented with back pain and L3 radicular pain in the right leg. The axial scan performed through L3 demonstrates complete obliteration of the epidural space (*arrows*) and severe compression of the thecal sac.

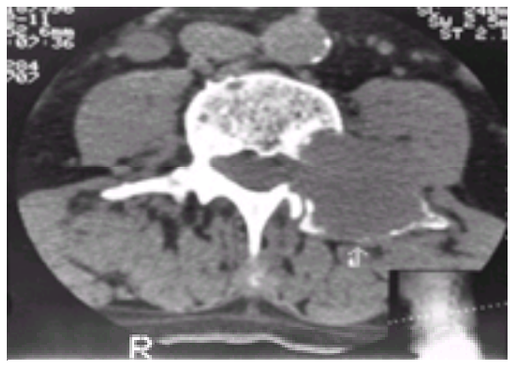

FIGURE 1-5. Computed tomography scan of lumbar vertebra demonstrating a large metastasis involving the left transverse process, invading into the intervertebral foramen and encroaching into the epidural space.

Untreated, EC leads inevitably to neurological damage. Effective treatment can potentially prevent these complications. The most important determinate of the efficacy of treatment is the degree of neurological impairment at the time therapy is initiated. Seventy-five percent of patients who begin treatment while ambulatory remain so. The efficacy of treatment declines to 30–50% for those who begin treatment while markedly paretic and is 10–20% for those who are plegic (239,273,274,275,276,277,278,279,280 and 281). Despite this, delays in diagnosis are commonplace (282).

Back pain is the initial symptom in almost all patients with EC (62). In 10% it is the only symptom at the time of diagnosis (283). Because pain usually precedes neurological signs by a prolonged period, it should be viewed as a potential indicator of EC, which can lead to treatment at a time that a favorable response is most likely. Back pain, however, is a nonspecific symptom that can result from bony or paraspinal metastases without epidural encroachment, from retroperitoneal or leptomeningeal tumor, epidural lipomatosis due to steroid administration (284), or from a large variety of other benign conditions. Because it is infeasible to pursue an extensive evaluation in every cancer patient who develops back pain, the complaint should impel an evaluation that determines the likelihood of EC and thereby selects patients appropriate for definitive imaging of the epidural space. The selection process is based on symptoms and signs and the results of simple imaging techniques.

Clinical Features of Epidural Extension

Some pain characteristics are particularly suggestive of epidural extension (285). Rapid progression of back pain in a crescendo pattern is an ominous occurrence (275). Radicular pain, which can be constant or lancinating, has similar implications (285). It is usually unilateral in the cervical and lumbosacral regions and bilateral in the thorax, where it is often experienced as a tight, belt-like band across the chest or abdomen (285). The likelihood of EC is also greater when back or radicular pain is exacerbated by recumbency, cough, sneeze, or strain (274). Other types of referred pain are also suggestive, including Lhermitte's sign (286) and central pain from spinal cord compression, which usually is perceived some distance below the site of the compression and is typically a poorly localized, nondermatomal dysesthesia (62).

Weakness, sensory loss, autonomic dysfunction, and reflex abnormalities usually occur after a period of progressive pain (285). Weakness may begin segmentally if related to nerve root damage or in a multisegmental or pyramidal distribution if the cauda equina or spinal cord, respectively, is injured. The rate of progression of weakness is variable; in the absence of treatment, following the onset of weakness one-third of patients will develop paralysis within 7 days (287). Patients whose weakness progresses slowly have a better prognosis for neurological recovery with treatment than those who progress rapidly (288,289). Without effective treatment, sensory abnormalities, which may also begin segmentally, may ultimately evolve to a sensory level, with complete loss of all sensory modalities below site of injury. The upper level of sensory findings may correspond to the location of the epidural tumor or be below it by many segments (285). Ataxia without pain is the initial presentation of EC in 1% of patients. This finding is presumably due to early involvement of the spinocerebellar tracts (239). Bladder and bowel dysfunction occur late, except in patients with a conus medullaris lesion who may present with acute urinary retention and constipation without preceding motor or sensory symptoms (285).

Other features that may be evident on examination of patients with EC include scoliosis, asymmetrical wasting of paravertebral musculature, and a gibbus (palpable step in the spinous processes). Spinal tenderness to percussion, which may be severe, often accompanies the pain.

Imaging Modalities

Definitive imaging of the epidural space confirms the existence of EC (and thereby indicates the necessity and urgency of treatment), defines the appropriate radiation portals, and determines the extent of epidural encroachment (which influences prognosis and may alter the therapeutic approach) (61). The options for definitive imaging include MRI, myelography, and CT-myelography, or spiral CT without myelographic contrast.

MRI is noninvasive and offers accurate imaging of the vertebrae, intraspinal, and paravertebral structures. When available it is generally the preferred mode of evaluation. A recent study comparing state-of-the-art MRI techniques with CT-myelography demonstrated equivalent sensitivity and specificity (290). Data suggests that a “scanning” midsagittal MRI is clearly inadequate (291). Whenever possible, total spine imaging should be performed because multiple level involvement is common and other sites may be clinically occult. In a recent study of 65 patients with cord compression, 32 (49%) had multiple level involvement and of these, 28 (66%) were clinically occult (292). MRI is relatively contraindicated in patients with severe claustrophobia and certain metallic implants and is absolutely contraindicated for patients with cardiac pacemakers or aneurysm clips. Several other groups who may not be suitable for MRI include very obese patients and those with severe kyphosis or scoliosis.

Previously, myelography was considered the standard examination for imaging the spinal cord (2,293). In contrast to MRI or CT imaging, it is invasive and evaluation may be limited if there is a complete block to the flow of contrast which precludes demonstrating the extent of the compressing lesion. It has the advantages of facilitating simultaneous evaluation of the CSF for cytology when leptomeningeal metastases are part of the differential diagnosis.

Postmyelographic CT is a useful tool that provides additional information about the vertebral and paravertebral structures. It can usually define the extent of the cord compression (294). It may help distinguish between cord compression caused by displaced bony fragments from soft-tissue extension and in the identification of paraspinal tumors with extension through the intervertebral foramina (290).

Besides immediate patient discomfort, myelography is often complicated by postprocedure side effects that include back pain, headache, vomiting, seizures, and adverse neurobehavioral reactions. The risk of adverse effects is related to the gauge and type of needle used (295), the contrast medium (296), and the anatomy of the EC.

Similar to MRI, CT scanning is noninvasive. It provides excellent visualization of the vertebrae, vertebral structural integrity, paravertebral soft tissues, and the vertebral

foramina. The improved resolution observed with contemporary spiral techniques facilitates very clear imaging of the spinal canal contents. Although no comparative data are yet available, in the author's experience, CT scanning of regions identified by either plain radiography or bone scan usually provides excellent visualization of cortical integrity, the intervertebral foramina, and canal contents. Bone and soft-tissue windows are used in a complimentary manner; bone windows allow evaluation of bony integrity and, in particular, of cortical breach; and soft-tissue windows are used to evaluate the contents of the spinal canal. Using this approach we reserve more expensive and less readily available MRI imaging for equivocal cases when leptomeningeal metastases are suspected or when total spinal imaging is required.

Algorithm for the Investigation of Cancer Patients with Back Pain

Given the prevalence and the potential for dire consequences of EC, and the recognition that back pain is a marker of early (and therefore treatable) EC, algorithms have been developed to guide the evaluation of back pain in the cancer patient. The objective of these algorithms is to select a subgroup of patients who should undergo definitive imaging of the epidural space from the large number of patients who develop back pain (61). Effective treatment of EC before irreversible neurological compromise occurs is the overriding goal of these approaches.

One such algorithm defines both the urgency and course of the evaluation (Fig. 1-6). Patients with emerging symptoms and signs indicative of spinal cord or cauda equina dysfunction are designated Group 1. The evaluation (and, if appropriate, treatment) of these patients should proceed on an emergency basis. In most cases, these patients should receive an intravenous dose of corticosteroid before epidural imaging is performed.

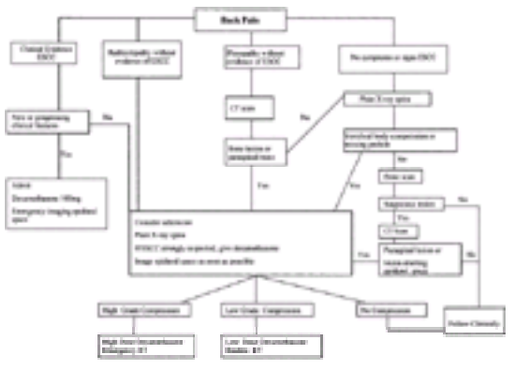

FIGURE 1-6. Algorithm for the management of back pain in the cancer patient. CT, computed tomography; ESCC, extradural spinal cord compression; RT, radiation therapy.

Patients with symptoms and signs of radiculopathy or stable or mild signs of spinal cord or cauda equina dysfunction are designated Group 2. These patients are also usually treated presumptively with a corticosteroid and are scheduled for definitive imaging of the epidural space as soon as possible. Group 3 patients have back pain and no symptoms or signs suggesting EC. These patients should be evaluated in routine fashion starting with plain spine radiographs. The presence at the appropriate level of any abnormality consistent with neoplasm indicates a high probability (60%) of EC (293,297). This likelihood varies, however, with the type of radiological abnormality. For example, one study noted that EC occurred in 87% of patients with greater than 50% vertebral body collapse, 31% with pedicle erosion, and only 7% with tumor limited to the body of the vertebra without collapse (298). Definitive imaging of the epidural space is thus strongly indicated in patients who have >50% vertebral body collapse and is generally recommended for patients with pedicle erosion. Some patients with neoplasm limited to the vertebral body can be followed expectantly. Imaging should be performed if pain progresses or changes (e.g., becomes radicular) or if radiographical evidence of progression is obtained.

Among patients with vertebral collapse, it is often difficult to distinguish malignant from nonmalignant pathology. Vertebral metastases are suggested by destruction of the anterolateral or posterior cortical bone of the vertebral body, the cancellous bone or vertebral pedicle, a focal paraspinal soft-tissue mass, and an epidural mass. Nonmalignant causes are suggested by cortical fractures of the vertebral body without cortical bone destruction, retropulsion of a fragment of the posterior cortex of the vertebral body into the spinal canal, fracture lines within the cancellous bone of the vertebral body, an intravertebral vacuum phenomenon, and a thin diffuse paraspinal soft-tissue mass (299).

Normal spine radiographs alone are not adequate to ensure a low likelihood of epidural tumor in patients with back pain. The bone may not be sufficiently damaged to change the radiograph or the tumor may involve the epidural space with little or no involvement of the adjacent bone (such as may occur when paraspinal tumor grows through the intervertebral foramen). The latter phenomenon has been most strikingly demonstrated in patients with lymphoma, in whom EC presents with normal radiography more than 60% of the time (300,301). Damage to the vertebra that is not seen on the plain radiograph may potentially be demonstrated by bone scintigraphy. In patients with back pain and normal bone radiography, a positive scintigram at the site of pain is associated with a 12–17% likelihood of epidural disease (273,302). Although such patients can also be followed expectantly, definitive imaging of the epidural space should be considered, particularly if the pain is progressive.

If both radiographs and scintigraphy are normal but the patient has severe or progressive pain, evaluation with CT, or preferably MRI, may still be warranted. If the CT scan demonstrates either a bony lesion abutting the spinal canal, a paraspinal mass, or a perivertebral soft-tissue collar, imaging of the epidural space is still justified (273,303).

Pain Syndromes of the Bony Pelvis and Hip

The pelvis and hip are common sites of metastatic involvement. Lesions may involve any of the three anatomical regions of the pelvis (ischiopubic, iliosacral, or periacetabular), the hip joint itself or the proximal femur (304). The weight bearing function of these structures, essential for normal ambulation, contributes to the propensity of disease at these sites to cause incident pain with ambulation.

Hip Joint Syndrome

Tumor involvement of the acetabulum or head of femur typically produces localized hip pain that is aggravated by weight bearing and movement of the hip. The pain may radiate to the knee or medial thigh, and occasionally, pain is limited to these structures (304,305). Medial extension of an acetabular tumor can involve the lumbosacral plexus as it traverses the pelvic sidewall (Fig. 1-7). Evaluation of this region is best accomplished with CT or MRI, both of which can demonstrate the extent of bony destruction and adjacent soft-tissue involvement more sensitively than other imaging techniques (306).

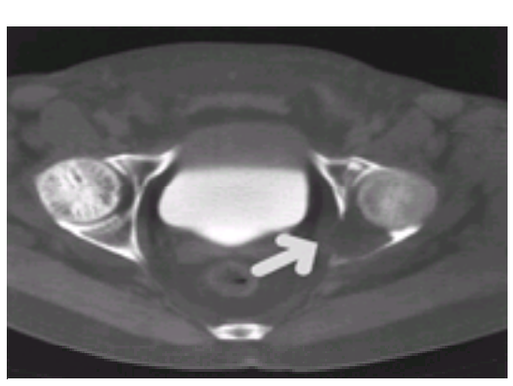

FIGURE 1-7. Computed tomography scan demonstrating lytic lesion of the right acetabulum with tumor extension into the pelvis (*arrow*).

Acrometastases

Acrometastases, metastases in the hands and feet, are rare and often misdiagnosed or overlooked (307). In the feet, the larger bones containing the higher amounts of

red marrow, such as the os calcis, are usually involved (308). Symptoms may be vague and can mimic other conditions such as osteomyelitis, gouty rheumatoid arthritis, Reiter's syndrome, Paget's disease, osteochondral lesions, and ligamentous sprains.

Arthritides

Hypertrophic Pulmonary Osteoarthropathy

Hypertrophic pulmonary osteoarthropathy is a paraneoplastic syndrome that incorporates clubbing of the fingers, periostitis of long bones, and occasionally a rheumatoid-like polyarthritis (309). Periosteitis and arthritis can produce pain, tenderness, and swelling in the knees, wrists, and ankles. The onset of symptoms is usually subacute, and it may precede the discovery of the underlying neoplasm by several months. It is most commonly associated with non–small cell lung cancer. Less commonly it may be associated with benign mesothelioma (310), pulmonary metastases from other sites (311), smooth muscle tumors of the esophagus (312), breast cancer (313), and metastatic nasopharyngeal cancer (314). Effective antitumor therapy is sometimes associated with symptom regression (315). Hypertrophic pulmonary osteoarthropathy is diagnosed on the basis of physical findings, radiological appearance, and radionuclide bone scan (309,316,317).

Other Polyarthritides

Rarely rheumatoid arthritis, systemic lupus erythematosus, and an asymmetrical polyarthritis may occur as paraneoplastic phenomena that resolve with effective treatment of the underlying disease (318,319). A syndrome of palmar plantar fasciitis and polyarthritis, characterized by palmar and digital with polyarticular painful capsular contractions, has been associated with ovarian (320) and breast (321) cancers.

Muscle Pain

Muscle Cramps

Persistent muscle cramps in cancer patients are usually caused by an identifiable neural, muscular, or biochemical abnormality (322). In one series of 50 patients, 22 had peripheral neuropathy, 17 had root or plexus pathology (including six with leptomeningeal metastases), two had polymyositis and one had hypomagnesemia. In this series, muscle cramps were the presenting symptom of recognizable and previously unsuspected neurological dysfunction in 64% (27 of 42) of the identified causes (323).

Skeletal Muscle Tumors

Soft-tissue sarcomas arising from fat, fibrous tissue or skeletal muscle are the most common tumors involving the skeletal muscles. Skeletal muscle is one of the most unusual sites of metastasis from any malignancy (324,325). Lesions are usually painless but they may present with persistent ache.

Headache and Facial Pain

Headache in the cancer patient results from traction, inflammation, or infiltration of pain-sensitive structures in the head or neck. Early evaluation with appropriate imaging techniques may identify the lesion and allow prompt treatment, which may reduce pain and prevent the development of neurological deficits (326).

Intracerebral Tumor

Among 183 patients with new onset chronic headache as an isolated symptom, investigation revealed underlying tumor in 15 cases (327). The prevalence of headache in patients with brain metastases or primary brain tumors is 60–90% (328,329). The headache is presumably produced by traction on pain-sensitive vascular and dural tissues. Patients with multiple metastases and those with posterior fossa metastases are more likely to report this symptom (328). The pain may be focal, overlying the site of the lesion, or generalized. Headache has lateralizing value, especially in patients with supratentorial lesions (329). Posterior fossa lesions often cause a bifrontal headache. The quality of the headache is usually throbbing or steady and the intensity is usually mild to moderate (329).

Among children clinical features predictive of underlying tumor include sleep-related headache, headache in the absence of a family history of migraine, vomiting, absence of visual symptoms, headache of less than 6 months duration, confusion, and abnormal neurological examination findings (330).

The headache is often worse in the morning and is exacerbated by stooping, sudden head movement, or Valsalva maneuvers (cough, sneeze, or strain) (329). In patients with increased intracranial pressure, these maneuvers can also precipitate transient elevations in intracranial pressure called “plateau waves.” These plateau waves, which may also be spontaneous, can be associated with short periods of severe headache, nausea, vomiting, photophobia, lethargy, and transient neurological deficits (331,332). Occasionally these plateau waves produce life-threatening herniation syndromes (331,332).

Leptomeningeal Metastases

Leptomeningeal metastases, which are characterized by diffuse or multifocal involvement of the subarachnoid space by metastatic tumor, occur in 1–8% in patients with systemic cancer (333). Non-Hodgkin's lymphoma and acute lymphocytic leukemia both demonstrate predilection for meningeal metastases (333). The incidence is lower for solid tumors alone. Of solid tumors, adenocarcinomas of the breast and small cell lung cancer predominate (334).

Leptomeningeal metastases present with focal or multifocal neurological symptoms or signs that may involve any level of the neuraxis (333,335,336). More than one-third of patients presents with evidence of cranial nerve damage, including double vision, hearing loss, facial numbness, and decreased vision (335,336). This is particularly true among patients with underlying hematological malignancy (336). Less common features include seizures, papilledema, hemiparesis, ataxic gait, and confusion (337). Generalized headache and radicular pain in the low back and buttocks are the most common pains associated with leptomeningeal metastases (335,336,338). The headache is variable and may be associated with changes in mental status (e.g., lethargy, confusion, or loss of memory), nausea, vomiting, tinnitus, or nuchal rigidity. Pains that resemble cluster headache (339) or glossopharyngeal neuralgia with syncope (340) have also been reported.

The diagnosis of leptomeningeal metastases is confirmed through analysis of the CSF. The CSF may reveal elevated pressure, elevated protein, depressed glucose, and/or lymphocytic pleocytosis. Ninety percent of patients ultimately show positive cytology, but multiple evaluations may be required. After a single LP, the false-negative rate may be as high as 55%; this falls to only 10% after three LPs (335,338,341). The sensitivity and specificity of CSF cytology is enhanced by the use of fluorescence *in situ* hybridization (342,343) or immunocytochemical techniques (344). Tumor markers, such as lactic dehydrogenase isoenzymes (335), carcinoembryonic antigen (345), b_2-microglobulin (345), and tissue polypeptide antigen (346), may help to delineate the diagnosis. Flow cytometry for detection of abnormal DNA content may be a useful adjunct to cytologic examination (347).

Gadolinium-enhanced MRI imaging of the neuroaxis can assist in identifying leptomeningeal metastases (Fig. 1-8). When headache is the presenting feature, gadolinium-enhanced MR examination of the brain is the initial imaging investigation, especially if signs of cranial nerve involvement are present (348,349). If this is nondiagnostic and if the pain distribution indicates spinal involvement, sensitivity is enhanced by performing an examination of the whole spine (Fig. 1-4). There is evidence that gadolinium-enhanced spinal MRI may be positive in almost 50% of patients without clinical findings related to the spinal region and in 60% of patients with negative CSF cytology (350). Additionally, findings of contrast enhancement of the basilar cisterns, parenchymal metastases, hydrocephalus without a mass lesion, or spinal subarachnoid masses or enhancement may all have therapeutic implications (333).

FIGURE 1-8. Gadolinium-enhanced magnetic resonance imaging scan of the thoracolumbar spine demonstrating multifocal meningeal enhancement consistent with leptomeningeal metastases.

Untreated leptomeningeal metastases cause progressive neurological dysfunction at multiple sites, followed by death in 4 to 6 weeks. Current treatment strategies, which includes radiation therapy to the area of symptomatic involvement, corticosteroids, and intraventricular or intrathecal chemotherapy or systemic chemotherapy, are of limited efficacy and in general patient outlook remains poor (337,351,352).

Base of Skull Metastases

Base of skull metastases are associated with well-described clinical syndromes (353), which are named according to the site of metastatic involvement: orbital, parasellar, middle fossa, jugular foramen, occipital condyle, clivus, and sphenoid sinus. Cancers of the breast, lung, and prostate are most commonly associated with this complication (353,354), but any tumor type that metastasizes to bone may be responsible. When base of skull metastases are suspected, axial imaging with CT (including bone window settings) is the usual initial procedure (Fig. 1-9) (353). MRI is more sensitive for assessing soft-tissue extension and CSF analysis may be needed to exclude leptomeningeal metastases.

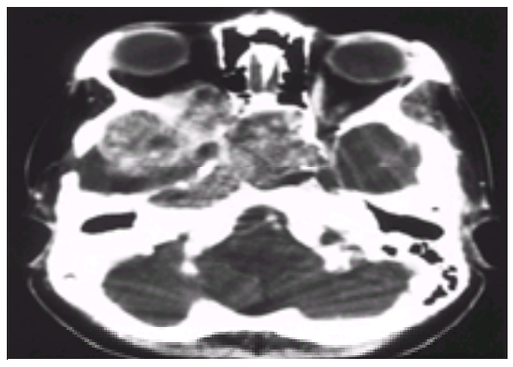

FIGURE 1-9. Computed tomography scan of the base of skull of a woman with proptosis and right-sided facial pain. There is extensive tumor erosion of the orbital wall, clivus, and the floor of the middle cranial fossa.

Orbital Syndrome

Orbital metastases usually present with progressive pain in the retro-orbital and supraorbital area of the affected eye. Blurred vision and diplopia may be associated complaints. Signs may include proptosis, chemosis of the involved eye, external ophthalmoparesis, ipsilateral papilledema, and decreased sensation in the ophthalmic division of the trigeminal nerve. Imaging with MRI or CT scan can delineate the extent of bony damage and orbital infiltration.

Parasellar Syndrome

The parasellar syndrome typically presents as unilateral supraorbital and frontal headache, which may be associated with diplopia (355). There may be ophthalmoparesis or papilledema, and formal visual field testing may demonstrate hemianopsia or quadrantanopsia.

Middle Cranial Fossa Syndrome

The middle cranial fossa syndrome presents with facial numbness, paresthesias, or pain, which is usually referred to the cheek or jaw (in the distribution of second or third divisions of the trigeminal nerve) (356). The pain is typically described as a dull continual ache, but may also be paroxysmal or lancinating. On examination, patients may have hypesthesia in the trigeminal nerve distribution and signs of weakness in the ipsilateral muscles of mastication. Occasionally patients have other neurological signs such as abducens palsy (353,357).

Jugular Foramen Syndrome

The jugular foramen syndrome usually presents with hoarseness or dysphagia. Pain is usually referred to the ipsilateral ear or mastoid region and may occasionally present as glossopharyngeal neuralgia, with or without syncope (353). Pain may also be referred to the ipsilateral neck or shoulder. Neurological signs include ipsilateral Horner's syndrome, and paresis of the palate, vocal cord, sternocleidomastoid, or trapezius. Ipsilateral paresis of the tongue may also occur if the tumor extends to the region of the hypoglossal canal.

Occipital Condyle Syndrome

The occipital condyle syndrome presents with unilateral occipital pain that is worsened with neck flexion (358,359). The patient may complain of neck stiffness. Pain intensity is variable but can be severe. Examination may reveal a head tilt, limited movement of the neck, and tenderness to palpation over the occipitonuchal junction. Neurological findings may include ipsilateral hypoglossal nerve paralysis and sternocleidomastoid weakness.

Clivus Syndrome

The clivus syndrome is characterized by vertex headache, which is often exacerbated by neck flexion. Lower cranial nerve (VI-XII) dysfunction follows and may become bilateral.

Sphenoid Sinus Syndrome

A sphenoid sinus metastasis often presents with bifrontal and/or retro-orbital pain, which may radiate to the temporal regions (360). There may be associated features of nasal congestion and diplopia. Physical examination is often unremarkable although unilateral or bilateral sixth-nerve paresis can be present.

Painful Cranial Neuralgias

As noted, specific cranial neuralgias can occur from metastases in the base of skull or leptomeninges. They are most commonly observed in patients with prostate and lung cancer (361). Invasion of the soft tissues of the head or neck, or involvement of sinuses can also eventuate in such lesions. Each of these syndromes has a characteristic presentation. Early diagnosis may allow effective treatment of the underlying lesion before progressive neurological injury occurs.

Glossopharyngeal Neuralgia

Glossopharyngeal neuralgia has been reported in patients with leptomeningeal metastases (340), the jugular foramen syndrome (353), or head and neck malignancies (362,363 and 364). This syndrome presents as severe pain in the throat or neck, which may radiate to the ear or mastoid region. Pain may be induced by swallowing. In some patients, pain is associated with sudden orthostasis and syncope.

Trigeminal Neuralgia

Trigeminal pains may be continual, paroxysmal, or lancinating. Pain that mimics classical trigeminal neuralgia can be induced by tumors in the middle or posterior fossa

(357,365,366 and 367) or leptomeningeal metastases (339). Continual pain in a trigeminal distribution may be an early sign of acoustic neuroma (368). All cancer patients who develop trigeminal neuralgia should be evaluated for the existence of an underlying neoplasm.

Ear and Eye Pain Syndromes

Otalgia

Otalgia is the sensation of pain in the ear. Referred otalgia is pain felt in the ear but originating from a nonotological source. The rich sensory innervation of the ear derives from four cranial nerves and two cervical nerves that also supply other areas in the head, neck, thorax, and abdomen. Pain referred to the ear may originate in areas far removed from the ear itself. Otalgia is reported among patients with carcinoma of the oropharynx or hypopharynx (369,370), acoustic neuroma (371), and metastases to the temporal bone or infratemporal fossa (372,373).

Eye Pain

Blurring of vision and eye pain are the two most common symptoms of choroidal metastases (374,375 and 376). More commonly chronic eye pain is related to metastases to the bony orbit, intraorbital structures such as the rectus muscles (377,378), or optic nerve (379).

Uncommon Causes of Headache and Facial Pain

Headache and facial pain in cancer patients may have many other causes. Unilateral facial pain can be the initial symptom of an ipsilateral lung tumor (380,381,382 and 383). Presumably this referred pain is mediated by vagal afferents. Facial squamous cell carcinoma of the skin may present with facial pain due to extensive perineural invasion (384). Patients with Hodgkin's disease may have transient episodes of neurological dysfunction that has been likened to migraine (385). Headache may occur with cerebral infarction or hemorrhage, which may be due to nonbacterial thrombotic endocarditis or disseminated intravascular coagulation. Headache is also the usual presentation of sagittal sinus occlusion, which may be due to tumor infiltration, hypercoagulable state, or treatment with L-asparaginase therapy (386). Headache due to pseudotumor cerebri has also been reported to be the presentation of SVC obstruction in a patient with lung cancer (387). Tumors of the sinonasal tract may present with deep facial or nasal pain (388).

Neuropathic Pains Involving the Peripheral Nervous System

Neuropathic pains involving the peripheral nervous system are common. The syndromes include painful radiculopathy, plexopathy, mononeuropathy, or peripheral neuropathy.

Painful Radiculopathy

Radiculopathy or polyradiculopathy may be caused by any process that compresses, distorts, or inflames nerve roots. Painful radiculopathy is an important presentation of epidural tumor and leptomeningeal metastases (see the section Leptomeningeal Metastases).

Postherpetic Neuralgia

Postherpetic neuralgia is defined solely by the persistence of pain in the region of a zoster infection. Although some authors apply this term if pain continues beyond lesion healing, most require a period of weeks to months before this label is used. A criterion of pain persisting beyond 2 months after lesion healing is recommended (205). One study suggests that postherpetic neuralgia is two to three times more frequent in the cancer population than the general population (204). In patients with postherpetic neuralgia and cancer, changes in the intensity or pattern of pain, or the development of new neurological deficits may indicate the possibility of local neoplasm and should be investigated.

Cervical Plexopathy

The ventral rami of the upper four cervical spinal nerves join to form the cervical plexus between the deep anterior and lateral muscles of the neck. Cutaneous branches emerge from the posterior border of the sternocleidomastoid. In the cancer population, plexus injury is frequently due to tumor infiltration or treatment (including surgery or radiotherapy) to neoplasms in this region (389). Tumor invasion or compression of the cervical plexus can be caused by direct extension of a primary head and neck malignancy or neoplastic (metastatic or lymphomatous) involvement of the cervical lymph nodes (389). Pain may be experienced in the preauricular (greater auricular nerve) or postauricular (lesser and greater occipital nerves) regions, or the anterior neck (transverse cutaneous and supraclavicular nerves). Pain may refer to the lateral aspect of the face or head, or to the ipsilateral shoulder. The overlap in the pain referral patterns from the face and neck may relate to the close anatomical relationship between the central connections of cervical afferents and the afferents carried in cranial nerves V, VII, IX, and X in the upper cervical spinal cord. The pain may be aching, burning, or lancinating, and is often exacerbated by neck movement or swallowing. Associated features can include ipsilateral Horner's syndrome or hemidiaphragmatic paralysis. The diagnosis must be distinguished from EC of the cervical spinal cord and leptomeningeal metastases. MRI or CT imaging of the neck and cervical spine is usually required to evaluate the etiology of the pain.

Brachial Plexopathy

The two most common causes of brachial plexopathy in cancer patients are tumor infiltration and radiation injury. Less common causes of painful brachial plexopathy include trauma during surgery or anesthesia, radiation-induced second neoplasms, acute brachial plexus ischemia, and paraneoplastic brachial neuritis.

Malignant Brachial Plexopathy

Plexus infiltration by tumor is the most prevalent cause of brachial plexopathy. Malignant brachial plexopathy is most common in patients with lymphoma, lung cancer, or breast cancer. The invading tumor usually arises from adjacent axillary, cervical, and supraclavicular lymph nodes (lymphoma and breast cancer) or from the lung (superior sulcus tumors or so-called Pancoast tumors) (390,391). Pain is nearly universal, occurring in 85% of patients, and often precedes neurological signs or symptoms by months (391). Lower plexus involvement (C7, C8, T1 distribution) is typical, and is reflected in the pain distribution, which usually involves the elbow, medial forearm and fourth and fifth fingers. Pain may sometimes localize to the posterior arm or elbow. Severe aching is usually reported, but patients may also experience constant or lancinating dysesthesias along the ulnar aspect of the forearm or hand.

Tumor infiltration of the upper plexus (C5–C6 distribution) is less common. This lesion is characterized by pain in the shoulder girdle, lateral arm and hand. Seventy-five percent of patients presenting with upper plexopathy subsequently develop a panplexopathy, and 25% of patients present with panplexopathy (390).

Cross-sectional imaging is essential in all patients with symptoms or signs compatible with plexopathy (Fig. 1-10). In one study, CT scanning had 80–90% sensitivity in detecting tumor infiltration (392). Others have demonstrated improved diagnostic yield with a multiplanar imaging technique (393). Although there are no comparative data on the sensitivity and specificity of CT and MRI in this setting, MRI does have the theoretical advantage of reliably assessing the integrity of the adjacent epidural space (394).

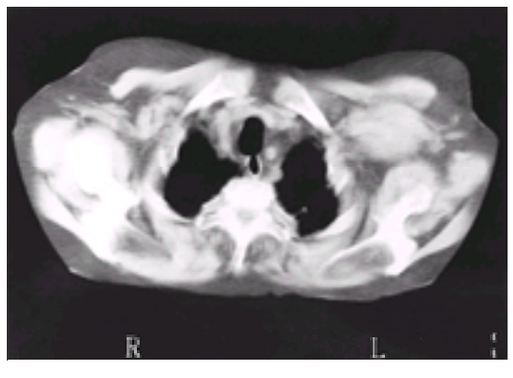

FIGURE 1-10. Contrast-enhanced computed tomography scan of the brachial plexus in a 64-year-old woman who has a past history of breast cancer and presents with

left arm and hand pain. There is a mass in the left brachial plexus. L, left; R, right.

Electrodiagnostic studies may be helpful in patients with suspected plexopathy particularly when neurological examination and imaging studies are normal (395). Although not specific for tumor, abnormalities on electromyography (EMG) or somatosensory evoked potentials may establish the diagnosis of plexopathy and thereby confirm the need for additional evaluation.

Patients with malignant brachial plexopathy are at high risk for epidural extension of the tumor (273,389). Epidural disease can occur as the neoplasm grows medially and invades vertebrae or tracks along nerve roots through the intervertebral foramina. In the latter case, there may be no evidence of bony erosion on imaging studies. The development of Horner's syndrome, evidence of panplexopathy, or finding of paraspinal tumor or vertebral damage on CT or MRI are highly associated with epidural extension and should lead to definitive imaging of the epidural tumor (273,389).

Radiation-Induced Brachial Plexopathy

Two distinct syndromes of radiation-induced brachial plexopathy have been described: (a) early onset transient plexopathy (see the section Early Onset Brachial Plexopathy) and, (b) delayed onset progressive plexopathy. Delayed onset progressive plexopathy can occur 6 months to 20 years after a course of radiotherapy that included the plexus in the radiation portal. In contrast to tumor infiltration, pain is a relatively uncommon presenting symptom (18%), and when present is usually less severe (390). Weakness and sensory changes predominate in the distribution of the upper plexus (C5, C6 distribution) (396,397 and 398). Radiation changes in the skin and lymphedema are commonly associated. The CT scan usually demonstrates diffuse infiltration that cannot be distinguished from tumor infiltration. There is no specific advantage to MRI scanning. In particular, increased T2 signal in or near the brachial plexus is commonly seen in both radiation plexopathy and tumor infiltration (394). EMG may demonstrate myokymia (396,399,400). Although a careful history, combined with neurological findings and the results of CT scanning and electrodiagnostic studies, can strongly suggest the diagnosis of radiation-induced injury, repeated assessments over time may be needed to confirm the diagnosis. Rare patients require surgical exploration of the plexus to exclude neoplasm and establish the etiology. When due to radiation, plexopathy is usually progressive (389,401), although some patients plateau for a variable period of time.

Uncommon Causes of Brachial Plexopathy

Malignant peripheral nerve tumor or a second primary tumor in a previously irradiated site can account for pain recurring late in the patient's course (402,403). Pain has been reported to occur as a result of brachial plexus entrapment in a lymphedematous shoulder (398), and as a consequence of acute ischemia many years after axillary radiotherapy (404). An idiopathic brachial plexopathy has also been described in patients with Hodgkin's disease (405).

Lumbosacral Plexopathy

The lumbar plexus, which lies in the paravertebral psoas muscle, is formed primarily by the ventral rami of L1-4. The sacral plexus forms in the sacroiliac notch from the ventral rami of S1-3 and the lumbosacral trunk (L4-5), which courses caudally over the sacral ala to join the plexus (406). Lumbosacral plexopathy may be associated with pain in the lower abdomen, inguinal region, buttock, or leg (407). In the cancer population, lumbosacral plexopathy is usually caused by neoplastic infiltration or compression. Radiation-induced plexopathy also occurs, and occasional patients develop the lesion as a result of surgical trauma, infarction, cytotoxic damage, infection in the pelvis or psoas muscle, abdominal aneurysm, or idiopathic lumbosacral neuritis. Polyradiculopathy from leptomeningeal metastases or epidural metastases can mimic lumbosacral plexopathy.

Malignant Lumbosacral Plexopathy

The primary tumors most frequently associated with malignant lumbosacral plexopathy include colorectal, cervical, breast, sarcoma, and lymphoma (389,407). Most tumors involve the plexus by direct extension from intrapelvic neoplasm. Metastases account for only one-fourth of cases. In one study, two-thirds of patients developed plexopathy within 3 years of their primary diagnosis and one-third presented within 1 year (407).

Pain is, typically, the first symptom and it is experienced by almost all patients at some point, and it is the only symptom in almost 20% of patients. The quality is aching, pressure-like, or stabbing; dysesthesias are relatively uncommon. Most patients develop numbness, paresthesias or weakness weeks to months after the pain begins. Common signs include leg weakness that involves multiple myotomes, sensory loss that crosses dermatomes, reflex asymmetry, focal tenderness, leg edema, and positive, direct, or reverse, straight-leg raising signs.

An upper plexopathy occurs in almost one-third of patients with lumbosacral plexopathy (407). This lesion is usually due to direct extension from a low abdominal tumor, most frequently colorectal. Pain may be experienced in the back, lower abdomen, flank, or iliac crest, or the anterolateral thigh. Examination may reveal sensory, motor and reflex changes in a L1-4 distribution. A subgroup of these patients presents with a syndrome characterized by pain and paresthesias limited to the lower abdomen or inguinal region, variable sensory loss and no motor findings. CT scan may show tumor adjacent to the L1 vertebra (the L1 syndrome) (407) or along the pelvic sidewall, where it presumably damages the ilioinguinal, iliohypogastric, or genitofemoral nerves. Another subgroup has neoplastic involvement of the psoas muscle and presents with a syndrome characterized by upper lumbosacral plexopathy, painful flexion of the ipsilateral hip, and positive psoas muscle stretch test. This has been termed the malignant psoas syndrome (408). Similarly, pain in the distribution of the femoral nerve has been observed in the setting of recurrent retroperitoneal sarcoma (409) and tumor in the iliac crest can compress the lateral cutaneous nerve of the thigh, producing a pain that mimics meralgia paresthetica (410).

A lower plexopathy occurs in just over 50% of patients with malignant lumbosacral plexopathy (407). This lesion is usually due to direct extension from a pelvic tumor, most frequently rectal cancer, gynecological tumors, or pelvic sarcoma. Pain may be localized in the buttocks and perineum, or referred to the posterolateral thigh and leg. Associated symptoms and signs conform to an L4–S1 distribution. Examination may reveal weakness or sensory changes in the L5 and S1 dermatomes and a depressed ankle jerk. Other findings include leg edema, bladder or bowel dysfunction, sacral or sciatic notch tenderness, and a positive, straight-leg raising test. A pelvic mass may be palpable.

Sacral plexopathy may occur from direct extension of a sacral lesion or a presacral mass. This may present with predominant involvement of the lumbosacral trunk, characterized by numbness over the dorsal medial foot and sole, and weakness of knee flexion, ankle dorsiflexion, and inversion. Other patients demonstrate particular involvement of the coccygeal plexus, with prominent sphincter dysfunction and perineal sensory loss. The latter syndrome occurs with low pelvic tumors such as those arising from the rectum or prostate.

A panplexopathy with involvement in a L1–S3 distribution occurs in almost one-fifth of patients with lumbosacral plexopathy (407). Local pain may occur in the lower abdomen, back, buttocks, or perineum. Referred pain can be experienced anywhere in distribution of the plexus. Leg edema is extremely common. Neurological deficits may be confluent or patchy within the L1–S3 distribution and a positive, straight-leg raising test is usually present.

Autonomic dysfunction, particularly anhydrosis and vasodilation, has been associated with plexus and peripheral nerve injuries. Focal autonomic neuropathy, which may suggest the anatomical localization of the lesion (411), has been reported as the presenting symptom of metastatic lumbosacral plexopathy (412).

Cross-sectional imaging, with either CT or MRI, is the preferred diagnostic procedure to evaluate lumbosacral plexopathy (Fig. 1-11). Scanning should be done from the level of the L1 vertebral body, through the sciatic notch. When using CT scanning techniques, images should include bone and soft-tissue windows. Limited data suggests superior sensitivity MRI over CT imaging (413). Definitive imaging of the epidural space adjacent to the plexus should be considered in the patient who has features indicative of a relatively high risk of epidural extension, including bilateral symptoms or signs, unexplained incontinence, or a prominent paraspinal mass (273,407).

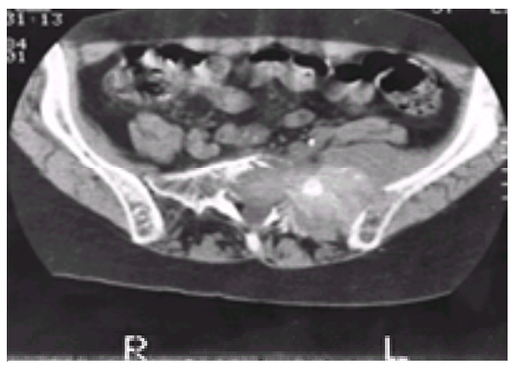

FIGURE 1-11. Computed tomography scan at the S1 level in a man with low back pain and pain radiating down the posterior aspect of the left leg. The scan shows a large mass invading the left sacrum with extension to the pelvic sidewall. L, left; R, right.

Radiation-Induced Lumbosacral Plexopathy

Radiation fibrosis of the lumbosacral plexus is a rare complication that may occur from 1 to over 30 years following radiation treatment. The use of intracavitary radium implants for carcinoma of the cervix may be an additional risk factor (414). Radiation-induced plexopathy typically presents with progressive weakness and leg swelling. Pain is not usually a prominent feature (414,415). Weakness typically begins distally in the L5–S1 segments and is slowly progressive. The symptoms and signs may be bilateral (415). If CT scanning demonstrates a lesion, it is usually a nonspecific diffuse infiltration of the tissues. EMG may show myokymic discharges (415).

Uncommon Causes of Lumbosacral Plexopathy

Lumbosacral plexopathy may occur following intraarterial cisplatinum infusion and embolization techniques. This syndrome has been observed following attempted embolization of a bleeding rectal lesion. Benign conditions that may produce similar findings include hemorrhage or abscess in the iliopsoas muscle (406), abdominal aortic aneurysms, diabetic radiculoplexopathy, vasculitis, and an idiopathic lumbosacral plexitis analogous to acute brachial neuritis (406).

Painful Mononeuropathy

Tumor-Related Mononeuropathy

Tumor-related mononeuropathy usually results from compression or infiltration of a nerve from tumor arising in an adjacent bony structure. The most common example of this phenomenon is intercostal nerve injury in a patient with rib metastases. Constant burning pain and other dysesthesias in the area of sensory loss are the typical clinical presentation. Other examples include the cranial neuralgias previously described, sciatica associated with tumor invasion of the sciatic notch, and common peroneal nerve palsy associated with primary bone tumors of the proximal fibula and lateral cutaneous nerve of the thigh neuralgia associated with iliac crest tumors.

Other Causes of Mononeuropathy

Cancer patients also develop mononeuropathies from many other causes. Postsurgical syndromes are well described (see the section Chronic Post Pain Syndormes) and radiation injury of a peripheral nerve occurs occasionally. Rarely cancer patients develop nerve entrapment syndromes (such as carpal tunnel syndrome) related to edema or direct compression by tumor (416).

Painful Peripheral Neuropathies

Painful peripheral neuropathies have multiple causes, including nutritional deficiencies, other metabolic derangements (e.g., diabetes and renal dysfunction), neurotoxic effects of chemotherapy, and, rarely, paraneoplastic syndromes.

Toxic Peripheral Neuropathy

Chemotherapy-induced peripheral neuropathy is a common problem, which is typically manifested by painful paresthesias in the hands and/or feet, and signs consistent with an axonopathy, including “stocking-glove” sensory loss, weakness, hyporeflexia, and autonomic dysfunction (417). The pain is usually characterized by continuous burning or lancinating pains, either of which may be increased by contact. The drugs most commonly associated with a peripheral neuropathy are the vinca alkaloids (especially vincristine) (142,418), cisplatinum (419,420), and oxaliplatin (421). Procarbazine, carboplatinum, misonidazole, and hexamethylmelamine have also been implicated as causes for this syndrome (146,422). Data from several studies indicates that the risk of neuropathy associated with cisplatinum can be diminished by the coadministration of the radioprotective agent amifostine at the time of treatment (423).

Paraneoplastic Painful Peripheral Neuropathy

Paraneoplastic painful peripheral neuropathy can be related to injury to the dorsal root ganglion (also known as *subacute sensory neuronopathy* or *ganglionopathy*) or injury to peripheral nerves (424). These syndromes may be the initial manifestation of an underlying malignancy. Except for the neuropathy associated with myeloma (425,426), their course is usually independent of the primary tumor (424,427).

Subacute sensory neuronopathy is characterized by pain (usually dysesthetic), paresthesias, sensory loss in the extremities, and severe sensory ataxia (428). Although it is usually associated with small cell carcinoma of the lung (429), other tumor types, including breast cancer (430), Hodgkin's disease (431), and varied solid tumors, are rarely associated. Both constant and lancinating dysesthesias occur and typically predate other symptoms. Neuropathic symptoms (pain, paresthesia, sensory loss) were asymmetric at onset, with a predilection for the upper limbs. Indeed, in one instance a painful bilateral ulnar neuropathy is described (432). The pain usually develops before the tumor is evident and its course is typically independent. Coexisting autonomic, cerebellar, or cerebral abnormalities are common (428). The syndrome, which results from an inflammatory process involving the dorsal root ganglia, may be part of a more diffuse autoimmune disorder that can affect the limbic region, brainstem, and spinal cord (427,428,433). An antineuronal IgG antibody (“anti-Hu”), which recognizes a low molecular weight protein present in most small cell lung carcinomas, has been associated with the condition (427).

A sensorimotor peripheral neuropathy, which may be painful, has been observed in association with diverse neoplasms, particularly Hodgkin's disease and paraproteinemias (427,428). The peripheral neuropathies associated with multiple myeloma, Waldenström's macroglobulinemia, small-fiber amyloid neuropathy, and osteosclerotic myeloma, are thought to be due to antibodies that cross-react with constituents of peripheral nerves (426). Clinically evident peripheral neuropathy occurs in approximately 15% of patients with multiple myeloma, and electrophysiologic evidence of this lesion can be found in 40% (426). The pathophysiology of the neuropathy is unknown.

Pain Syndromes of the Viscera and Miscellaneous Tumor-Related Syndromes

Pain may be caused by pathology involving the luminal organs of the gastrointestinal or genitourinary tracts, the parenchymal organs, the peritoneum, or the retroperitoneal soft tissues. Obstruction of hollow viscus, including intestine, biliary tract, and ureter, produces visceral nociceptive syndromes that are well described in the surgical literature (434). Pain arising from retroperitoneal and pelvic lesions may involve mixed nociceptive and neuropathic mechanisms if both somatic structures and nerves are involved.

Hepatic Distention Syndrome

Pain sensitive structures in the region of the liver include the liver capsule, blood vessels, and biliary tract (435). Nociceptive afferents that innervate these structures travel via the celiac plexus, the phrenic nerve, and the lower right intercostal nerves. Extensive intrahepatic metastases, or gross hepatomegaly associated with cholestasis, may produce discomfort in the right subcostal region, and less commonly in the right mid-back or flank (435,436 and 437). Referred pain may be experienced in the right neck or shoulder, or in the region of the right scapula (436). The pain, usually described as a dull aching, may be exacerbated by movement, pressure in the abdomen, and deep inspiration. Pain is commonly accompanied by symptoms of anorexia and nausea. Physical examination may reveal a hard

irregular subcostal mass that descends with respiration and is dull to percussion. Other features of hepatic failure may be present. Imaging of the hepatic parenchyma by either ultrasound or CT will usually identify the presence of space-occupying lesions or cholestasis (Fig. 1-12).

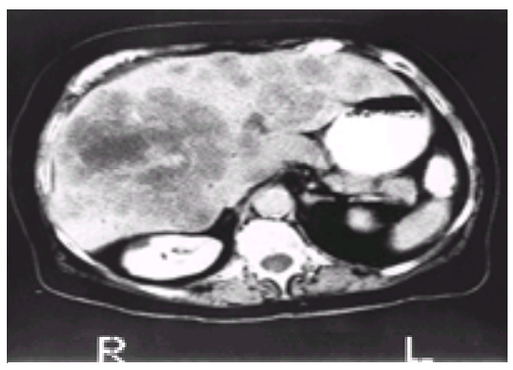

FIGURE 1-12. Computed tomography scan of the abdomen of a 72-year-old man with metastatic colon cancer and persistent, right, upper-quadrant abdominal pain. The scan demonstrates extensive liver metastases. L, left; R, right.

Occasional patients who experience chronic pain due to hepatic distention develop an acute intercurrent subcostal pain that may be exacerbated by respiration. Physical examination may demonstrate a palpable or audible rub. These findings suggest the development of an overlying peritonitis, which can develop in response to some acute event, such as a hemorrhage into a metastasis.

Midline Retroperitoneal Syndrome

Retroperitoneal pathology involving the upper abdomen may produce pain by injury to deep somatic structures of the posterior abdominal wall, distortion of pain sensitive connective tissue, vascular and ductal structures, local inflammation, and direct infiltration of the celiac plexus. The most common causes are pancreatic cancer (438,439 and 440) and retroperitoneal lymphadenopathy (441,442 and 443), particularly celiac lymphadenopathy (444). The reasons for the high frequency of perineural invasion and the presence of pain in pancreatic cancer may be related to locoregional secretion and activation of growth factor and its high-affinity receptor TrkA. These factors are involved in stimulating epithelial cancer cell growth and perineural invasion (445). In some instances of pancreatic cancer, obstruction of the main pancreatic duct with subsequent ductal hypertension generates pain which can be relieved by stenting of the pancreatic duct (446). The pain is experienced in the epigastrium, in the low thoracic region of the back, or in both locations. It is often diffuse and poorly localized. It is usually dull and boring in character, exacerbated with recumbency, and improved by sitting. The lesion can usually be demonstrated by CT, MRI, or ultrasound scanning of the upper abdomen (Fig. 1-13). If tumor is identified in the paravertebral space, or vertebral body destruction is identified, consideration should be given to careful evaluation of the epidural space (273).

FIGURE 1-13. Computed tomography scan of the abdomen of a 47-year-old woman with epigastric pain and jaundice. The computed tomography shows a large mass in the head of the pancreas (*arrow 2*), dilatation of the common bile duct (*arrow 1*), and dilatation of the pancreatic duct (*arrow 3*). L, left; R, right.

Chronic Intestinal Obstruction

Abdominal pain is an almost invariable manifestation of chronic intestinal obstruction, which may occur in patients with abdominal or pelvic cancers (447,448). The factors that contribute to this pain include smooth muscle contractions, mesenteric tension and mural ischemia. Obstructive symptoms may be due primarily to the tumor, or more likely, to a combination of mechanical obstruction and other processes such as autonomic neuropathy and ileus from metabolic derangements or drugs. Both continuous and colicky pains occur which may be referred to the dermatomes represented by the spinal segments supplying the affected viscera. Vomiting, anorexia, and constipation are important associated symptoms.

Peritoneal Carcinomatosis

Peritoneal carcinomatosis occurs most often by transcelomic spread of abdominal or pelvic tumor. Excepting breast cancer, hematogenous spread of an extraabdominal neoplasm in this pattern is rare. Carcinomatosis can cause peritoneal inflammation, mesenteric tethering, malignant adhesions, and ascites, all of which can cause pain. Pain and abdominal distention are the most common presenting symptoms. Mesenteric tethering and tension appears to cause a diffuse abdominal or low back pain. Tense malignant ascites can produce diffuse abdominal discomfort and a distinct stretching pain in the anterior abdominal wall. Adhesions can also cause obstruction of hollow viscus, with intermittent colicky pain (449). CT scanning may demonstrate evidence of ascites, omental infiltration, and peritoneal nodules (450) (Fig. 1-14).

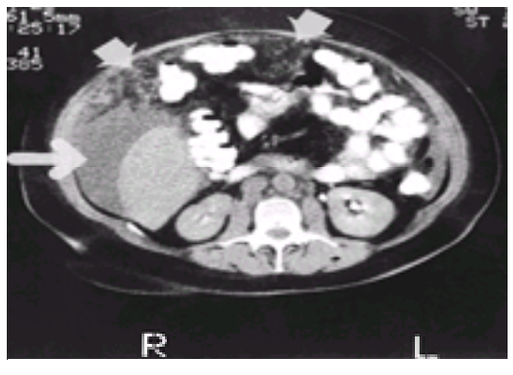

FIGURE 1-14. Computed tomography scan of the abdomen of a 66-year-old woman with stage IV ovarian cancer. The short arrows indicate areas of peritoneal thickening and infiltration. The large horizontal arrow indicates ascitic fluid interposed lateral to the lower lobe of the liver. L, left; R, right.

Malignant Perineal Pain

Tumors of the colon or rectum, female reproductive tract, and distal genitourinary system are most commonly responsible for perineal pain (451,452,453,454 and 455).

Severe perineal pain following antineoplastic therapy may precede evidence of detectable disease and should be viewed as a potential harbinger of progressive or recurrent cancer (451,452,455). There is evidence to suggest that this phenomenon is caused by microscopic perineural invasion by recurrent disease (456). The pain, which is typically described as constant and aching, is often aggravated by sitting or standing, and may be associated with tenesmus or bladder spasms (451).

Tumor invasion of the musculature of the deep pelvis can also result in a syndrome that appears similar to the so-called “tension myalgia of the pelvic floor” (457). The pain is typically described as a constant ache or heaviness that exacerbates with upright posture. When due to tumor, the pain may be concurrent with other types of perineal pain. Digital examination of the pelvic floor may reveal local tenderness or palpable tumor.

Adrenal Pain Syndrome

Large adrenal metastases, common in lung cancer, may produce unilateral flank pain, and less commonly, abdominal pain. Pain is of variable severity, and it can be severe (458).

Ureteric Obstruction

Ureteric obstruction is most frequently caused by tumor compression or infiltration within the true pelvis (459,460). Less commonly, obstruction can be more proximal, associated with retroperitoneal lymphadenopathy, an isolated retroperitoneal metastasis, mural metastases, or intraluminal metastases. Cancers of the cervix, ovary, prostate, and rectum are most commonly associated with this complication. Nonmalignant causes, including retroperitoneal fibrosis resulting from radiotherapy or graft-versus-host disease, occur rarely (461,462 and 463).

Pain may or may not accompany ureteric obstruction. When present, it is typically a dull chronic discomfort in the flank, with radiation into the inguinal region or genitalia. If pain does not occur, ureteric obstruction may be discovered when hydronephrosis is discerned on abdominal imaging procedures or renal failure develops. Ureteric obstruction can be complicated by pyelonephritis or pyonephrosis, which often present with features of sepsis, loin pain, and dysuria. Diagnosis of ureteric obstruction can usually be confirmed by the demonstration of hydronephrosis on renal sonography. The level of obstruction can be identified by pyelography. CT scanning techniques will usually demonstrate the cause (464).

Ovarian Cancer Pain

Moderate to severe chronic abdominopelvic pain is the most common symptom of ovarian cancer. It is reported by almost two-thirds of patients in the 2 weeks prior to the onset or recurrence of the disease (3). In patients who have been previously treated, it is an important symptom of potential recurrence (3).

Lung Cancer Pain

Even in the absence of involvement of the chest wall or parietal pleura, lung tumors can produce a visceral pain syndrome. In a large case series of lung cancer patients, pain was unilateral in 80% of the cases and bilateral in 20%. Among patients with hilar tumors, the pain was reported to the sternum or the scapula. Upper and lower lobe tumors referred to the shoulder and to the lower chest respectively (465,466). As previously mentioned (see the section Uncommon Causes of Headache and Facial Pain), early lung cancers can generate ipsilateral facial pain (380,381,383,467). It is postulated that this pain syndrome is generated via vagal afferent neurones.

Other Uncommon Visceral Pain Syndromes

Sudden onset severe abdominal or loin pain may be caused by nontraumatic rupture of a visceral tumor. This has been most frequently reported with hepatocellular cancer (468). Kidney rupture due to a renal metastasis from an adenocarcinoma of the colon (469) and metastasis-induced perforated appendicitis (470) have been reported. Torsion of pedunculated visceral tumors can produce a cramping abdominal pain (471,472 and 473).

Paraneoplastic Nociceptive Pain Syndromes

Tumor-Related Gynecomastia

Tumors that secrete chorionic gonadotrophin, including malignant and benign tumors of the testis (474,475,476 and 477) and rarely cancers from other sites (478,479), may be associated with chronic breast tenderness or gynecomastia. Approximately 10% of patients with testis cancer have gynecomastia or breast tenderness at presentation, and the likelihood of gynecomastia is greater with increasing chorionic gonadotrophin level (477). Breast pain can be the first presentation of an occult tumor (474,475 and 476).

Paraneoplastic Pemphigus

Paraneoplastic pemphigus is a rare mucocutaneous disorder associated with non-Hodgkin's lymphoma; chronic lymphocytic leukemia. The condition is characterized by widespread shallow ulcers with hemorrhagic crusting of the lips, conjunctival bullae, and, uncommonly, pulmonary lesions. Characteristically, histopathology reveals intraepithelial and subepithelial clefting and immunoprecipitation studies reveal autoantibodies directed against desmoplakins and desmogleins (480,481).

Chronic Pain Syndromes Associated with Cancer Therapy

Most treatment-related pains are caused by tissue-damaging procedures. These pains are acute, predictable, and self-limited. Chronic, treatment-related pain syndromes are associated with either a persistent nociceptive complication of an invasive treatment (such as a postsurgical abscess), or more commonly, neural injury. In some cases, these syndromes occur long after the therapy is completed, resulting in a difficult differential diagnosis between recurrent disease and a complication of therapy.

Postchemotherapy Pain Syndromes

Chronic Painful Peripheral Neuropathy

Although most patients who develop painful peripheral neuropathy due to cytotoxic therapy gradually improve, some develop a persistent pain. In particular, peripheral neuropathy associated with cisplatinum may continue to progress months after discontinuation of therapy and may persist for months to years (482,483). This is less common with vincristine or paclitaxel (484). The characteristics of this pain syndrome were described previously (see the section Toxic Peripheral Neuropathy).

Avascular (Aseptic) Necrosis of Femoral or Humeral Head

Avascular necrosis of the femoral or humeral head may occur either spontaneously or as a complication of intermittent or continuous corticosteroid therapy (485,486). Osteonecrosis may be unilateral or bilateral. Involvement of the femoral head is most common and typically causes pain in the hip, thigh, or knee. Involvement of the humeral head usually presents as pain in the shoulder, upper arm, or elbow. Pain is exacerbated by movement and relieved by rest. There may be local tenderness over the joint, but this is not universal. Pain usually precedes radiological changes by weeks to months; bone scintigraphy and MRI are sensitive and complementary diagnostic procedures. Early treatment consists of analgesics, decrease or discontinuation of steroids, and sometimes surgery. With progressive bone destruction, joint replacement may be necessary.

Plexopathy

Lumbosacral or brachial plexopathy may follow cisplatinum infusion into the iliac artery (487) or axillary artery (488), respectively. Affected patients develop pain, weakness, and paresthesias within 48 hours of the infusion. The mechanism for this syndrome is thought to be due to small vessel damage and infarction of the plexus or nerve. The prognosis for neurological recovery is not known.

Raynaud's Phenomenon

Among patients with germ cell tumors treated with cisplatin, vinblastine, and bleomycin, persistent Raynaud's phenomenon is observed in 20–30% of cases (170,489).

This effect has also been observed in patients with carcinoma of the head and neck treated with a combination of cisplatin, vincristine, and bleomycin (490). Pathophysiological studies have demonstrated that a hyperreactivity in the central sympathetic nervous system results in a reduced function of the smooth muscle cells in the terminal arterioles (491).

Chronic Pain Associated with Hormonal Therapy

Gynecomastia with Hormonal Therapy for Prostate Cancer

Chronic gynecomastia and breast tenderness are common complications of antiandrogen therapies for prostate cancer. The incidence of this syndrome varies among drugs. It is frequently associated with diethylstilbestrol (492) and bicalutamide (493), less commonly with flutamide (494) and cyproterone (495), and uncommonly among patients receiving LRF agonist therapy (175,176). Gynecomastia in the elderly must be distinguished from primary breast cancer or a secondary cancer in the breast (496,497).

Chronic Postsurgical Pain Syndromes

Surgical incision at virtually any location may result in chronic pain. Although persistent pain is occasionally encountered after nephrectomy, sternotomy, craniotomy, inguinal dissection, and other procedures, these pain syndromes are not well described in the cancer population. In contrast, several syndromes are now clearly recognized as sequelae of specific surgical procedures. The predominant underlying pain mechanism in these syndromes is neuropathic, resulting from injury to peripheral nerves or plexus.

Breast Surgery Pain Syndromes

Chronic pain of variable severity is a common sequel of surgery for breast cancer. In two large surveys, pain, paresthesias, and strange sensations were reported by 30–50% of the patients (498,499,500 and 501). The most common sites of pain were the breast scar region and the ipsilateral arm. Pain was more common among women who underwent breast conserving treatments than those who underwent mastectomy. The highest incidence of pain was reported by patients who had had both radio- and chemotherapy (499). Data from a retrospective survey of 408 mastectomy patients revealed that this phenomenon was more common among younger patients and that the pain severity attenuated over time (500).

Although chronic pain has been reported to occur after almost any surgical procedure on the breast (from lumpectomy to radical mastectomy), it is most common after procedures involving axillary dissection (398,502,503 and 504). Pain may begin immediately or as late as many months following surgery. The natural history of this condition appears to be variable, and both subacute and chronic courses are possible (505). The onset of pain later than 18 months following surgery is unusual, and a careful evaluation to exclude recurrent chest wall disease is recommended in this setting.

Postmastectomy pain is characterized as a constricting and burning discomfort localized to the medial arm, axilla, and anterior chest wall (504,506,507,508 and 509). On examination there is often an area of sensory loss within the region of the pain (508). The etiology is believed to be related to damage to the intercostobrachial nerve, a cutaneous sensory branch of Tl,2,3 (504,508). There is marked anatomical variation in the size and distribution of the intercostobrachial nerve and this may account for some of the variability in the distribution of pain observed in patients with this condition (510).

In some cases of pain after breast surgery, a trigger point can be palpated in the axilla or chest wall. The patient may restrict movement of the arm leading to frozen shoulder as a secondary complication.

Postradical Neck Dissection Pain

Long-standing locoregional pain after radical neck dissection is uncommon (511). Several types of postradical neck dissection pain are recognized. A persistent neuropathic pain can develop weeks to months after surgical injury to the cervical plexus. Tightness, along with burning or lancinating dysesthesias in the area of the sensory loss, are the characteristic symptoms. More commonly, chronic pain can result from musculoskeletal imbalance in the shoulder girdle following surgical removal of neck muscles (511). Similar to the droopy shoulder syndrome (512), this syndrome can be complicated by development of a thoracic outlet syndrome or suprascapular nerve entrapment, with selective weakness and wasting of the supraspinatus and infraspinatus muscles (513). Data from a large survey demonstrated that neck dissections sparing CN XI, and not dissecting level V of the neck when CN XI is spared, are associated with less shoulder and neck pain (514).

Escalating pain in patients who have undergone radical neck dissection may signify recurrent tumor or soft-tissue infection. These lesions may be difficult to diagnose in tissues damaged by radiation and surgery. Repeated CT or MRI scanning may be needed to exclude tumor recurrence. Empiric treatment with antibiotics should be considered (515,516).

Postthoracotomy Pain

There have been two major studies of postthoracotomy pain (517,518). In the first (518), three groups were identified: The largest (63%) had prolonged postoperative pain that abated within 2 months after surgery. Recurrent pain, following resolution of the postoperative pain, was usually due to neoplasm. A second group (16%) experienced pain that persisted following the thoracotomy, then increased in intensity during the follow-up period. Local recurrence of disease and infection were the most common causes of the increasing pain. A final group had a prolonged period of stable or decreasing pain that gradually resolved over a maximum 8-month period. This pain was not associated with tumor recurrence. Overall, the development of late or increasing postthoracotomy pain was due to recurrent or persistent tumor in greater than 95% of patients. This finding was corroborated in the more recent study that evaluated the records of 238 consecutive patients who underwent thoracotomy which identified recurrent pain in 20 patients. All were found to have tumor regrowth (517).

Patients with recurrent or increasing postthoracotomy pain should be carefully evaluated, preferably with a chest CT scan (Fig. 1-15) or MRI. Chest radiographs are insufficient to evaluate recurrent chest disease. In some patients, postthoracotomy pain appears to be caused by a taut muscular band within the scapular region. In such cases, pain may be amenable to trigger point injection of local anesthetic (519).

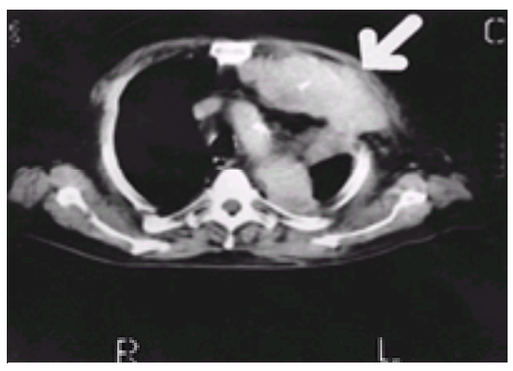

FIGURE 1-15. Chest computed tomography scan of a 55-yearold man who had recurrent left-sided chest wall pain 9 months after right upper lobectomy for squamous cell carcinoma of the lung. There is a chest wall recurrence associated with rib destruction and soft-tissue mass (*arrow*).

Postoperative Frozen Shoulder

Patients with postthoracotomy or postmastectomy pain are at risk for the development of a frozen shoulder (502). This lesion may become an independent focus of pain, particularly if complicated by RSD. Adequate postoperative analgesia and active mobilization of the joint soon after surgery are necessary to prevent these problems.

Phantom Pain Syndromes

Phantom limb pain is perceived to arise from an amputated limb, as if the limb were still contiguous with the body. Phantom pain is experienced by 60–80% of patients following limb amputation but is only severe in about 5–10% of cases (520,521). The incidence of phantom pain is significantly higher in patients with a long duration of preamputation pain and those with pain on the day before amputation (522,523). Patients who had pain prior to the amputation may experience phantom pain that replicates the earlier one (524). Phantom pain is more prevalent after tumor-related than traumatic amputations, and postoperative chemotherapy is an additional risk factor (525). The pain may be continuous or paroxysmal and is often associated with bothersome paresthesias. The phantom limb may assume painful and unusual postures and may gradually telescope and approach the stump. Phantom pain may initially magnify and then slowly fade over time. There is growing evidence that preoperative or postoperative neural blockade reduces the incidence of phantom limb pain during the first year after amputation (526,527,528 and 529).

Some patients have spontaneous partial remission of the pain. The recurrence of pain after such a remission, or the late onset of pain in a previously painless phantom limb, suggests the appearance of a more proximal lesion, including recurrent neoplasm (530).

Phantom pain syndromes have also been described after other surgical procedures. Phantom breast pain after mastectomy, which occurs in 15–30% of patients (498,531,532), also appears to be related to the presence of preoperative pain (532). The pain tends to start in the region of the nipple and then spread to the entire breast. The character of the pain is variable and may be lancinating, continuous, or intermittent (532). A phantom anus pain syndrome occurs in approximately 15% of patients who undergo abdominoperineal resection of the rectum (452,533). Phantom anus pain may develop either in the early postoperative period or after a latency of months to years. Late onset pain is almost always associated with tumor recurrence (452,533). Rare cases of phantom bladder pain after cystectomy (534) and phantom eye pain after enucleation (535,536) have also been reported.

Stump Pain

Stump pain occurs at the site of the surgical scar several months to years following amputation (537). It is usually the result of neuroma development at a site of nerve transection. This pain is characterized by burning or lancinating dysesthesias, which are often exacerbated by movement or pressure and blocked by an injection of a local anesthetic.

Postsurgical Pelvic Floor Myalgia

Surgical trauma to the pelvic floor can cause a residual pelvic floor myalgia, which like the neoplastic syndrome described previously (see the section Malignant Perineal Pain) mimics so-called tension myalgia (457). The risk of disease recurrence associated with this condition is not known, and its natural history has not been defined. In patients who have undergone anorectal resection, this condition must be differentiated from the phantom anus syndrome (see the section Phantom Pain Syndrome).

Chronic Postradiation Pain Syndromes

Chronic pain complicating radiation therapy tends to occur late in the course of a patient's illness. These syndromes must always be differentiated from recurrent tumor.

Radiation-Induced Brachial and Lumbosacral Plexopathies

Radiation-induced brachial and lumbosacral plexopathies were described previously (see the sections Brachial Plexopathy and Lumbosacral Plexopathy).

Chronic Radiation Myelopathy

Chronic radiation myelopathy is a late complication of spinal cord irradiation. The latency is highly variable but is most commonly 12–14 months. The most common presentation is a partial transverse myelopathy at the cervicothoracic level, sometimes in a Brown-Sequard pattern (538). Sensory symptoms, including pain, typically precede the development of progressive motor and autonomic dysfunction (538). The pain is characterized as a burning dysesthesia localized to the area of spinal cord damage or below. Imaging studies, particularly MRI, are important to exclude an epidural metastasis and demonstrate the nature and extent of intrinsic cord pathology, which may include atrophy, swelling, or syrinx. On MRI the signs of radiation myelitis include high-intensity signals on T2-weighted images or gadolinium enhancement of T1-weighted images (539,540). The course of chronic radiation myelopathy is characterized by steady progression over months, followed by a subsequent phase of slow progression or stabilization.

Chronic Radiation Enteritis and Proctitis

Chronic enteritis and proctocolitis occur as a delayed complication in 2–10% of patients who undergo abdominal or pelvic radiation therapy (197,541). The rectum and rectosigmoid are more commonly involved than the small bowel, a pattern that may relate to the retroperitoneal fixation of the former structures. The latency is variable (3 months–30 years) (197,541). Chronic radiation injury to the rectum can present as proctitis (with bloody diarrhea, tenesmus, and cramping pain), obstruction due to stricture formation, or fistulae to the bladder or vagina. Small bowel radiation damage typically causes colicky abdominal pain, which can be associated with chronic nausea or malabsorption. Barium studies may demonstrate a narrow tubular bowel segment resembling Crohn's disease or ischemic colitis. Endoscopy and biopsy may be necessary to distinguish suspicious lesions from recurrent cancer.

Radiation Cystitis

Radiation therapy used in the treatment of tumors of the pelvic organs (prostate, bladder, colon/rectum, uterus, ovary, and vagina/vulva) may produce a chronic radiation cystitis (542,543 and 544). The late sequelae of radiation injury to the bladder can range from minor temporary irritative voiding symptoms and asymptomatic hematuria to more severe complications such as gross hematuria, contracted nonfunctional bladder, persistent incontinence, and fistula formation. The clinical presentation can include frequency, urgency, dysuria, hematuria, incontinence, hydronephrosis, pneumaturia, and fecaluria.

Lymphedema Pain

One-third of patients with lymphedema as a complication of breast cancer or its treatment experience pain and tightness in the arm (545). Some patients develop nerve entrapment syndromes of the carpal tunnel syndrome or brachial plexus (398,546). Severe or increasing pain in a lymphedematous arm is strongly suggestive of tumor invasion of the brachial plexus (390,391).

Burning Perineum Syndrome

Persistent perineal discomfort is an uncommon delayed complication of pelvic radiotherapy. After a latency of 6–18 months, burning pain can develop in the perianal region; the pain may extend anteriorly to involve the vagina or scrotum (547). In patients who have had abdominoperineal resection, phantom anus pain and recurrent tumor are major differential diagnoses.

Osteoradionecrosis

Osteoradionecrosis is another late complication of radiotherapy. Bone necrosis, which occurs as a result of end-arteritis obliterans, may produce focal pain. Overlying tissue breakdown can occur spontaneously or as a result of trauma such as dental extraction or denture trauma (548,549). Delayed development of a painful ulcer must be differentiated from tumor recurrence.

Breakthrough Pain

Transitory exacerbations of severe pain over a baseline of moderate pain or less may be described as “breakthrough pain” (550). Breakthrough pains are common in both acute or chronic pain states. These exacerbations may be precipitated by volitional actions of the patient (so-called incident pains) such as movement, micturition, cough, or defecation, or by nonvolitional events such as bowel distention. Spontaneous fluctuations in pain intensity can also occur without an identifiable precipitant.

Breakthrough pains must be distinguished from exacerbations of pain associated with failure of analgesia. “End-of-dose failure (of analgesia)” is commonly observed as therapeutic levels of analgesic fall. This phenomena is observed most commonly when the interval between scheduled doses exceeds the known duration of action of short half-life analgesics. Because there is substantial interindividual differences in drug metabolism and excretion, some analgesics which may typically have a 4-hour duration of action, may be effective for only 2–3 hours in some individuals. Similarly, variability in the duration of analgesic effect is observed with long-acting

formulations such as oral morphine or transdermal fentanyl. End-of-dose failure is addressed through either dose or schedule modification.

In a survey by Portenoy and Hagen (550) of 63 cancer patients with pain requiring opioid analgesics, 41 (64%) reported breakthrough pain. Patients had a median of four episodes per day, the duration of which ranged seconds to hours (median/range: 30 min/1–240 min). Pain characteristics were extremely varied. Twenty-two (43%) pains were paroxysmal in onset; the remainder were more gradual and 21 (41%) were both paroxysmal and brief (lancinating pain). Fifteen (29%) of the pains were related to end-of-dose failure from a fixed dose of opioid on a regular schedule. Twenty-eight (55%) of the pains were precipitated; of these, 22 were caused by an action of the patient (incident pain), and six were associated with a nonvolitional precipitant such as flatulence. The pathophysiology of the pain was believed to be somatic in 17 (33%), visceral in 10 (20%), neuropathic in 14 (27%), and mixed in 10 (20%). Pain was related to the tumor in 42 (82%), the effects of therapy in seven (14%), and neither in two (4%). Diverse interventions were employed to manage these pains, with variable efficacy. In a study of 194 cancer patients with pain, Jacobsen (551) reported that 61% reported one or more episodes of breakthrough pain. These episodes were typically paroxysmal (56%), predictable (63%), and precipitated by patient action (67%). They had a mean duration of 20 minutes (range, 5 seconds–1.5 hours) and occurred an average of ten times per day (range, 1–80). In a survey of 22 hospice patients by Fine (552), 86% reported breakthrough pain, with an average of 2.9 episodes per 24-hour period and a mean pain intensity of seven on a 10-point scale. These episodes lasted an average of 52 minutes (range, 1–240). The range of time to relief of breakthrough pains was 5–60 minutes, with a mean of 30 minutes.

Syndromes of Breakthrough Pain

Pain exacerbations represent a heterogeneous phenomenon. The clinical approach to these problems is influenced by the specific underlying mechanism. It is useful, therefore, to define the specific breakthrough pain syndrome.

- Somatic movement-related pain (volitional and nonvolitional)
- Somatic nonmovement-related pain
- Neuropathic movement-related pain
- Neuropathic nonmovement-related pain
- Visceral pains—volitional
- Visceral pains—nonvolitional

Somatic, Movement-Related Breakthrough Pain

Volitional. This is the most common mechanism of breakthrough pain. It is most commonly observed when the pain associated with skeletal metastases is exacerbated by movement. This is particularly common when the axial skeleton and weight-bearing bones are involved; these episodes are generally predictable. The site of disease involvement influences which volitional movement produces pain. Thus the pain associated with vertebral, pelvic, or femoral metastases may be exacerbated by walking. The pain of shoulder girdle or humeral metastases my be exacerbated by reaching or lifting. The pain of rib metastases may be exacerbated by deep breathing. Often this sort of breakthrough pain may be prevented or modified by preemptive analgesia, orthotics, bone stabilization, or movement modification.

Nonvolitional. Nonvolitional movements, such as laughing, sneezing, coughing, or myoclonus, may also exacerbate skeletal pain. The spontaneous and nonpredictable nature of these episodes commonly precludes preemptive analgesia and management must address the possibility of reducing the frequency of the nonvolitional precipitant.

Somatic, Nonmovement-Related Breakthrough Pain

Occasionally, somatic structures can spontaneously produce transient exacerbation of pain unrelated to movement. In the setting of cancer pain, this is a relatively uncommon phenomenon. The best recognized syndrome is that of muscle cramps (322,323). Muscle cramps involve a focal transient exacerbation of pain related to a change in muscle tone, but without necessarily involving movement.

Neuropathic, Movement-Related Breakthrough Pain

Neuropathic pains are common among patients. Because of the proximity of neural and somatic structures, neuropathic pains are often exacerbated by volitional or nonvolitional movement.

Volitional. Neuropathic pain associated with compression of neural structures, such as the brachial plexus, lumbosacral plexus, spinal cord, and nerve roots, are commonly exacerbated by specific volitional activities. Indeed, these associations are often important in the clinical diagnosis. For example, back pain that is exacerbated by lying suggests EC of the cord or nerve roots (273,285,553,554 and 555) and headache that is exacerbated by stooping or Valsalva suggests raised intracranial pressure (556).

Nonvolitional. Coughing and sneezing are nonvolitional movements that generate a Valsalva maneuver (329). Valsalva maneuvers can precipitate transient elevations in intracranial pressure called “plateau waves.” In patients with cerebral tumors, these plateau waves can be associated with short periods of severe headache, nausea, vomiting, photophobia, lethargy, and transient neurological deficits (331,332). Occasionally these plateau waves produce life-threatening herniation syndromes (331,332). Similarly, among patients with spinal cord compression, the transient pressure shifts can exacerbate back or radicular pain.

Neuropathic, Nonmovement-Related Breakthrough Pain

Transient episodes of spontaneous lancinating or burning pain are a common manifestation of neuropathic pain syndromes. The frequency of pain exacerbations is very variable; from many hundred episodes of brief lancinations per day, to vary rare episodes with weeks to months between events (550). Lancinating neuropathic pains are often of very brief duration. This feature has therapeutic implications insofar as responsive analgesia is not likely to take effect until well after the pain has resolved and is thus not likely to be effective. This sort of pain commonly requires a preventative therapy to diminish the frequency and severity of events (42,49,557,558).

Visceral Breakthrough Pains

Visceral nociceptors respond primarily to mechanical and chemical nociceptive stimuli. Functionally, there is evidence for three classes of visceral afferents: low-threshold mechanosensitive afferents which respond to distention and contraction, specific chemosensitive afferents, and high-threshold mechanosensitive afferents (559).

Volitional. Initiation of the activity of some visceral organs is influenced by volitional activity. This is true for upper, gastrointestinal-tract activity associated with swallowing and digestion, micturition, defecation, and sexual climax (male and female). Indeed exacerbations of visceral pain may be associated with any one of these activities. Transient visceral pains initiated by volitional activity may benefit from preemptive therapies or specific therapies targeted at the underlying mechanism.

Nonvolitional. Visceral motility is usually spontaneous and is often unrelated to any volitional activity. Spontaneous muscular contractions of hollow organs commonly results in paroxysmal transient pain exacerbations. Pain of this sort is commonly generated by the esophagus, intestines, gallbladder, and urinary bladder. Obstruction or inflammation of any hollow viscus may generate paroxysmal pains associated with spontaneous muscle contraction.

CONCLUSION

Adequate assessment is a necessary precondition for effective pain management. In the cancer population, assessment must recognize the dynamic relationship between the symptom, the illness, and larger concerns related to quality of life. Syndrome identification and inferences about pain pathophysiology are useful elements that may simplify this complex undertaking.

BONE PAIN: ASSESSMENT AND MANAGEMENT

ANN M. BERGER
CHRISTOPHER KOPROWSKI

Approximately 60–84% of cancer patients with solid tumors develop bone metastases (1). Although almost any tumor can spread to bone, some are more osteotropic than others. Breast and prostate cancer, along with multiple myeloma, lung, thyroid, and kidney tumors, metastasize to bone more frequently. Nielsen et al. (2) demonstrated at autopsy that up to 85% of patients with breast, lung, or prostate cancer have bone involvement. The metastatic spread to bone is primarily due to the hematogenous spread of tumor cells from a primary tumor. After a tumor grows through the wall of a blood vessel, tumor cells are released and can be distributed to other organs or bone. Substances released during normal bone resorption may act as chemotactic factors in cancer patients and disrupt the normal bone remodeling process. Parathyroid hormone-related protein and cytokines induce this disruption by the induction of osteoclasts, usually resulting in a net loss of bone at the site of increased activity. Osteoblastic activity may not equal osteoclastic activity, or the site may not be able to attract osteoblasts. Lytic bone lesions result from this net loss of bone and are a significant cause of morbidity in cancer patients with bone metastases. Complications include pain, pathological fracture, loss of functioning and mobility, inadequate hematopoiesis due to bone marrow involvement, disruption of calcium homeostasis with the development of hypercalcemia, and spinal cord compression. Bone pain is the most frequent cause of morbidity. Furthermore, the most common pain syndrome encountered in cancer patients is that of metastatic bone pain (3).

PATHOPHYSIOLOGY OF BONE PAIN IN CANCER

Several mechanisms are probably involved in the pathophysiology of bone pain. The two most likely mechanisms that contribute to pain in bone metastasis include the inflammatory mediators, such as prostaglandins (PGs), and mechanical stimulation of nociceptors when the tumor mass distorts the periosteum and increases intraosseal pressure. Bone metastases are associated with edema and inflammation so that nociceptors are activated and sensitized by chemical mediators of the inflammatory response such as PGs, bradykinin, and potassium (4).

PG biosynthesis appears to be involved in the process of bone destruction and in the new bone formation that accompanies bone metastases. PGs in the A and E series may stimulate tumor cells directly, whereas PGs in the E series are involved in osteoclastic bone resorption and enhance interleukin-1 (IL-1), which is involved in bone metastasis. In addition to PGs, other humoral mechanisms involved in osteolytic destruction of bone in bone metastasis include cytokines, growth factors, and parathormone (5). Many of the chemical mediators such as IL-1, IL-6, and tumor necrosis factor involved in osteolysis also activate nociceptors (6).

The gender or age of the patient, the type of tumor, and the location, number, and size of metastases do not correlate well with the presence or absence of pain (7). Patients with multiple bone metastases usually report pain only at a few sites, and more than 25% of patients with bone metastases are pain-free (8). It is probable that pain receptors are activated by cytokines and other algesic chemicals in the bone marrow. Other causes of pain secondary to bone metastases include reactive muscle spasm, nerve root infiltration, and nerve compression.

CLINICAL PRESENTATION

The most common presentation of osteolytic bone metastases is pain. The pain is usually somatic and is characterized by a dull ache that is well localized and is increased with weight-bearing or at night. The pain is usually constant, gradually increasing in intensity, and is exacerbated by different positions or movements.

The sites most commonly involved in bone metastases include the pelvis, vertebrae, femur, ribs, and skull (9). Metastases to these areas often lead to pain that occurs during changes in posture or body position. Such pain is called *incident* pain and is difficult to manage with analgesic therapies alone. When a patient experiences incident pain, the best treatment often consists of removal of the tumor, with or without orthopedic stabilization or denervation of the painful part, such as with neurolytic anesthetic techniques or cordotomy. Many different symptoms and syndromes are associated with pain from bone metastases. Bone pain can be referred, and a secondary pain can be caused by reactive muscle spasm (10). Bony lesions that infiltrate and compress nerves may cause paroxysms of sharp, shooting, lancinating pain. Several different specific syndromes are associated with neurological involvement, including vertebral syndromes and metastases to the skull (11).

The most common site of bone metastases is the vertebrae, with more than two-thirds of cases affecting the thoracic spine, 20% affecting the lumbosacral spine, and 10% affecting the cervical spine (12). More than 85% of patients have metastatic bone involvement at multiple levels (13). Early recognition of pain due to tumor involvement is essential because pain usually precedes tumor compression of adjacent neural structures, which can result in the development of irreversible neurological deficits.

Four well-recognized vertebral syndromes secondary to bone metastases include atlantoaxial destruction and odontoid fracture, C7-T1 syndrome, T12-L1 syndrome, and sacral syndrome (Table 2-1). Atlantoaxial destruction and odontoid fracture usually present with nuchal or occipital pain radiating from the posterior aspect of the skull to the vertex. Usually this pain is exacerbated by flexion of the neck. Concomitant compression of the spinal cord at the cervicomedullary junction is accompanied by sensory, motor, and autonomic involvement of the upper extremities. Magnetic resonance imaging (MRI) is probably the best method for visualizing this area of the spine.

Syndrome	Presentation of pain
Atlantoaxial destruction and odontoid fracture	Nuchal or occipital pain radiating from the posterior aspect of the skull to the vertex.
C7-T1 syndrome	Pain exacerbated by flexion of the neck. Pain referred to the interscapular region.
T12-L1 syndrome	Pain referred to sacroiliac joint or ipsilateral iliac crest.
Sacral syndrome	Pain radiating to buttocks, perineum, and posterior thighs, exacerbated by sitting or lying down. Relieved with walking or standing.
"Pyriformis syndrome"	Buttock or posterior leg pain with internal rotation of the hip if the neoplasm spreads laterally to involve muscles that rotate the hip.

TABLE 2-1. VERTEBRAL PAIN SYNDROMES

The C7-T1 syndrome involves pain that is referred to the interscapular region. In assessing for this syndrome, it is essential to have patients undergo radiography of both the cervical and the thoracic spine. Pain from a T12 or L1 lesion is usually referred to the sacroiliac joint or the ipsilateral iliac crest. Destruction of the sacrum may cause severe pain that radiates to the buttocks, perineum, or posterior thighs. This pain is relieved with walking or standing and is exacerbated by sitting or lying down. If the tumor metastasizes to muscles, such as the pyriformis, the patient will experience severe incident pain of the buttock or posterior leg with internal rotation of the hip. The tumor can also infiltrate nerves, which leads to a sacral plexopathy (14).

In evaluating a patient with back pain, it is important to keep in mind that almost all patients with epidural compression initially present with back pain and that it occurs in 10% of patients with cancer. Epidural compression is the second most common neurological complication of cancer (15). Some characteristics of back pain are clearly suggestive of epidural extension. These include back pain that rapidly progresses in intensity, and radicular pain that is either lancinating or constant. When the back or radicular pain is exacerbated by coughing, sneezing, straining, or recumbency, the likelihood of epidural compression is greater. In the thorax, the radicular pain may present as a belt-like band across the abdomen or chest, whereas in the lumbosacral or cervical regions the radicular pain is usually unilateral. Because back pain precedes neurological signs, it is essential to undertake a diagnostic evaluation at a time when the neurological evaluation is still normal.

Other sites of metastatic involvement include the bony pelvis and hip. Tumor involvement of the acetabulum or head of the femur usually produces localized hip pain, which is aggravated by weight-bearing or ambulation. The pain may radiate to the medial thigh or knee and is usually an incident pain with ambulation. Evaluation by computed tomography (CT) or MRI is essential to demonstrate the extent of bony destruction. Bone pain can be focal, multifocal, or generalized. Multifocal bone pain is usually secondary to bone metastases in multiple areas. However, rarely there is generalized bone pain caused by replacement of bone marrow. This bone marrow replacement syndrome is more common in hematogenous malignancies than solid tumors (16). This syndrome may be difficult to diagnose because it can occur in the absence of any abnormalities on bone scintigraphy or radiography. Moreover, another rare syndrome, paraneoplastic osteomalacia, can mimic multiple metastases. Other possible nonneoplastic causes of bone pain that must be differentiated from bone metastases include osteoporotic fractures and focal osteonecrosis, which may be related to corticosteroids or radiotherapy.

ASSESSMENT OF BONE PAIN

Development of individualized treatment for the patient with osseous metastases requires diagnostic imaging. Although now in use for more than 100 years, plain x-ray imaging continues to be important in the definition of bony changes secondary to neoplastic disease. It is particularly important in the assessment of cortical integrity of long bones (17) and almost invariably demonstrates abnormality in areas of epidural compression (18). Although it lacks the sensitivity of bone scanning, it complements it and is still useful in diseases that are predominantly osteolytic, especially multiple myeloma.

Radionucleotide bone scanning is probably the most widely used radiographical procedure for detection of suspected metastatic disease. Because of its ability to detect asymptomatic disease, it is favored in the initial staging of many carcinomas. Conventional technetium-99m (Tc-99m) bone scanning, which reflects osteoblastic activity, is an order of magnitude more sensitive than plain x-rays (19). It is a very important extension of the physical examination, it can aid in evaluation of the results of therapy and, above all, it provides superior anatomical characterization when a target for external beam radiation is being selected. In the emerging field of bone-seeking radioisotopes, bone scanning may also serve to measure the administered dose to bone metastases (20).

Although not suitable for screening asymptomatic patients for occult disease, MRI is even more sensitive than bone scanning for marrow lesions (21) and is therefore useful when the bone scan fails to reveal spinal lesions in the symptomatic patient. It is extremely useful in differentiation of soft tissue from bone in spinal lesions and in depiction of the soft-tissue component of bone disease when that knowledge is necessary for treatment planning.

CT, although now largely supplanted by MRI in the evaluation of spinal disease, continues to be appropriate in a more limited set of circumstances. CT retains a role in patients with suspected spinal epidural disease when the level is known with certainty and the MRI cannot be performed. In addition, CT remains important in the evaluation of pelvic and thoracic wall disease.

TREATMENT OF BONE PAIN IN THE CANCER PATIENT

The treatment of pain caused by bone metastases involves the use of many different approaches based on the needs of the individual patient (Table 2-2). The complementary approaches employed include non-opioid and opioid analgesics, bisphosphonates, antineoplastic therapies and, less commonly, neurosurgical and anesthetic procedures. To improve mobility, the treatment plan should also include physiotherapy and occupational therapy.

Surgery
Radiation therapy
External beam radiation therapy
Local field radiotherapy
Wide-field radiotherapy
Systemic radionuclides
Strontium
Sm-153 EDTMP
Chemotherapy
Hormonal therapy
Hypophysectomy
Nonsteroidals
Opioid analgesics
Corticosteroids
Calcitonin and gallium nitrate
Bisphosphonates
Neural blockade
Spinal analgesia
Cordotomy or pituitary ablation
Physiatry, physical therapy

TABLE 2-2. DIFFERENT MODALITIES FOR THE TREATMENT OF BONE PAIN SECONDARY TO BONE METASTASES

RADIOTHERAPY

Despite great progress in pharmacological pain management, hormonal manipulations of breast and prostate cancer, prevention of metastases with osteoclast inhibitors, cytotoxic chemotherapy, and other approaches, radiation remains important and perhaps underutilized in the treatment of osseous metastases (22).

There is potentially an expanded role for radiotherapy in the treatment of bone metastases, and there is a need for better definition of its indications and applications. The traditional prescription of 3 Gy administered on ten occasions to all sites of bone pain, regardless of diagnosis, performance status, or the results of staging, is antediluvian in the light of advances in diagnostic imaging and surgical techniques, newer forms of radiation therapy, and the increasing (although still far from adequate) knowledge of prognosis based on modern statistical investigations. The above considerations suggest the need for an individualized approach to radiotherapy prescription.

RADIOBIOLOGY OF BONE AND BONE MARROW

Discriminating among treatment strategies requires insight into the effects of radiation on bone and bone marrow. When photons strike bone and tumor, a stereotypical cascade of events occurs, culminating ideally in elimination of the cancer and restoration of normal healing of bone. However, achieving this necessitates skillful manipulation of time, dose, and fractionation. For an exhaustive discussion of these topics, the reader is referred to Rubin and Casarett's textbook of radiation pathology (23) and to Hall's textbook of radiobiology (24). However, a few concepts are necessary before we continue discussion of the radiotherapy of bone metastases.

There are several consequences to radiation of the bone marrow. First, there is an immediate and complete intermitotic elimination of the megakaryocytes and of red cell and leukocyte precursors within the irradiated bone marrow, along with an analogous necrosis of circulating lymphocytes, which are similarly sensitive. Mature red cells are unaffected. The net effect, if the field is large enough, is a rapid depopulation of circulating lymphocytes with more general leukopenia and thrombocytopenia following in a few days. In general, leukopenia and thrombocytopenia peak at 3 weeks after exposure and recover over 4–6 weeks. Anemia, if it occurs, does not usually appear for several months, consistent with the long circulating life of mature red cells. Rapid proliferation of the remaining bone marrow determines hematopoietic recovery but not repopulation of the irradiated area, which may take a year or more. Therefore, in patients with generally compromised bone marrow, whether caused by disease, by chemotherapy, or by previous radiation, recovery may be incomplete or delayed for long periods even at doses below that expected to

cause irreversible stromal damage (a late effect). Delayed bone marrow recovery occurs only at cumulative doses greater than 40–50 Gy delivered by conventional fractionation schedules, and the reaction is characterized not by the typical radiation fibrosis, but by replacement of the hematopoietic tissues with adipocytes, precluding any recovery of the irradiated area.

Fortunately, bone is more radioresistant than bone marrow. However, radiation may nevertheless have undesirable consequences. Radiation at doses characteristically employed in the treatment of metastases can be expected to temporarily inhibit chondrogenesis (25), which may delay healing in irradiated areas. Patients should therefore be informed that weakened bone needs time to repair itself. From the patient standpoint, radiation cannot be expected to result in rapid and complete relief of symptoms, and weight-bearing bones that are compromised may fracture before successful remodeling and repair are completed. In addition, doses in excess of 50 Gy extensively damage small vessels and may result in avascular necrosis of bone.

CRITERIA FOR SURGERY

Although radiation is the mainstay of treatment for bone metastases, adjuvant surgery should be considered in two instances: epidural compression and extensive lytic involvement of weight-bearing bones. Unfortunately, in neither instance are interventional criteria well established, and good practice necessitates clinical judgment.

In the case of extensive lytic involvement of long bones, literature can be found both favoring early and vigorous operative intervention (26) or questioning its merit (27). Pathological fractures involve the proximal femur more than other sites (28) and, for obvious reasons, the consequences are graver than those of fractures at other sites; this is the case in which internal fixation is most often considered. The American College of Radiology (ACR) consensus panel on radiation of bone metastases (29) recommends surgical stabilization for lytic lesions greater than 3 cm and involvement of greater than one-third of the cortex.

Determining whether or not surgery should be used to relieve epidural compression caused by vertebral metastases is often difficult. Normally, radiation therapy is the first choice for treatment of these lesions because the additional use of surgery has not demonstrated to improve outcome (12,30,31), and most patients who are ambulatory at the time of diagnosis will remain ambulatory after radiation alone. In one analysis, the proportion of patients ambulatory after radiation therapy was 96% if they walked in at diagnosis (32).

Settings deemed appropriate for surgery include diagnostic uncertainty, unstable vertebral relationships, radiation failure, large paravertebral masses, and perhaps the rapid progression of neurological symptoms (30). It is noteworthy that the ACR consensus committee (32) reached agreement on only one of three clinical vignettes concerning the use of operative intervention and spinal metastases. In the proffered vignette, a patient with symptomatic epidural compression in a previously irradiated area, the group felt that posterior decompression was appropriate.

PROGNOSIS

Once a patient develops bony metastases from carcinomas, the disease is considered incurable. However, the duration of survival and the quality of life may vary tremendously. In the three most common malignancies—breast, lung, and prostate—breast metastases have the best prognosis and lung the worst. In patients with breast cancer and metastases limited to bone, median survival is approximately 3 years (33). Prostate cancer patients with a high performance status, lower alkaline phosphatase levels, and higher hemoglobin may live many years (34,35). In an interesting examination of patients with unknown primaries (36), a group from the Rotterdam Cancer Institute found that in a multivariate analysis only performance status and alkaline phosphatase were predictive of outcome, with those patients whose alkaline phosphatase was less than 1.25 times normal and with the World Health Organization performance of 0 having a median survival of greater than 4 years. Unfortunately, no literature comprehensively addresses this topic, and there is a compelling need for more information related not only to prediction of life expectancy but also to quality of life.

EXTERNAL BEAM RADIOTHERAPY

Conventional Field Sizes

The ideal radiotherapy prescription for the palliation of pain from bone metastases differs markedly from that prescribed for curative treatments. In the case of the latter, there is less concern about overall treatment time and acute side effects, the goal being to maximize cure rates at a reasonable level of risk. In contrast, palliative treatments are intended to maximize the chances of local control during the patient's limited life span while minimizing the inconvenience and acute side effects associated with a protracted course of fractionated radiotherapy. Often palliative radiotherapy courses are administered using hypofractionation, which would be unacceptable in the patient treated definitively because of the serious risk for long-term complications and the often low rates of longterm control. Nevertheless, care must be taken in patients with a greater than 1-year life expectancy not to expose them to undue risk for pathological fracture because of high-dose/large fraction size or spinal cord compression from an inadequately treated region.

The current literature deals extensively with the central issues of dose and fractionation in teletherapy of bone metastases. Tong et al. (37) and the subsequent reanalysis by Blitzer (38) are the landmark publications in the investigation of how to treat bony metastases with external beam radiation. These articles report and analyze the Radiation Therapy Oncology Group (RTOG) 74-02 study, which is the largest randomized trial looking specifically at time, dose, and fractionation, with a total of 1016 randomized patients.

Earlier case series and nonrandomized investigations had suggested a wide range of possible treatment schedules for bone involvement. Jensen and Roesdahl (39) found good relief in 85% of patients treated with 3–7 Gy. Allen et al. (40) found effective palliation at NSD doses ranging from 500 to 1700 in various fractionation schemes. Penn found that at 6 months 70% of patients had achieved complete or almost complete palliation with either 3 Gy administered 10 fractions or with single fractions from 8–15 Gy. In the study of Hendrickson et al. (41), patients who received an NSD of 900 achieved the same degree of analgesia as patients receiving one of 1200 (equivalent to 5% 4 Gy or 10% 3 Gy in daily fractions). Gilbert et al. (42) found that 63% of patients who survived more than 3 months had a satisfactory quality of life after radiation and that radiation dose did not correlate with quality of life. Somewhat surprisingly, Garmatis and Chu (43) found that recalcification occurred in 75% of patients irradiated to a total dose of only 20–25 Gy in 2.0- to 2.5-Gy fractions.

RTOG 74-0237 divided patients into two groups: those with solitary metastases and those with multiple bone metastases. Those with solitary metastases were randomized to receive either 40 Gy in 3 weeks or 20 Gy in 1 week. Those with multiple osseous lesions received either 30 Gy in 2 weeks, 15 Gy in 1 week, 20 Gy in 1 week, or 25 Gy in 1 week. Patients scored their own pain severity and frequency and the frequency of pain medication administration. Overall, 83% achieved partial or complete pain relief. Some 86% of the patients experienced some pain relief in the first 2 weeks, and almost all patients by the end of 4 weeks. Complete relief was slower, coming more than 4 weeks after the commencement of treatment and consistent with the healing of injured bone. The rapidity of pain relief was somewhat less in those with pelvic metastases and those treated with the 3-week fractionation scheme. Patients with prostate and breast cancer tended to fare better than those with lung cancer.

In the initial analysis (37), inferential statistics were performed on the two sets of patients—the solitary metastases group and the group with multiple metastases—individually, reducing the power of the study. No statistically significant differences emerged between groups with reference to pain control, although there appeared to be a trend toward better control in the higher-dose sets (30 and 40.5 Gy). Blitzer in his reanalysis (38), however, approached the analysis from a different perspective. He reasoned that both the cohort with solitary metastases and those with multiple metastases could be expected to achieve local relief similarly and that there was therefore no reason to perform separate inferential analyses. In addition, he controlled for the effect of retreatment on long-term pain control. Blitzer found a rather striking stepwise association between the combined effect of higher doses and greater numbers of fractions and complete pain relief, but did not find that a dose response was quantifiable using classical time-dose factor conversions.

More recent randomized trials have demonstrated that fractionation schemes ranging from 8 Gy × 1 to 4 Gy × 5 are equally effective in producing palliation for most patients (44,45 and 46). A study from the Royal Marsden Hospital did, however, conclude that a single dose of 4 Gy was insufficient to maintain durable control (47).

The preponderance of evidence about external beam radiation favors short, even single-fraction irradiation for most palliative situations, with the caveat that retreatment may be both necessary and feasible in the lowest dose/fractionation schema. The ACR Consensus Committee suggested a wide range of acceptable prescriptions, 5% 4 Gy to 14% 2.5 Gy, but did suggest caution in generalizing these to all presentations (31). They pointed out that 6 × 6 Gy might be an appropriate fractionation schedule for melanoma, a tumor known to be radioresistant because of the efficient repair of sublethal damage, and 15% 2.5 Gy was considered appropriate for hypernephroma metastases because of possible radioresistance. Single-fraction schedules are probably not appropriate if large amounts of bowel are in the field, because the consequent diarrhea or nausea is not justifiable in a patient with limited life expectancy.

Wide-Field Radiotherapy

Although large fields and total body irradiation have been used for the greater part of this century in lymphoid malignancies, the modern era of wide-field radiotherapy

for the relief of osseous metastases began in the early 1970s. Investigators (48) from Princess Margaret Hospital, discouraged by the frequency of retreatment, developed the concept of half-body radiation. This technique required the sequential treatment of the two halves of the body. They postulated that 8 Gy would produce 99.5% cell kill, enough for a remission but clearly far beyond the tolerance of stem cells within the bone marrow (4–5 Gy). They hypothesized that the unirradiated bone marrow would rapidly repopulate the stem cells killed in the initial hemibody exposure and that this would permit treatment of the other half of the body 4–6 weeks later. The treatment was administered in less than 1 hour and the eyes and upper skull were shielded. These investigators noted the occurrence of the acute radiation syndrome of total body irradiation (vomiting and diarrhea, and occasionally fever, occurring for a few hours after exposure) in the majority of patients irradiated to the upper half of the body, but little in the way of acute toxicity following treatment of the lower half of the body. Salazar et al. (49) noted that the limiting factor was pulmonary toxicity, which occurred in 9% of patients treated at 8 Gy.

Because of the many issues of dose and toxicity involved in wide-field radiotherapy, the RTOG began a trial in 1978 looking at hemibody radiation for bone metastases. The final report of RTOG 78-1050 provided extensive guidelines for the use of this technique. These patients were treated to the upper, mid-, or lower body with simple parallel opposed fields delivering about 30 cGy per minute. Upper body patients were hospitalized and premedicated to lessen the severity of the acute radiation syndrome. The final analysis revealed that single-dose hemibody radiation provided complete pain relief in about 20% of the patients and some pain relief in about twothirds. The treatment was felt to be endurable by about 50% of the patients. Median time to pain relief was 1–2 days, in contrast to the patients in RTOG 74-02, who generally achieved pain relief only after several weeks. However, almost twice as many patients were able to obtain complete relief with more conventionally fractionated radiation delivered to local fields. Only mild pneumonitis was seen, and approximately 11% of the patients experienced life-threatening hematological toxicity. The investigators felt that the safest and most effective doses were 6 Gy for upper body and 8 Gy for lower and mid-body treatments.

RTOG 82-0651 examined whether the addition of hemibody irradiation to local field radiation retarded disease progression. Modest improvement was seen in disease progression at 1 year (35% vs. 46%) and a more impressive difference in the time to disease progression in the irradiated hemibody (12.6 vs. 6.3 months). The issue of fractionated wide-field radiotherapy was also examined by the RTOG. A small trial (52) suggested an improvement in the median duration of palliation, but RTOG 88-22 (53), which looked at the addition of several schemes of fractionated wide-field radiation to the local administration of 3 Gy and did not conclude that there was any advantage over single-dose administration.

Wide-field radiotherapy has the advantage of providing more rapid pain relief. It also increases the time to retreatment at other metastatic sites and may improve local control when added to localized irradiation. Hemibody radiation is more toxic than conventional treatment. The most daunting problems are management of the acute radiation syndrome in upper body patients and hematological suppression, which may be life threatening.

SYSTEMIC RADIONUCLIDES

Radiopharmaceutical agents are an attractive alternative to wide-field radiotherapy. Because they do not evoke the acute radiation syndrome and can be administered over a few minutes, their use is less cumbersome. The field of artificial radioactivity, developed by the Joliot-Curies in the 1930s, has provided a host of isotopes not found in nature, some of which are useful for treatment. Perhaps the best known is iodine-131 (I-131), useful in the palliation and treatment of thyroid carcinomas but is not generally applicable for palliation of bone metastases and is therefore beyond the scope of this discussion. However, in the past decade, interest in the palliative use of radioisotopes has been rekindled, largely because of the U.S. Food and Drug Administration approval of strontium chloride-89 (Sr-89) several years ago.

Prior to 1990, phosphorus-32 (P-32) was used occasionally for pain relief in bony metastatic disease. P-32, which has a half-life of 14.2 days and an average energy b-particle of approximately 695 keV, is cumbersome to use because of the ubiquitousness of P-32 in intracellular metabolism. As a result, doses required to obtain a tumor response in bony metastatic disease prove excessive for bone marrow tolerance. Because of the pronounced myelosuppression and thrombocytopenia, the use of P-32 has largely been abandoned for this indication.

Sr-89 has a number of advantages over P-32. It mimics the metabolism of calcium and consequently is found where bone turnover is greatest (54). Because bone metastases produce a luxuriant osteoblastic response, the accumulation of Sr-89 is severalfold greater in areas of metastatic disease than in normal bone. In addition, the Sr-89 is washed out of the normal bone but is fixed in a stable configuration within the area of metastatic bone disease (55). Sr-89, a b-emitting isotope with a physical half-life of 50.5 days, has a mean energy of approximately 1.5 MeV. It does not emit a b-particle. The biological half-life of Sr is about 14 days in normal bone and is virtually the same as the physical half-life in metastases. This is an obvious therapeutic gain over P-32 and results in doses to metastases estimated to be 8.5 Gy per mCi (56).

Strontium-89 in solution is administered intravenously over 2 minutes. To be eligible for treatment, Nycomed/ Amersham, the manufacturer, suggests that patients have adequate white blood cell and platelet counts. There is appreciable excretion in the urine over a 1-week period, and this can present a problem in patients with bladder dysfunction. It is virtually free of acute side effects. About 10% of patients develop a “flare” reaction with increase in pain, which is of no particular prognostic significance. Sr-89 is generally easy to manage with steroids and nonsteroidal anti-inflammatory drugs (NSAIDs). The major toxicity is myelosuppression. In general, this becomes apparent in 3–4 weeks and recovers to some degree at the end of 3 months, the earliest time at which the manufacturer suggests repeat administration.

The current recommended dose is 4 mCi. However, the issue of dose is not well established. In the United Kingdom Metastron (57) trial, 5.4 mCi of Sr-89 was used and was compared to local radiation and hemibody radiation. The results suggested that patients on this study did as well with Sr-89 as with hemibody radiation and better than with local radiation only. The Trans-Canada trial (58) showed Sr-89 to be an effective addition to local field radiation. A total of 126 patients received local field radiotherapy and either 10.8 mCi of Sr or placebo. This study focused very specifically on quality of life issues and demonstrated a markedly decreased analgesic intake with Sr-89, as well as a significant number of complete responses. Although objective antitumor responses are relatively transient with Sr, there was a statistically significant difference in decrease in prostate-specific antigen between the group that received Sr in the Trans-Canada trial and patients who received placebo. Pain relief typically began 10–20 days after injection. In a recent study from the Health Economics Unit at Gothenburg (59), the analysis suggested that the addition of Sr-89 to local radiotherapy would be more cost-effective than no further treatment; the potential cost savings derived from the reduction in radiotherapy retreatments.

Recently, a number of chelating agents have been used to bind metals and form bone-seeking ligand complexes that are stable and chemically active in osteoblastic metastases. As of this writing, the only one that has full Food and Drug Administration approval is samarium 153-EDTMP, which is avidly bound by osteoblastic metastases and excreted intact in the urine within 12 hours (60). Sm-153 has some potential advantages over Sr-89: a shorter half-life (46 hours) and a gamma-emission useful for imaging (103 keV) while retaining betaradiation with a range of 1.7 mm. As a result, pain relief can be expected to be more rapid and the myelotoxicity of lesser duration than seen with Sr-89. Clinical studies have tended to support these anticipated outcomes (60,61), showing pain relief within a week or two and hematological recovery within 2 months. In two recent controlled trials (61,62), pain palliation was observed in roughly 70% of patients, which was comparable to that seen in the Sr-89 trials, and a benchmark dose of 1.0 mCi per patient was established.

A number of radioisotope ligand complexes are candidates for use in treatment of bone metastases. These include Re-186, Re 188-HEDP, and Sn117m DTPA (63,64,65,66,67,68,69,70,71 and 72,74). Of these, the most clinical data are available on Re-186. This isotope, which has a half-life of 3.77 days and an average beta-energy of 323 keV, has a gamma-ray yield of 8.5%. The gamma has an energy of 137 keV, again very suitable for imaging. A single i.v. infusion of 30–35 mCi of Re-186 has been associated with significant pain relief in 80% of patients. (68) In an interesting study design, Re-186 was evaluated with a double-blind crossover comparison to Tc 99-MDP as placebo (69). There was a significantly reduced pain requirement. Toxicity was primarily hematological, although the authors found it difficult to distinguish in the crossover design between the results of treatment and those of the disease itself with respect to the white count. The platelet count appeared to be depressed from baseline to between 60,000 and 90,000. The authors noted that all blood counts had returned to baseline by the end of the 8-week study and that this was double the recovery reported for strontium chloride. More recent studies have confirmed thrombocytopenia as being the dose-limiting factor for this isotope (64,65 and 66,71), and in one study (64) of prostate cancer patients the pretherapy Tc bone scan correlated highly (r2 = 0.78) with the degree of platelet decline.

Radioisotopes provide an alternative option to widefield radiotherapy. They are easier to administer and have less acute toxicity. Although the promptness of pain relief is less, the available literature suggests that pain relief is still relatively rapid, within 1–2 weeks, and that the ultimate degree and duration of pain relief compare very favorably with those achieved by hemibody irradiation.

SUMMARY OF RADIOTHERAPY

Despite the excellent advances in pharmacological intervention over the past few decades, radiotherapy remains firmly entrenched as an important form of palliation for metastatic disease. To maximize its utility, individualized treatment strategies should be developed. These require, foremost, a subjective judgment of the patient's prognosis. In addition, diagnostic imaging should be used appropriately as necessary and the clinician should be aware of the indications for surgery in patients with metastatic disease to the spine and long bones.

Most of the literature favors the use of shorter fractionation schemes. The convenience of hypofractionation and the possibility of retreatment appear to negate any dose-response advantage to greater numbers of fractions and higher doses. Wide-field radiotherapy can improve on the results of local field radiation and has the advantage of providing more rapid relief of pain. However, it is technically daunting, and upper body radiation is associated with the acute radiation syndrome and the

necessity for hospitalization. As a result, bone-seeking radionuclides are becoming more enticing and the field is burgeoning with the development of new isotopes (72). These isotopes have many advantages over wide-field radiotherapy and are lacking only in some of the promptness of relief that one observes with wide-field radiotherapy.

Despite all the conclusions of the recent literature, the medical establishment has been dilatory in implementing new radiotherapeutic approaches to relieve bone pain. Although there are substantial variations in palliative practice among different countries, there is a general tendency to resist the most efficient strategies (72a,72b and 72c). Some of this variability can be attributed to different health care systems and different economic incentives. The Canadian standard palliative regimen for bone metastasis is five fractions instead of the typical ten-fraction regimen in the United States, and they do employ radionuclides and wide-field radiotherapy more readily (72a), but there is still resistance to the use of single fractions that can be attributed purely to monetary influence and may simply be related to tradition and inertia (72b,72c). Why the overwhelming evidence from clinical trials has influenced practice so modestly is curious and worthy of further inquiry.

CHEMOTHERAPY

The degree of palliation of pain from bone metastases is difficult to measure with the use of chemotherapy. It would be expected that, if there is an objective response rate, chemotherapy would also benefit pain relief. However, this is not always the case; patients sometimes experience pain relief without any objective tumor response (73). In some tumors for which chemotherapy is effective, a small percentage of patients with bone metastases may report pain relief with it. These tumors include breast cancer, smallcell lung cancer, lymphoma, multiple myeloma, and germcell tumors (74). Pain responses that may occur with chemotherapy can begin 2 weeks after the chemotherapy is received (75). There is very little justification for the use of chemotherapy for bone pain in patients with cancer that is very far advanced. The toxicity of the chemotherapy in patients with far-advanced disease far outweighs the benefits.

HORMONAL THERAPIES AND HYPOPHYSECTOMY

Endocrine therapy hormone-dependent tumors, such as metastatic breast, prostate, or endometrial carcinoma, may be effective at relieving bone pain while treating the tumor. Endocrine manipulation may produce pain relief in 50% of patients with hormone-responsive breast tumors (76). Patients with prostate carcinoma treated with gonadotrophin agonists or other hormones may experience sustained pain relief, even with widespread bone metastases (77).

Chemical hypophysectomy has been used in the past and may provide pain relief in as many as 35–93% of patients (78). To obtain pain relief does not require complete hypopituitarism or even a hormone-responsive tumor. The pain relief obtained usually lasts up to 20 weeks. However, chemical hypophysectomy is usually reserved until after radiation therapy has failed, and is currently rarely performed.

The role of levodopa, which is an inhibitor of prolactin release, is unclear in the management of painful metastatic lesions in the bone. An early study (79) in the 1970s noted that 33% of patients with breast carcinoma metastatic to bone reported pain relief when given levodopa. A suggestion made at that time was that responsiveness to levodopa might predict responsiveness to hypophysectomy. However, a more recent study revealed that only one of 14 patients with metastatic bone pain experienced any pain relief with carbidopa-levodopa (80). Therefore, additional studies are required to define the role of levodopa in relief of bone pain.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

The mainstay of drug therapy for cancer pain relief includes the NSAIDs and opioids. NSAIDs are believed to be effective in the treatment of bone pain by virtue of their actions on PG synthesis. A decrease in PGs leads to a reduction in PG-induced pain sensitization and also reduces edema which, if present, can increase intraosseous pressure and stretching of the periosteum. Another action of NSAIDs, independent of a decrease in PG synthesis, is a direct effect on spinal nociceptive processing (81). It is probable that both of these mechanisms are involved with the use of NSAIDs in bone pain because it is now understood that skeletal pain involves both peripheral and central mechanisms (1).

It is important to understand that NSAIDs, unlike opioids, have a “ceiling” to their analgesic effect. The minimal analgesic dose for the individual patient with pain secondary to cancer is unknown. However, failure with one NSAID may be followed by success with another NSAID. Therefore, if a patient is not having moderate or severe pain one can attempt sequential NSAID trials (82). With more severe pain, an opioid should be started immediately. Maximal doses for nonsteroidals generally recommended for analgesia are no more than 1.5–2.0 times the standard recommended dose. It is difficult to ascertain the value of NSAIDs in bone pain because bone pain per se was usually not separated from cancer pain of other origins in the controlled clinical trials done with NSAIDs. Patients with cancer who are receiving many medications may benefit from a long-acting NSAID once or twice a day. However, there is also some suggestion that a shorter-acting NSAID may be useful in the treatment of incident bone pain (1).

Several placebo-controlled, prospective studies have shown NSAIDs to be efficacious in the treatment of cancer pain. In a placebo-controlled study that compared ketoprofen, 100 mg and 300 mg, versus aspirin and codeine, ketoprofen, 100 mg, provided pain relief superior to that achieved in the other two arms of the study. The side effects in all three arms were approximately the same (83). In another study that compared i.m. morphine, 5 mg and 10 mg, versus p.o. ketoprofen, 75 mg and 200 mg, in patients with cancer pain, including bone pain, within the first hour patients obtained more pain relief from the morphine. However, 2–3 hours after administration patients reported more pain relief from both doses of ketoprofen (84).

Several studies have suggested that combination analgesia is superior to either NSAIDs or opioids alone. One study compared the combination of ibuprofen, 600 mg, and methadone, 2.5 mg and 5.0 mg, and found that the combination of the NSAID with the opioid provided better pain relief than methadone alone for cancer pain (85). In another study in patients with moderate-to-severe cancer pain, adequate analgesia was obtained with the use of oxycodone. After this, either a placebo or ibuprofen was added to the analgesic regimen. This study found a significant reduction in the amount of oxycodone needed to manage the pain in the patients who received ibuprofen compared to those who received placebo (86).

The most significant factor limiting the use of NSAIDs is their toxicity profile. NSAIDs are associated with potentially serious side effects, which can include gastrointestinal bleeding, suppression of fever with a resultant undetected infection, and renal toxicity, particularly in patients receiving concomitant chemotherapy. The nonacetylated salicylates, such as sodium salicylate and choline magnesium trisalicylate, are less potent *in vitro* inhibitors of cyclooxygenase (COX) than aspirin and appear to be associated with less gastrointestinal bleeding and fewer side effects but with comparable efficacy (87). A study performed with choline magnesium trisalicylate revealed an analgesic effect in malignant bone pain, although this did not reach statistical significance (88). COX-2 inhibitors are NSAIDS that can provide the anti-inflammatory therapeutic benefits of NSAIDS without significant side effects (88a). To date, human studies involving selective COX-2 agents have shown efficacy in rheumatoid and osteoarthritic pain and in acute dental pain (88b). Meloxicam is the first COX-2 inhibitor marketed in Europe. Celecoxib and rofecoxib (Vioxx) are both approved COX-2 inhibitors commercially available in the United States in 1999. NSAIDs are clearly the starting medications of choice for mild pain. However, if the pain becomes more severe or the toxicity profile becomes a concern, the patient should be started on an opioid.

OPIOID ANALGESICS

The mainstay of drug therapy for moderate-to-severe acute or chronic cancer pain are the opioids. With improved understanding of the clinical pharmacology of opioids, as well as wide clinical experience with their use, well-written guidelines are now available to all health care professionals and to the public (89). Reitera-tion of these guidelines is beyond the scope of this chapter. However, several points are extremely important and should be noted.

In general, for any patient with chronic pain, such as bone pain, the goal of treatment with opioids is to keep the patient comfortable and functional with as few side effects as possible. In treating chronic pain, oral administration is the best route because it is convenient, less expensive, and efficacious. Only full agonists are used, which include drugs such as morphine, oxycodone, hydrocodone, hydromorphone, methadone, fentanyl, and levorphanol. Partial agonists and mixed agonist-antagonists are never used in the treatment of cancer pain. Meperidine is also contraindicated because its metabolite normeperidine can accumulate and lead to a variety of neurological and psychiatric disturbances.

To achieve continuous pain relief without peaks and troughs, patients should be placed on sustained-release or long-acting opioids that treat the pain around the clock rather than on a p.r.n. basis. No opioid is inherently better than another, and with incomplete cross-tolerance the recommendation is sequential trials of different opioids with the hope of achieving adequate pain relief with minimal side effects. In changing from one opioid to another, it is very important to remember that there is equianalgesic dosing, with all of the different opioids being compared to 10 mg of parenteral morphine.

Bone pain not complicated by any neural involvement is a somatic pain, and is typically very responsive to opioids. Unlike NSAIDs, there is no ceiling dose with opioids, and the correct dose is the dose that treats the pain with minimal side effects. When opioids are used in a patient with pain, the side effects must be treated aggressively. Examples include the use of antiemetics for nausea and vomiting, use of neuroleptics for hallucinations, and placing patient on an aggressive bowel regimen, including a stool softener, such as docusate, and a largebowel stimulant such as senna. Tolerance develops to most opioid side effects except for constipation, which must always be treated in patients who are receiving opioids. If side effects become intolerable, a different opioid can be tried. Sometimes it is

essential to change from oral to parenteral or epidural/intrathecal administration, although this is not very common.

Two different types of problems can develop with bone pain that make it more difficult to treat. The first problem is that patients often experience both continuous pain and incident pain. Incident pain occurs when the patient moves the affected limb but is absent when the limb is at rest. Incident pain is usually the major limiting factor to activity (90). In a study done by Portenoy and Hagen (91), 63% of patients with controlled baseline pain had one or more episodes of breakthrough pain. To treat incident pain, Portenoy and Hagen suggest supplementing the basal regimen with opioids that have a rapid onset of action and a short duration immediately before the patient performs the activity that causes the pain. A relatively new formulation of oral transmucosal fentanyl citrate, which can produce analgesic blood levels of fentanyl within 5 minutes of placement in the oral mucosa, can be very helpful in the treatment of severe incident pain (92). In general, the recommended dose for the rescue opioid is 5–10% of the total daily dose (91). Even with such a small dose the patient may experience excessive sedation at rest. Psychostimulant drugs such as methylphenidate, dextroamphetamine sulfate, or caffeine can be added to the regimen to relieve some of the sedation. One study done with methylphenidate demonstrated that patients are less sedated and are able to tolerate higher doses of opioids (93).

The second problem arises when bone metastases invade neural structures and the patient develops a mixed somatic and neuropathic pain. When this occurs, the patient may require both opioids and adjuvant analgesics for neuropathic pain. Although a full discussion of neuropathic pain is beyond the scope of this article, some useful adjuvants include tricyclic antidepressants, anticonvulsants, oral local anesthetics such as mexiletine and flecainide, clonidine (Catapres), baclofen, N-methyl-D-aspartate antagonists such as ketamine HCl or dextromethorphan, and corticosteroids. To help prevent or relieve these difficult problems that may develop with bone metastases and bone pain, early use of radiotherapy as well as orthopedic and neurosurgical procedures is recommended.

CORTICOSTEROIDS

Even though only one placebo-controlled trial has been performed with corticosteroids in which oral methylprednisolone, 16 mg twice a day, was shown to be effective in relieving cancer pain (94), they are thought of as co-analgesics for both metastatic bone pain and neuropathic pain. In neurological emergencies, such as brain herniation or spinal cord compression, corticosteroids are used in high doses and may dramatically relieve headache and back pain (95). Corticosteroids may have beneficial effects in relieving bone pain by blocking the formation of leukotrienes and PGs via inhibition of COX and lipoxygenase enzymes. Corticosteroids may also be effective in reducing pain by decreasing peritumoral edema (96). Because the analgesic response of corticosteroids may be short-lived and because serious complications such as myopathies, immunosuppression, edema, pathological fractures, and delirium can develop, their use is usually limited to patients with neurological emergencies or those who have only days or weeks to live.

CALCITONIN AND GALLIUM NITRATE

Only small studies have been performed on the use of calcitonin and gallium nitrate in the treatment of bone pain. Calcitonin is a hormone that decreases blood calcium and inhibits osteoclastic bone resorption. In a small study using salmon calcitonin, 5 of 13 patients reported pain relief, whereas none of the 12 patients who received placebo had any pain relief (97). In another placebo-controlled trial in which eight patients with cancer pain received salmon calcitonin via lumbar puncture as well as weekly saline (placebo) injections, seven of the patients reported pain relief 15 minutes after receiving the injection via lumbar puncture, which lasted up to 48 hours, and in four patients the relief lasted up to 60 hours. The patients did experience side effects, which included nausea, vomiting, and diuresis. The fact that the patients experienced relief of pain when salmon calcitonin was given intrathecally supports the idea that its analgesic actions may not be related merely to its effect on bone, it may also act as a neurotransmitter in the central nervous system (98). The role of salmon calcitonin appears to be limited because it has a short duration of action and tachyphylaxis develops rapidly (99). Gallium nitrate, a potent osteoclast inhibitor, may have the potential to be useful as a co-analgesic. However, because the method of administration (a continuous 5-day i.v. infusion) is inconvenient and the risk for nephrotoxicity is high, its use appears unattractive (1).

BISPHOSPHONATES

Bisphosphonates—pyrophosphate analogues—are potent inhibitors of bone resorption. Although their mechanism of action is not completely understood, they are believed to exert their effects in several different ways. First, they may bind directly to bone and block dissolution of the mineral component. Second, they may inhibit osteoclast activity. Third, they may impair osteoclast chemotaxis to sites at which bone resorption is ongoing. Three bisphosphonate compounds have been studied for use in tumorinduced bone disease and bone pain. The three compounds, in order of increasing potency, are etidronate, clodronate, and pamidronate.

Oral bisphosphonates have also been studied. However, their place in the management of patients with cancer remains unclear. In general, the drugs' absorption when given orally is less than 5% of the administered dose and is variable. Concomitant ingestion of calcium, such as milk, can completely abolish their absorption. Patients may also have severe gastrointestinal intolerance to the medications. The bisphosphonates must be taken 1 or more hours before or after meals; this is difficult for patients who already have decreased appetite and other gastrointestinal complaints (100).

Most data concerning the roles of p.o. and i.v. bisphosphonates in pain control have been obtained with clodronate and pamidronate. A double-blind trial of oral etidronate, the least potent bisphosphonate, in 173 patients with multiple myeloma demonstrated its lack of efficacy in preventing the complications of metastatic bone disease (101). In a trial using 1600 mg of p.o. clodronate versus placebo, it was observed that, as measured by a visual analogue scale, there was a significant reduction of pain. What was not found was a significant reduction in analgesic use. Indeed, in both groups there were increases in the analgesic requirements (102). Similar results—a significant reduction of pain without a reduction in analgesic use—were reported when i.v. clodronate was studied (103).

In a prospective unblinded trial of 161 patients with metastatic breast carcinoma who received prolonged oral pamidronate, the incidence of hypercalcemia, bone pain, and symptomatic imminent fractures was reduced by 65%, 30%, and 50%, respectively. In this study, greater effects were seen in the patients who received pamidronate, 600 mg/day, versus 300 mg/day. However, the higher dosage could not be maintained because of gastrointestinal toxicity (104).

Several studies on the use of i.v. pamidronate in breast cancer and multiple myeloma have revealed a decrease in pain. In a placebo-controlled, randomized trial of 90 mg i.v. pamidronate versus placebo given as 12 monthly 2- hour infusions in addition to chemotherapy in 382 patients with metastatic breast carcinoma, there was a reduction in the occurrence of skeletal complications as well as a decrease in bone pain. The decrease in bone pain was seen after three, six, and nine cycles of pamidronate. At the final measurement, pain scores increased over baseline in both groups, but the increase was significantly greater in the placebo group. For patients with pain at baseline, 44% of pamidronate patients compared to 32% of placebo patients had a decrease in their pain score at the last measurement (105). Similar benefits were noted by Lipton et al. (106) in a study of 372 patients with metastatic breast carcinoma receiving hormonal therapy. Pain scores decreased from baseline for patients receiving pamidronate, whereas an increase was seen with placebo, and fewer patients receiving pamidronate required an increase in analgesic use than did the patients receiving placebo (30% vs. 43%). At the last measurement, the changes in baseline in the pain score, analgesic score, and Eastern Cooperative Oncology Group performance status were worse in the placebo group compared to the pamidronate group (106).

Symptomatic improvement in bone pain with the use of i.v. pamidronate has been reported at doses that may differ from those currently recommended. Glover et al. (107) and Lipton et al. (108) reported on the same doseranging study in breast cancer patients with bone metastases. Doses employed included 90 mg every 4 weeks, 60 mg every 4 weeks, 60 mg every 2 weeks, and 30 mg every 2 weeks. Reduction in bone pain by week 6 of treatment was noted with the 60-mg and 90-mg treatments. The 30-mg treatment was not effective. In a trial of pamidronate 45 mg every 3 weeks in patients with breast carcinoma, there was a prolongation to the time of progressive bone disease and improved bone pain (109). In a randomized, double-blind trial of pamidronate in multiple myeloma patients with at least one lytic lesion, quality of life assessments noted a significant decrease in bone pain from baseline, as well as no increase in analgesic use or deterioration in Eastern Cooperative Oncology Group performance status, in those who received pamidronate versus placebo (110). Thiebaud et al. (111) used 60 mg of pamidronate by continuous infusion in patients with painful bone metastases from multiple myeloma, lymphoma, and breast carcinoma. Symptomatic improvement in pain score was noted in eight of nine patients with multiple myeloma and in 9 of 18 patients with breast carcinoma. There also was a reduction in analgesic use and an increase in mobility (111).

Intravenous pamidronate has also been studied in patients with metastatic prostate carcinoma. In Lipton's study looking at patients with breast cancer and prostate cancer, there was some reduction in pain in prostate cancer, but not to the same degree as seen in the patients with breast cancer, and no dose-response relationship was evident (108). Clarke et al. (112) treated 25 patients with advanced prostate carcinoma over a 6-month period. During the first month of therapy, pamidronate, 30 mg, was given once weekly for 4 weeks and twice weekly for the next 5 months. Eleven of 17 patients with pain at the start of the study were pain-free after 6 months. These authors concluded that pamidronate may be effective in palliating bone pain in some patients with prostate carcinoma. However, further controlled trials should be conducted.

There is some evidence with i.v. clodronate, and even more evidence with i.v. pamidronate, that the bisphosphonates can potentiate the effects of analgesics in the treatment of bone pain from bone metastases. However, the effect is modest and there is not a significant decrease in analgesic consumption. Newer, more potent bisphosphonates are being developed for clinical use and may prove to be beneficial in the treatment of bone pain. One example is zoledronic acid, a new-generation highpotency bisphosphonate. A recent phase II trial was undertaken in which patients with metastatic breast cancer or multiple myeloma were randomized to doubleblind treatment with either 0.4 mg, 2.0 mg, or 4.0 mg of zoledronic acid or 90 mg pamidronate. Among the 232 patients with pain at study entry, a decrease in pain score was reported by a greater proportion of patients in the 4.0 mg zoledronic acid group (67%) than in the 0.4 mg, 2.0 mg, and pamidronate groups (51%, 48%, and 50%, respectively), not statistically significant. Similarly, a decrease in analgesic score among patients taking pain medications was reported for 27% of patients in

the 4.0 mg zoledronic acid group, compared to 19%, 11%, and 21% of patients in the 0.4 mg and 2.0 mg zoledronic acid groups and the pamidronate group (112a).

INVASIVE INTERVENTIONS

In the treatment of cancer-related pain, invasive interventions such as neural blockade, neurosurgical procedures, or epidural and spinal analgesia are usually undertaken when the pain is either resistant to other modalities or when there are intolerable side effects from the treatments that are being used. Neural blockade may be efficacious when the pain is well localized. Local anesthetics can be injected in various locations including the brachial plexus, lumbar sympathetic plexus, and pleural cavity. Depending on the concentration of the local anesthetic, either afferent blockade or afferent and motor blockade can be obtained. When the pain is not well localized and is innervated by multiple nerves, intraspinal analgesia is more appropriate than neural blockade. Intraspinal analgesia usually involves use of opioids, local anesthetics, and/or clonidine.

A new technique that has shown some promise in the treatment of metastatic bone lesions is radiofrequency ablation (RFA). RFA is a treatment that has been traditionally used for treatment of intractable back pain due to failed back syndrome, and chronic back pain due to facet joint osteoarthritis as well as for the treatment of osteoid osteomas (112b). A preliminary study using CT-guided RFA revealed that subjective pain relief can be obtained in patients with metastatic bone tumors that remain painful after radiation therapy or are solitary and can be treated without subjecting the bone marrow to immunosuppressive doses of external beam radiation therapy (112c). Currently, this is a potentially innovative and cost effective treatment that is being studied at both the National Institutes of Health and nationally in a phase II design.

The most invasive procedures, with significant irreversible side effects, include neuroablative procedures. These procedures are performed only when a patient has both intractable pain and a limited life expectancy. The two procedures that have been used for bone pain include percutaneous cordotomy and pituitary ablation. Percutaneous cordotomy involves interruption of the ascending spinothalamic tract and is a possibility when there is unilateral pain, especially of the lower limbs. Possible complications include paresis and bladder dysfunction. There is also a risk that patients may develop pain above or below the level of analgesia, or even at the opposite side of the body. With bilateral cordotomy, there is a significant risk for respiratory failure. There is a potential role for pituitary ablation in patients with hormone-responsive tumors and widely metastatic bone disease. Although the success rate has been quoted as high as 74– 94%, long-term follow-up has not been performed with these patients. In addition, the procedure involves significant complications, including meningitis, visual disturbances, diabetes insipidus, headaches, hypothalamic disturbances, and death. Clearly, before any invasive procedure is undertaken the risks must be measured against the potential benefits (1).

CONCLUSION

In addition to the already discussed treatments, physiatry, including bracing, prostheses of various types, wheelchairs, and both physical therapy and occupational therapy, is critical in improving pain, ambulation, and quality of life in patients with bone metastases and bone pain. In addition, it is essential to address issues such as depression, anxiety, and spiritual concerns in patients who have bone pain and metastatic disease that they know is not curable. The suffering component of the total pain picture must be addressed to achieve relief from pain. Cancer pain, including bone pain, can usually be effectively managed if one does a comprehensive assessment and develops a multimodality treatment plan.

OPIOID PHARMACOTHERAPY

RICHARD PAYNE

PHARMACOTHERAPY OF PAIN: BASIC PRINCIPLES

Advances in pain management techniques have made it possible to provide adequate control for the vast majority of patients with cancer, acquired immunodeficiency syndrome, and other chronic medical disorders using relatively simple means. Unfortunately, pain often remains inadequately treated for cancer and many other illnesses (1). Several factors contribute to the undertreatment of cancer pain, including poor physician assessment, inadequate knowledge of management techniques (including pharmacotherapy measures), and negative physician and patient attitudes towards the use of opioids for pain (2).

In a large, prospective study, physicians identified inadequate pain assessment as the primary reason for poor pain management (2). Successful management of pain in the cancer patient begins with a thorough assessment of the pain complaint. Adequate pain assessment includes the documentation of pain intensity and quality and the evaluation of exacerbating and relieving factors, and requires knowledge of the common pain syndromes occurring in a specific disease or disorder. Principles of pain assessment are covered elsewhere in this book and by other references (1).

Treating the cause of pain should be a high priority for the clinician. For example, in one study, 18% of cancer patients evaluated by a pain service required additional antineoplastic therapies to treat their pain (3). Recently, two chemotherapeutic agents, gemcitabine hydrochloride (4) and mitoxantrone hydrochloride (5), were approved by the U.S. Food and Drug Administration for the palliative treatment of pancreatic cancer and hormone-refractory prostate cancer, respectively. Similarly, radiotherapy is effective in relieving metastatic bone pain. For localized bone pain, external beam treatment reduces pain in up to 80% of patients (6). More pertinent to the subject of pharmacotherapy, the administration of systemic radio-isotopes such as strontium-89 has also been shown to be effective in treating diffuse pain from bone metastases (7). However, pain relief with strontium-89 may not be seen until the third or fourth week after treatment, although it may be sustained for several months (7).

Pharmacotherapy must be individualized to maximize pain relief and minimize adverse effects. The World Health Organization (WHO) has developed a three-step analgesic ladder for the treatment of cancer pain (8), which serves as a model paradigm for pharmacotherapy approaches to pain management (Fig. 3-1).

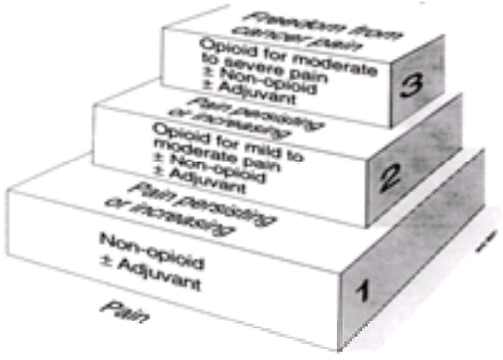

FIGURE 3-1. World Health Organization analgesic ladder. (From World Health Organization. *Cancer pain relief and palliative care: report of a WHO expert committee*, 3rd ed. Geneva, 1996, with permission.)

The WHO approach advises clinicians to match the patient's reported pain intensity with the potency of the analgesic to be prescribed. For mild pain, one should administer a nonopioid drug such as acetaminophen or a nonsteroidal anti-inflammatory drug (NSAID), unless contraindicated (Table 3-1). For moderate pain that cannot be controlled by an NSAID alone, a so-called “weak” opioid such as codeine phosphate or hydrocodone bitartrate should be administered, often in a fixed combination with aspirin, another NSAID, or acetami-nophen (Table 3-2). For severe pain, a so-called “strong” opioid drug such as morphine sulfate, hydro-morphone, methadone hydrochloride, or fentanyl should be administered (Table 3-2). NSAIDs and adjuvant analgesic drugs (see the section Adjuvant Analgesics in Cancer Pain Management) can be administered at any stage of the WHO ladder. It is important to note that patients presenting with severe pain should not be walked up the ladder starting from the first step, which is a common mistake, but should be administered a strong opioid immediately. Cleeland et al. (9) reported that 46% of ambulatory cancer patients were under-treated for pain as measured by a tool called the “pain management index.” The pain management index is based on the WHO analgesic ladder, and relates the potency of the analgesic regimen prescribed to the patient's reported pain intensity, assigning negative values (indicating undertreatment) when the pain intensity is not matched by an appropriate analgesic class, as often happens when patients with severe pain are inappropriately started on the first or second step of the analgesic ladder. The WHO analgesic ladder approach has been validated (10). However, many of the validation studies have been criticized because they have not included prospective evaluation of individual patient outcomes (11). Nonetheless, the WHO analgesic ladder approach remains the standard method for prescribing pharmacotherapies for pain.

Drug type	Name/ brands	Typical starting dose
Acetaminophen	Tylenol and others	650 mg q4h p.o.
Aspirin	Multiple	650 mg q4h p.o.
Ibuprofen	Motrin and others	200–800 mg q6h p.o.
Choline magnesium trisalicylate	Trilisate	1000–1500 mg three times daily p.o.
Diclofenac sodium	Voltaren	50–75 mg q8–12h p.o.
Diflunisal	Dolobid	500 mg q12h p.o.
Etodolac	Lodine	200–400 mg q8–12h p.o.
Flurbiprofen	Ansaid	200–300 mg q4–8h p.o.
Naproxen	Naprosyn	250–750 mg q12h p.o.
Naproxen sodium	Anaprox	275 mg q12h p.o.
Oxaprozin	Daypro	600–1200 mg q daily p.o.
Sulindac	Clinoril	150–200 mg q12h p.o.
Piroxicam	Feldene	10–20 mg q daily p.o.
Nabumetone	Relafen	1000–2000 mg q daily p.o.
Ketoprofen	Orudis	50 mg q6h p.o.
Ketorolac tromethamine	Toradol	10 mg q4–6h p.o. (not to exceed 10 d??)
Ketorolac tromethamine	Toradol	30 mg i.m. or i.v. × 1 then 15 mg i.m. or i.v. q6h (not to exceed 5 d)

TABLE 3-1. PARTIAL LIST OF ACETAMINOPHEN AND NONSTEROIDAL ANTI-INFLAMMATORY DRUGS USED FOR CANCER PAIN

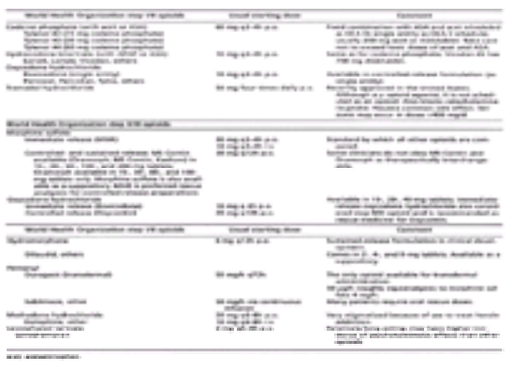

TABLE 3-2. COMMONLY USED OPIOIDS FOR CANCER PAIN

Acetaminophen and Nonsteroidal Anti-Inflammatory Analgesics

The basic principles of pain assessment and management apply when using acetaminophen and NSAIDs (Table 3-3). The NSAIDs constitute a large class of compounds that have analgesic, anti-inflammatory, and antipyretic effects. Of course, aspirin is the prototype drug in this class. Many of these analgesics are available over the counter; a 1995 survey in the *Wall Street Journal* estimated the sales of acetaminophen and NSAIDs to be more than $3 billion in the United States alone, with Tylenol brand of acetaminophen producing almost $800 million in sales alone.

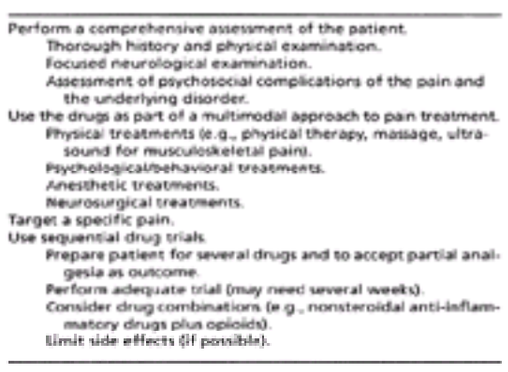

TABLE 3-3. BASIC PRINCIPLES IN USE OF NONOPIOID DRUGS

Acetaminophen is considered to be in this class, although it has only weak anti-inflammatory potency (12). Acetaminophen and NSAIDs constitute the first line of management in the pharmacotherapy of acute and cancer pain, as recommended by the WHO guidelines (8) and the Agency for Health Care Policy and Research acute pain and cancer pain clinical practice guidelines (13,14). Although widely used by consumers and patients, NSAIDs are seldom the sole agents used to treat pain and are therefore more often part of a multimodal approach to management.

NSAIDs and acetaminophen have a ceiling effect to their analgesic efficacy such that increasing the dose beyond this level produces no increase in therapeutic effect, although it may produce more side effects (15). Therefore their use as sole agents in the management of pain should be restricted to mild or moderate pain because severe pain is often above their ceiling dose for analgesic efficacy.

The minimum effective dose and the ceiling dose of NSAIDs may vary among individuals, however, so that some dose titration may be necessary within a narrow range of doses (15,16). Because patients vary in their response to NSAIDs, a trial of an alternative drug in the same class may be justified if side effects outweigh benefits for a particular drug (16).

The NSAIDs inhibit cyclooxygenase, thereby inhibiting prostaglandin synthesis (17). Prostaglandins are important mediators of the inflammatory process that may serve to activate and sensitize nociceptors; NSAIDs appear to produce analgesia by this peripheral action on prostaglandin inhibition (16). However, recent data also indicate that NSAIDs have a central nervous system (CNS) site of action at the brain or spinal cord level that is important for their analgesic effects (18).

Recently, two isoforms of the enzyme cyclooxygenase (COX-1 and COX-2) have been demonstrated (19). The COX-1 isoenzyme is normally found in blood vessels, stomach, and kidney, whereas COX-2 is induced in peripheral tissues by inflammation. Inhibition of COX-1 is associated with the well-known gastric and renal side effects linked with NSAID use, whereas COX-2 inhibition produces therapeutic effects (Fig. 3-2).

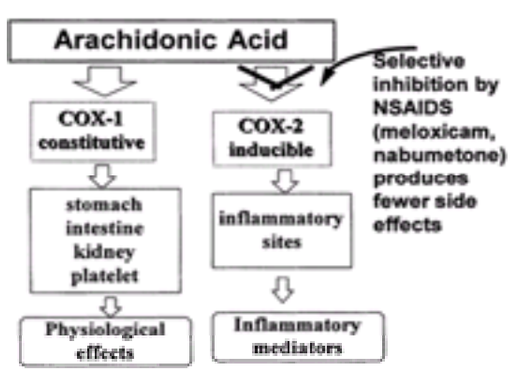

FIGURE 3-2. Cyclooxygenase (COX) inhibitors. NSAIDS, nonsteroidal anti-inflammatory drugs.

Most NSAIDs nonselectively inhibit the COX isoenzyme, thereby producing toxic and therapeutic effects. Relatively selective COX-2 inhibitors such as meloxicam and nabumetone have been shown to have fewer gastrointestinal (GI) and renal side effects (20).

Acetaminophen is equipotent to aspirin in terms of analgesic efficacy, is generally very well tolerated, and is not associated with the risks of GI hemorrhage that are linked with NSAID use. Acetaminophen is a weak inhibitor of COX, which presumably explains its poor antiinflammatory potency. This analgesic is the principal metabolite of phenacetin, which is a known nephrotoxin. Renal failure has been described with long-term use of acetaminophen (21), in addition to its well-known hepatotoxicity. Acute hepatotoxicity occurring during overdose is correlated with acetaminophen plasma concentrations above 200 mg/ml at 4 hours after ingestion, or if plasma concentration persists above 10 mg/ml at 24 hours after ingestion (22). Although not as well correlated with plasma concentrations, it is well known that chronic ingestion of acetaminophen ranging from 2.5 to 4.0 g/day increases the risk for hepatotoxicity (21). In addition, the odds of chronic renal failure have been shown to be doubled for patients who have a cumulative lifetime intake of more than 1000 pills of acetaminophen (21). NSAID and acetaminophen use is relatively safe, but these data, combined with the well-known risks of GI bleeding and platelet dysfunction that occur with acute and chronic NSAID use, indicate that these drugs should be used judiciously.

Many NSAIDs are now available. They differ in dosing interval and cost, and to some extent, in their analgesic ceiling and safety. The choice of NSAID must be individualized to the patient's needs (Table 3-1). Ketorolac tromethamine is available in an oral and parenteral formulation; it is currently the only NSAID available in both an intramuscular and intravenous formulation. This NSAID is used often in hospitalized patients to manage postoperative pain and other acute pains, including

exacerbations of chronic cancer pain and sickle cell pain. Another use of ketorolac tromethamine is in acutely ill patients experiencing side effects such as opioid-induced ileus or delirium, in which the addition of a parenteral NSAID often has an important opioid-sparing effect to allow dose reduction and the lessening of GI and CNS side effects of opioids without compromising analgesia.

Several studies have confirmed the effectiveness of the NSAIDs in the treatment of cancer pain (23,24). Of interest, prior studies that documented the additive analgesic effects of NSAIDs when combined with opioids in singledose postoperative pain studies (27) have not been confirmed in a more recent meta-analysis of repeated dose studies (24). This is puzzling because NSAIDs and opioids have different mechanisms of action and logically could have additive analgesia. Furthermore, much anecdotal clinical practice suggests that additive analgesic effects do occur when NSAIDs and opioids are coadministered (8), and it is still common clinical practice to use NSAIDs and opioids in combination despite the findings of the more recent meta-analysis.

Certain adverse effects are common to most of the drugs in this group. All may be associated with GI toxicity, with the most serious complications being ulceration and bleeding. A meta-analysis of the risks of GI toxicity associated with NSAID use compared 12 studies (25). Ibuprofen in doses less than 1600 mg/day was associated with the least risk for serious GI hemorrhage; aspirin, indomethacin, naproxen, and sulindac were associated with intermediate risk, and ketoprofen and piroxicam were highest risk (25).

NSAIDs also inhibit platelet function to a variable degree; aspirin is the strongest platelet inhibitor, whereas the nonacetylated salicylates, such as choline magnesium trisalicylate, have minimal effects on platelets (26). However, all NSAIDs must be used with caution in patients with coagulopathies and coexisting GI pathology, and when coadministered with drugs that also have GI toxicity (e.g., corticosteroids). Another relative contraindication to the use of NSAIDs relates to their antipyretic effects, which may mask fever as an early sign of serious infection in immunocompromised patients.

Commonly Used Opioids for Pain Management

Because opioids alter the unpleasant emotional experience associated with nociception and provide pain relief by interacting with specific receptors (28), they are essential components in the pharmacotherapy of pain (8,13,14). Drugs that bind to opioid receptors are classified as *agonists* (e.g., morphine sulfate) if they produce analgesia. Opioids are classified as *antagonists* (e.g., naloxone hydrochloride) if they block the action of an agonist. *Agonist-antagonists* (e.g., pentazocine hydrochloride) are opioids that produce analgesia by interacting with a specific receptor (e.g., k) but also bind to other receptors (e.g., μ), where they can block the action of an agonist. *Partial-agonist opioids* (e.g., buprenorphine hydrochloride) bind to receptors and produce analgesia, but unlike morphine sulfate they exhibit a ceiling effect: Increases in doses do not parallel increases in analgesia (16).

As noted above, the WHO analgesic ladder paradigm classified opioids as “weak” or “strong” depending on their relative efficacy in relieving pain (8), although this concept of distinguishing weak and strong opioids has been challenged, and some have even advocated the elimination of the second step of the WHO analgesic ladder (29). The so-called “weak” opioids are used for less severe pain because their efficacy is limited by an increased incidence of side effects at higher doses (e.g., nausea and constipation with codeine phosphate, CNS excitation with propoxyphene). Furthermore, these weak opioids are usually formulated as a fixed oral dose mixture with a nonopioid analgesic so that their efficacy is limited also by the maximum safe daily dose of acetaminophen (4 g/day) or aspirin. By contrast, so-called “strong” opioids are used for severe pain. Opioids such as morphine sulfate, hydromorphone, fentanyl, methadone hydrochloride, and levorphanol tartrate have a relatively wide therapeutic window and no ceiling effect for analgesia-increasing doses. They produce a greater level of analgesia with a lesser likelihood for dose-limiting side effects than the weak opioids. However, as noted below, the management of side effects is critical to achieving optimal results with the administration of opioids in either class.

Codeine phosphate, the demethylated congener of morphine sulfate, is the prototype of the weak or step II opioid analgesics. Although a parenteral preparation is available, codeine phosphate is nearly always given by mouth, often in a fixed mixture with a nonopioid analgesic. A 200-mg dose is equipotent to 30 mg of morphine sulfate (30). The half-life of codeine phosphate is 2.5–3.0 hours; approximately 10% of orally administered codeine phosphate is demethylated to morphine sulfate, and free and conjugated morphine sulfate can be found in the urine. The analgesic action is thought to be related to the *in vivo* conversion to morphine sulfate (30). Constipation and nausea are the most common side effects at the usual therapeutic doses of codeine phosphate (30–60 mg every 4 hours). Codeine phosphate is useful to administer as an alternative to NSAIDs for patients with mild pain in whom the antipyretic, antiplatelet, or GI toxicity of NSAIDs contraindicate their use.

Hydrocodone bitartrate is a codeine phosphate derivative available only in combination with acetaminophen or aspirin. At the usually prescribed doses, its analgesic effect is weak and probably only slightly superior to acetaminophen alone.

Two opioids classified as weak or WHO step II analgesics, meperidine hydrochloride and propoxyphene, although widely used for the treatment of acute and chronic pain, are not generally recommended by pain clinicians.

Propoxyphene is a synthetic analgesic that is structurally related to methadone hydrochloride. It is approximately equipotent to codeine phosphate. Although its analgesic effect lasts only 3–6 hours, the plasma half-life is as long as 6–12 hours. This disparity between the relatively short analgesic duration of effect in comparison to the longer plasma half-life is similar to that of methadone hydrochloride, and patients are at significant risk for sedation and increased toxicity due to drug accumulation when it is dosed according to the analgesic duration of effect. Furthermore, propoxyphene has norpropoxyphene as its major metabolite; norpropoxyphene has a long plasma half-life of 30–36 hours and may also be responsible for some of the observed toxicity (31). Norpropoxyphene has local anesthetic effects similar to those of lidocaine and high doses may cause arrhythmias. Seizures occur more often with propoxyphene intoxication than with opiate intoxication. Naloxone hydrochloride antagonizes these toxic effects of propoxyphene (31).

Meperidine hydrochloride is an opioid agonist. The dose equianalgesic to 10 mg of parenteral morphine sulfate is 75–100 mg. The reasons for its widespread use in the treatment of pain is unclear. Although often cited as a reason to use meperidine hydrochloride in preference to morphine sulfate, the lesser rise in pressure in the common bile duct with meperidine hydrochloride administration has not been shown to be clinically advantageous (32). Furthermore, the CNS excitatory effects that appear after chronic use are well substantiated and occur as a result of the accumulation of the metabolite normeperidine, which causes multifocal myoclonus and grand mal seizures (33). The normeperidine toxicity is correlated with plasma concentration and is probably not opioid receptor-mediated because it is not reversed by naloxone hydrochloride. The half-life of meperidine hydrochloride is 3 hours. Normeperidine has a half-life of 15–30 hours and therefore accumulates with repetitive dosing of meperidine hydrochloride, particularly in patients with renal dysfunction. Meperidine hydrochloride also has an important drug interaction with monoamine oxidase inhibitors, which produces two patterns of toxicity: (a) severe respiratory depression, or (b) excitation, delirium, hyperpyrexia, and convulsions. This toxicity may lead to fatalities.

Oxycodone hydrochloride is a semisynthetic opioid. Because of its high bioavailability (>50%) after oral dosing, it is a useful opioid analgesic (33). It has a half-life of 2–3 hours and a duration of action of 4–6 hours. It is metabolized by demethylation and conjugation in the liver, in a manner similar to codeine phosphate, and is excreted in the urine (34). Part of the analgesic action is mediated by active metabolites. Traditionally, oxycodone hydrochloride has been considered a weak or WHO step II analgesic because it is most often used in a fixed combination with acetaminophen and aspirin. These combinations limit its dose to 10 mg every 4 hours. However, oxycodone hydrochloride can also be prescribed as a single-entity compound, and as such it is often used as a WHO step III or strong opioid (35,36), especially now that it is available in a sustained-release formulation. Therefore, oxycodone hydrochloride straddles the second and third steps of the WHO analgesic ladder, depending on which formulations are used. Oxycodone hydrochloride has been reported to have fewer side effects than morphine sulfate (36,37), although these studies have limitations to their interpretation because they were not done in a rigorous study design in which patients were blinded to the specific drugs being administered. Like morphine sulfate, the availability of oxycodone hydrochloride in sustained- and immediate-release formulations provides a means for the clinician to carefully titrate the dose of drug to the patient's response.

Morphine sulfate is, of course, the prototype opioid agonist. The WHO has designated morphine sulfate as the “drug of choice” for the treatment of severe pain associated with cancer (8). The half-life of morphine sulfate is approximately 2 hours, and oral immediate-release morphine sulfate preparations generally provide pain relief for 2–4 hours. Slow-release preparations that permit once- or twice-a-day regimens are safe and effective; they are generally best used after dose titration with immediate-release morphine sulfate.

Recently, morphine sulfate has been shown to have active metabolites. Morphine sulfate is metabolized in the liver, where it undergoes glucuronidation at the 3 and 6 positions. Morphine-3-glucuronide (M3G) and morphine-6-glucuronide (M6G) accumulate with chronic morphine sulfate administration (38). M6G binds to μ receptors with affinity similar to that of morphine sulfate (39). M6G appears to be 20 times more potent than morphine sulfate when administered directly into the periaqueductal gray (39), indicating that only a fraction of this water-soluble metabolite need cross the blood–brain barrier to produce an analgesic effect (38). In single-dose comparative analgesic trials, the parenteral to oral relative potency ratio for morphine was shown to be 1:6 (27). Chronic morphine sulfate dosing has been shown to produce a parenteral to oral relative potency ratio of 1:3 (40); this difference is likely due to the presence of the M6G metabolite.

Although the M3G metabolite has a negligible affinity for opioid receptors and does not produce analgesia (39), it may be responsible for some of the toxicity seen with chronic dosing of morphine sulfate, especially when relatively large doses are administered. The M3G metabolite has excitatory effects on neurons and can cause myoclonus and possibly a hyperanalgesic state (41,42), paradoxically causing increased pain. Morphine sulfate metabolites are eliminated by glomerular filtration; they accumulate in renal failure, leading to an increased incidence of side effects (43). Morphine sulfate should be used with caution in renal failure, with an increase in the

interval time between doses. Hydromorphone is another semisynthetic opioid agonist commercially available as a highly water-soluble salt. When administered parenterally, 1.5 mg of hydromorphone is equipotent to 10 mg of morphine sulfate. Its bioavailability is 30–40% when given orally, and the oral to parenteral relative potency ratio is 5:1 (44). Hydromorphone has a half-life of approximately 2 hours. Recently, a 3-0 methyl metabolite of hydromorphone has been measured, which may be responsible for analgesic effects and toxicity such as myoclonus that occurs with continuous high-dose hydromorphone administration (45). Because of its availability in a high-potency formulation (10 mg/ml) and its water solubility, hydromorphone is the drug of choice for the chronic subcutaneous route of administration (44).

Levorphanol tartrate is a synthetic potent μ opioid agonist that also binds d and k receptors (46). This k receptor binding may explain its relatively high prevalence of psychotomimetic effects (e.g., delirium, hallucinations) in comparison to other opioids when given to patients. When administered parenterally, 2 mg of levorphanol tartrate is equianalgesic to 10 mg of morphine sulfate (46). This opioid has a half-life of 12–30 hours and a duration of analgesia of 4–6 hours (47). As is the case with other opioids in which the plasma half-life exceeds the duration of analgesia, repeated administration is associated with drug accumulation. Therefore, a dose reduction may be required 2–4 days after commencement of the drug to avoid side effects from overdose. For the same reason, it is best to avoid this opioid in patients with impaired renal function or encephalopathy. Levorphanol tartrate is used as a second- or third-line drug in patients who cannot tolerate morphine sulfate, hydromorphone, or fentanyl.

Methadone hydrochloride is a synthetic μ opioid agonist with high oral bioavailability (49). When administered orally, it is rapidly absorbed from the GI tract with measurable plasma concentrations within 30 minutes after oral administration (49). When administered in single parenteral doses it is equipotent to morphine sulfate; the duration of analgesia is 4–6 hours (49).The plasma level declines in a biexponential manner, with a half-life of 2–3 hours during the initial phase and 15–60 hours during the terminal phase (50). This biexponential decline accounts for the relatively short analgesic action and the tendency for drug accumulation with repeated dosing. A reduction in dose and interval frequency is often needed during the first days of treatment to prevent side effects from overdose (51). Methadone hydrochloride is an effective second-line drug for patients who experience unrelieved pain and intolerable side effects with morphine sulfate (54,55).

Because of the large disparity between the plasma half-life and the analgesic duration of effect, dosing recommendations for methadone hydrochloride are complex. For example, it has been recommended to use a tenth of the daily morphine sulfate dose as the starting methadone hydrochloride dose, but not to exceed 100 mg, and to give this dose at intervals to be determined by the patient (but not more frequently than every 3 hours) (55). The calculated equianalgesic doses of methadone hydrochloride may be as little as 3% of the predicted dose when this opioid is administered chronically (56).

Methadone hydrochloride is an alternative to morphine sulfate in several circumstances. Because of its low cost, it is an attractive alternative to morphine sulfate. It should also be considered for the rare patient who is allergic to morphine sulfate because its very different chemical structure makes cross-sensitivity less likely than with other opioids, such as hydromorphone or oxycodone hydrochloride. The pharmacokinetics of methadone hydrochloride can be influenced by impaired renal clearance and decreased plasma protein binding. Methadone hydrochloride is excreted almost exclusively in the feces; it has been proposed as a safe and effective analgesic for patients with chronic renal failure (57).

Fentanyl is a very potent synthetic, lipophilic μ opioid agonist (58). It is 80–100 times more potent than morphine sulfate. These properties allow this opioid to be administered by the transdermal route (58). A special rate-controlling membrane provides additional control of drug release, although the kinetics of the transdermal fentanyl system can be altered by fever and obesity of the patient. The transdermal absorption of fentanyl is the same from chest, abdomen, and thigh (58). A skin reaction at the application site is found in 4% of patients (58). After application of the transdermal patch the systemic absorption is negligible for the first 4 hours, and then increases steadily from 8 to 24 hours (59). Patients reach steady-state concentrations within 12–24 hours from the application (60,61). After removal of the transdermal patch, the serum fentanyl concentration falls approximately 50% in approximately 16 hours (61). This apparently long half-life is likely due to the slow washout of fentanyl from cutaneous reservoirs and mobilization of this lipophilic drug from fat stores (61). These pharmacokinetic considerations translate clinically in a severalhour delay in the onset of analgesia after an initial application and a persistence of analgesia and eventual side effects long after removal of the transdermal system. In patients with chronic pain, it is possible to obtain relatively constant serum fentanyl concentrations comparable with continuous intravenous or subcutaneous infusions after a variable period of titration (61). More recently, the use of oral transmucosal fentanyl has been proposed for the treatment of breakthrough pain (64). Fentanyl can be formulated in a syrup-candy matrix that can be sucked. This fentanyl oral formulation can provide analgesic fentanyl blood concentrations within 5–10 minutes of active sucking, with a peak effect in 20–30 minutes and a duration ranging from 1 to 4 hours (64). Oral transmucosal fentanyl has recently been approved for the treatment of breakthrough pain, which is defined as acute transient exacerbations of pain on a baseline of otherwise controlled chronic pain (65).

Intraspinal Administration of Analgesics

Opioid analgesics can be introduced into the epidural or intrathecal space for the management of pain in selected patients with cancer pain. Small doses of opioids administered by these routes are delivered in close proximity to their receptors in the dorsal horn of the spinal cord, thus achieving high local concentrations. Because the amount of drug administered is reduced, these routes of delivery may produce good analgesia with fewer of the side effects associated with equianalgesic doses of systematically administered opioids (83). Spinally administered opioids should be considered for patients whose pain is at least partially opioid-responsive but who cannot tolerate the side effects of oral or parenteral opioids, especially if attempts at managing these side effects have been unsuccessful.

Adverse effects of spinal opioids are thought to result in part from supraspinal redistribution of drug, and include pruritus, urinary retention, nausea, vomiting, and respiratory depression (83). Respiratory depression may occur early (1–2 hours) or late (6–24 hours), but the risk of respiratory depression in patients who are not opioid-naïve is quite low. Tolerance to the analgesic effects of spinal opioids may develop rapidly in some patients, possibly limiting the usefulness of this route of administration in some individuals (83).

When a patient is considered a potential candidate for spinal opioids, an initial trial of opioid administered through a temporary epidural or intrathecal catheter is recommended. If the individual's response to spinal opioids is sufficient to warrant more prolonged therapy, the temporary catheter should be replaced with a permanent implanted catheter to reduce the risks of infection and catheter migration (84). A number of implanted drug delivery systems are available for both epidural and intrathecal administration of opioids. The opioid may be delivered by intermittent bolus or by continuous infusion; the two methods are equally efficacious (85). Catheter placement is associated with a low but definite risk of epidural infection. Nevertheless, long-term epidural analgesia is safe and effective when patients are monitored carefully and receive prompt treatment if signs of infection develop (86). When spinal opioids are considered for the treatment of back pain in the cancer patient, magnetic resonance imaging of the spine should ideally precede placement of an epidural catheter. This precaution avoids the potential for unexpected neurological deterioration from injection in the presence of epidural tumor (83). Coadministration of local anesthetics such as bupivacaine hydrochloride (0.025% concentration) with opioids into the epidural space may also enhance analgesia in selected cases and may be useful when opioid tolerance develops (86).

Practical Clinical Guidelines for Opioid Use

The onset, peak, and duration of analgesia vary with the opioid drug, the route of administration, and the particular patient. The recognition of this variability allows the appropriate choice of drug, route, and scheduling. When switching from one opioid to another, one-half of the calculated equianalgesic dose is recommended as the initial dose for titration (1,8,13,14).

Oral administration is recommended in most patients because it is convenient, well tolerated, and usually the least expensive method (8,14). However, transdermal administration of fentanyl has the advantage of convenience and long duration of action, and may improve patient compliance by deemphasizing the need to take something by mouth on a regular basis. However, most patients who take transdermal fentanyl require an oral or transmucosal rescue dose for breakthrough pain. All opioids should be titrated to effect, with intravenous boluses repeated every 15 minutes if necessary, until either analgesia or intolerable side effects develop, and oral doses of an immediate release morphine sulfate or oxycodone hydrochloride preparation as often as every 1–2 hours as need. The concomitant use of NSAIDS, antiemetics, and other coanalgesics is often warranted (8,14).

When pain is continuous, as is often the case, medications should be administered on an around-the-clock basis (8,14,16). Administering medications on an asneeded (p.r.n.) basis often results in the patient experiencing multiple episodes of pain during the day, and so is generally undesirable. However, p.r.n. administration is highly desirable for the first 24–48 hours after initiation of opioid therapy to determine the 24-hour dose requirement. If patients are started on an around-the-clock regimen and the starting dose is too high, unnecessary sedation and other side effects may occur, thereby reinforcing negative attitudes about taking opioids on the part of the patient. Once the optimum 24-hour dose is determined, the opioid should be prescribed by the clock. Many patients continue to experience “breakthrough pain,” or transitory increases in pain above its baseline level (65). For such pain, p.r.n. “rescue dose” of a shortacting opioid should be available, starting at 10–20% of the total scheduled daily dose.

There is enormous inter-individual variation in the dose that is necessary to provide adequate analgesia, even among patients with similar pain syndromes. The variability in opioid responsiveness is caused by pharmacokinetic and pharmacodynamic factors (66). Genetic factors such as race and gender have also been shown to be important in determining opioid responsiveness (67). For example, 15% of whites lack the oxidative phosphorylative enzyme CYPD211 needed to metabolize codeine phosphate to morphine sulfate *in vivo* and thereby require higher doses of codeine phosphate than do patients with normal metabolism (67). Kaiko et al. (68) noted that black and Asian patients participating in single-dose clinical trials to determine opioid efficacy reported twice the analgesic effect as whites in a retrospective analysis of the variations in opioid responsiveness. In another important recent study, Levine et al. (69) demonstrated that women achieved greater analgesia than men

when administered k opioid agonist drugs.

Patients on chronic opioid therapy often require relatively large dose increments to control acute exacerbations of pain. An infusion pump with a device for self-administration of extra doses of medication every few minutes (patient-controlled analgesia, PCA) should be used, if available (70). The PCA dose can be as high as the hourly rate during the titration phase and when incident pain is a concern. The continuous basal rate should be frequently adjusted based on the patient's report and the PCA usage. When venous access is problematic the subcutaneous route should be used. Once the acute pain exacerbation is controlled the medication should be changed to the oral or transdermal route. Long-term intravenous and subcutaneous opioid administration can be used in patients outside of the hospital; intravenous administration is only possible when long-term access is obtained through a central venous line (71,72).

Management of Side Effects of Opioid Analgesics

Constipation is the most common adverse effect of opiates. Tolerance to the constipating effects does not usually develop. Opioids cause constipation by a variety of mechanisms: decreased gastric, biliary, pancreatic, and intestinal secretions, and a decrease in the propulsive motility of stomach and intestine resulting in delayed passage of increasingly viscous stool. Central and peripheral opioid receptor mechanisms are implicated (73). A prophylactic laxative regimen must be instituted at the same time the opioid is started and maintained for the duration of opioid therapy.

Nausea and vomiting related to opioid administration is thought to be caused by direct stimulation of the chemoreceptor trigger zone for emesis in the area postrema of the medulla (31). Nausea can also be caused by an increased vestibular sensitivity or delayed gastric emptying. A vestibular component is suggested by the fact that nausea is uncommon in recumbent patients but occurs in 40% of ambulatory patients after 15 mg of parenteral morphine sulfate (31). It is still unclear whether these effects involve specific opioid receptors because it has not been established as to whether they are reversed by naloxone hydrochloride (31). Tolerance to this effect is the rule, and generally the nausea subsides in 2–3 days. M6G may be implicated in some patients with protracted nausea (74). Inadequately treated constipation can be a cause of persistent nausea.

Transient sedation is very common when opioid therapy is initiated (75). Opiate-induced sedation must be differentiated from the predictable deep sleep that follows pain relief in sleep-deprived patients. Excessive sedation is frequently seen when patients are given relatively large doses of opioids to relieve movement-related pain. Large doses of opioids have the effect of producing plasma concentrations of opioids that are too high since the patient is having minimal to no pain at rest. Strategies for managing sedation include eliminating all other (unnecessary) CNS depressant drugs, switching opioid drugs, increasing the caffeine content in the diet, and using potent psychostimulants such as dextroamphetamine or methylphenidate hydrochloride (see section Adjuvant Analgesic Drugs to Counteract Opioid-Induced Side Effects).

Unfounded fears of respiratory depression are often cited as a reason to limit opioid therapy. Respiratory depression is mediated by μ_2 opioid receptors in the brainstem, rendering the respiratory centers less responsive to the stimulatory effect of arterial carbon dioxide tension (31). Fortunately, tolerance to the respiratory depressant effect of opioids develops rapidly, and uncontrolled pain is a natural antagonist of opiate-induced respiratory depression. Respiratory depression is always associated with sedation. When a life-threatening opiate overdose is suspected, the patient should be stimulated vigorously to awaken. If this does not reverse sedation and hypoventilation, naloxone hydrochloride, an opiate antagonist, should be given intravenously. Patients on chronic opioids are more sensitive to naloxone hydrochloride than patients relatively naive to opioid administration; therefore it is recommended that a dilute naloxone hydrochloride solution should be used in this setting (14). The 0.4-mg ampule of naloxone hydrochloride can be diluted in 10 ml of normal saline and injected slowly, with titration bringing the dose to effect; this careful titration prevents the precipitation of severe withdrawal symptoms and return of pain. Naloxone hydrochloride has a half-life of only 1 hour (35) and a short duration of action; therefore, close monitoring and repeated injections might be needed in the event of a morphine sulfate overdose. Prolonged monitoring is required with opiates with a longer half-life, like methadone hydrochloride, propoxyphene, and levorphanol tartrate. It must be kept in mind that excessive drug intake is a rare cause of encephalopathy and respiratory depression in patients with cancer on a stable dosage of opiates. In fact, one study has indicated that the majority of naloxone hydrochloride administrations in a large cancer center were inappropriate (76) and could have been avoided if more care were taken to determine the true cause of sedation or if the patient were simply physically stimulated.

Other relatively uncommon opioid side effects are listed in Table 3-4. It should be noted that long-term effects of chronic opiate use on intellectual function have not been demonstrated, although acute transient cognitive effects can be seen when opioid doses are increased (77). Opioids do not mask pain from new or ongoing tissue injury, and fears of masking medical emergencies like “acute abdomen” and myocardial infarction with opioids are unfounded.

Common side effects	Uncommon side effects
Constipation	Respiratory depression
Nausea	Seizures
Sedation	Pruritus
Mental clouding	Xerostomia
	Myoclonus

TABLE 3-4. SIDE EFFECTS OF OPIOID ANALGESICS

Tolerance, Physical Dependence, and Psychological Dependence

Tolerance, which implies the need to continuously increase the dose to obtain the desired effect, is a complex and incompletely understood phenomenon. However, the overwhelming clinical experience with patients on chronic opioids indicates that when the pain is stable, tolerance to the analgesic effects of opiates does not generally develop at the rate that would be predicted by animal studies (78). When rapid escalation of the opioid dose in cancer patients is required, this almost always means that the pain stimulus has increased in relation to progressive disease associated with new or ongoing tissue injury (78). However, because tolerance to the different opioid effects develops at different rates (e.g., rapidly for respiratory depression, slower for analgesic effects, very slow if at all for constipating effects), it is usually possible to titrate the opioid doses to appropriately balance analgesia and side effects. Cross-tolerance among different opiates is incomplete, indicating that analgesia might develop when switching to a different strong opiate at an equianalgesic dose, but side effects may develop as well (78). Therefore, a 50% dose reduction of the calculated equianalgesic dose and a gradual upward titration are recommended. It has been observed that true pharmacological tolerance is seen when, in the setting of an unchanging pain stimulus, the duration of analgesia shortens (78).

Physical dependence is an altered physiologic state, produced by repeated administrations of a drug, which necessitates the continued administration of the drug to prevent the appearance of withdrawal symptoms that are characteristic for the particular drug (31). When opiates are abruptly discontinued, often in error, the withdrawal syndrome consists of lacrimation, rhinorrhea, restlessness, and tremors; these symptoms are usually mild and don't have the dramatic flavor of the withdrawal syndrome seen in the chemically dependent patient. Patients who have received repeated doses of morphine sulfate daily for 1 or 2 weeks have mild and often unrecognized withdrawal symptomatology when the drug is stopped; symptoms are delayed and even less pronounced with opioids with a long half-life like methadone hydrochloride and levorphanol tartrate. However, if an opioid antagonist is administered, symptoms of withdrawal may appear after a single dose (31). Appropriate counseling and a gradual taper of the opiate over a few days effectively prevents the development of a withdrawal syndrome. The inappropriate administration of naloxone hydrochloride may precipitate profound withdrawal in patients taking chronic opioids for pain relief.

Psychological dependence—now the preferred term for addiction—is described as compulsive drug-seeking behavior and overwhelming involvement in drug procurement and use (31). The inexperienced clinician may misinterpret the behavior of the patient with severe unrelieved pain for drug-seeking behavior because poorly managed pain may produce many of the behaviors that physicians have come to fear in “addicted” individuals. This phenomenon is recognized by the term *pseudoaddiction* (79). The rarity of psychological dependence after chronic opioid treatment has been clearly documented in several studies and reviewed in detail (80). For example, in a study involving 11,882 patients who received at least one opioid prescription, the development of addiction occurred in only four instances (81). The analysis of patterns of drug intake in patients with cancer suggests that chemical dependence does not occur in this population, or occurs only very rarely (82). An exception to this rule is offered by patients with a history of chemical dependence that antedates the cancer. Exaggerated and unfounded fears of addiction should not prevent patients from receiving opioids on a chronic basis for severe pain.

Adjuvant Analgesics in Cancer Pain Management

The adjuvant analgesics are a heterogeneous group of drugs that were marketed and approved for indications other than pain, but that may be analgesic in certain clinical conditions or counteract adverse effects of conventional opioid and nonopioid analgesics (87). As indicated in Table 3-5, adjuvant analgesics can be grouped into three broad categories: (a) general purpose drugs (e.g., tricyclic antidepressants); (b) drugs used in specific pain syndromes such as neuropathic, bone, or visceral pain (e.g., anticonvulsants for neuropathic pain, radiopharmaceuticals for bone and visceral pain); and (c) drugs used to counteract opioid analgesic side effects (e.g., caffeine, methylphenidate hydrochloride, phenothiazine antiemetics). Adjuvant analgesic drugs usually require severalweek trials to determine their usefulness and often do not provide complete analgesia. Patients should be educated as to these facts so as to make their compliance more likely.

TABLE 3-5. ADJUVANT ANALGESIC DRUGS USED TO TREAT CANCER-RELATED PAIN

General Purpose Adjuvant Analgesics

These drugs are used for a variety of pains, including those of musculoskeletal, neuropathic, and visceral origin, as well as chronic headache. The tricyclic antidepressants are the most widely used in this group. They probably produce analgesia by increasing levels of norepinephrine or serotonin in the CNS and thus may enhance the activity of endogenous pain-modulating pathways (88). Amitriptyline hydrochloride, imipramine hydrochloride, nortriptyline hydrochloride, and desipramine hydrochloride have all been demonstrated to have some analgesic efficacy (89) in chronic pain, especially pain of neuropathic origin. The doses required to produce analgesia are generally lower and the analgesic effect quicker (typical onset within 1 week) in comparison to antidepressant effects.

The selective serotonin reuptake inhibitors, although attended by fewer side effects than the tricyclic antidepressants, have a mixed picture as analgesics. For example, one randomized, controlled trial using fluoxetine hydrochloride in diabetic neuropathy could not demonstrate an analgesic effect in nondepressed patients, although at least some analgesic effect has been demonstrated for paroxetine hydrochloride in the management of painful diabetic neuropathy (90).

In general, one should start with relatively low doses of tricyclic antidepressants (especially in elderly patients) and increase the dose every 3 days. For example, a typical regimen for amitriptyline hydrochloride calls for starting at 10 mg at bedtime, increasing to 25 mg in 3 days, then increasing by 25 mg every 3–7 days until a dose of 75–150 mg is reached. Sequential trials of different tricyclics should be considered, especially selection of drugs in the secondary amine family (e.g., desipramine hydrochloride or nortriptyline hydrochloride) if the tertiary amine drugs such as amitriptyline hydrochloride are not tolerated because of adverse effects. For this reason, some clinicians prefer initiating tricyclic antidepressant therapy with desipramine hydrochloride or nortriptyline hydrochloride. The selective serotonin reuptake inhibitors are generally used as second- or third-line agents because the data supporting their efficacy in neuropathic pain are not as strong as those regarding the tricyclic antidepressant family.

Methotrimeprazine is a phenothiazine compound that has analgesic activities. Analgesic studies have confirmed that 15 mg of methotrimeprazine given intramuscularly is equipotent to 10 mg of morphine sulfate given intramuscularly (91). This drug is most useful in the setting of hospitalized patients with opioid-induced ileus because it can provide an opioid-sparing analgesic effect. The side effect profile is the same as for other phenothiazines, and orthostatic hypotension and sedation can be dose-limiting effects. Other limitations to its use are its relative expense and the fact that it is not available in an oral formulation in the United States. The parenteral formulation has been used orally by mixing in juice and drinking.

Corticosteroids may enhance analgesia in a variety of situations, including metastatic bone pain, pain related to nerve compression, and pain from epidural spinal cord compression (92). The response to corticosteroids may be rapid and dramatic. Because of the potential for serious adverse effects with prolonged use, corticosteroids are best reserved for patients with advanced disease or for short-term use.

Marijuana has attracted renewed attention as an analgesic, antiemetic, antiglaucoma agent, and appetite stimulant. When smoked, the marijuana delivers over 60 cannabinoid compounds with known or potential pharmacological activity, although the D-9 tetrahydrocannabinoid (D-9 THC) metabolite is the most pharmacologically active (93). This compound, D-9 THC, is also available as 2.5-mg dronabinol capsules. A controlled trial of dronabinol in doses of 2.5 mg twice daily (b.i.d.) compared to placebo demonstrated effectiveness in increasing appetite, improving mood, and decreasing nausea in patients with acquired immunodeficiency syndrome-related anorexia and weight loss (94).

The data regarding the efficacy of D-9 THC as an analgesic are less clear. A controlled trial comparing 10- and 20-mg oral doses to placebo and to oral doses of codeine phosphate at 30 and 60 mg in patients with cancer pain demonstrated that only the 20-mg dose could be distinguished from placebo, although dysphoria and delirium were quite prominent at this dose (95). There are no studies of the analgesic effect of smoked marijuana, although there are anecdotal reports of the use of inhaled marijuana as an analgesic (96). In summary, the existing data are unclear as to whether inhaled marijuana or D-9 THC has any advantage over existing analgesics in terms of analgesic efficacy or side effect profile.

Adjuvant Analgesic Drugs Used for Bone Pain

A more complete list of drugs useful for metastatic bone pain is given in Table 3-5. It has been shown that bisphosphonate compounds inhibit the reabsorption of bone and reduce bone pain in lytic bone metastasis, such as is typical of breast cancer (97). Table 3-5 lists the usual dosage schedule for pamidronate disodium, perhaps the most widely used bisphosphonate currently. A recent randomized, controlled trial in which pamidronate disodium was used in patients with stage IV breast cancer showed that this drug reduced further skeletal complications in this disease and significantly reduced bone pain when compared to placebo controls.

Adjuvant Analgesics Used in Neuropathic Pain

Many types of pharmacological agents have been used to manage neuropathic pain, including tricyclic antidepressants, anticonvulsants, systemic local anesthetic agents, topical anesthetic creams, capsaicin, baclofen, and clonidine. Doses of these drugs and their general indications are listed in Table 3-5. In addition, two old drugs, ketamine and dextromethorphan hydrobromide, are being reevaluated in neuropathic pain because of their ability to inhibit N-methyl-D-aspartate (NMDA) receptors, which have recently been shown to be important in neuropathic pain states (98).

Anticonvulsant drugs generally are used to manage pain refractory to conventional analgesic drugs and as first-line agents to treat lancinating pain of neuropathic origin (99). Current estimates indicate that approximately 5% of anticonvulsant drug prescriptions are written for neuropathic pain. Generally, these drugs are given in the dose ranges usually administered to treat epilepsy. Gabapentin, a g-aminobutyric acid analog, is a relatively new anticonvulsant that has received recent attention for its use in pain, particularly pain associated with neuropathic pain, sympathetically maintained pain, or other complex regional pain syndromes (100). This drug is relatively free of side effects, although drowsiness, dizzi- ness, and ataxia have been associated as dose-related effects.

Systematically administered local anesthetics may have a role in the management of neuropathic pain. Intravenous lidocaine is usually given as a 2–5 mg/kg dose over 20–30 minutes. Most clinicians do the infusion while monitoring blood pressure and heart rate in a monitored environment. Intravenous lidocaine often provides dramatic relief of neuropathic pain (101); however, the analgesic effect is usually short-lived, although it may persist well beyond the duration of the infusion (101). The efficacy of intravenous lidocaine in the management of cancer-related neuropathic pain has not been established definitively because a placebo-controlled trial could not demonstrate a difference between lidocaine and the inactive treatment (102). Mexiletine hydrochloride, an oral analog of lidocaine, may be administered to patients

in doses of 150–600 mg/day (102).

Baclofen is a g-aminobutyric acid agonist that has been used in many neuropathic pain syndromes, most notably trigeminal neuralgia, in which it is used in combination with carbamazepine when this condition is refractory to carbamazepine alone (103). There is a wide range of effective oral doses, staring at 5 mg b.i.d. up to 150 mg/day.

Epidural clonidine may be effective in selected patients with cancer pain, particularly for neuropathic pain. In one study, 85 cancer patients were titrated to pain relief on epidural morphine sulfate and then randomized to receive epidural clonidine (30 mg/hour) or placebo, with either group receiving epidural morphine sulfate rescue doses as needed. Analgesia was reestablished in 45% of the epidural clonidine group, but only 21% of the placebo group, and was more likely to occur when a neuropathic pain mechanism was the predominant pain (104). Hypotension occurred as a serious complication in only two patients on epidural clonidine.

As already mentioned, activation of the NMDA receptor by endogenous ligands, such as the excitatory amino acids, glutamate, and aspartate, promotes pain and hyperalgesia after experimental peripheral nerve injury, and blockade of this receptor by drugs such as dextromethorphan hydrobromide relieves pain (105). Ketamine and dextromethorphan hydrobromide are competitive NMDA receptor antagonists and produce analgesia in neuropathic pain (98). Ketamine blocks NMDA receptors and produces analgesia in doses much lower than those needed to produce anesthesia, and is typically given by continuous infusion at 0.1–1.5 mg/kg/hour. The infusion can be repeated as needed. Dextromethorphan hydrobromide is an antitussive and is present in many cough syrup formulations. It also can be given as a single entity in a slow-release preparation known as Delsym, in doses ranging from 15 mg to 500 mg b.i.d. Better controlled trials of these agents are required to determine the ultimate usefulness of ketamine and dextromethorphan hydrobromide as NMDA receptor blockers in neuropathic pain. Side effects common to these agents include sedation (ketamine and dextromethorphan hydrobromide) and delirium (ketamine).

Adjuvant Analgesics Used for Visceral Pain

Several drugs useful for visceral pain are listed in Table 3-5. Octreotide acetate, a synthetic analog of somatostatin, can be given intrathecally to produce analgesia but has also been administered as a subcutaneous infusion to manage nausea, vomiting, and diarrhea associated with malignant bowel obstruction (106).

Adjuvant Analgesic Drugs to Counteract

Opioid-Induced Side Effects Psychostimulants such as caffeine (107), methylphenidate hydrochloride, pemoline, and dextroamphetamine also have a place in cancer pain treatment (Table 3-5). Methylphenidate hydrochloride has been shown to enhance the analgesic effect of opioid drugs and to decrease the sedation associated with opioid use (108).

SUMMARY

Currently available pain management techniques make adequate pain control a realistic and achievable goal for virtually all patients with cancer. A thorough evaluation of the pain complaint to establish a pain diagnosis is the key to successful management. Special attention should be paid to those pain syndromes potentially responsive to primary antineoplastic treatment so that such treatment can be initiated in a timely manner when appropriate.

Individualized pharmacotherapy is the cornerstone of cancer pain management, and usually requires the use of opioid analgesics, often in combination with nonopioid analgesics and adjuvant medications. Opioids should be administered on a scheduled basis with the dose titrated to achieve a balance between pain control and adverse side effects. The risk of addiction in the cancer patient with pain is negligible and should not discourage the appropriate use of this highly effective class of analgesics.

In a minority of patients, cancer pain cannot be adequately controlled by systematically administered analgesics, often because of intractable dose-limiting side effects. For these patients, interventional approaches should be considered, including either anesthetic or neurosurgical procedures. Appropriate patient selection is critical to maximizing the success of these procedures. Optimal pain management in the patient with cancer requires individualization of treatment and the integration of pain management approaches.

Many factors affect the pain experience, including physical, psychosocial, and emotional influences. Conversely, uncontrolled pain may have a disastrous impact on all aspects of patient function and quality of life. Adequate pain management, ideally in a multidisciplinary setting, should therefore be viewed as a high priority for all patients with cancer.

NONOPIOID AND ADJUVANT ANALGESICS

DAVID J. WALLENSTEIN
RUSSELL K. PORTENOY

Analgesic drugs can be divided into three categories: opioid, nonopioid, and adjuvant analgesics. The term nonopioid analgesic is conventionally applied to acetaminophen (paracetamol), all of the nonsteroidal anti-inflammatory drugs (NSAIDs), and several other compounds, such as dipyrone. The term *adjuvant analgesic* refers to any drug that has a primary indication other than pain, but is known to be analgesic in specific circumstances.

NONOPIOID ANALGESICS

The NSAIDs constitute a very diverse group of drugs (Table 4-1), all of which inhibit the enzyme cyclooxygenase and thereby reduce the synthesis of prostaglandins. As recommended in the “analgesic ladder” approach to the management of cancer pain (1), these drugs may be used alone for mild to moderate pain, or may be combined with opioid and adjuvant analgesics during the treatment of more severe pain.

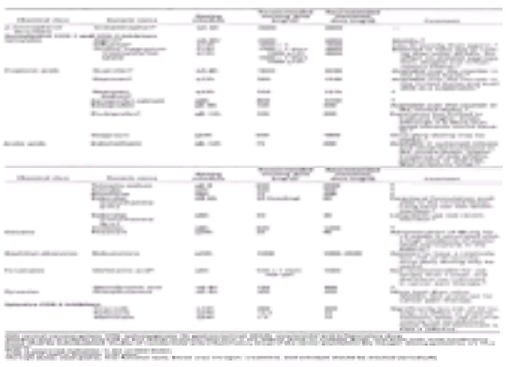

TABLE 4-1. NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

Clinical Pharmacology of Nonsteroidal Anti-Inflammatory Drugs

Cyclooxygenase has two isoforms: the constitutive variety known as *cyclooxygenase-1* (COX-1) and an inducible variety known as *cyclooxygenase-2* (COX-2)(2,3). COX-1 is involved in the normal physiology of the stomach, kidney, platelets, and, presumably, other organs and tissues as well. Although COX-2 appears to be constitutive in limited tissues (e.g., brain and kidney), it is largely produced in response to injury and, as such, is a key element in the inflammatory cascade.

As a result of this pharmacology, it has been recognized for some time that preferential inhibition of COX-2 might lead to a relatively improved toxicity profile without loss of anti-inflammatory or analgesic effects (4). As expected, studies of selective COX-2 inhibitors have provided strong evidence of a relatively reduced risk of gastrointestinal toxicity and no effect on platelet function (5,6). There is, however, no evidence of improved renal toxicity from these drugs.

At the present time, the selective COX-2 inhibitors include celecoxib, rofecoxib, valdecoxib, and meloxicam (at lower doses). Other compounds are in development and are likely to enter the marketplace. All other NSAIDs are nonselective inhibitors of both COX-1 and COX-2. There are, however, very large differences in the degree to which these drugs inhibit the two isoforms, and to some extent, these differences may account for the variation in risk of gastrointestinal toxicity identified in epidemiological surveys (7).

All NSAIDs are both analgesic and anti-inflammatory. In contrast to acetaminophen (paracetamol), the mechanism of which presumably involves inhibition of COX in the central nervous system, NSAIDs inhibit both central and peripheral COX (8). The central effects of the NSAIDs presumably account for some of the observed disparity between the anti-inflammatory and analgesic potencies of some of the drugs in this class (9).

The NSAIDs produce dosedependent analgesic effects, and have dose–response relationships characterized by a minimal effective dose and a ceiling dose for analgesia. Doses higher than the ceiling do not provide additional analgesia, but appear to increase the risk of toxicity. There is large individual variation in the minimal effective dose, toxic dose, ceiling dose, and the recommended therapeutic doses for each drug. Because the recommended doses have been extrapolated from dose-ranging studies in relatively healthy populations, they should be viewed as broad guidelines rather than as absolute requirements, particularly in the medically ill and the elderly. To enhance the safety of long-term NSAID therapy, dose escalation from a relatively low initial dose is appropriate.

There is great variability in response to NSAIDs. Although there are few empirical data, clinical observations suggest that these drugs have relatively better efficacy in pain related to bone injury and inflammatory processes, and relatively poorer efficacy in neuropathic pain. Notwithstanding, there is no evidence that some types of pain are wholly unresponsive to these drugs.

There is also large intraindividual variability in the response to the different NSAIDs. Although the reason for this is not understood, it suggests the potential utility of sequential trials in those who do not respond initially to treatment.

NSAIDs have well-defined toxicities. The most important risk of the nonselective COX inhibitors is gastroduodenopathy, which affects approximately 10% of patients treated overall; ulcers occur in approximately 2% (10). As noted, this risk is substantially reduced, but not eliminated, during treatment with the COX-2 selective drugs (4–6). Nausea and abdominal pain are poor predictors of serious NSAID-related toxicity. As many as two-thirds of patients being treated with NSAIDS experience no symptoms before hemorrhage or perforation. Among the factors that have been associated with an increased risk of ulceration are advanced age, the use of higher NSAID doses, concomitant administration of a corticosteroid, and a history of either ulcer disease or previous gastrointestinal complications from NSAIDs (10,11). Heavy alcohol or cigarette consumption may also increase risk. The bacterium *Helicobacter pylori* also has been implicated as a factor in NSAID-related gastropathy

(12).

The risk of NSAID-induced ulcer disease can be reduced by coadministration of other drugs (13). For example, misoprostol, a prostaglandin analog, reduces the incidence of NSAID-induced gastric ulcers without reversing anti-inflammatory and analgesic effects (14). The cost of long-term therapy, as well as its tendency to produce diarrhea and abdominal bloating, limit the use of this drug. Several studies have confirmed that coadministration of a proton pump inhibitor, such as omeprazole, can reduce the risk of NSAID-induced gastric and duodenal ulcers (15), and although studies of H_2 blockers have not been uniformly favorable, there is evidence that these drugs can also be beneficial. One such study indicates that higher-dose (40 mg per day), but not lower-dose, famotidine is effective (16), suggesting that the dose of these drugs may need to be relatively high to reduce the risk of NSAID-induced ulcer formation.

Other agents, such as antacids and sucralfate, have never been shown to reduce NSAID risk. These therapies can be used to blunt disturbing symptoms, such as pyrosis, but should not be coadministered for ulcer prophylaxis unless patients are not candidates for therapy with misoprostol, a proton pump inhibitor, or an H_2 inhibitor.

Acetaminophen (paracetamol) and the NSAIDs, including the selective COX-2 inhibitors, can cause serious renal toxicity. These drugs must therefore be used cautiously in patients who have clinically evident renal disease, or who are likely to have subclinical disease as a result of advanced age, prior nephrotoxic therapy (e.g., platinum-based chemotherapy), or underlying disease (e.g., diabetes or sickle cell disease) known to place the microcirculation at risk of compromise. NSAIDs also are associated with fluid overload, which may occur in the absence of renal insufficiency and contribute to edema or other major complications such as congestive heart failure (17).

NSAID-induced inhibition of platelet aggregation may cause a clinically significant bleeding diathesis. A single dose of aspirin irreversibly alters exposed platelets and can double the bleeding time for up to 1 week. The effect of other NSAIDs on platelet function is reversible, and these drugs prolong bleeding time only when circulating in the plasma. Acetaminophen and the selective COX-2 inhibitors do not affect bleeding time. The nonacetylated salicylates, such as choline magnesium trisalicylate and salsalate, are believed to have minimal platelet effects and also presumably pose less risk.

A secondary analysis of a controlled trial of rofecoxib raised concern about excess risk of cardiovascular events associated with selective COX-2 inhibition (18). However, a combined analysis of controlled trials has not confirmed this risk (19), and suggests instead that the difference in cardiac events between those treated with the COX-2 selective and the nonselective COX inhibitors is more likely due to a relatively reduced risk among the latter group.

Patients occasionally develop dizziness, confusion, or headache during NSAID therapy. Headache appears to be relatively more frequent during treatment with indomethacin than with other NSAIDs. Dizziness and confusion appear to be more common in the elderly, and patients rarely develop a delirium after NSAID treatment.

Nonsteroidal Anti-Inflammatory Drug Administration

In the medically frail, the need to avoid a gastrointestinal complication may be sufficient to justify the first-line use of a relatively selective COX-2 inhibitor, such as celecoxib, rofecoxib, or meloxicam. If the costs of these drugs are prohibitive or they are unavailable, the use of a relatively safe nonselective NSAID, perhaps combined with a gastroprotective drug, may be appropriate. Although pharmacoeconomic modeling suggests that COX-2 selective drugs may be relatively cost beneficial, particularly in the medically ill (19), further empirical studies are needed to confirm this. Indeed, there have been no clinical trials of the COX-2 selective inhibitors in the medically ill, and the degree to which the use of these drugs improves outcomes remains speculative.

Regardless of the drug selected, it is prudent in those with serious medical illness to consider initiating NSAID therapy at a relatively low dose and then to gradually increase the dose based on response. In patients who are less frail, conventional starting doses can be used as initial therapy. Those with acute, relatively severe pain should be considered for an initial loading dose of 1–2 times the conventional starting dose.

If dose titration is attempted, patients must be carefully monitored between dose changes. Although several weeks may be needed to produce maximal effects, the likelihood of benefit from a dose change can usually be judged within 1–2 weeks. The occurrence of increased analgesia after a dose change suggests that the patient is below the ceiling dose for the drug. If analgesia is not adequate in this setting, the dose can be increased further unless side effects occur or the dose has reached the conventionally accepted maximum. This maximum dose is usually 1–2 times the recommended starting dose. If a dose increment does not yield greater analgesia, the ceiling dose presumably has been reached and further dose increases are not justified. If a satisfactory balance between analgesia and side effects cannot be attained at a dose below the maximal safe dose, the drug should be discontinued, and an alternative NSAID should be considered.

Long-term NSAID therapy usually should be accompanied by regular monitoring for common adverse effects. This may include screening for occult fecal blood and tracking hemoglobin, renal function, and hepatic function. Patients who are predisposed to adverse effects and those who are receiving relatively high doses should be monitored every few months; others may be monitored less frequently.

ADJUVANT ANALGESICS

The term “adjuvant analgesic” can apply to numerous drugs in a variety of classes (Table 4-2) (20). In populations with serious medical illness, these medications usually are considered after opioid therapy has been optimized. This conventional practice derives from the observation that opioid drugs generally are more reliable and have a more predictable side effect profile. Although first-line use of an adjuvant analgesic sometimes is pursued when patients have a marked predisposition to opioid toxicity, or a type of pain that experience suggests may be relatively more responsive to the adjuvant (e.g., first-line treatment of lancinating neuralgias with an anticonvulsant), these occurrences are relatively uncommon in the medically ill. Typically, the adjuvant analgesics are administered to those patients whose pain has responded poorly to optimal opioid therapy.

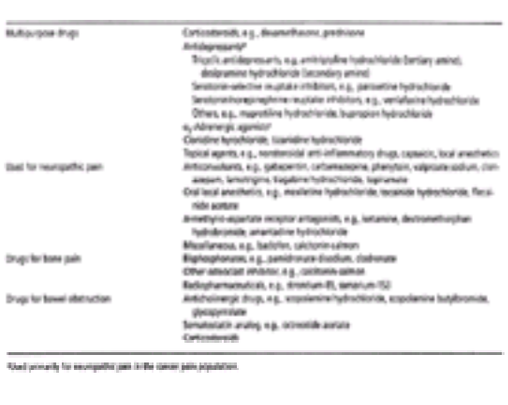

TABLE 4-2. ADJUVANT ANALGESICS

To administer an adjuvant analgesic appropriately, the clinician should be familiar with the approved indications, unapproved indications accepted in medical practice, likely side effects, potential serious adverse reactions, usual time–action relationship, pharmacokinetics, and specific dosing guidelines for pain. Very few of the adjuvant analgesics have been studied in the medically ill, and the information used to develop dosing guidelines usually is extrapolated from other patient populations. The existence of large inter-individual and intraindividual variability in the response to all adjuvant analgesics suggests that sequential therapeutic trials often are needed to identify the most useful drug. A patient's response to other drugs, including those in the same class, does not reliably predict the outcome of a therapeutic trial.

Some classes of adjuvant analgesics have been studied in a variety of pain syndromes and are best considered multipurpose analgesics. These include the corticosteroids, the antidepressants, the a_2-adrenergic agonists, and a variety of topical therapies. With the exception of the corticosteroids, however, this designation as multipurpose analgesics has limited resonance in the medically ill because of the widespread use of opioid therapy. Although the antidepressants, the a_2-adrenergic agonists, and topical therapies potentially could be used for all types of pain, they are typically administered to those who have not responded adequately to opioid therapy. Of the latter group, patients with refractory neuropathic pain usually are the targets for therapeutic trials with these agents.

CORTICOSTEROIDS

In the cancer population, corticosteroids have been shown to improve pain and appetite, diminish nausea and malaise, and increase patients' overall quality of life (21,22 and 23). They are commonly used to treat refractory neuropathic pain, bone pain, pain associated with capsular expansion or duct obstruction, pain from ascites or bowel obstruction, pain caused by lymphedema, and headache caused by increased intracranial pressure (21,23,24,25 and 27). Although the data suggest a relatively high likelihood of favorable outcomes during treatment with these drugs, most studies are uncontrolled, and there has been no evaluation of drug-selective differences, dose–response relationships, predictors of efficacy, or the durability of favorable effects.

The analgesic effects of corticosteroids likely result from a variety of mechanisms. They are anti-inflammatory and may reduce mass effect caused by edema or inhibit the release of inflammatory mediators that sensitize or activate primary afferent nerves. They also may have direct actions on injured neurons (28). If positive mood effects occur, these may augment analgesic effects, as well as increase a sense of well-being.

The risk of adverse effects associated with corticosteroid therapy increases with both the dose and duration of therapy. Long-term administration is usually considered only for patients with advanced disease whose limited life expectancy and overriding need for symptom control justify the risk. In this context, surveys of low-dose corticosteroid therapy indicate that the risk of serious adverse effects is low (24,26). The most common adverse effects are oral candidiasis and myopathy. Potential serious adverse effects include increased risk of infection, diabetes, fluid overload (ranging from peripheral edema to congestive heart failure), cushingoid habitus, increased risk of skin breakdown, and neuropsychiatric syndromes (ranging from mild dysphoria or mental clouding to severe anxiety, depression, or even psychosis).

Most corticosteroid therapy involves long-term administration of relatively low doses. This may involve treatment with prednisone (5–10 mg) or dexamethasone (1–2 mg) once or twice daily. Treatment is continued as long as potential benefits appear to outweigh adverse effects. Dose escalation for worsening symptoms is appropriate if benefits decline with progressive disease, particularly at the end of life.

Another approach to corticosteroid therapy is appropriate for selected patients with severe pain. The usual setting is characterized by rapidly worsening pain related to nerve injury, bony lesion, or duct obstruction that has failed to respond promptly to an opioid. The regimen often begins with dexamethasone, 100 mg intravenously, followed by 96 mg daily in four divided doses. The dose is gradually tapered over weeks as an alternative analgesic approach is implemented, such as radiation therapy or neural blockade.

ADJUVANT ANALGESICS USED FOR NEUROPATHIC PAIN

Many adjuvant analgesics are primarily used in medically ill populations for the treatment of neuropathic pain that has not responded adequately to opioid therapy. Drug selection usually reflects the clinician's best judgment about the risks associated with the therapy, the likelihood of analgesia, and the possibility of secondary beneficial effects on symptoms other than pain.

Neuropathic pain is perhaps the most common target of adjuvant analgesic therapy. At the present time, gabapentin is the most common adjuvant analgesic used for neuropathic pain. This drug is an anticonvulsant with an obscure primary mechanism of action and proven efficacy in different neuropathic pain syndromes (29,30 and 31). Favorable effects and good tolerability have been demonstrated in a series of patients with cancer-related neuropathic pain (32). It has an acceptable adverse effect profile, is not metabolized in the liver, and has no known drug-drug interactions. Treatment usually starts with 100–300 mg per day, and dose titration usually continues until benefit occurs, side effects supervene, or the total daily dose is at least 3600 mg per day. The rate of titration is usually determined by the severity of the pain and the development of side effects. Dose increments can occur daily or every other day, or be instituted much more gradually. The dose at which response occurs is highly variable. Some patients respond favorably (or conversely, develop treatment-limiting side effects) at 600 mg per day in divided doses, whereas others do not reach a maximal response until the dose is increased to 6000 mg per day or higher.

Numerous other drugs may be effective for neuropathic pain. Patients who have not responded well to gabapentin, or lack access to this drug, are usually offered an antidepressant, an alternative anticonvulsant, or a corticosteroid. Other drug classes are tried in refractory cases.

Antidepressants

The analgesic efficacy of antidepressant medications has been well established (31,33). This analgesia is believed to result from their actions on endogenous monoaminergic pain-modulating systems, particularly those that use norepinephrine or serotonin. Although the positive mood effects of these agents may be beneficial, they are not required for analgesic efficacy. As noted, the broad range of pain syndromes that may respond and the analgesic response of patients without mood disorders suggest that these drugs could be categorized as multipurpose analgesics. Unfortunately, there are almost no controlled trials in populations with serious medical illness.

There is an extensive body of evidence-based data supporting the analgesic efficacy of the tricyclic antidepressants (TCAs) (31,33,34,35,36 and 37). Both the tertiary amine TCAs, such as amitriptyline hydrochloride, doxepin hydrochloride, imipramine hydrochloride, and clomipramine hydrochloride, and the secondary amine compounds, such as desipramine hydrochloride and nortriptyline hydrochloride, are analgesic. The evidence is strongest for amitriptyline hydrochloride.

In contrast to the TCAs, there are very few controlled trials of the selective serotonin reuptake inhibitors (SSRIs) or the selective serotonin and norepinephrine reuptake inhibitors. There are also few trials of other nontricyclic compounds, such as maprotiline hydrochloride or bupropion hydrochloride. There is evidence to support the analgesic effects of some of these drugs, such as the SSRI paroxetine hydrochloride (38), maprotiline hydrochloride (39), and bupropion hydrochloride (40). Anecdotal reports of some of the others, such as venlafaxine hydrochloride, also have been favorable. There are very few comparative trials of the antidepressants. Those extant have generally indicated that the tertiary tricyclic drugs are the most likely to yield analgesia (36).

The available evidence suggests that the antidepressant drugs can relieve both continuous and paroxysmal neuropathic pains (35,36). Extensive clinical experience supports greater utility in continuous pain. At this time, therefore, the usual practice is to consider other categories of adjuvant analgesics first for lancinating or paroxysmal neuropathic pains (see the section Anticonvulsants and Related Drugs)

On the basis of the available evidence, it is reasonable to select a TCA first if pain is the target symptom. As noted, amitriptyline is the best studied TCA, but the anticholinergic, sedative, or hypotensive effects of this drug may relatively contraindicate it in the medically ill. If so, a trial with a secondary amine TCA, desipramine hydrochloride or nortriptyline hydrochloride, is appropriate given the better side effect profile of this class. If the tricyclics are not tolerated, a trial of an SSRI (e.g., paroxetine hydrochloride) or one of the other established analgesics should be considered.

It is prudent to initiate antidepressant therapy at relatively low doses, regardless of the drug class. The TCAs are most safely begun at 10–25 mg at night. The dose should be increased every few days by the size of the starting dose. Studies of the TCAs indicate that analgesic effects usually occur within 4 to 7 days after achieving an effective daily dose, which is typically in the range of 50–150 mg for amitriptyline hydrochloride and desipramine hydrochloride. Doses should be increased further if neither analgesia nor intolerable side effects occur, or if pain is complicated by depression.

Although there are no data correlating specific plasma drug concentrations with effective analgesia, measurement of TCA plasma drug concentration can be a useful therapeutic guide. If adherence to therapy is good, a relatively low concentration (compared to the reference antidepressant range) suggests poor absorption or rapid metabolism of the drug. In the absence of side effects, such a finding warrants dose escalation regardless of the administered dose. Conversely, dose escalation usually is not attempted if the plasma concentration equals or exceeds the upper limit of the range for antidepressant efficacy. Monitoring of the TCAs with an electrocardiogram is also prudent as higher doses are reached, given the association between these drugs and atrioventricular conduction disorders.

An antidepressant should be discontinued if unsatisfactory side effects occur despite appropriate dose escalation. After a few weeks of treatment, it is prudent to taper the dose gradually before treatment is terminated to reduce the risk of withdrawal phenomena, such as insomnia or mood change.

Similar to antidepressant effects, the analgesic effects produced by the different antidepressant drugs can vary remarkably in the individual patient. This observation is true even among drugs in the same subclass, such as the tertiary tricyclic compounds. As a result, the failure of one antidepressant drug does not portend the failure of others, and patients should be considered for other antidepressant trials if treatment is not beneficial.

Anticonvulsants and Related Drugs

Numerous anticonvulsant drugs other than gabapentin have been evaluated as treatments for neuropathic pain (31,41,42). Based on several decades of clinical experience, the commercial success of gabapentin, and a slowly growing evidence base, these drugs are now often considered first for neuropathic pain that is

paroxysmal or lancinating in quality, and, along with the antidepressants, are among the first-line treatments for neuropathic pains of other types.

Many of the older anticonvulsant drugs have longstanding use in pain management. These include carbamazepine, phenytoin, divalproex sodium, and clonazepam (41,42). Clinical experience is most extensive with carbamazepine, but this drug's utility may be lessened by its potential to produce bone marrow suppression, particularly leukopenia. Phenytoin and divalproex sodium can be initiated with loading doses, which may be favorable in the setting of very severe pain. Clonazepam, a benzodiazepine, has anxiolytic and hypnotic effects that may address other problems in the medically ill.

All of the newer anticonvulsants, including lamotrigine, topiramate, tiagabine hydrochloride, oxcarbazepine, pregabalin, zonisamide, and levetiracetam, are used empirically in the treatment of refractory neuropathic pain. The evidence of analgesic efficacy is strongest for lamotrigine (43). However, this drug requires a relatively slow initial dose titration period to reduce the likelihood of cutaneous hypersensitivity, which may limit its utility among those with advanced illness. A trial of felbamate should be considered only in extreme cases because of its potential for life-threatening aplastic anemia.

All anticonvulsants are administered using the dosing schedules typically employed for seizures. Plasma concentrations of carbamazepine, phenytoin, and valproate sodium can be monitored to ensure that maximum anticonvulsant doses have been reached if pain relief does not occur with routine dose escalation.

Like other adjuvant analgesics, anticonvulsant agents are characterized by large interindividual and intraindividual variability in analgesic responses. Sequential trials may be necessary to identify the most useful agent.

Several nonanticonvulsants also have been evaluated in patients with paroxysmal neuropathic pain, and historically have been considered together with the anticonvulsants for this reason. Both the gamma-aminobutyric acid agonist baclofen (44) and the neuroleptic pimozide (45) have been shown to be effective in treating trigeminal neuralgia. Whereas the side effect profile of pimozide has limited its applications, baclofen has attained widespread acceptance as a useful drug for all types of neuropathic pain. It has not been studied in syndromes other than trigeminal neuralgia, however, and has not been specifically evaluated in populations with serious illness. Nonetheless, the favorable anecdotal experience suggests that a trial may be considered for patients with any type of neuropathic pain. The therapeutic dose appears to vary widely, ranging from 30 mg to more than 200 mg/d. Gradual dose escalation from a low initial dose reduces the risk of side effects. Serious withdrawal phenomena can occur after abrupt discontinuation of this drug, and tapering of the dose is necessary if treatment has been in place for more than a few days.

Oral Local Anesthetics

Systemic administration of local anesthetics may produce analgesia in a variety of pain syndromes, including neuropathic pain. In controlled clinical trials, these drugs have been shown to be effective in treating both continuous and paroxysmal pains (46,47). Brief intravenous local anesthetic infusions also are analgesic (48).

There is limited experience in the use of these drugs for neuropathic pain in the medically ill (49). Accordingly, they are generally considered second-line analgesic agents for neuropathic pains that have not responded to one or more trials of the anticonvulsant and antidepressant analgesics.

In the United States, mexiletine hydrochloride has been the most frequently used oral local anesthetic for the treatment of pain. This preference is not based on comparative trials with other local anesthetics, such as tocainide hydrochloride or flecainide acetate. The latter drugs are also used for this indication, and regional preferences based on anecdotal experience appear to determine the drug selected. Mexiletine hydrochloride may have a relatively wider therapeutic index and the decreased incidence of cardiac and neurological toxicity, and this may justify its use in the medically ill.

All the local anesthetics are sodium channel blockers and can cause clinically significant cardiac dysrhythmias. These drugs should be used cautiously in patients with cardiac disease (previous myocardial infarction, symptomatic coronary artery disease, or dysrhythmia), and the electrocardiogram should be monitored as doses are increased.

Although the mexiletine hydrochloride plasma concentration–response relationship has not been defined in terms of analgesia, measurement of the plasma level can be informative in a manner similar to drug concentration monitoring during a TCA trial. Gastrointestinal toxicity (usually nausea) and central nervous system side effects (usually dizziness) often are dose limiting, and may require a change to an alternative therapy.

Brief intravenous local anesthetic infusion can produce pain relief that outlasts the period of measurable drug concentration by a prolonged period. Some patients who have not been responsive to oral therapy appear to respond to infusions, although this is anecdotal. More important, an intravenous local anesthetic infusion may be a useful approach to rapidly manage severe, opioid-unresponsive neuropathic pain. Although there are very limited data suggesting that the response to a brief infusion predicts the effects of oral local anesthetic therapy (50), the use of infusion to guide decisions about oral therapy is not yet justified.

The largest clinical experience with local anesthetic infusions involves lidocaine. This drug is usually administered at a dose range of 2–5 mg/kg over 20–30 minutes. This dose range has not been systematically evaluated in the medically ill, and safety considerations warrant a relatively low initial dose. Given empirical data that indicate dose-dependent effects and a possible “threshold” dose (51,52), the decision to initiate therapy with a modest lidocaine dose should be accompanied by a willingness to repeat the infusion one or more times at progressively higher doses, if neither beneficial effects nor side effects occur.

Topical Therapies

Topical analgesic therapies can benefit medically ill patients with chronic pain by providing pain relief that complements a systemic analgesic regimen with limited risk of additional systemic side effects. The role of topical therapies in pain management is evolving as clinical trials and anecdotal experience expands (53).

Topical local anesthetics have been used empirically for all types of neuropathic pain. Additionally, these formulations may have a role to play in the treatment of pains sustained by injury to skin or subcutaneous tissues.

Cutaneous anesthesia can be produced by topical application of local anesthetics, such as EMLA (*e*utectic *m*ixture of *l*ocal *a*nesthetics) (54) or high-concentration lidocaine (55). EMLA is the only commercially available topical local anesthetic formulation that can produce dense cutaneous anesthesia. Although this phenomenon may offer a theoretical advantage, cutaneous anesthesia may not be needed to yield analgesic effects in patients with neuropathic pain, and alternative local anesthetic creams or gels may be useful.

A lidocaine-impregnated patch has been developed and is approved in the United States for the treatment of postherpetic neuralgia (56). This formulation has been well accepted by patients and is now used for all types of neuropathic pain (57).

Comparative trials of the various topical local anesthetics have not been performed. Given the cost of EMLA, it is reasonable to consider a trial of this formulation after an initial trial of the lidocaine patch or a 5% lidocaine cream. The patch has been approved with instructions to apply it 12 hours per day. Anecdotal experience suggests that some patients have a better outcome with 24-hour administration. The dosing method and frequency for creams and gels are empiric. If simple application is not effective, an effort should be made to apply these formulations under an occlusive dressing.

There is substantial evidence that topical NSAIDs can be effective for soft tissue pain and perhaps joint pain (58). A trial of a formulation containing diclofenac, ketoprofen, or another NSAID is reasonable when pain is related to chronic soft tissue injury. Although there is no evidence that these formulations are useful for neuropathic pain, an NSAID is sometimes added to a compounded multidrug formulation for refractory cases, based on anecdotal experience.

Patients with neuropathic pain resulting from peripheral nerve injury can also be considered for a trial of topical capsaicin, a compound that depletes peptides in small primary afferent neurons, including those that mediate nociceptive transmission (e.g., substance P). Although efficacy in treating neuropathic pain has been suggested in both open-label and controlled studies (59,60 and 61), clinical experience has been mixed. A therapeutic trial of the high-concentration formulation (0.075%) is reasonable in patients with neuropathic pain presumed to have a strong peripheral input. An adequate trial is generally believed to require three to four applications daily for 3–4 weeks. Some patients experience burning, which may disappear over time or remit with the use of an oral analgesic, cutaneous application of lidocaine 5% ointment, or use of the lowerconcentration formulation (0.05%).

There is limited evidence that topical capsaicin may be effective for painful arthropathy affecting small joints (62). An empirical trial for this type of pain may be implemented like those for neuropathic pain. Capsaicin dissolved in a lozenge also has been suggested as a novel approach to pain related to mucositis (63). This observation has yet to be confirmed.

Other drugs are now being used topically, most with limited proof of efficacy. A trial of a TCA, such as doxepin hydrochloride, gains support from a controlled clinical trial in neuropathic pain (64). There are favorable anecdotal reports of topical opioids for pain associated with a variety of lesions (65,66). The effectiveness of this

approach remains to be confirmed. A variety of other drugs have been compounded and tried empirically as topical therapy, including ketamine and gabapentin. There have been limited favorable anecdotal observations, and further studies of these approaches are needed.

a_2-Adrenergic Agonists

The a_2-adrenergic agonists, including clonidine hydrochloride and tizanidine hydrochloride, have established analgesic efficacy in a variety of pain syndromes (67,68). Like the antidepressants, these drugs are nonspecific analgesics typically used as adjuvant analgesics for neuropathic pain in populations with serious medical illness.

The efficacy of clonidine hydrochloride in neuropathic pain has been suggested by controlled trials of transdermally administered drug in patients with painful diabetic neuropathy (67) and a controlled study of epidurally administered clonidine hydrochloride in cancer pain (69). The transdermal trial demonstrated that only approximately one-fourth of patients report any significant analgesic effect. The epidural trial revealed relatively better efficacy for neuropathic pain than pain of other types. Although tizanidine hydrochloride relieves experimental neuropathic pain in animal models (70), and anecdotal experience has been favorable, there have been no controlled trials in clinical neuropathic pain.

A systemic trial of an a_2-adrenergic agonist for neuropathic pain is usually considered after trials of other adjuvant analgesics have failed. There have been no comparative trials, and drug selection is empirical. The most common side effects of the a_2-adrenergic agonists are somnolence and xerostomia, and the most serious risk is hypotension. Tizanidine hydrochloride may be less likely to produce a change in blood pressure, and for this reason, may be preferred in populations with serious medical illness. Regardless of the drug, treatment typically begins with a very low dose, which is followed by gradual dose escalation until analgesia occurs or treatmentlimiting toxicity supervenes.

N-Methyl-D-Aspartate-Receptor Antagonists

Preclinical studies during the last decade have established that binding of the excitatory amino acid glutamate at various subunits of the N-methyl-D-aspartate (NMDA) receptor is involved in the mechanisms that may underlie some neuropathic pains and the mechanisms involved with the development of opioid tolerance (71,72). On the basis of these findings, NMDA-receptor antagonists have undergone intensive investigation as potential analgesics. Results have been mixed, but the hope remains that drugs that interact with this receptor will become useful in the treatment of refractory pain.

Three NMDA antagonists are commercially available in the United States: the dissociative anesthetic ketamine, the antitussive dextromethorphan hydrobromide, and the antiviral amantadine hydrochloride. Intravenous and oral ketamine has been shown to be analgesic in both controlled trials and case reports (73,74,74,75,76 and 77). The side effect profile of this drug, which includes mental clouding, mood changes, nightmares, and delirium, is troublesome, and its relatively narrow therapeutic window suggests that future use is likely to be limited. It has been administered in cases of severe refractory pain, either as an infusion at subanesthetic doses or orally. The infusion typically is initiated at a dose as low as 0.1–1.5 mg/kg/h, then gradually increased. Coadministration of a benzodiazepine or neuroleptic may be used to reduce the likelihood of adverse effects.

In a controlled trial, dextromethorphan hydrobromide was analgesic for the pain of diabetic neuropathy but not postherpetic neuralgia (78). This effect was associated with a relatively high mean dose of approximately 350 mg/d. Other controlled studies suggest that a 1:1 combination of dextromethorphan hydrobromide and morphine sulfate increases the analgesic effects produced by the morphine sulfate alone (79). The difference in potency suggested in these studies may relate to the effect of tolerance reversal in contributing to the analgesia produced when the drug is added to an opioid regimen. Although these studies together suggest that dextromethorphan hydrobromide may be a useful analgesic or coanalgesic, clinical experience continues to be very limited, and the utility of the drug in practice remains ill defined. A trial of dextromethorphan hydrobromide may be initiated using a commercially available antitussive that contains neither alcohol nor guaifenesin. The starting dose, which can be as high as 120–240 mg/d in three to four divided doses, can be increased gradually. Doses higher than 1 g have been administered safely, at least for the short term.

A single dose controlled trial of amantadine hydrochloride demonstrated that this drug can have analgesic effects in cancer-related neuropathic pain (80). Additional experience with chronic administration is needed to determine whether the drug can play a role in medically ill patients with opioid-refractory pain.

Magnesium also interacts with the NMDA receptor. Increased local concentration of this ion inhibits the receptor in a manner similar to competitive antagonists (81). There have been some anecdotal observations suggesting that magnesium infusion may be useful in chronic opioid unresponsive neuropathic pain (82). Further evaluation of this observation is warranted.

Neuroleptics

As described previously, pimozide may be analgesic in patients with lancinating or paroxysmal pains (45). Other neuroleptics, such as fluphenazine and haloperidol, have been administered for other types of neuropathic pain. The supporting data are very meager, however, and given the potential for side effects, the use of these drugs is best limited to the treatment of delirium. Although methotrimeprazine, a phenothiazine neuroleptic, has established analgesic effects and did at one time play a role in analgesic management at the end of life, it is no longer commercially available in the United States. There is no evidence at this time that any of the newer atypical neuroleptics have analgesic effects.

Benzodiazepines

The anticonvulsant clonazepam often is used to treat paroxysmal neuropathic pains. Although a survey of patients with mixed types of cancer-related neuropathic pains suggested that alprazolam also may have analgesic effects (83), the use of this drug is still focused on the management of anxiety. Patients with pain commonly experience both anxiety and muscle spasms, phenomena that may exacerbate the intensity of pain and respond well to benzodiazepines, such as diazepam. It may be useful, therefore, to try a benzodiazepine if these comorbidities are noted, even if the primary goal of treatment is pain control.

Calcitonin-Salmon

Two controlled trials, one in patients with reflex sympathetic dystrophy (84) and the other in patients with acute phantom pain (85), have suggested that calcitoninsalmon may be effective in neuropathic pain. Its mechanism of action in these conditions is not understood, and additional trials are needed to confirm benefit. Nonetheless, the favorable side effect profile of this drug and the convenience of the available intranasal formulation may justify a therapeutic trial in patients with refractory neuropathic pain. The usual starting dose is 200 IU/d, which may be increased several times to clarify the pain response.

DRUGS FOR COMPLEX REGIONAL PAIN SYNDROME

Complex regional pain syndrome (type I, also known as *reflex sympathetic dystrophy*, and type II, also known as *causalgia*) is a subtype of neuropathic pain characterized by regional pain, swelling, and other signs of autonomic dysregulation (86). A clinical diagnosis, it is presumably a set of disorders that ultimately will be distinguished by variation in pathophysiology. An important subtype is sustained by sympathetic efferent function (so-called sympathetically maintained pain), and the potential for pain relief from sympathetic nerve block usually indicates an early trial of this approach.

Complex regional pain syndrome can occur in the medically ill (87), and when it is suspected, sympathetic nerve block is usually considered. Some patients are too ill to undergo this procedure and many receive no benefit (complex regional pain syndrome without sympathetically maintained pain). For these patients, drug therapy becomes the usual mainstay approach. Those who do not respond adequately to an opioid may be offered any of the drugs used for neuropathic pain, as described. Additionally, some drugs have been used specifically for this diagnosis (88). There is some evidence from controlled trials that calcitonin-salmon, corticosteroids, and bisphosphonates may be effective (88,89). Other drugs are tried based on anecdotal observations. Trials of sympatholytic drugs, including peripheral a-antagonists (e.g., phenoxy-benzamine hydrochloride and prazocin hydrochloride), central a-agonists (e.g., clonidine hydrochloride), and B-antagonists (e.g., propranolol hydrochloride) may be considered for patients who cannot undergo neural blockade. Other patients may be offered trials of a calcium channel blocker (e.g., nifedipine) again based on anecdotal observations.

Adjuvant Analgesics for Bone Pain

Malignant bone pain may respond adequately to therapy with an opioid, or an opioid in combination with an NSAID or a corticosteroid. Radiation therapy is usually considered when bone pain is focal and responds poorly to opioid therapy, or is associated with impending pathological fracture. Multifocal bone pain that responds poorly to an opioid trial may benefit from treatment with an adjuvant analgesic. These drugs include bisphosphonate compounds, calcitoninsalmon, gallium nitrate, and

bone-seeking radionuclides.

There have been no comparative trials of these adjuvant analgesics for bone pain. Based on the abundance of supporting evidence, the benefit to nonpainful skeletal comorbidities (e.g., fracture rate), and convenience, the bisphosphonates are generally preferred as the first-line approach. There is strong evidence that certain bisphosphonates, including pamidronate disodium and clodronate, can be analgesic, reduce fracture rate, and improve quality of life (90,91,92 and 93). Pamidronate is available in the United States and usually is administered via brief infusion at a biweekly dose of 60 mg or a monthly dose of 90 mg. Side effects are usually mild and consist of flu-like symptoms and injection site reactions (94); the oral drugs are associated with esophagitis, which can be treatment limiting. Newer bisphosphonates are in development and will further increase the convenience and safety of this approach. The cost of these drugs is relatively high, and although the cost benefit may be favorable given their effectiveness in reducing skeletal comorbidities, further studies of the pharmacoeconomic aspects of bisphosphonate therapy is warranted (95).

The data supporting the use of calcitonin-salmon (96,97 and 98) and gallium nitrate (99) are very limited. Experience with calcitonin-salmon may warrant a trial in patients with refractory multifocal bone pain. Evidence is much better for the bone-seeking radiopharmaceuticals, strontium-89 and samarium-153 (100,101). These drugs should be considered for patients with refractory multifocal pain caused by osteoblastic lesions or lesions with an osteoblastic component. Samarium-153 allows imaging with bone scintigraphy during treatment for bone pain. Patients who receive these drugs should have life expectancies greater than 3 months, adequate bone marrow reserve, and no further planned therapy with myelosuppressive chemotherapy. Patients with a platelet count below 60,000 or a white blood cell count below 2400 generally should not be treated. The onset of effect is often slow (2 weeks or longer), and peak effects may not be attained for more than 1 month. Some patients experience a flare of pain before analgesic effects occur. The chief adverse effect is bone marrow suppression, with thrombocytopenia that may be irreversible. Patients who tolerate the therapy but experience a return of pain can undergo repeated administration.

Adjuvant Analgesics for Bowel Obstruction

Patients with malignant bowel obstruction who are not candidates for surgical decompression require intensive palliative interventions to reduce pain and other obstructive symptoms, including distention, nausea, and vomiting. Evidence-based guidelines have begun to clarify the role of nasogastric suctioning, venting gastrostomy, and pharmacotherapy for symptoms in populations with advanced cancer (102).

Although controlled trials with symptom end points are very limited, there is wide acceptance of a role for cortico-steroids, anticholinergic drugs, and somatostatin analog (e.g., octreotide acetate) in the treatment of bowel obstruction (102,103,104,105 and 106). The optimal use of these drugs may minimize the number of patients who must be considered for chronic drainage using nasogastric or percutaneous catheters.

Corticosteroid therapy may relieve obstruction in some cases, or merely reduce symptoms (107,108). The specifics of the treatment, including the drug and the dosing regimen, are currently empiric. Dexamethasone is commonly used and treatment typically involves a low-dose regimen, or a modest loading dose followed by a low-dose regimen. One case series, for example, described the use of dexamethasone in a dose range of 8–60 mg/d (106).

Anticholinergic drugs presumably relieve the symptoms of bowel obstruction by reducing motility and intraluminal secretions (109,110). Scopolamine hydrochloride or scopolamine butylbromide, hyoscyamine, and glycopyrrolate have all been used in practice. The use of a quarternary compound, such as scopolamine butylbromide or glycopyrrolate, is likely to reduce the potential for centrally mediated side effects from this approach. Dosing with each of these drugs is empirical. Low initial doses are usually titrated cautiously until benefit occurs or patients begin to report uncomfortable side effects.

Patients with refractory pain from bowel obstruction may also be considered for a trial of the somatostatin analog octreotide acetate. This drug inhibits the secretion of gastric, pancreatic, and intestinal secretions, and reduces gastrointestinal motility. Like the anticholinergic drugs, the use of this compound in the symptomatic treatment of bowel obstruction is now supported by case series and small, randomized trials (102,109,110). In practice, treatment has been implemented by repetitive subcutaneous dosing or by continuous subcutaneous infusion. Doses must be titrated to effect and typically begin at approximately 0.3 mg/d.

CONCLUSION

Translational research has yielded numerous advances in the pharmacotherapy of pain during the past three decades. Although opioid therapy continues to be the mainstay approach for the management of moderate or severe pain in patients with serious illness, the outcome of opioid therapy is not uniformly favorable and clinicians must understand a range of alternative analgesic strategies. The appropriate use of nonopioid and adjuvant analgesics represents one such strategy, which may have particular benefit in those populations with neuropathic pain, bone pain, or pain associated with bowel obstruction. Clinical research is needed to further establish the analgesic effects of the many new drugs that are now being used empirically. Comparative trials are needed to provide guidance on the selection of specific therapies in future.

NONPHARMACOLOGIC MANAGEMENT OF PAIN

KAREN LESLIE SYRJALA
SARI ROTH-ROEMER

Progress has been made in the pharmacological treatment of cancer pain in the past decade. Yet many cancer patients continue to receive inadequate pain care, despite increased awareness of the public, extensive physician and nurse training, guidelines, regulations, and increased use of opioids by oncologists (1,2,3,4,5 and 6). Even carefully implemented clinical trials or specialist consultations indicate that pharmacological or invasive treatments do not eliminate all cancer-related pain, but rather make it manageable for most patients (4,7). Other explanations for less than complete pain relief include entirely nonmedical reasons: reluctance of patients to take prescribed medications because of fears of side effects or addiction, reluctance of patients to discuss their pain, inadequate assessment, inadequate knowledge of patients about what is appropriate to discuss and treat, myths that disrupt communication between patients and health care providers, and real-world limitations such as cost or accessibility of medications (8,9 and 10).

As the vast majority of patients are treated in ambulatory clinics, their adherence to treatment cannot be assumed. They leave appointments to return home and treat themselves, or not. Because patient factors can entirely undo an optimal treatment plan and some pain usually remains unrelieved even with the best treatment, knowledge of nonpharmacologic approaches is required not only for specialists, but for all clinicians who treat patients with cancer pain.

Although pain experts recognize that barriers to management of pain exist and that nonpharmacologic methods can be as effective as more invasive treatments in some circumstances, there is little to guide the clinician in how to practically integrate these methods into the day-to-day demands of a busy medical practice. The basic question becomes not *should* we use nonpharmacologic techniques, but rather *how* can we use them to our patients' best advantage within the realistic parameters of today's health care.

In this chapter, we review nonpharmacologic methods all clinicians need to integrate into their practice of cancer pain management. We focus particularly on simple, yet effective, communication and education methods that can be used in any medical practice by any professional treating a cancer patient with pain. We then add brief information on physical methods of pain relief and more specialized cognitive-behavioral approaches used by psychologists and other behavioral medicine specialists. Additional information on assessment, rehabilitation, physical, music and art therapy, and complementary and alternative treatments can be found in Chapter 1,Chapter 2,Chapter 4, Chapter 70, Chapter 72 and Chapter 73.

BACKGROUND

As everyone working in oncology recognizes, cancer patients have all types of pain, from brief but repeated procedures, to time-limited surgical-, chemotherapy-, or irradiation-induced pains, and for many patients the addition of progressively worsening disease-related pain. Within this diversity, it is not surprising that different strategies are needed for different types and durations of pain. Moreover, patients who experience different pains, usually accompanied by other symptoms, can be expected to have thoughts, feelings, and behavioral reactions to both experienced sensations and the anticipation of further discomforts. Although standard pharmacological approaches primarily treat the existing sensory component of pain, nonpharmacologic approaches can treat all the dimensions of pain including sensory, cognitive, affective, and functional. In this context these strategies also offer patients a method for taking more control of their experience and for moderating fearful anticipation of treatments or increased pain that can in turn escalate their pain experience (11,12).

Nonpharmacologic approaches rarely replace pharmacological or invasive treatments; rather they are an essential component of any adequate treatment. Nonpharmacologic strategies become tools to assist the clinician in addressing stumbling blocks that impede care, or these methods can provide options for improved patient comfort with no side effects.

One caveat to selecting nonpharmacologic treatments is that they generally require patients to be active participants in their care. Most methods are based on verbal communications that require patients to have some motivation, to sustain attention, and to provide some feedback. All non-pharmacologic methods work best when they are used early in treatment as a part of a comprehensive treatment plan, not after everything else has failed and patients are worn out and distracted by severe pain. When employed early in care, nonpharmacologic approaches can optimize the effectiveness of all other medical treatments.

These strategies are intended for use with any patient who is experiencing discomfort. Because we know that psychological factors are influential, but not causal in the maintenance of cancer pain symptoms (11,13), we know that most patients can benefit from these strategies, not only those patients in psychological distress or those who have psychiatric diagnoses (14,15). Of course, those patients who are in continuous, severe, disease-related pain need aggressive medical treatment before use of nonpharmacologic methods (5). Similarly, patients with delirium or severe psychiatric disruption in their functioning will need additional care beyond the methods discussed here.

ADHERENCE TO MEDICAL TREATMENT

Lack of adherence to treatment is recognized as threatening the health and even survival of patients, and analgesics are included as an area of major concern for unsafe treatment (16,17). From 1983 to 1993 all-cause outpatient deaths from medication errors increased more than 800% while the number of outpatient medical visits increased 75% (16). In spite of the attention recently to medical errors, adherence to cancer pain treatment by well-intentioned patients and physicians is an under-recognized problem. Although cancer patient adherence may be nearly complete with chemotherapy, pain treatment is rarely so well defined. Most patients are given relatively loose parameters for medications, leaving them free to adjust dosing as needed. Patients act on their own beliefs or their families' beliefs; they adjust doses, skip doses, and simply stop taking a medication because they do not like a side effect. Increasingly patients do not even fill prescriptions because costs are not covered by insurance. Physicians usually do not hear about this unless they specifically ask about cost coverage or actual medication behaviors of patients. Conversely patients may take too much medication simply because they do not remember to stop one drug when another is started. We commonly see patients on multiple nonsteroidal antiinflammatory drugs or opioids, without a clear idea of what the medications are for. Adherence data indicate that about 40% of cancer patients do not take their pain medications as prescribed (18). The same data indicate that adherence is a significant factor in level of pain; better adherence improves pain relief.

Although extensive discussion has taken place regarding the need for increased training of physicians, nurses and pharmacists, far less effort has been directed toward under-standing patient and family training needs. The literature on adherence makes it clear just how difficult this area is to assess, much less to intervene. When patients' beliefs do not fit what we tell them to do, they often will not argue or even ask questions, but will nod their heads and then proceed to act on their beliefs or concerns (18,19).

When asked why they do not ask more questions, patients say, “I don't really know what to ask,” or “There are so many possible questions that I don't know where to start or which ones are important.” Furthermore, as with all of us, when we think we know an answer, we don't ask the question. Along the lines of the classic “We don't

know what we don't know," patients have said: "I know they save morphine until you're dying," or "I know morphine is addicting." The physician will never hear a question from these patients who think they already know. Unless clinicians ask directly, they will not know that these thoughts are on a patient's mind, but the patient will do whatever he or she can not to take morphine.

The past decade of research has clearly established the importance of beliefs in influencing pain treatment behavior, the difficulty patients have in knowing what to ask their physicians or nurses, and the strong resistance patients have to taking more pills, especially pills that cause side effects. These factors have led us to conclude that we, as clinicians, must take more initiative in raising those concerns that we know are important in determining patient outcomes.

COMMUNICATION INTERVENTIONS FOR ALL CLINICIANS

Communication is the most basic intervention used in patient care. At a time when illness-related concerns become the focus of patient and family thinking, communications with the medical staff are given enormous significance. Words and behaviors are repeated, over-interpreted, and scrutinized for underlying messages. Families use medical team words as a primary source to define their unspoken and spoken rules, beliefs, and behaviors (20). Research has demonstrated that effective communication between physician and patient can lead to improved health outcomes (21). Nurses and physicians routinely convey information, they listen, they reassure patients and family members, and they actively educate patients about both the pain and potential treatments. Each of these interactions can enhance patients' beliefs in their ability to cope with the symptoms they have, can foster adherence to the medical plan, or conversely, can escalate patient fear or helplessness, often without signaling the medical team that this is happening.

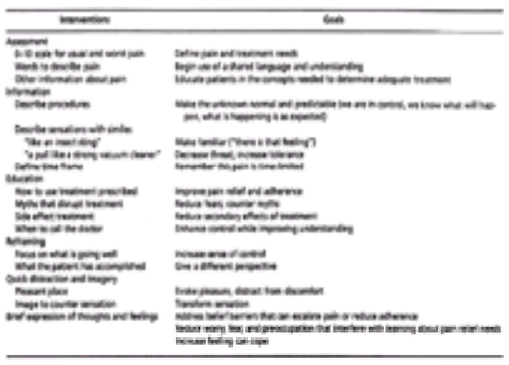
Patients turn the words of the medical team into internal "cognitions" or thoughts which either increase fear or provide reassurance when they have pain or other unfamiliar experiences. When medical team members are aware of the types of communication they are providing, they can positively influence these cognitions. When they remain unaware of the importance of their words, an opportunity can be lost or a valuable tool can be unintentionally misused. One of the contributions clinicians can make to the long-term mental health of patients and their families is to model, by example, the acceptability of talking about and planning for pain management, disease progression, and death.

Standard Practice Tools

In order to provide comprehensive pain management, the following communication tools should be understood by all clinicians:

- Assessment of pain and concurrent symptoms
- Provision of information
- Interactive methods of education
- Reframing within standard care
- Quick distraction and imagery for unpredictable or procedure pain
- Brief expression of thoughts and feelings

Table 5-1 lists examples and intentions of these methods. All clinicians can use these in everyday practice. Their use may take a few extra minutes at first, but will save extensive time and distress required by patients who misunderstand, resist necessary care, or require more time and more visits from symptoms that are uncontrolled. Used with awareness, these strategies can be strikingly effective in making care easier while helping patients manage their pain.



Interventions	Goals
Assessment	
0–10 scale for usual and worst pain	Define pain and treatment needs
Words to describe pain	Begin use of a shared language and understanding
Other information about pain	Educate patients in the concepts needed to determine adequate treatment
Information	
Describe procedures	Make the unknown normal and predictable (we are in control, we know what will happen, what is happening is as expected)
Describe sensations with similes	
"like an insect sting"	Make familiar ("there is that feeling")
"a pull like a strong vacuum cleaner"	Decrease threat, increase tolerance
Define time frame	Remember this pain is time-limited
Education	
How to use treatment prescribed	Improve pain relief and adherence
Myths that disrupt treatment	Reduce fears, counter myths
Side effect treatment	Reduce secondary effects of treatment
When to call the doctor	Enhance control while improving understanding
Reframing	
Focus on what is going well	Increase sense of control
What the patient has accomplished	Give a different perspective
Quick distraction and imagery	
Pleasant place	Evoke pleasure, distract from discomfort
Image to counter sensation	Transform sensation
Brief expression of thoughts and feelings	Address belief barriers that can escalate pain or reduce adherence Reduce worry, fear, and preoccupation that interfere with learning about pain relief needs Increase feeling can cope

TABLE 5-1. COMMUNICATION INTERVENTIONS USED BY ALL CLINICIANS

Assessment Provides a Shared Language for Patients and Clinicians

Pain assessment is the cornerstone of both pharmacological and nonpharmacologic intervention. Inadequate assessment is the first step toward inadequate treatment (9,22). Adequate assessment is an essential step to effective treatment and to facilitating patient adherence. Proper pain assessment begins the process of communication that determines medical treatment, and also begins to teach patients how to think about and report their pain. By asking the same questions at each assessment and giving the patient some options for answers, the physician and patient begin to develop a common language for communication, e.g., "Does your pain feel like burning, shooting, or pins and needles, or is it an aching, sharp, or throbbing kind of pain?" Patients begin to recognize different qualities in their pain. Physicians begin to determine whether intervention should be oriented to neuropathic and/or nociceptive treatments. In our recent study of an educational intervention for cancer-related pain (23), a patient called to thank us profusely for "teaching me so much about pain—it changed my life and gave me a mission for the time I have left." We of course thanked her for letting us know. We then became puzzled when we realized that she was in the control group that did not receive pain education. When we called her and asked what had been so helpful, she told us how she learned so much from assessment of her pain in the study, that it changed the information she gave her doctor and this changed her treatment, bringing her far more pain relief.

Information Provides Familiarity and Predictability

Whenever possible, it always helps to make the unfamiliar more predictable by informing patients of what is going to happen. This can be very reassuring for patients because uncertainty is known to increase distress and threaten perceptions of ability to cope (24). Yet, the informed consent process used in many clinics emphasizes provision of medical information that patients often do not fully comprehend (25). The legally required process of reviewing risks forces patients to recognize the limits of their own, and the medical staff's, control over the outcome of treatment. Although this process is necessary and valuable to patients, the emphasis on uncertainty can increase patient and family distress related to what is unknown and unfamiliar. This can decrease self-efficacy, the belief that one has the ability to manage the difficulties one faces. Of all psychological concepts related to pain, none are as consistently and significantly shown to influence pain level and treatment outcome as elevated distress and lowered self-efficacy (11).

Some of the effects of this informed consent process and the overall uncertainty about what will happen can be countered by providing specific information about what is known. Information can help patients to "label" their sensations with familiar, less frightening terms. Information also gives patients a way of "reframing," thinking about their situation from a less threatening or more incontrol perspective.

Three kinds of information are helpful to patients:

1. Describing procedures, risks, and benefits (informed consent)
2. Describing predictable sensations
3. Defining the duration of each predictable sensation

Describing procedures provides patients with specific information about what will happen. By giving patients a concrete description of the steps that will occur, patients can later remind themselves that what is happening is expected. In describing what will happen it is essential to include the benign steps in this description, ("You'll sit on the bed and bend your back. We'll clean your lower back with antiseptic.") not only the invasive steps ("We'll stick a needle into your pelvic bone.") This helps patients mentally balance the event in a way that reminds them that most of what is happening is unthreatening. When patients know what to expect, the amount of uncertainty is reduced, which in turn increases confidence that the situation is under control.

Describing sensations helps patients because it tells them exactly how they will feel. By using specific descriptions, patients are able to label what they feel with familiar sensations. Vague terms, such as *pain* or *hurt*, leave patients worrying about how much pain and whether they will be able to tolerate it. Even something unpleasant can be made less threatening by associating it with something familiar. Describing a sensation as “like a bee sting” or “a heavy pressure” does not deny discomfort; rather it allows patients to prepare themselves. When these sensations occur, patients are able to reassure themselves that these are expected and familiar. Use of a simile can be particularly helpful when describing a sensation and reminding the patient that the experience is tolerable. For example, “When I pull the marrow out you may feel a sharp pull all the way down your legs as if a strong vacuum cleaner is tugging from your back down your legs.” Although the feelings are not pleasant, the experience of them—if predicted—can be reassuring.

Defining time frame may be the most useful type of information clinicians can provide, particularly with pain resulting from procedures or treatment (26). For most people, knowing there will be an end makes an unpleasant event much more tolerable than thinking it might last forever. It is particularly helpful to break the events into the smallest time frames possible. So, for instance, we do not talk about a bone marrow aspiration as taking “only 20 minutes.” We break the aspiration down into sections. The local anesthetic might take 30 seconds; the pressure of the needle going into the bone marrow might take 5 seconds; feeling of the pull might take another 10 seconds. Although the overall procedure might take 20 minutes including preparation, we help patients to recognize that the painful section lasts less than 2 minutes, and that most of the procedure is not painful at all. For any of us, our belief in our ability to tolerate 2 minutes of pain is much greater than our belief that we can withstand 20 minutes of intense pain.

In general, procedural information is the most frequently provided, however, it is typically less useful in reducing worry and discomfort than temporal or sensory information (27,12). Sensation and procedure information provided in combination have been shown to be superior to sensory information alone in the reduction of pain and distress (28).

Ideally, patients receive all three types of information for the greatest effect on pain and distress. To familiarize and normalize the experience all information must be provided before beginning a new process. During a treatment or procedure, the focus should usually shift to active distraction, imagery, or storytelling so thoughts are focused away from discomforts that cannot be alleviated. Although it is tempting to ask patients if they are hurting, this refocuses attention on pain and can entirely undo the benefits of distraction strategies. It is ideal to make a plan before starting for how the patient will let a clinician know if pain is too intense by lifting a hand or another signal. This allows both the patient and whoever is assisting in distraction to continue with imagery or storytelling while letting clinicians know that pain has increased and may require additional analgesic.

For the small number of patients who are phobic of a procedure or who need to remain vigilant, systematic desensitization can be done with very short-term treatment and is effective if sedation is not appropriate. These patients need to receive constant feedback from the clinician doing the procedure about what is happening and what they can expect of sensations and time frame. Additionally, these patients need to control the timing of the procedure whenever possible. With highly anxious and control-oriented patients, there is a tendency for physicians and nurses to want to get the procedure over with as quickly as possible to reduce the patient's distress. They sometimes push ahead as fast as possible while the patient fights all the way. It does initially take longer to slow down and give patients time to maintain their control, and to let them set the pace. However, if this extra time is taken with these infrequent patients, the long-term trauma and the resistance to further treatment will be far less.

Education

Although information provides facts, education requires an interactive process in which patients learn and then use their new knowledge to direct their own behavior. Education does more than label an experience, it allows patients to take the information presented to them, adapt it to their changing situations, and then adjust their thoughts and behaviors accordingly. Education involves both the telling of facts, training of how to accomplish a goal, and brief addressing of patient questions, concerns, and problem-solving potential obstacles. For reluctant patients or those with strong beliefs, adherence can be greatly aided by asking patients what they will do when they have pain and then problem-solving any remaining barriers. This rehearsal can facilitate patient adherence to treatment and can point out to the clinician where the patient may have difficulty implementing the plan.

Clinicians are often frustrated by patients who are given information, but seem not to hear it. Anxiety, unfamiliarity, and the numerous amnestic medications used in cancer treatment may impact patient ability to retain seemingly learned material. Research indicates that opioids, although they have minimal effects on most areas of function, do affect long-term retention of new information (29,30). Although patients may appear to comprehend information during their office visit, they may not be able to recall the information later at home. In addition to these physiologic aspects of learning interference, the distress and helplessness brought about by a cancer diagnosis, compounded by the experience of pain, can disrupt long-term retention. Recognizing these limitations, it seems an obvious solution to write down important instructions or details so they can be recalled later. It helps to have standard practice prescribing sheets and pain report forms so this information does not have to be written anew each time. Some examples of standard written tools that can be adapted to individual clinical settings are in Appendix 5-1. Diaries can also be used to track pain level and medication use.

Education has conclusively demonstrated improvement in many medical outcomes, including pain, in many types of patients. Recently, clinical trials have demonstrated the effectiveness of education as a tool for cancer patients with progressive, disease-related pain (23,31,32 and 33). In a randomized controlled trial we conducted with adult cancer patients, all participants watched a videotape, reviewed a printed handbook, and received brief nursing training tailored to their needs, which lasted about 15 minutes (23). Patients were randomized to either a pain or a nutrition active control group. Patients who received the pain training demonstrated significant increases in their knowledge about cancer pain barriers and, more important, they reported 25% declines in pain report when compared to the nutrition group 1 month later. These improvements remained in 3-month follow-up, although no intervention was provided differentially to physicians and nurses of these patients. The improvements occurred despite the fact that research nurses were not available to apply the patients' training in future appointments. It seems likely that the results of the education and patient training could only be strengthened if implemented by clinic nurses and physicians who will be at the patients' next appointments to reinforce the training. Oliver and colleagues (32) similarly found pain intensity improvement with brief individualized patient training, and DeWit et al. (31) reported decreased pain with a multi-method, pain education program. Further demonstrating that education methods are effective across sites and populations, in a study targeted to elderly patients with cancer and their family caregivers, Ferrell et al. (33) evaluated a structured pain education program during home care visits with elderly patients and found improvement in knowledge, attitudes, and compliance.

With time demands on practice, it is important to note that written materials and videos are effective strategies for reducing the face-to-face interaction time with nurses or physicians. Numerous booklets, books, and videotapes are available to use as educational tools with patients, and data consistently indicate that patient training should be incorporated into routine oncology practice (1,33,34,35,36 and 37). Written materials are useful because they reduce the burden of having to retain information solely in memory. However, we are aware of no data to indicate that print material or videotape alone is effective in improving pain outcomes, without some review and tailoring to the patient's needs. Specific education needs of patients and their family members are listed in Table 5-2. These targets for education should be addressed when disease-related pain is mild and when opioids are first needed. At that time patients are interested, motivated to take charge of their care, and usually have the energy to focus and learn new information and strategies. If patients are in severe pain or have other major symptoms, training will be more effective if held until symptoms are better controlled (5).

TABLE 5-2. EDUCATION NEEDS OF PATIENTS AND FAMILY MEMBERS

Reframing

Reframing offers a fresh, more capable, and less catastrophic look at a difficult situation. When cancer patients experience numerous bad things, and then have

recurring or persistent pain, it is not surprising if they begin to feel that nothing they do makes a difference, that their efforts are useless, and that the pain—along with everything else—will keep getting worse. Reframing means, quite simply, changing the perspective one has on this situation, thus shifting the way one thinks and feels. This shift in perspective reduces the threat without denying realities. Reframing generally implies changing a fearful thought to a neutral or positive thought.

However, reframing may not be needed if the original framework is adaptive. If clinicians remember that their words will be retained and repeated over and over by patients and families, and if they use this fact to actively select communications to facilitate capable, self-efficacious patient and family perceptions, this will be one of the simplest and most helpful strategies for managing the distress and fear related to cancer and pain. Although most patients and families look for statements that offer hope, they also hang on to negative information. It can be extremely valuable, when providing feedback about the patient's condition, to include statements about what is going well medically, without being misleading, and to recognize some action of the patient that warrants praise. Specific positive accomplishments are always possible to find.

The process of framing or reframing does not change most of what clinicians do in communication with patients. When entering a patient's room, symptoms, problems, and patient concerns can be addressed first. This allows patients to express concerns and helps validate their experiences. Next, patients can be asked about symptoms the clinician believes they do *not* have and then about what they have been doing in activities. Finally, to reinforce what has just occurred, the clinician can comment on the many accomplishments of the patient and family and on those areas of functioning that are not problems. For example: “You've been able to walk a little bit each day, that's wonderful, that's the best thing you can do to keep your strength.” For a very ill patient for whom getting out of bed is a huge effort, the acknowledgment may be quite different: “You've been able to get a bath today, that's great; I know that must have taken a lot of energy and effort.” Although the accomplishment may seem quite small, the patient knows how much energy the activity took and will appreciate having this recognized.

With this strategy the clinician can acknowledge the problems that are of concern to patients and their families, while also honestly helping them to recognize that, no matter how difficult the situation, there are things that are not problems, and they are doing a good job of managing a very challenging situation. This simple, positive perspective can do much to contribute to feelings of control, self-efficacy, and reduction of fear for patients and their families.

One key to remember in giving people bad news is that nearly all people can deal with anything, even death and pain, if they feel capable and like they are doing a good job in managing a situation anyone would find difficult. Reminding others or even ourselves that we still have control in some area and are doing well at controlling what we can helps virtually all of us to feel that we can manage our problems.

In summary, the process of reframing is to

1. Acknowledge, validate, and respond to the problems.
2. Widen the perspective to include medical areas that are not problems and to include specific accomplishments of the patient.
3. Give the patient credit for an accomplishment so that the patient feels recognized and proud of what he or she is doing.
4. Whenever possible remind the patient that the situation today is not forever and define the time frame if it is known or can be estimated.

Reframing as a strategy has not been tested on its own in clinical trials. Still it is the foundation of cognitive-behavioral training in coping with anything mentally or physically painful. In this training, the model is to learn to observe thoughts and feelings that make a person feel worse and shift these thoughts to more adaptive, less out of control thoughts that assist anyone to feel better and adapt more effectively to problems. With the reframing described in this section, clinicians offer patients the results that contribute to this effective thinking without taking time beyond that required for adequate care.

Quick Distraction and Imagery

Distraction can take many forms when dealing with pain. Many types of distraction have been used effectively, such as focusing on breathing or relaxing, doing math, counting ceiling tiles, saying a poem, meditating over a calming phrase, doing massage, and listening to music.

Clinical trial data clearly demonstrate that imagery/hypnosis is the most effective of cognitive strategies, with little data to clearly distinguish the efficacy of imagery versus hypnosis (15,38,39). With intense pain that is not driven by tension, active imagery is most effective when it engages as many sites and senses in the brain as possible in processing information.

When pain is of brief duration and/or medical treatment can not reduce discomforts, most patients can be assisted in placing their attention elsewhere by using imagination. This can be accomplished easily through using simple strategies such as talking with patients about a pleasant experience they have had. Having patients tell you stories about an experience helps to engage patients away from their discomfort. Talking requires more focus and more brain occupation than just listening. When using this strategy, it is important to elicit a memory of a place where patients have felt particularly at ease and happy but also active. For example, you can ask patients to tell you about a favorite vacation, or another favorite place they most enjoy being. Rather than lying on a beach and relaxing with their imagery, encourage them to share as much detail as possible: what it looks like, the sounds, the feelings, the temperature, and especially the activities they do there. Memories of physical activity can help to block pain processing similar to actual activity if the bodily sensations of that activity are evoked. Patients can become so engrossed in the reliving of that experience that they become unaware of their pain in the present moment. Recounting these positive events reintroduces feelings of pleasure as well as providing distraction. These in turn counter perception of pain.

Brief imagery also can be used to counteract the sensory qualities of intense but brief unpredictable pain. To change the pain itself, we take the patient's description of sensation and create an image to counter this sensory quality. For burning, stabbing pain we might have the patient focus on deep breaths while imagining blowing freezing arctic air through the sensation. With extreme pressure pain, we might use an image of a heavy load of bricks lifting off the painful area, lifting higher and feeling lighter with each exhale, until the patient can float away from that pressing, heavy feeling. At the most intense time during procedures, we insert into any distraction the image of blowing up a balloon, blowing hard with the patient, mentioning the pressure in the cheeks, and asking what kind of balloon, what color, what shape. At these points, it is also helpful to raise one's voice and speak more rapidly, along with increased pressure on a shoulder if appropriate, and any other shift that pulls attention to the images and voice of the clinician.

Control of breathing is a natural part of most imagery and is usually the first step toward reducing the tension associated with pain. Focus on breathing also begins the process of focusing away from the pain perceptions.

For quick and easy imagery or distraction, the following components are helpful to keep in mind. Have the patient choose an image or participate in the selection so that it is relevant. For intense pain, an image that includes physical action by the patient will be more engaging of attention than a passive, purely relaxing image. Having the patient talk, rather than just listen to you, maintains the patient's focus far more effectively. Sound made by the patient, whether talking, breathing out through the mouth with a “whooshing” sound, or any other sound, counters acute pain better than silent imagination. Adding a physical stimulus will help counter the pain stimulus. This can be squeezing the shoulder, having the patient squeeze your hand, having a family member massage feet or hands, or including physical stimulus within the imagery. It is optimal to provide pressure at a location between the pain and the spinal cord. The goal is to create as much input into the brain as possible, to flood the brain with nonpain messages and thus prevent the pain message from being processed.

Brief Expression of Thoughts and Feelings

Presence of distress, especially distress specific to the pain or cancer situation, will contribute to a patient's perception of pain (11). For patients who are acutely anxious about a procedure, or who are generally anxious about their pain or cancer, a chance to express their thoughts, concerns, and feelings is essential before continuing with any of the nonpharmacologic methods described above, and for maximal efficacy of pharmacological methods. The fact is that patients who are preoccupied will not hear information, will not learn what they need to about their treatment, will not hear reframes, and will not benefit from the distractions of imagery or massage. As a consequence they will have more difficulty following prescribed medical treatment. These will be the patients who require more effort and time at each visit and will have poorer pain relief. Ten minutes of expressing feelings and addressing of concerns can save numerous future appointments and can contribute significantly to improved outcomes (13,40). As we discuss below in the section Structured Support and Psychological or Psychiatric Referral, talking and expressing concerns in a supportive setting has been nearly as effective as more advanced techniques in relieving cancer pain (14,15).

Sometimes people just need to know that they have been listened to and understood. Cancer patients who are fearful for their life or future sometimes just need to have a chance to have those fears and concerns acknowledged. Angry, upset patients and family members can be difficult to deal with, especially if they are coping with their fears by accusing health care providers of not being helpful. One of the best ways to diffuse an angry or potentially explosive situation is to allow this expression of upset, followed by an acknowledgment that you have heard them, will do what is possible, and will be available to discuss further, if needed. An expression of empathy, “Tell me about what happened … I can see that this has been difficult and upsetting for you. Let's see if we can do something that will make things better. Do you have ideas about what we might do?” This is not the same as colluding with the patients' anger; rather it facilitates communication, by assuring patients that their experiences and thoughts have been heard. By this expression, it allows you and the patient or family to move past the hurt feelings. For very demanding and difficult-to-control families, a regularly scheduled meeting to go over care and concerns can save more time than recurrent unpredictable demands that result in a need to meet more often or at times that are ineffective in addressing the overall care of a patient. Treating a patient's pain and suffering must include

addressing suffering on multiple levels, including that patient's fears and anger (41).

PHYSICAL AND COMPLEMENTARY METHODS

Thus far, we have focused largely on verbal methods of relieving pain. Physical methods, such as massage, ice and heat, as well as music therapy, are also nonpharmacologic techniques that allow patients and family members to participate in providing pain relief, thereby increasing their sense of control. Although few randomized controlled clinical trials exist to establish the efficacy of these methods (1,42,43), a nascent literature and clinical reports indicate that these techniques are received well by patients and are reported to provide some relief (33,42,44,45). Despite the dearth of experimental evidence for many of these strategies, patients are often receptive to these methods. It is use-ful for clinicians to have some knowledge of the pros and cons of using these approaches. Advantages of these methods are that they provide physical contact for patients, they have few (but can have some) side effects, and they give family members an opportunity to be involved, while at the same time they may directly reduce pain.

Massage may be most easily accepted by patients, requires minimal preparation, and can be easily implemented. It generally requires another person willing to assist, although mechanical massagers can be used. It is noninvasive and can be performed by health care professionals or family members. Professionals trained in therapeutic massage may achieve greater efficacy beyond relaxation and distraction. In a randomized controlled trial examining the impact of massage therapy during high-dose treatment, patients who received 20-minute sessions of shoulder, neck, head, and facial massage had lower levels of cancer-related symptomatology, but not lower pain, than those who did not receive massage (42). Foot massage or reflexology has also been the subject of study and has been shown to reduce cancer pain, nausea, and anxiety (43,45). Use of a lotion, massage oil, or powder helps reduce friction on the skin. Movements should almost always be continuous, even, and rhythmic (52). If provided by family, instruction should include the importance of feedback from the patient and making sure that massage is not painful. Generally, massage should not occur directly over a tumor location or directly over a pain area, but rather proximal to the pain or tumor or in another area of the body altogether. Health care providers using massage for pain treatment should have appropriate training and licensing for both efficacy and legal reasons.

Choice of heat or cold and of the method used depends largely on trial and error. As a rule, patients are more easily convinced to use heat than cold, but cold can be as effective, or more effective, and relief may last longer (33,47,48). Alternating between heat and cold can also be an effective option. Applying heat can be done with hot water bottles, electric heating pads, hot moist compresses, bath, or whirlpool/hot tub. Applying cold can be done with ice and water combined in a waterproof bag, terry cloth filled with ice and wrung out, frozen gel packs, or bags of frozen corn hit to gently loosen contents. All options should be sealed to prevent dripping, wrapped as needed to prevent skin irritation or burning, and should be flexible to conform to body contours. Location directly on the pain, proximal, distal, or contralateral to the pain is a question of trial and error and patient tolerance (46). Patients should be instructed to stop when the area becomes numb, excessively red, blisters, or when they want to. Time of use to be effective ranges from 5 to 30 minutes. Patients should not sit or lie on the heat or cold packs. Heat should not be used directly over tumor sites (1). Other contraindications include use over a recent radiation therapy site where skin may be more sensitive, if bleeding is occurring, if patients have impaired sensation, or if skin blanches and turns red after the application of cold.

Music Therapy

Use of music to relieve suffering and pain has grown in popularity over the past few years. A few randomized or other experimental trials indicate some success in relieving pain. Certainly no harmful effects have been indicated (49). However, most of the literature remains anecdotal (50,51). The most careful research indicates that music therapy is about equivalent to relaxation training in efficacy for pain treatment (44,49). Numerous different styles of music therapy have been used, and success may vary depending on what method is used. However, to our knowledge these distinctions have not been tested. Music can be played for patients, patients may select their own music then change music depending on preference, and, alternatively, patients can make their own music using simple instruments. Two suggestions are most clear in methods for music therapy as a pain and suffering treatment. One is to have patients select their own music rather than having it given to them or to all patients at once in a particular setting. Another is that for effective use, a clinician should at minimum read about how to use this method and preferably should receive training in using music therapy. For more on music and art therapy, see Chapter 72.

Specialized Cognitive-Behavioral Interventions

There are times when medications and brief strategies are not adequate to manage a chronic or recurring pain, and invasive strategies are inappropriate. These circumstances include those in which distress or depression are substantially elevated, in which a history or active substance abuse complicates treatment, when panic or phobia contribute to procedure discomfort, or when a situation requires expertise in imagery or hypnosis. At such times, it is appropriate to consult with a psychologist or other behavioral medicine specialist who can provide more specialized cognitive-behavioral pain management techniques. Table 5-3 lists strategies used most often by psychologists, social workers, nurses, or psychiatrists after specialized training in these skills for pain treatment. Because most of these are methods that can be taught to the patient for use when a therapist is not present, they can be excellent methods for increasing coping options, self-efficacy, and self-control of pain. Most practitioners combine the techniques described in the following sections into a package of coping skills integrated with medical treatment, not as alternatives to medical treatment (14,15,52).

Intervention	Assists with
Relaxation/imagery/hypnosis	Possible neuroendocrine changes
Relaxation	Reduction of autonomic arousal and tension
Progressive muscle relaxation	Learn to identify and change tension
Deep breathing	Learn control over somatic states
Imagery/hypnosis	Mental activity competes with pain
Pleasant places	Introduces feelings incompatible with pain
Analgesic images	Blocks pain sensations
Reframing and cognitive-behavioral training	Reminds patient that situation is manageable
	Balances positives with negatives
	Reminds patients of their competence when learning to do for themselves
Distraction	Stimulation competes with pain sensations
Focus on mental activity	Blocks attention to pain
Focus on physical activity	Addition of pleasure to daily experience
Structured support, psychotherapy, psychopharmacology	Decreases isolation/alienation
	Allows expression of feelings
	Treats concurrent depression, anxiety
	May reduce somatic expression of tension, anxiety, depression

TABLE 5-3. SPECIALIZED COGNITIVE-BEHAVIORAL INTERVENTIONS

Imagery/Hypnosis

Imagery is one of the most easily accepted, most useful noninvasive methods for managing pain. An increasing number of patients and physicians are familiar with relaxation and imagery techniques, leading to its growing use with cancer pain patients (53). A recent meta-analysis reported that hypnosis for pain has a moderate-to-large effect size with 75% of lab and clinical participants receiving substantial analgesia (39). Thus hypnosis and imagery strategies repeatedly have demonstrated the greatest effect size of all cognitive-behavioral strategies tested for efficacy in pain control (38,54). Although relaxation is not essential for imagery or hypnosis, these methods usually begin with relaxation as a way for patients to “tune in” to their bodies and begin to become more aware of internal sensations as preparation for changing these sensations. Progressive muscle relaxation can be provided either by focusing on deep breathing and relaxing muscles from head to toe or by moving through the body and physically tensing and relaxing each muscle in turn (55,56). Learning to recognize the physical sensations of tension and relaxation in the various parts of the body can be helpful to patients so that they may notice tension when it occurs and relax muscles. Once patients understand relaxation and deep breathing, imagery moves to exploring places and events where they have felt comfortable, healthy, strong, and capable. This is usually referred to as *pleasant place* imagery. Nearly everyone enjoys and responds to these positive images, which provide patients with an opportunity to turn their focus away from their pain and strain for a time. In turn, their enjoyment of the experience enhances the likelihood they will continue to use these methods. Imagining a pleasant place provides an image which is incompatible with the experience of pain. Neumann et al. (57) demonstrated that training in pain-incompatible imagery significantly increased pain tolerance, while also decreasing psychophysiological pain reaction.

Often, clinicians provide an audiotape of a session for patients and ask them to practice between sessions so that they learn to use these skills on their own, whenever needed. We have found, as have others (33), that few patients benefit from just buying or being given an audiotape with imagery. Most people need the connection with a person who understands their unique circumstances and can help them adapt imagery to their preferences and needs. Tapes alone can bias patients against use of imagery, as we often hear in, “I tried that. It didn't work.” Treatment needs to be tailored to an individual's needs and preferences for optimal effectiveness (58).

When possible, we incorporate suggestions for analgesia in the painful area (59). Sensory transformation involving the use of images that transform the pain, such as seeing the pain as an object and watching as it changes color and shape, moves to a distant location, or decreases in intensity, can be very effective for brief or persistent pain (15,59,60 and 61). Our clinical experience indicates that pleasant-place imagery is effective as a distraction from discomfort, but to extend pain relief in the absence of the clinician, specific analgesic suggestions are needed. To assist patients in applying these skills on their own, we teach them the steps for using

imagery and provide suggestions for how easy and automatic imagery and increased comfort can be. For the purposes of pain management, research does not yet allow us to clearly distinguish effects of hypnosis from those of relaxation and imagery. Because of the negative connotations of hypnosis for some patients, we usually use the term *relaxation with imagery* unless a patient would benefit from the perceived magic of the term *hypnosis* (62).

When in-depth imagery is not possible because the patient is not interested or does not have the needed attention span, brief images or having the patient tell about their favorite experience or place can still provide a “time out” from pain and illness. When we begin imagery training, hypnosis or imagery itself may last for 20–30 minutes. As patients become familiar with the experience and as they are more ill, sessions may be as brief as 10 minutes.

Reframing

Just as the messages we give to patients are powerful, so are the messages patients give to themselves. Using this awareness, along with providing information and education, we help patients prepare “I can cope” statements to use in the face of major stressors. For patients with continuous pain or who are giving themselves negative messages, we teach them to do their own reframing. Reframing involves teaching patients to turn negative, unhelpful self-talk into neutral or more positive self-statements.

We prepare these statements by first exploring the messages a person is naturally giving him or herself. Many patients initially deny having any helpless or self-defeating thoughts. With an accepting approach, exploration, and some provision of examples from other patients, most people acknowledge specific fears or concerns that sometimes enter their minds about what might go wrong. Patients then develop alternative phrases to remind themselves of methods of pain relief where they have control such as, “This pain is really bothering me. What can I do right now?” With cognitive-behavioral skills training, patients will then learn to act on the added thought of, “The doctor said I should take another pain pill when the pain increases. I'll do that and then do some breathing and imagery until the pill starts to work. If it doesn't get better I can always call the doctor and he/she will find a better treatment.” It is important to emphasize that this approach is most effective when it is individualized. Specific self-statements and reframes must be adapted by, and developed with, each patient.

In discussing any cognitive modifications such as this with patients and families, it is essential to assure them that these messages alone will neither cure them nor kill them. They need not struggle to maintain only the “right” or only positive thoughts. Fears and helpless thoughts are normal and should be understood and tolerated as normal. More emotional and health damage is done by suppressing real feelings and thoughts than by expressing negative ones. At the same time, we encourage patients to use these thoughts to help them identify when they need more information or when they need reassurance from someone else whose knowledge or support they value.

In addition to working out reframes with the patient, we teach patients to reframe for themselves. After teaching them to identify negative self-talk, times when they expect the worst, or situations that really bother them, we teach them to

1. Focus on what they have accomplished rather than on what remains to be done.
2. Find something positive that they will gain from the situation and focus on that: “I'm coming through this. This is hard but I've learned I'm stronger than I ever imagined.”
3. Focus on what they would do to help someone else in the same situation: “If this were happening to my close friend, what would I tell him or her?”
4. Focus on the temporary nature of what is difficult: “This is difficult, but I know this will not last forever. In a half hour, I'll feel better.”

Cognitive-Behavioral Skills Training, Including Imagery or Hypnosis

Although there has been considerable interest in the use of psychological interventions for cancer, few controlled clinical trials have examined the utility of these techniques for pain management in cancer patients (63). Those done with a target of chronic nonmalignant pain or cancer-related general distress (which often accompanies persistent pain) demonstrate success (64,65).

We have completed two prospective studies testing the efficacy of cognitive-behavioral skills training for pain related to high-dose treatment for cancer. In both randomized controlled trials, we found that, when training was completed in two sessions before cancer treatment, patients learned the skills and used them to reduce severe pain even when opioids were used concurrently. In the first study we found that a hypnosis group reported significantly less pain without using more opioids than three comparison groups: a cognitive behavioral training with relaxation but without imagery, an attention control, or standard treatment (52). In a second clinical trial, we modified the groups, maintaining the hypnosis content but calling the intervention relaxation with imagery (15). This imagery alone was compared with three other groups again: (a) patient training in a cognitive-behavioral package that included reframing, distraction, self-affirmations, and relaxation with imagery; and (b) an active supportive therapy group that included education and reframing by the therapist; and (c) standard medical treatment. The imagery only and cognitive-behavioral groups reported significantly less pain than the standard care group. The supportive therapy group was not significantly different from either the standard medical treatment control group or the two intervention groups. We found that patients who received active therapeutic support had lower mean pain report, but the addition of either imagery or cognitive-behavioral skills training decreased pain further.

These results are similar to those reported by Spiegel and Bloom (14). In that study, breast cancer patients with progressive, disease-related pain were randomized to a standard-care control group, supportive group therapy, or supportive group therapy plus brief hypnosis for pain control. Groups continued for 1 year. The support and support plus hypnosis groups both reported lower pain and distress than the control group, with the hypnosis group reporting nonsignificantly lower pain than the support-only group.

A randomized controlled study conducted by Gaston-Johansson and colleagues (66) combined imagery with other cognitive-behavioral skills versus a standard care control group for breast cancer patients receiving autologous bone marrow transplant. The skills group reported reduced symptoms, particularly nausea and fatigue, but not pain.

Distraction

Similar to the quick, clinician-assisted distraction strategy previously described, distraction skills taught to patients teach them to focus attention away from their discomfort on their own. Distraction is something many of us do automatically when we have exhausted our abilities to solve problems or simply want a break from problems or preoccupations. Just getting through the day comfortably may be the greatest problem for patients suffering from cancer pain. In this case, focusing attention away from discomforts can be one of the more effective coping strategies. Individuals each have their own preferred distractions. We work with patients to identify which distractions work best for them and help them to plan when, where, and how they will use specific strategies.

Distraction is not the same as denial, which implies an inability to recognize reality. Nor is it the same as avoidance, which implies an unwillingness or inability to cope with reality. Distraction involves a willingness to accept reality while actively engaging ourselves in a positive portion of it.

Some distractions involve focusing on thoughts or *mental activity*. This can include self-statements, prayers, reading, listening to someone read, or listening to music. Focusing on pleasant images is another example. Other distractions focus on *active behaviors* such as working on a hobby, playing a game, or using deep breathing or relaxation. One of the most effective distractions reported by patients involves simply spending time with and talking with family and friends. Often the best way to focus attention away from discomfort is to create more pleasant or neutral sensations. Massage and exercise, such as walking, are commonly used. Regardless of the distraction, these types of activities provide a sense of achievement that reminds patients of their control over their own experience, but also recognizes that some problems cannot be “solved.”

Structured Support and Psychological or Psychiatric Referral

Support is one of the essential needs of cancer patients and family members. Although women are particularly likely to seek out emotional support, men are often more reluctant to use support. As a generalization, men are more likely to focus on problem-solving types of support provision. Including education as a part of support efforts can be an effective inducement for men who otherwise might resist support groups or individual support.

The value of support is being increasingly recognized in numerous studies examining the relationship of social support to physical and emotional well-being. A now classic group of research studies demonstrates that cancer patients who receive active psychological support, with or without skills training, from groups or individuals, report less pain and live longer (67,68). The expression of feelings and the sharing of experiences involved in supportive interaction may help patients to participate more fully in medical treatment. Researchers are exploring whether these support interventions have effects on survival and function through adherence to treatment, improved treatment through education, improved health-related behaviors, or neuroendocrine or immunologic effects that enhance survival.

Pain is among the significant contributors to emotional distress for cancer patients and vice versa (11,69,70,71 and 72). Pain intensity is related to negative cognitions, anxiety, and depression (69). Over time, unrelieved pain engenders feelings of helplessness and hopelessness. Helplessness or hopelessness leads to depression.

Depression needs to be treated concurrent with pain whether the depressed thoughts or actions seem related to unrelieved pain. It is most rare that depression resolves immediately on relieving pain. At the same time, treatment for pain should never wait for a test of depression or anxiety treatment. No data indicate that depression or anxiety cause physical pain in cancer patients.

Some patients develop or begin cancer treatment with phobias or panic that disrupts treatment and greatly reduces their ability to tolerate pain. Fortunately, these phobias and panic can be treated very effectively with desensitization strategies that use imagery and gradual introduction of the feared event to reduce anxiety. This treatment can make the difference between a patient's ability to proceed with medical treatment that may include discomfort or canceling all further disease-related care. If a patient seems particularly anxious, does not make repeated appointments either in a specific location or for a particular procedure but is otherwise responsible, or if a family member or patient reports fear to a health care provider, the patient should be evaluated for phobia or panic. Relatively small fears to those of us without them, such as needle phobia, elevator phobia, claustrophobia, or another procedure fear, can entirely prevent a patient from continuing lifesaving treatment.

When to Use Nonpharmacologic Methods

We are more likely to prevent difficult symptom management problems if we begin using nonpharmacologic strategies before pharmacological treatment fails. When pain is mild or new, patients are most receptive and able to learn strategies to help increase their control over symptoms. Once pain is moderate or has become chronic, patients may benefit from imagery done by a therapist, but are less likely to learn new cognitive-behavioral skills for use on their own. Attention span, concentration, and energy are necessary for learning new coping skills; all of these things can be affected by disease and its treatment. When patients are sedated or confused from medical treatments or a disease, or when patients are exhausted and frustrated because all other attempts to manage pain have not worked, we have a very difficult time teaching cognitive techniques for relieving pain. Information and education are always useful, but again are best provided when the pain problem is in early, mild stages. Physical methods, such as massage, ice, or heat, can be introduced at any point.

Although we do not have strong data yet on which psychological methods of cancer pain control are best for which types of patients, clinical experience with patients experiencing pain is quite similar to reports of cancer patients who have other distressing cancer-related symptoms such as chemotherapy-related nausea and vomiting. We can use this knowledge to provide us with some general guidelines (Table 5-4). Very anxious patients or those who avoid unpleasant topics or expect physicians and nurses to be in control have difficulty learning cognitive coping skills. These patients also may do well with hypnosis. After anxiety has been reduced and patients are feeling more in control of their own symptoms, cognitive-behavioral skills training may be introduced.

Method	Who will benefit
Assessment language for communication about pain	All patients, but ideally early in treatment to optimize care as treatment progresses
Use of 0–10 scale	
Verbal descriptors of pain	
Education and/or information about medical treatments and myths	All patients, as early in pain treatment as possible
Brief cognitive strategies	
Distraction, storytelling, or brief imagery	Patients with painful procedures or relatively brief pains
Reframing or meaningful phrase to repeat	Patients feeling out of control or with distressed views of their pain
Brief expression of thoughts and feelings	Patients with beliefs or distress disrupting relief of pain
Physical and complementary methods	Patients interested in alternative medicine techniques integrated with medical care
Massage	
Ice and heat	Patients with a caregiver or nurse able to assist or with adequate health to provide for themselves
Music therapy	Patients with finances or insurance to cover costs and a willingness to experiment
Other methods with physical therapist, rehab specialist, or complementary methods training	
Specialized cognitive-behavioral methods	
Imagery, hypnosis	Patients able to focus attention, relatively alert, with some motivation
Reframing and cognitive-behavioral training	Patients with residual pain after optimal medical treatment
Desensitization	Patients with phobia or distress related to needed treatment or procedures
Structural support, psychotherapy or psychopharmacology evaluation	Patients with moderate to severe distress

TABLE 5-4. WHEN AND WITH WHOM TO USE NONPHARMACOLOGIC STRATEGIES

At the other extreme, for patients who cope actively and manage anxiety well, it may be hard to measure improvement with skill training, but these patients are the most eager for additional coping techniques and report them to be very effective. Patients with moderate anxiety and those who have not prepared any coping plans may benefit the most from cognitive-behavioral methods. These patients are often motivated to learn skills that help them to feel like participants in their care. They feel more in control of their physical reactions when they learn the skills, and they respond well to the additional support provided by the trainer.

Conclusions

The nonpharmacologic interventions that we have described provide the clinician with simple and effective tools to assist with the management of cancer pain. In addition, these interventions give patients more control over their pain and treatment without making them choose between pharmacological and nonpharmacologic interventions. Because they are based on communication with the patient, the majority of these strategies can be easily used within the context of routine medical visits with the patient.

All patients need, and all clinicians can provide

- Assessment that teaches the patient what the physician needs to know to prescribe the appropriate treatment
- Procedural, sensory, and time-frame information that normalizes the experience, creates nonthreatening expectations, makes the experience more predictable, and reminds the patient that the current situation won't last forever
- Education that facilitates patient and family participation by teaching about treating pain, addressing barriers to patients reporting pain or taking medication, and informing why and when to call the doctor's office
- Simple cognitive strategies that remind patients of what is going well and help them recognize that they are doing a good job coping with a difficult situation
- Brief imagery that reduces focus on pain or reduces intensity of pain
- Information on physical and other complementary methods such as massage, ice and heat, music, and other methods of active distraction or use of alternative sensations to counter pain messages
- Brief time for expression of worries, concerns, fears, or helpless feelings

With specialized training, clinicians can help patients significantly reduce pain with the use of advanced imagery or hypnosis, reframing skills, distraction, and structured support. Nonpharmacologic strategies can become part of the overall treatment plan, alongside pharmacological treatments, to assure patients maximum pain relief and optimal quality of life.

APPENDIX 5-1

EXAMPLES OF PATIENT PAIN TOOLS FOR HOME AND CLINIC USE.

YOUR COMFORT IS OUR CONCERN

[a handout to be adapted to your site, for patients & families]
These topics can be put in a brochure describing specific services for pain or given to patients before any procedure, surgery, or beginning of new treatment.
Key elements: large type for vision impairment, target for sixth grade reading level.

When you receive health care with us, we want you to know a few things.

Pain is important to us. If you have pain:

1. Tell your doctor or nurse.
2. We will keep working with you to treat the pain until it is managed.
3. There is NO BENEFIT from suffering with pain. Untreated pain is unhealthy.

   REMEMBER:
   "use your energy to get stronger or to do what is important to you, not to fight the pain"
4. If your first treatment doesn't work, we have MANY other options. Strong medicines like morphine are often used for strong pain;

   ➪ ADDICTION is rarely a problem.
   If you have been a heavy drinker, have taken pain medication or other drugs often, tell your doctor or nurse so they can plan your care.

   ➪ Let us know if you have any concerns about taking pain medicines.
5. COMMUNICATION is essential:
   We depend on you to tell us how much pain you have.
   We cannot know if you do not tell us.

   ➪ Tell us about problems with pain or treatment.

   ➪ Bring a pain diary or checklist to your appointment to tell us how your treatment has worked since we last saw you.

Fill out this form and take it to your doctor when your pain or symptoms change.

Your Name: _____

Date: _____

Tell Your Doctor about Your Pain

1. How strong is your **pain**?
   - Mark a "**W**" on the **Pain Scale** below to show how strong your pain is at its **worst.**
   - Mark an "**M**" on the **Pain Scale** to show how strong your pain is **most of the time.**

0	1	2	3	4	5	6	7	8	9	10
No Pain			Mild		Moderate			Severe		Pain As Bad As Can Be

PAIN SCALE

2. Where is the pain? On the picture below, mark the areas where you feel pain.

3. What does the pain feel like?
   - ☐ Pressure, Heavy
   - ☐ Aching
   - ☐ Throbbing
   - ☐ Cramping
   - ☐ Hot, burning
   - ☐ Sharp
   - ☐ Itchy
   - ☐ Numb or Tingling

4. Does the pain make it harder for you to:
   - ☐ walk
   - ☐ sleep
   - ☐ sit
   - ☐ work at home or out of the house
   - ☐ enjoy life
   - ☐ eat
   - ☐ be active

5. When is the pain worse?
   - ☐ In the **morning**
   - ☐ During the **night**
   - ☐ Before my **next dose of medicine**
   - ☐ When I **move**
   - ☐ I **can't predict** when it will get worse

6. How long does the pain last?
   - ☐ A few **minutes** but less than an hour
   - ☐ An **hour** or more but not all day
   - ☐ The pain is the **same all the time**
   - ☐ I have some pain **all the time**, but sometimes it gets worse

7. What other problems are you having?
   - ☐ Constipation
   - ☐ Dry Mouth
   - ☐ Dizziness or Confusion
   - ☐ Other Symptoms_____
   - ☐ Sleepiness
   - ☐ Nausea or Vomiting
   - ☐ Change in Mood

STANDARD ORDERS FOR AMBULATORY PAIN PATIENTS
Example

Pain Plan for:____[NAME]_____ Date:_____

1. Medications to take:

Medication	What to take it for: How much to take:	When to take it:
Long-acting morphine 30 mg (pink pill)	**Pain** 1 pill to keep pain controlled	Breakfast, 3–4 PM, Bedtime (every 8 hours)
Short-acting morphine 10 mg (white pill)	**Pain Breakthrough** 1–2 pills if pain increases. Up to 6 pills a day.	When pain increase starts.
Laxative	**Prevent Constipation** 2 pills 2 times a day. Do not wait until you have constipation, take this each day you take pain pills.	Morning Bedtime
Metoclopramide	**Nausea or Vomiting** Take when nausea starts, 1 pill at a time, 30 minutes between pills	When needed, up to 4 pills a day

2. Medications to stop taking: [LIST]

3. ___(phone #)_____ _____(name of RN or MD to call)_____
Call this phone number immediately if you have:

- Problems getting medication (either your pharmacy does not have it or it costs more than you can pay)
- New pain, Change in pain, No Relief with pain treatment
- Nausea or Vomiting more than 1 day
- No Bowel movement for 3 days
- Difficulty waking up in daytime
- Other mental or physical change that makes it hard to take medication

4. Your next appointment with Dr._____ **is:**

DATE: _____

Bell: _____

LOCATION: _____

PHYSIATRIC APPROACHES TO PAIN MANAGEMENT

ANDREA C. CHEVILLE
LAUREN A. SHAIOVA

Rehabilitation has too often remained marginalized in the care of cancer patients. The perception that rehabilitation only offers meaningful benefit to patients capable of full community and vocational integration with unrestricted life spans is inaccurate and shortsighted. Although physiatry, or physical medicine and rehabilitation, initially emerged as a field dedicated to transitioning individuals stricken with anatomically and functionally disruptive injuries back to productive lives, the scope of the field has broadened considerably as medicine has increasingly altered the prognoses of many formerly fatal diseases. Integration of rehabilitation services in the care of patients with faradvanced pulmonary and cardiac disease has become standard. Sadly, similar services are rarely offered to cancer patients, even in the early stages of disease.

Physiatric strategies geared toward enhancing pain control can be loosely grouped into three categories: (a) nonpharmacological nociceptive modulation, (b) adaptive functional training to allow pain-free mobility and self-care, and (c) restoration or preservation of normal biomechanics. These categories are theoretically separate but highly interrelated in practical application. Similar interventions are used to realize the goals of each. It is helpful, however, to consider them individually in developing an integrated plan to control pain, enhance function, and preserve autonomy in a given cancer patient.

FORMULATION OF AN INTEGRATED PAIN MANAGEMENT PROGRAM

Rehabilitative strategies fail in the absence of effective pain control. Adequate pharmacological analgesia lays a foundation on which physiatry can begin the work of advancing patients from a state of static to dynamic pain control. Pain management services allow rehabilitation professionals to effect functional gains and realize therapeutic goals. In turn, information gleaned during attempts to mobilize patients permits refinement of the analgesic regimen. Successful pain control is never fully achieved until the patient moves. For example, formerly quiescent pain from osseous metastases may become intensely problematic during attempts to transfer and ambulate.

Rehabilitation comprises an essential component of an integrated pain management program able to provide both symptom control and autonomous function. Ideally, physiatric approaches are seamlessly combined with appropriate disease-modifying, pharmacologic, and interventional analgesic strategies. This chapter addresses the three general categories of physiatric interventions (nociceptive modulation, achievement of pain-free function, and restoration of normal biomechanics). Approaches common to each are outlined, with special attention paid to their efficacy and limitations in cancer.

NONPHARMACOLOGICAL NOCICEPTIVE MODULATION

The capacity of thermal, manual, and electrical modalities to alleviate pain has long been recognized by clinicians. The classical Hippocratic texts outline the use of heat and massage to enhance comfort and reduce the virulence of disease (1). Investigative efforts have revealed the tremendous complexity of the neuroanatomical apparatus subserving nociception. Despite a baffling array of neurotransmitters and interneuronal connections, physiologists are now able to explain longstanding clinical observations. This understanding has led to increasing support for the use of manual, thermal, and electrical modalities in conjunction with conventional analgesic therapies.

Massage

Massage is one of the oldest and most widely accepted forms of treatment. Today more than 75 types of massage are practiced. Some forms are ancient, dating back over thousands of years (2). There has been a considerable increase in the popularity of massage over past decades. Its use in the treatment of illness ranging from minor myalgias to dire systemic disease processes has become accepted. The physiological effects of massage have been credited with promoting healing, restoring function, and enhancing physical performance. Specifically, massage has been described as assisting with circulation and lymphatic drainage, enhancing the elastic and inelastic properties of connective tissue and muscle, fostering relaxation, counteracting edema, and alleviating muscle pain (3,4,5,6 and 7). Malignancy has been cited as a relative contraindication to massage in the past. The concern stems from the possibility that massage may accelerate dissemination of malignant cells by enhancing the flow of lymph and blood. Several facts illustrate the limitations in this line of reasoning. Firstly, aerobic exercise is a more potent stimulant of blood and lymph flow than massage (8). No association between aerobic exercise and the acceleration of malignant spread has even been suggested. Secondly, manual lymph drainage, a massage technique specifically designed to enhance the transport capacity of the lymphatic system, has been use extensively in the treatment of lymphedema (9). Despite documented acceleration of lymph transport, manual lymph drainage has never been reported to potentiate recurrence or dissemination of cancer cells.

Thermal Modalities

This part of the chapter focuses on thermal modalities in treatment of cancer-related pain. Thermal modalities have been used by physiatrists for many medical conditions associated with disabilities. Some of the best applications of thermal modalities have been described in the literature on stroke, traumatic brain injury, and degenerative neuromuscular disease. Thermal modalities commonly employed in rehabilitation medicine include topical heat and cold, hydrotherapy, heat lamps, ultrasound, diathermy, fluidotherapy, and paraffin baths. Each of these is discussed in the following section on modalities used to treat pain in cancer patients.

Therapeutic Heat

The following discussion is limited to local applications of heat and cold as they pertain to cancer pain management and symptom control. There are three primary modes of heat transfer: (a) conduction, which includes hot packs and paraffin baths; (b) convection, which includes fluidotherapy, hydrotherapy, and moist air; and (c) conversion, which includes radiant heat, laser, microwaves, short waves, and ultrasound. Superficial heating modalities are discussed initially and deep heating modalities subsequently in this section.

Hot Packs or Hydrocollator Packs

Topical heat treatments attempt to warm tissues to between 40° and 45°C. They are primarily used to increase the mobility of a joint or the extensibility of collagen tissue; decrease muscle spasm; assist in the resolution of inflammatory infiltrates, edema, or exudates; increase blood flow; and afford analgesia. Hot packs, also referred to as “hydrocollator” packs, are the best known conductive heating modality. These packs are available in various sizes and consist of canvas bags filled with silicon dioxide. This compound, when exposed to moisture, absorbs many times its own weight in fluid, thus acquiring the large heat capacity of water. Heat has been

used as a part of cancer therapy and rehabilitation but certain safeguards must be applied when it is used (10,11). When a patient has a malignancy in an area to be heated, heat generally should not be directly applied, as temperatures below those therapeutic for cancer may accelerate tumor growth (12). Along the same lines, the increase in heat can increase the likelihood of metastases resulting from the improved blood flow and vascularity. The advantages of hot packs are many, including low cost and long life; suitability for use at home as well as in the hospital; patient satisfaction; and ease of use.

Hydrotherapy

Whirlpool baths and Hubbard tanks are currently the most common forms of hydrotherapy. These units, which are used to agitate water, are safe and provide convective heating, massage, and gentle débridement. When using hydrotherapy, treatment goals should be joint mobilization, débridement, or wound therapy. Temperatures can be adjusted, making this safe for cancer pain modalities (13). Hydrotherapy tanks can be used to immerse the whole body; this is useful in a patient with a large surface area that needs to be treated, whereas superficial heat is used for local pain relief.

Paraffin Baths

Paraffin baths are used far less than hot packs or hydrotherapy. Nonetheless they continue to have a definite role in cancer pain management. The typical bath is a container filled with a mixture of mineral oil and paraffin maintained at a temperature of 54°C. Although this temperature is somewhat higher than water-based therapy, it is tolerated because the mixture has a low heat capacity and an insulating layer of wax builds up on the treated area (20). There are two types of paraffin treatments. One is the dip method, in which a patient repeatedly dips a joint or extremity into the bath, removing the joint between dips to allow the paraffin to solidify. The area is covered or wrapped with plastic for approximately 20 minutes. The paraffin is then stripped off and placed back into the bath.

The alternate technique is for the patient to use the continuous immersion method for the treated part for 20–30 minutes at a time. Heating with this approach ensures a more intense warming of the joint or extremity; this is tolerated because a layer of solid insulating paraffin forms on the skin (14,15). This modality is useful in an extremity that may have a contracture, such as a hemiparetic or plegic patient who has a contracture or spasticity from a primary brain tumor.

Radiant Heat/Heat Lamps

Heat lamps are inexpensive, versatile, and an easy way to warm superficial tissues. Ordinary incandescent light bulbs can produce large amounts of infrared energy, so special infrared sources, such as quartz, are seldom essential. Heating rates and temperatures are adjusted by distance between the lamp and the patient—the $1/r^2$ law (16). In a cancer population this type of modality is not readily used except for instances in which it would be advantageous for the skin to stay dry or for heat application without body contact. For heating purposes, the portions of the viable light from yellow to red and the near and far infrared are used. The temperature distribution is highest on the skin surface and drops off in deeper tissues.

Ultrasound

The therapeutic ultrasound machine consists of a generator that produces a high-frequency alternating current of approximately 0.8–1.0 MHz. This high-frequency electric current is then converted by a transducer into mechanical, i.e., acoustic, vibrations (15). The transducer is a crystal inserted between two electrodes. The conversion of the high-frequency alternating voltage into mechanical vibrations is accomplished by reversal of the piezoelectrical effect (17,18 and 19). The goal is to produce vigorous therapeutic effects in deep tissues. This is effectively done by allowing the therapeutic applicator to produce average ultrasonic intensities of 3–4 W per cm^2. The physics of ultrasound is defined as a form of acoustic vibration occurring at frequencies too high to be perceived by the human ear. Thus, frequencies less than 17,000 Hz are usually called sound, whereas those above this level are designated as ultrasound. Of interest, with the exception of the differences in frequency, the physics of ultrasound is no different than audible sound.

The therapeutic temperature distribution of ultrasound is such that relatively little heat is absorbed into the subcutaneous fat; not much more energy is converted into heat in the musculature. One-half of the intensity at the muscle surface is still available at a depth of approximately 3 cm. Most energy is converted into heat at the bone surface. This makes this type of modality unique among deep-heating modalities and ideal for pain relief at the bone interface, as it does not cause extreme temperature elevation in the superficial tissues. Short-wave and microwave diathermies do not possess the depth of penetration of ultrasound and have fallen out of practical use in the treatment of pain. These physical modalities may be helpful in the cancer patient with pain of muscular or bone origin; however, heat can increase local blood flow and may be contraindicated in the cancer patient whose pain is at the site of a tumor mass (19,20). This modality may be beneficial and may provide analgesia on an area of local muscle spasm.

Therapeutic Cold

Cold modalities are traditionally used for acute musculoskeletal trauma, including edema, hemorrhage, and analgesia. Other uses include pain, muscle spasm, spasticity, muscle reeducation (as an adjunct), and reduction of local and systemic metabolic activity (21,22). Cold treatments are limited to superficial agents, and although marked decreases in skin and subcutaneous tissue temperatures are possible, the cooling of deeper tissue is restricted to a few degrees. In the treatment of cancer, the modality of cold might be employed with a patient who had an acute hemorrhage to a joint or had tumor fever in which cold might be of therapeutic benefit. Therapeutic cold causes vasoconstriction; it can be used as a counterstimulant, tending to inhibit the projection of pain information in the central nervous system. It should be avoided in areas of the body that have been previously irradiated (19).

Electrical Stimulation

Electrical stimulation may have a counterstimulation effect; it is usually applied superficially for pain and can provide analgesia through transcutaneous electrical nerve stimulation. If the pain is myogenic or of muscle origin, electrical current may be employed to fatigue muscle spasm or relieve muscular strain or tightness (20,23).

FUNCTION-ENHANCING THERAPIES

Classically, rehabilitation focuses on reducing the level of disability and handicap associated with a particular impairment. For example, the severe lower extremity motor deficits associated with complete paraplegia can be mitigated through the prescription of an appropriate wheelchair, instruction in independent transfer techniques, and use of assistive devices for the performance of activities of daily living (ADLs). A similar clinical approach can be extremely effective in reducing the functional morbidity associated with cancer pain. Discrete functional impairments can be identified and alternative means devised for accomplishing affected tasks. The goals behind this clinical approach are twofold: Pain is reduced while patients' functional status is simultaneously enhanced. Strategies routinely employed toward this end are outlined in the following sections.

Compensatory Strategies

A fundamental rehabilitation approach involves instructing patients in compensatory strategies for mobility and the performance of ADLs. This intervention assumes that a particular task or activity associated with pain can be accomplished in an alternate, less painful manner. For example, a patient with a pathological femoral fracture would be taught how to transfer from a seated to a standing position using the arms and unaffected leg for weight bearing. By deconstructing tasks required for mobility and ADL performance into discrete steps, therapists can determine which step(s) in a task sequence are sources of pain. Alternative means of completing the affected steps can then be devised and taught to patients. This approach allows intact, painless physiological systems and adaptive equipment to substitute for impaired structures. Therapeutic exercise is often used to supplement this approach. A common example involves instructing a patient to use his or her “good” leg and a toe loop to raise a plegic or painful extremity into bed during a sit-to-supine transfer.

Compensatory strategies can be used to minimize tactile stimulation of structures rendered allodynic by malignant involvement of the nervous system. Osseous structures affected by bony metastases can be “deweighted” to various degrees contingent on the risk of fracture and the degree of pain engendered by their use. Cancer patients with vertebral compression fractures can be taught how to transfer without imposing painful flexion moments on affected portions of the spine. It is critical to determine the musculoskeletal integrity of the extremities that will be used to relieve painful structures. This is particularly important for patients whose cancers have a predilection for osseous spread.

Adaptive Equipment—Mobility

Many patients require adaptive devices to enhance their safety and autonomy while moving about the home or community. Ready access to such devices is essential if advancedcancer patients are to remain socially integrated within their communities. Too often patients' social spheres collapse once the pace of advancing disease accelerates. Adaptive equipment designed to augment mobility ranges from prefabricated single-point canes to complex motorized wheelchair systems. Hand-held assistive devices are generally variations on canes, crutches, and walkers. A variety of available devices are pictured in Figure 6-1. Canes and walkers can be adapted

to distribute weight bearing onto intact structures to minimize the risk of pathological fracture. This is particularly important for patients with extensive osseous disease, as in multiple myeloma. Handheld assistive devices can greatly benefit patients with sensory impairments. Tactile feedback transmitted through the device supplements deficits in sensory input related to pathology in the afferent neural pathways. Chemotherapy-induced neuropathy is a common source of sensory impairment.

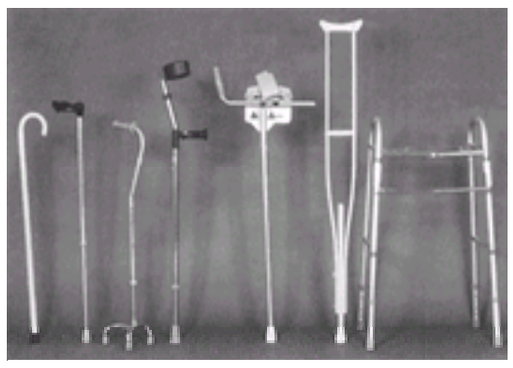

FIGURE 6-1. Common hand-held assistive devices to facilitate patient mobility.

Use of assistive devices enables deconditioned patients with limited exertional tolerance to participate in aerobic conditioning. Platform rolling walkers reduce the energy required for ambulation. As patients' stamina improves they are gradually transitioned to fewer and fewer supportive devices.

Adaptive Equipment— Wheelchairs and Scooters

Patients with severe deconditioning, paresis, osseous instability, or other sources of impaired mobility may require a wheelchair. Even when deficits are presumed transient, a wheelchair can sustain community integration and fragile social connections. Wheelchair tolerance and use are enhanced if an appropriate system is provided. There are many variables that can be specified to best serve the requirements and address the deficits of each patient. Arm-rests, for example, can be detachable to facilitate patient transfers. They are also available in “desk length,” enabling patients to maneuver close to desks and tables. Trough arm-rests can be used for patients requiring greater control of their upper extremities.

Seating systems are an element of wheelchair prescription with tremendous importance. If patients are uncomfortable, wheelchair use is inevitably reduced. Air cell, gel-filled, custom molded, and contoured foam cushions improve patient tolerance of sustained sitting and minimize skin breakdown. Chairs can be equipped with reclining backs, lateral trunk supports, and headrests to optimize patient comfort and stability. Cloth backing should not be used in the seating systems of patients at risk for vertebral compression fractures. Patients tend to slump forward in pronounced kyphosis, thereby increasing compressive forces on the anterior vertebral bodies.

Wheelchairs are available in manual and motorized configurations. Patients with sufficient strength to self-propel should be provided with handrims. These are placed slightly lateral to the wheel and are smaller in diameter. Cancer patients should not be provided with small diameter handrims. These require greater force per stroke. Knobby projections can be added to the handrims. These “lugs” assist patients with very poor grip related to distal arm weakness. If self-propulsion is not feasible, a motorized wheelchair is required. These chairs provide a high degree of independence, but are significantly more costly. Add-on power packs can be used to convert manual chairs to motorized power. These best serve individuals for whom a manual chair suffices most of the time.

Many advanced-cancer patients benefit from the use of motorized wheelchairs. Often the capacity to self-propel is lost as disease progresses. For this reason, anticipatory provision with a motorized chair is generally warranted. Wheelchair control can be adjusted to capitalize on muscle groups with sufficient power to manipulate a joy stick or switch. “Sip-and-puff “ drive control is available for patients with upper extremity paresis. Voice-controlled units remain experimental. Motorized scooters represent an excellent option for patients able to ambulate and transfer independently, but with insufficient endurance for extended ambulation.

Home and automobile adjustments must be considered when prescribing a wheelchair. Commercially purchased ramps are sufficient for many patients, requiring no home modification. If patients do not have access to a vehicle able to accommodate a motorized wheelchair or scooter, a collapsible manual chair equipped with an add-on power pack may represent the best option.

Adaptive Equipment— Activities of Daily Living

ADLs refer to the myriad functions required for personal grooming, hygiene, and feeding. Dependence for self-care has been shown to erode the quality of life of chronically ill patients (24,25). Minimizing each patient's requirement for external assistance is rehabilitation's most cherished goal. In the domain of self-care this is predominantly achieved through provision of appropriate assistive devices. Scoop dishes or plate guards (Fig. 6-2) can help patients with impaired motor control, or those who have the use of only one upper extremity to feed themselves. These devices allow patients to position food on their utensils independently. Nonskid mats, such as Dycem, can be helpful for patients with poor dexterity. Eating utensils can be easily adapted to the needs of each patient. Weight can be added for decreased stability or a bulbous handle can be used for reduced grip strength. A rocker knife (Fig. 6-3) can be used for impaired bilateral coordination. The knife is pushed down into food and rocked back and forth until the food is cut.

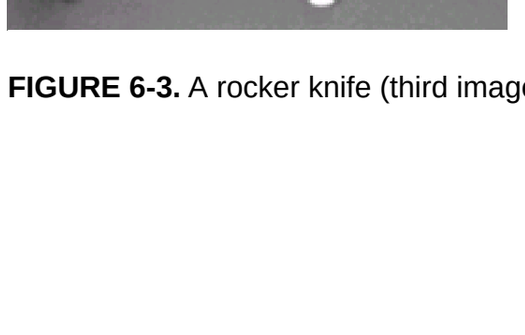

FIGURE 6-2. Scoop dishes to allow independent feeding for patients with impaired motor function.

FIGURE 6-3. A rocker knife (third image from the left) with other assistive devices for independent feeding.

Many devices are available to assist patients with independent dressing. When fine motor coordination is poor, fastening can be eased through the use of larger buttons, button aids, zipper pulls, elastic shoelaces, and Velcro. A button aid is a wire loop that hooks around a button and is then pulled through the hole. For patients lacking the mobility or dexterity to reach and grasp garments, reachers can retrieve items of clothing. A dressing stick (a long stick with a hook at the end) can help to pull clothing on. Stocking aids and long-handled shoehorns may help in a similar manner. A comparable array of assistive devices can be obtained to facilitate independent grooming.

Patients with impaired ADL performance should be referred for an occupational therapy evaluation. Most of the devices mentioned in this section can be obtained or fabricated by certified occupational therapists.

RESTORATION OF NORMAL BIOMECHANICAL ALIGNMENT

Cancer and its treatment have the capacity to adversely impact normal musculoskeletal physiology and biomechanics. Malignant lesions, particularly osseous metastases, can undermine the essential supporting structures of the musculoskeletal system. Tumors originating in or invading muscle tissue may cause severe weakness, requiring patients to recruit alternate, unaffected muscles in an effort to preserve their functional status. Patients with lower extremity sarcomas undergoing limb salvage procedures are an excellent example. Substantial portions of the knee and hip extensor muscles may be surgically resected. Continued ambulation requires recruitment of intact muscles and biomechanical adaptations. Anticancer treatments, including radiation therapy and chemotherapy, are known to cause muscle fibrosis and deconditioning, respectively. These effects may impact movement patterns when severe. Pain can also lead to significant biomechanical adaptations as patients attempt to avoid painful postures or movements. Ongoing biomechanical alterations are therefore an inescapable consequence of cancer and are experienced by virtually all patients.

Adaptive techniques become essential if patients are to remain mobile. Many biomechanical adaptations are adopted without conscious effort to avoid pain or to compensate for soft tissue contractures or muscle weakness. Unfortunately, the short-term benefit of such maneuvers may ultimately lead to long-term functional decompensation. For example, weight shifting and postural realignment used to relieve pressure from a compromised acetabular joint can eventually produce aberrant gait mechanics with associated pathology of the contralateral hip and bilateral sacroiliac joints. Another common clinical example involves head and neck cancer patients undergoing surgical neck dissection. These patients frequently develop spinal accessory nerve palsies with resulting weakness of the ipsilateral trapezius muscle. In an effort to continue using their affected upper extremities, patients recruit the remaining intact shoulder girdle muscles in a disorganized and deviant fashion. Although this maneuver may initially enhance shoulder abduction and forward flexion, rotator cuff and myofascial pathology eventually develop and may be a source of intense pain.

Three principal rehabilitative strategies permit restoration of normal alignment. Manipulative techniques abruptly return musculoskeletal structures to proper alignment through the controlled application of exogenous force. The therapeutic targets of such maneuvers are axial and appendicular joints. Manipulation is of limited benefit unless therapeutic exercise is concomitantly initiated. Therapeutic exercise, the second essential approach in biomechanical restoration, is frequently the initial and often the sole approach required. Muscles play a critical role in maintaining joint alignment and in modulating the body's many complex biomechanical rhythms (e.g., the gait cycle and scapulothoracic motion required for overhead reaching activities). Therefore, muscle weakness, contracture, and fatigability must be addressed if normal biomechanics are to be lastingly restored. Orthotics comprise the third strategy commonly used to align musculoskeletal structures for pain relief and functional enhancement. If weakness is severe, or if structures have been undermined to an irreparable degree, exogenous support (e.g., orthotics) can substitute and afford biomechanical normalcy. Often, as in the management of vertebral compression fractures, the use of orthotics is integrated with therapeutic exercise. For these patients the back extensor muscles can be strengthened while axial alignment is maintained through the use of an extension brace. Each of these three strategies (manipulation, exercise, and orthotics) is separately addressed in this section.

Manipulation or Manual Medicine

Manipulation has not been routinely offered to cancer patients despite the high prevalence of musculoskeletal dysfunction in this population. Many cancer patients develop aberrant biomechanical patterns as a result of pain, neuromuscular impairment, osseous instability, or radiation-induced soft tissue contractures (26). The adoption of such patterns is a normal response and necessary if patients are to remain mobile. However, the overuse of muscle groups in an unfamiliar repeated activity can lead eventually to spasm, malalignment, disproportionate muscle tone, and chronic pain. Manipulation provides a means of abruptly restoring normal biomechanical patterns and relief from musculoskeletal pain. Functional patterns can then be reinforced through physical therapy. Clearly the potential to harm cancer patients with irradiated tissue, bone metastases, and muscle weakness through the inappropriate application of exogenous force must be respected.

In the past, “manipulation” has traditionally been equated with high-velocity, thrusting techniques designed to maintain maximal, painless movement of the musculoskeletal system in postural balance (27). In actuality, a broad range of manipulative techniques has been developed. Manual approaches may involve stretching, passive soft tissue release, or strategic muscle contraction to produce counterstrain. The goal of manipulation or manual medicine is to restore optimal body mechanics and to improve motion in restricted areas. This is accomplished by treatments that attempt both to restore mechanical function of joints and to normalize altered reflex patterns in the muscles that control them (28). Manual medicine techniques are potentially useful for treatment of any musculoskeletal problem demonstrating a loss of functional range of motion. Complaints commonly treated with manual medicine techniques include “sciatica,” facet syndromes, mechanical cervical and lumbar pain, and piriformis syndrome.

Mobilization with impulse, or high-velocity, low-amplitude manipulation, is an approach widely equated with manual medicine. This technique is used to restore normal mobility to a discrete, dysfunctional segment (29). Similar effects can be achieved through the *articulatory technique*, which involves the combined use of leverage, patient ventilation, and a fulcrum to mobilize a joint limitation (30). This technique relies on repeated low-velocity, high-amplitude movements. *Muscle energy* is a gentle technique involving active muscle contraction by the patient against resistance supplied by the practitioner (31). Similar to the preceding approaches, the goal of muscle energy is to restore normal excursion to hypomobile segments. Strain and counterstrain is an additional well-tolerated technique designed to restore pain-free range of motion. It attempts to place a joint in its position of greatest comfort or ease by reducing exaggerated afferent proprioceptive activity.

Manual medicine techniques should only be used in patients having a reproducible musculoskeletal dysfunction. Each type of treatment technique has its own set of contraindications. Malignancy has been considered an absolute contraindication to high-velocity, low-amplitude thrusting maneuvers in the past. However, in experienced hands, symptomatic musculoskeletal structures documented as unaffected by malignancy can be safely manipulated. A cancer diagnosis warrants initial use of less forceful techniques. Muscle energy and strain and counterstrain measures should be applied first, in an effort to safely achieve clinical benefit. Caution must be taken in referring patients with severe osteoarthritis, genetic disorders with hypermobility, and metabolic bone disease.

Patients with mechanical pain or pain that can be reproduced through muscle recruitment in the absence of local tumor are candidates for manipulation. Osteopathic physicians are taught manipulation as an integral part of their medical education. Referral to an osteopath specializing in pain management and manual medicine is an appropriate initial step. Success depends largely on the skill and experience of the treating professional. Therefore, identification of a qualified individual is essential. Many physical therapists are trained in manual medicine. Physical therapy prescriptions should specify the desired treatment and precautions related to each patient's malignancy. For assistance in locating a qualified professional, the American Osteopathic Association can be contacted at (800) 621-1773 or http://www.aoa-net.org/.

Therapeutic Exercise

The prescription of exercise as a means of enhancing strength, coordination, stamina, and flexibility is the most important intervention offered by rehabilitation medicine. The recognition that our muscles and connective tissue respond predictably to imposed demands has spurred an elegant body of clinical research. Exercise should be prescribed at a clinically appropriate dose and frequency to optimize benefit and prevent injury. Too often the degree of infirmity found in advanced-cancer patients has resulted in their exclusion from exercise programs. Such patients can benefit significantly from conservative, incremental strengthening and conditioning programs despite their precarious health. This capacity has been demonstrated in other disease states characterized by comparable levels of morbidity (32,33).

When patients are hospitalized and medically stable, exercise can begin with gentle active and active-assisted twice-daily ranging of the extremities. Brief isometric muscle contractions can be performed in bed against gravity or with gravity eliminated. Isometric or static contractions are those involving no angular motion of the joint on which the exercising muscle acts. One brief isometric contraction per day was demonstrated to prevent loss of strength in bedridden rheumatoid arthritis patients (34).

Such an approach does not endanger the patient and minimizes deconditioning. As patients recover, exercise can be performed in a seated position isometrically or isotonically against resistance. An isotonic contraction is dynamic, with the tension on the muscle remaining constant throughout the contraction. More demanding resistive exercise, designed to build strength, can begin with resistance offered by a theraband. As patients improve, weighted ankle and wrist cuffs or free weights can be used. Resistive exercise has effectively improved strength in the elderly (35,36) and in patients with acquired immunodeficiency syndrome (37). Clinical investigation

with acquired immunodeficiency syndrome and aged patients suggests that the use of anabolic steroids augments the affect of exercise on cachectic muscles (38,39).

Aerobic conditioning differs from resistive exercise in its emphasis on continuous rhythmic contraction of large muscle groups. Jogging and cycling are examples. Conditioning programs have been demonstrated to benefit patients with end-stage chronic obstructive pulmonary disease (40) and end-stage congestive heart failure (41,42 and 43). Such programs do not significantly alter patients' cardiopulmonary status. However, the enhanced aerobic capacity of their muscles permits them to perform daily activities at a lower percentage of their maximal aerobic capacity. Progressive aerobic conditioning has been extensively integrated in standard care for cardiopulmonary patients, yet it is not routinely provided to cancer patients. Several investigations have demonstrated significant benefit with respect to fatigue, functional status, pain, and nausea when aerobic conditioning is administered concurrently with the delivery of adjuvant chemotherapy for breast cancer (44), or after high-dose chemotherapy during bone marrow transplantation (45).

Most of the research on exercise in the person with cancer has looked at the effect of aerobic exercise on functional capacity and quality of life. Presently, there is no consensus on an ideal type, frequency, intensity, duration, or mode of exercise. The trend of these studies indicates that there is a good cardiopulmonary response to interval training at 50–70% of the heart rate reserve or while working at an exertion of 11–14 on the 6–20 perceived rate of exertion scale (44,45). The intensity of the exercise program is dependent on baseline fitness levels, intensity of cancer treatment, and stage of cancer treatment. While undergoing treatment, most studies recommend decreasing the intensity to the lower end of the heart rate range. Once active therapy is over, the program should be progressed towards the higher end of the range. The intensity must also take into account daily lab values and patterns of fatigue associated with treatment. For example, fatigue seems to peak within the middle and end of the radiation cycle and the program should account for this pattern. Finally, duration and frequency should closely match the American College of Sports Medicine guidelines. It is recommended that patients exercise for a total of 20–30 minutes, 3–5 times per week. This recommendation must be applied carefully to patients with advanced cancer. Exercise may entail walking slowly for 5–10 minutes. The goal of a conditioning exercise program is to regularly stress the muscular aerobic apparatus to maintain or enhance physical capacity.

Exercise can also be used to enhance coordination, biomechanical balance, and flexibility. Motor learning and muscle recruitment are enhanced by appropriately prescribed exercise. Such neural factors, together with enhanced strength, account for improved biomechanics and coordination. Cancer patients whose functional decline arises from subtly impaired motor execution are excellent candidates for therapeutic exercise programs.

Orthotics

Orthotics are braces designed to alter articular mechanics when their integrity has been compromised by weak muscles, impaired sensation, bone metastases, or disrupted anatomical integrity. Orthotics may be used therapeutically to provide support, restore normal alignment, protect vulnerable structures, address soft tissue contractures, substitute for weak muscles, or maintain joints in positions of least pain. Orthotics are available prefabricated, “off the shelf.” Although such braces often suffice, patients may require more expensive custom orthoses for optimal benefit. Orthotics can be used to address pathology in virtually any articular structure. The use of these devices for cancer patients must be tempered by the overarching mandate of patient comfort. For example, a molded body jacket would provide maximal stability for a patient with diffuse vertebral metastases. However, the discomfort associated with wearing such devices, as well as the difficulty donning and doffing them, makes their use undesirable for many advanced-cancer patients. Similarly, Dynasplint produces orthotics designed to apply steady pressure on joints to elongate contracted soft tissue (Fig. 6-4). Although many cancer patients develop soft tissue contractures related to radiation therapy, the cost-benefit ratio of Dynasplint prescription must be carefully weighed before use in advanced-cancer patients.

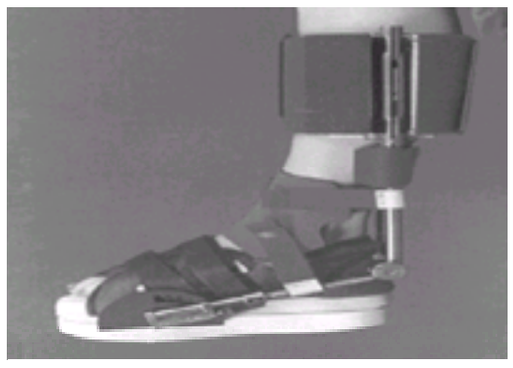

FIGURE 6-4. Dynamic splint, Dynasplint, for gentle stretching of soft tissue contractures.

Orthotics range from highly technical to remarkably simple. The orthotic most frequently prescribed by the author is an uncomplicated device called the universal cuff. This simple band encircles the metacarpal heads and has a small pocket into which eating utensils, brushes, pens, etc., can be inserted. For patients with distal upper extremity weakness related to neural compromise, this minimal device can restore the capacity for independent feeding, grooming, and keyboard manipulation. Additional commonly prescribed orthotics include the sternal-occipital mandibular immobilizer, molded ankle foot orthotic, and the Jewett brace. The sternal-occipital mandibular immobilizer (Fig. 6-5) deweights cervical vertebrae, thereby alleviating pain and instability in patients with cervical bony metastases. The molded ankle foot orthotic (Fig. 6-6) has been used extensively for patients with impaired ankle dorsiflexion due to tibialis anterior weakness. The Jewett brace (Fig. 6-7) is an anterior hyperextension orthotic designed to reduce compression of the anterior spinal elements. This device may control pain related to extensive metastatic involvement of the vertebral bodies. By limiting flexion, the device limits progressive vertebral collapse.

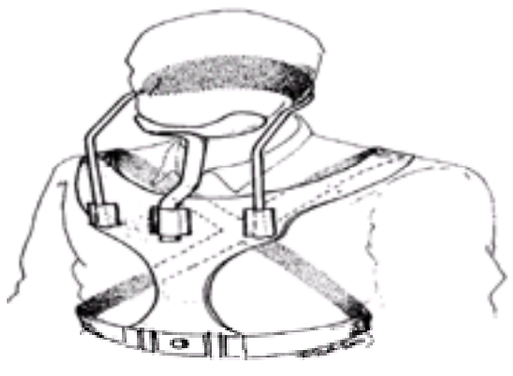

FIGURE 6-5. Sternal-occipital mandibular immobilizer orthosis.

FIGURE 6-6. Molded ankle foot orthotic.

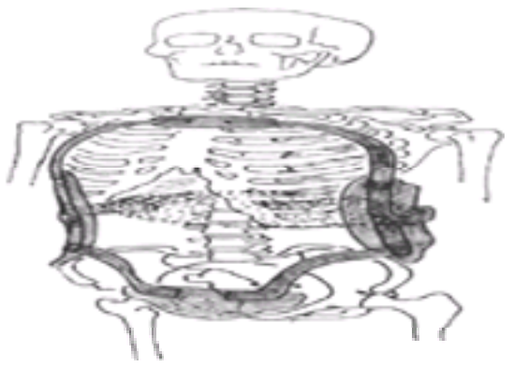

FIGURE 6-7. Jewett hyperextension orthotic.

Referral to an orthotist or physical medicine and rehabilitation specialist ensures that patients are provided appropriate orthoses. However, many rehabilitation professionals lack experience with cancer patients, particularly patients with advanced disease. It is important to communicate each patient's prognosis, goals of treatment, financial resources, and symptom-control issues to the rehabilitation professional. This gives patients the optimal chance of receiving the orthotic best suited to their unique requirements (Table 6-1).

TABLE 6-1. COMMON ORTHOSES USED FOR SPINAL STABILIZATION IN CANCER PATIENTS

Once an orthotic is in use, ongoing scrutiny of dermal integrity becomes a critical dimension of care. Cancer patients are rendered vulnerable to skin breakdown by a host of factors, several of which may collude in a given patient. Impaired dermal sensation, lymphedema, compromised nutritional status, immobility, diminished microarterial perfusion, and radiation-induced soft tissue change can render skin prone to breakdown. Dermal areas with prolonged redness after an orthotic has been doffed indicate the need for increased padding, pressure relief, or a return visit to the orthotist.

CONCLUSION

Rehabilitation offers the capacity to enhance pain control while preserving or restoring cancer patients' capacity to function independently. Physiatric evaluation can be of particular benefit to patients who experience pain with movement. Ideally, an integrated rehabilitative approach to pain management can be introduced concurrently with disease-modifying, pharmacologic, and interventional analgesic strategies. In the authors' experience, the combined use of modalities (manual, thermal, and electric) for nociceptive modulation; pragmatic task-oriented therapies for pain-free mobility and ADL performance; and strategies to restore biomechanical alignment optimizes both analgesia and functional autonomy. It is important to note that not all rehabilitation professionals are familiar with the fragility and unique requirements of cancer patients. For this reason it is critical that clinicians caring for cancer patients identify physiatrists; physical, occupational, and speech therapists; masseuses; and orthotists experienced in the care of patients with malignancy.

NEUROSURGICAL INTERVENTIONAL APPROACHES TO PAIN

JASON ERIC GARBER
SAMUEL J. HASSENBUSCH

A broad spectrum of neurosurgical operations and procedures have been used for the treatment and management of pain. The type of pain a patient is experiencing—cancerous or noncancerous, acute or chronic—and the quality of the pain depend on which of the various methods are used. For the purpose of organization, this chapter is subdivided into two sections. The first part is a brief discussion on the intracranial ablative procedures used in the treatment of pain. The second part of the chapter details the neurosurgical operations on the spinal cord for the management of pain. In addition to the various intracranial and spinal ablative procedures, a number of other surgical techniques have also been used in the treatment of pain. One of these techniques includes the use of electrical current—both deep brain as well as spinal cord stimulation. These are very broad topics that certainly deserve their own chapters for further discussion. For this reason, these two additional topics are not covered within the scope of this text.

Central ablative procedures remain important techniques in the neurosurgeon's management strategies against chronic pain. These are not entirely benign procedures, however, and often have potential risks to the patients. Furthermore, some of these intracranial ablative procedures are appropriate only after the failure of less invasive pain control measures.

MEDULLARY OR PONTINE TRACTOTOMY

Medullary or pontine spinothalamic tractotomy can be considered a treatment option for patients suffering from cancer-related pain that originates in the shoulder or cervical region (1). Specifically, one can consider this operation in patients affected with lung cancers that may produce Pancoast's syndrome or other squamous cancers that can affect the head and neck (2). There is a risk, however, of performing a medullary tractotomy—paralysis of the automatic phase of respiration. This can result in the development of sleep apnea. Furthermore, if the patient has a unilaterally paralyzed diaphragm due to lung cancer and this procedure is performed on the contralateral side, the patient may in fact die as the result of this procedure (3).

An open medullary or pontine tractotomy is usually performed under general anesthesia (Fig. 7-1). A posterior cervical midline incision is made, and a posterior fossa craniectomy and C-1 laminectomy are performed. The incision into the spinothalamic tract is made, with care as to not make the lesion above the obex. In this case, a spinothalamic tractotomy may damage the inferior cerebral peduncle and cause gait abnormalities.

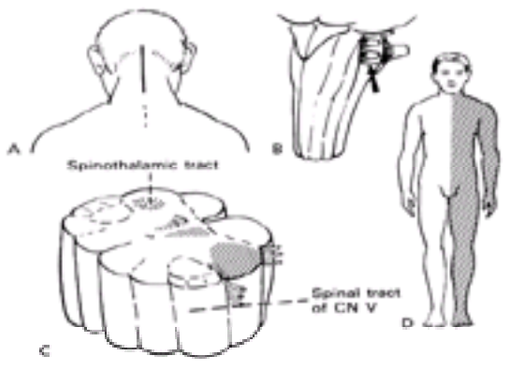

FIGURE 7-1. Medullary spinothalamic tractotomy. **A:** Site of skin incision. **B:** Dorsolateral view of medulla indicating site of incision in brainstem. **C:** Cross section of medulla indicating depth of incision into dorsolateral medulla. **D:** Extent of analgesia after right medullary spinothalamic tractotomy. CN, central nerve. (From Young R. Ablative brain operations for chronic pain. In: Loeser JD, ed. *Bonica's management of pain*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2001, with permission.)

These procedures also do not relieve the dysesthetic, burning pain that may often accompany malignancies. This is in part thought to be due to the fact that a large portion of the paleospinothalamic tract already branches off at the level where the surgical lesion is made. Consequently, these fibers are not interrupted with a tractotomy.

Past literature contains success rates between 80% and 90% for the relief of cancer pain (4,5). However, this is not a currently popular procedure for the treatment of pain. The reports in the literature make note of the fact that most individuals who did in fact undergo this procedure did not survive for longer than 6 months postoperatively (6). Furthermore, there is an overall complication rate of 14% with this procedure when used for the treatment of noncancerous pain (7). As a result, a number of therapeutic alternatives remain more appealing.

MEDULLARY TRIGEMINAL TRACTOTOMY

The medullary trigeminal tractotomy is a surgical procedure that is primarily performed for the management of facial pain. This procedure is somewhat advantageous to complete sectioning of the trigeminal nerve. It allows sparing of the sensation of proprioception and touch in the facial region, particularly the corneal reflex.

This procedure is usually performed under general anesthesia. The patient is placed in the prone position, and a posterior fossa and upper cervical exposure is performed. Once the dorsolateral sulcus is identified, as well as the obex, an incision is made into the dorsolateral medulla (Fig. 7-2).

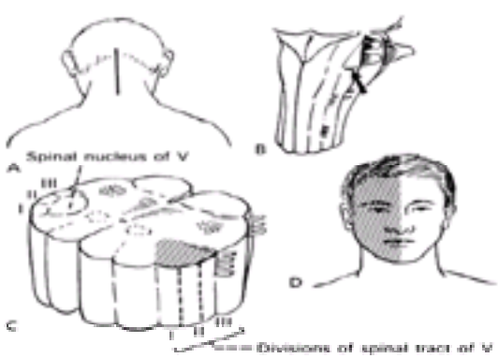

FIGURE 7-2. Medullary trigeminal tractotomy. **A:** Site of skin incision. **B:** Dorsolateral view of medulla indicating site of incision into brainstem. **C:** Cross section indicating depth of incision into dorsolateral medulla. **D:** Extent of analgesia after right medullary trigeminal tractotomy. (From Young R. Ablative brain operations for

chronic pain. In: Loeser JD, ed. *Bonica's management of pain*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2001, with permission.)

A stereotactic technique has also been described for the purpose of performing a tractotomy (8,9 and 10). This requires the patient to remain in the prone or sitting position and requires the neurosurgeon to perform this procedure via a smaller exposure. It has been used for the treatment of cancer pain, as well as for chronic, noncancerous pain conditions of the face—excluding anesthesia dolorosa.

MESENCEPHALOTOMY

The mesencephalon has long been thought of as a center for pain input from both the head and body (11,12). The primary indication for stereotactic mesencephalic tractotomy is cancer pain related to the head, neck, and upper extremities (13). Particularly, this procedure can be performed in individuals who may have unilateral diaphragmatic paralysis and in whom a high cervical cordotomy may be hazardous (13). In addition, conditions such as anesthesia dolorosa as well as postherpetic neuralgia may also respond to mesencephalotomy.

The procedure of stereotactic mesencephalotomy is performed in conjunction with stereotactic magnetic resonance imaging. This helps to better target where the lesion is to be performed. The ultimate target, however, is subject to debate. Some individuals believe that a lesion at the level of the superior colliculus results in up to 75% pain relief but causes a high percentage of ocular movement abnormalities (13). Lesions at the level of the inferior colliculus are less effective in pain control than those at the superior colliculus but have a significant reduction in possibility of ocular disturbances (14,15). In addition to the ocular disturbances that can occur with a stereotactic mesencephalotomy, dysesthesias as well as motor complications can occur.

THALAMOTOMY

Stereotactic thalamotomy remains a procedure that can be effective in patients with refractory pain (13). Specifically, thalamotomy can be used to treat cancers affecting the head and neck as well as tumors that may invade the upper brachial plexus and cause a Pancoast's syndrome (13,16).

This procedure is performed with the patient under local anesthesia, using stereotactic techniques. In addition, with the improvement in imaging, as well as with magnetic resonance imaging target localization, stereotactic thalamotomy is a relatively safe and accurate procedure. It may be a more appealing procedure for patients who may be at high risk for general anesthesia.

Other intracranial procedures that are noted within the literature include hypothalamotomy, hypophysectomy, precentral and postcentral gyrectomy, frontal lobe operations for pain, and cingulotomy. These procedures are used rather infrequently and are mentioned for reference (17).

This portion of the chapter focuses on the various neurosurgical operations carried out on the spinal cord for the relief of chronic or cancerous causing pain. The three major procedures discussed here include anterolateral cordotomy, myelotomy, and dorsal root entry zone (DREZ) lesions. These ablative spinal procedures serve as intermediate options between the intracranial–brainstem ablations and peripheral nerve lesions. The risks incurred with spinal procedures are generally lower than those associated with intracranial procedures. However, they have a more limited pattern of anatomical coverage. Peripheral denervations are technically easier to perform but often affect only a very limited anatomical area and have a higher chance of pain recurrence. The actual selection of an operation for a specific patient should be based on the type of pain (e.g., nociceptive, neuropathic, or visceral), the location of the pain, and the cause of the pain (e.g., cancer vs. noncancer).

Intraspinal ablative procedures, much like the previously described intracranial ablative procedures, are not first-line treatments for pain. They remain in a second tier of a long treatment continuum that includes (a) systemic treatments, such as various medications or physical therapy, (b) direct operations, such as spinal stabilization or surgical decompression, (c) thorough psychological evaluation and treatment as appropriate, and (d) chemotherapy and/or radiotherapy (for cancer patients).

ANTEROLATERAL CORDOTOMY

Anterolateral cordotomy is the surgical procedure by which the spinal anterolateral ascending system for the transmission of pain (spinothalamic tract) is interrupted for the relief of pain. A percutaneous and an open technique are options: The anatomical goal for each technique is the same, and results differ only with respect to the risks of each strategy and to long-term results. In many ways, it represents another example of an old procedure that has recently found increased use because of the percutaneous technique, especially with computed tomography (CT) guidance.

In 1910, Schuller first proposed the concept of relieving pain by sectioning the pain-conducting pathways in the anterolateral quadrant of the spinal cord (18). It was not until 2 years later, however, that Martin (19), at the urging of Spiller, performed the initial thoracic cordotomy in a patient with pain from a tuberculoma. Stookey was the first to report successful high cervical unilateral and bilateral cordotomy for severe pain (20). Foerster and Gagel reported similar unilateral procedures a year later (21).

The concept of a percutaneous stereotactic procedure was advanced by Mullan et al. to avoid or minimize the risks of an open procedure (22,23). Percutaneous methods could be accomplished under local anesthesia simply and easily and with a low morbidity rate in patients who otherwise might not be suitable for a major open operation (Fig. 7-3).

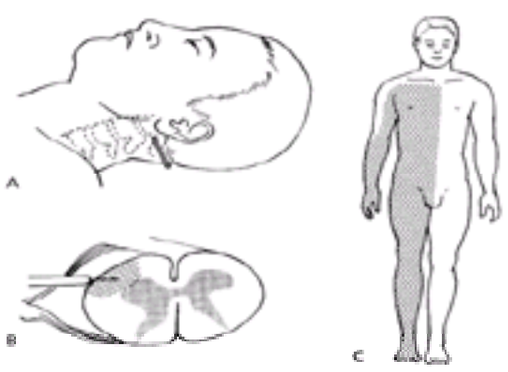

FIGURE 7-3. A: Site of percutaneous C-1–C-2 cordotomy. **B:** Lesion produced by percutaneous C-1–C-2 cordotomy. **C:**Extent of analgesia produced by left C-1–C-2 percutaneous cordotomy. (From Garber JE, Hassenbusch SJ. Neurosurgical operations on the spinal cord. In: Loeser JD, ed. *Bonica's management of pain*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2001, with permission.)

The initial method for percutaneous cordotomy first used a radiostrontium-tipped needle that was inserted into the spine at the C-1 to C-2 interspace laterally. This needle came to lie anterolaterally in the subarachnoid space adjacent to the ventral quadrant of the spinal cord. The next approach introduced a wire electrode into the parenchyma of the spinal cord so that anodal current could be used to create the lesion in the ventral quadrant. Rosomoff and associates in 1965 proposed a technique using a radiofrequency current to produce the lesion, which allowed for rapid and permanent lesion making (24). Electrophysiological monitoring of electrode position by electrical impedance and electrical stimulation were described by Gildenberg and associates and by Hitchcock and Tsukamoto and Tasker and Organ, respectively (25,26 and 27). The techniques have become standard with the use of myelography to confirm spinal cord and dentate ligament position (28). CT guidance has added another level of accuracy to this procedure (29). Two other approaches (low anterior cervical “through the disc” and occipital–C-1 dorsal cervical) have also been described but are not widely used (30,31).

Optimal candidates for this procedure should have unilateral severe pain not adequately treated by less invasive methods. With regard to neuropathic pain, cordotomy appears to be more effective in the treatment of intermittent shooting pain and evoked pain (i.e., allodynia and hyperpathia) rather than distressing dysesthesias, such as steady, burning, prickling, aching, or crawling (32). Tabetic or pseudotabetic pain, although it has a dysesthetic quality, seems to respond to cordotomy as well.

Anatomically, the procedure is indicated for pain in C-5 or lower dermatomes, preferably unilateral. It is almost entirely used for patients with pain from cancer, including those who previously could not be subjected to the major operation of laminectomy and spinothalamic section because of debilitation or a preterminal state. It is

increasingly rare to use cordotomy to treat painful conditions that are intractable and nonmalignant in nature, although some argument can be made for use in the treatment of nociceptive pain, albeit of noncancer origin (33). When bilateral cordotomy is required the contralateral procedure is performed as a second stage no less than 1 week after the first.

The major contraindication to either percutaneous or open surgical cordotomy is severe pulmonary dysfunction. A previous pneumonectomy is not an absolute contraindication, provided that remaining pulmonary function is satisfactory. The area of interest, the reticulospinal tract, is critical for automatic or unconscious breathing. Because of its proximity to the spinothalamic tract, this is somewhat of a concern when performing a cordotomy. Prior loss or significant decrease in this automatic breathing on the opposite side (e.g., from prior contralateral cordotomy or Pancoast's syndrome) can lead to a total loss of unconscious respiration (Ondine's curse).

Recently acquired neurological deficits, such as paresis or rectal or bladder disturbance, can be aggravated or recovery delayed by the superimposition of cordotomy. In this the case, the effect is usually temporary. Midline pain is a relative contraindication, even with bilateral cordotomy. General medical contraindications such as a severe bleeding diathesis, unstable cardiac function, and untreated severe systemic infection should also be taken into consideration before performing these procedures.

In the majority of series published in the literature, almost all cordotomies have been performed for pain from cancerous origin, often lung or gastrointestinal type cancers. Rarely, the procedure has been used in the treatment of lumbar radiculopathy or peripheral neuropathy (34).

The spinothalamic tract can be located in 95–99% of patients. However, the surgeon should not be hesitant to perform an early reoperation if appropriate analgesic levels are not obtained for technical reasons in the first cordotomy (33). “Adequate” levels of pain relief are found in as high as 95% of patients on discharge from the hospital. At last follow-up, however, the success rate can drop to 84% (33). Review of other published series suggests long-term success rates of 50–75%. Rosomoff and colleagues have shown that the satisfactory analgesia rates gradually drop over time since the operation: 84% at 3 months, 43% at 1–5 years, and then 37% at 5–10 years (34). It should be noted, however, that this refers to absolute pain relief. It is estimated that >50% of these patients felt they had received major help, could return to routine activities, and did not have problems of drug usage or distress severe enough to undergo repeat cordotomy.

Repeat cordotomies may be necessary in 10–20% of patients and, despite the prior cordotomy, can usually achieve levels of analgesia to acute testing pain. It appears that true pain relief, however, is captured in only approximately half of these patients undergoing a repeat cordotomy (33,34).

A comprehensive summary of complications from unilateral cordotomy indicates that, in general, the complication rate is low (33). The mortality rate can vary between 0.6% and 6.0%, almost always related to respiratory problems. Bowel incontinence and mild worsening of micturition can be seen in up to 2–10% of patients—both should be transient. Significant, permanent worsening of bladder function, however, can be seen in 2–10% of patients. Although information relative to sexual function is difficult to obtain, it appears that approximately 4% of males will note decreased sensation about the genitals on the analgesic side; true impotence appears to be very rare, even with bilateral cordotomies.

Although a postoperative Horner's syndrome is frequently seen (as often as 75% of patients), it is usually transient. Many patients will complain of transient neck pain, often described as burning or dysesthetic, from the area of the needle puncture. Transient hypotension can also be seen (2–8%).

Permanent weakness or ataxia, usually ipsilateral to the side of the cordotomy (2–10%), is a potential side effect. A mild or transient ipsilateral weakness/ataxia is reported in 3% to as many as 70% of patients. Contralateral limb weakness, presumably from lesioning too deep into the spinal cord, can also occur (1–6%).

Respiratory problems after unilateral cordotomy are rare and mild or transient (1–5% of patients). Severe respiratory failure can occur in 0.5–1.0% of patients but is more often seen as sleep-induced apnea (Ondine's curse) after bilateral cordotomies. The mechanism is related to an ascending system that contributes to the control of ventilation and is mediated through the upper cervical spinal cord (35). It is delayed in onset and can be predicted by testing the patient's response to breathing carbon dioxide (36). Ablation of the response, which is normally a two- to threefold increase in minute volume, predicts the appearance of the syndrome, but not all patients go on to apnea. The process is usually self-limiting, lasting a few days to 3 weeks.

Postcordotomy dysesthetic syndromes—burning distress throughout the entire area that was made analgesic—can occur in 1% to as many as 10% of patients. The mechanism of action is unknown. Dysesthesias in 16% are noted separately. These sensations (e.g., tingling, burning, prickling in the area of pathological implication) are not complications per se. They are uncomfortable feelings that were usually present preoperatively but were not conspicuous because of overriding pain. Once the pain had been ablated by the cordotomy, the dysesthesias became discernible and prominent, although it usually takes time to develop.

OPEN SURGICAL CORDOTOMY

Open surgical cordotomy has become largely of historical interest only (Fig. 7-4). However, the open technique might still be used in some rare circumstances such as in facilities in which percutaneous cordotomy equipment is not available or the surgeon performs the procedure so infrequently as to lose skill. When the patient is unable to tolerate any procedure while awake, a percutaneous cordotomy can be performed under general anesthesia in a manner similar to above except that, of course, sensory testing with 100-Hz stimulation cannot be performed. The indications for the open technique are the same as the percutaneous counterpart.

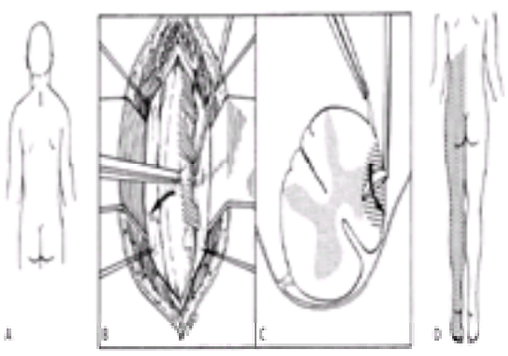

FIGURE 7-4. A: Site of open thoracic cordotomy. **B,C:** Method of performing open thoracic cordotomy. **B:** After T-1–T-2 laminectomy, the dura is opened and the dentate ligaments sectioned. The linea alba is grasped in a hemostat, and the spinal cord is rotated 45 degrees. **C:** A special cordotomy knife is used to section the anterolateral quadrant. **D:** Extent of analgesia on dorsal surface produced by right T-1–T-2 open cordotomy. (From Garber JE, Hassenbusch SJ. Neurosurgical operations on the spinal cord. In: Loeser JD, ed. *Bonica's management of pain*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2001, with permission.)

Following open cordotomy, immediate relief was reported in 70–90% of patients who had undergone unilateral procedures and in 40–78% of those with bilateral procedures. Mortality rates ranged from 3% for the unilateral procedure to 20% for bilateral procedures. Paresis and urinary complications were high (10–20%), especially after bilateral procedures. Respiratory complications comprised the most common cause of death (17). Postcordotomy dysesthetic syndromes can occur in 11% of patients. Open surgical cordotomy seems to be less effective and certainly has a higher risk of complication than the percutaneous techniques.

Percutaneous cordotomy is simpler and better tolerated than the open surgical technique. Because the anatomical and physiological bases for pain relief are the same for all cordotomies, true differences in long-term results might not be discernible. However, such advantages as the ease of performance and drastic reduction of risk and the additional advantages of repeatability ad infinitum, make percutaneous cordotomy the procedure of choice.

Percutaneous cordotomy is a valuable procedure for the treatment of severe pain syndromes, especially if located in one limb and nociceptive in quality. With the addition of CT guidance, the technique has become more facile. The risks of the procedure are significant but acceptable for this group of patients, especially those with limited expected survival times from cancer. The benefits, in terms of almost immediate pain relief and limited need for outpatient follow-up, are both cost effective and gratifying.

MYELOTOMY

Commissural myelotomy at the thoracolumbar level for the treatment of pain was first described by Armour in 1927 for a patient with tabetic abdominal pain (37).

Putnam (38) was apparently unaware of this report when he claimed to have performed the first myelotomy in 1934. Since then the popularity of this operation has waxed and waned. It seems quite logical that neurosurgeons would aim at producing bilateral pain relief with a single low-risk procedure that has little risk of damage to the important spinal axonal systems. Unfortunately, this apparently attractive operation has not been as effective as predicted on theoretical grounds. After the initial attempts on a few patients, commissural myelotomy was applied on a relatively large scale by French and German neurosurgeons in the 1940s and 1950s (39,40 and 41), subsequently becoming relatively obsolete for several years. At the end of the 1960s, Sourek (42,43 and 44) published encouraging results and once more aroused the interest of neurosurgeons in this technique. In the last 15 years the topic has recurred sporadically in the neurosurgical literature, with various results reported (45,46,47,48,49,50,51,52,53,54,55,56,57,58 and 59). Approximately 425 myelotomies have been reported in the neurosurgical literature.

The original aim of commissural myelotomy was to interrupt the decussating second-order spinothalamic fibers subserving pain perception on both sides of the body as they travel in the anterior commissure of the spinal cord. Theoretically, bilateral symmetrical analgesia should have been achieved, with pain relief restricted to the segments where sensation had been altered. The length of the myelotomy incision should have been proportional to the extent of pain. What was seen, however, even after extensive longitudinal splitting of the spinal cord over several centimeters, was that a girdle of analgesia was present in the expected area but that pain relief extended caudally into regions that had no demonstrable sensory changes. Hence, the role of the spinothalamic fibers in pain relief after myelotomy is not clear.

Various hypotheses have been proposed to explain this antalgic but not analgesic effect of myelotomy. Sourek (42,43 and 44) theorized that the spinal commissurotomy interrupts two systems that conduct pain information: the slowconducting anterolateral system and the fast-conducting mediodorsal system. The latter was believed to have a somatotopic arrangement and was contained in the medial portion of the posterior columns.

Sunder-Plassmann and Grunert (45) reported their experiences with 56 midline myelotomies and described only bilateral segmental analgesia appropriate to the level of the myelotomy. In contrast, Hitchcock (46,47) and Schvarcz (48,59) carried out cervical stereotaxic myelotomies and reported extensive areas of pain relief without sensory changes. They thought that their procedure specifically interrupts an extralemniscal centrospinal multisynaptic pathway, with Schvarcz referring to *extralemniscal tractotomy*.

From an anatomical standpoint, Kerr and Lippman reported that the projections to the periaqueductal gray matter seen in cordotomy are topographically different from those seen in myelotomy (60). The gray matter around the central canal has been shown to have anatomical connections to brainstem areas involved in nociception (61). In patients who have had an open myelotomy, disorders attributable to damage to the posterior columns are frequently observed for several weeks after surgery.

The two basic strategies for midline myelotomy are the following: open, requiring a laminectomy, opening of the dura, and making a lesion under direct vision; and closed, making a lesion through a needle that has been passed through the skin, between adjacent laminae, and into the spinal cord (Fig. 7-5).

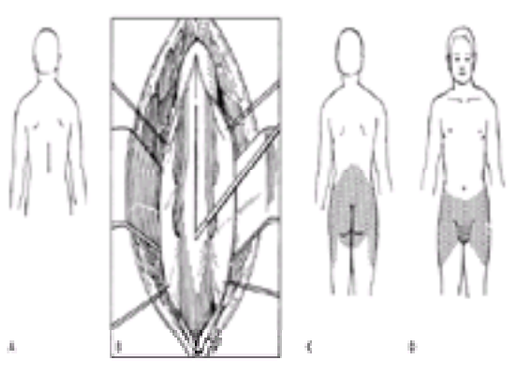

FIGURE 7-5. A: Site of thoracolumbar midline myelotomy. **B:** Method of performing midline myelotomy in thoracolumbar region. After a laminectomy of T-9–L-1, the dura is opened and the dorsal midline of the spinal cord identified. A microknife is used to make a midline incision to the ventral pial surface. **C** and D: Extent of analgesia produced by thoracolumbar midline myelotomy. (From Garber JE, Hassenbusch SJ. Neurosurgical operations on the spinal cord. In: Loeser JD, ed. *Bonica's management of pain*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2001, with permission.)

Open myelotomy is a major surgical procedure that should be considered with caution. Patients in poor condition who have a short life expectancy are not often suitable. On the other hand, even the most extensive myelotomies have not guaranteed long-lasting pain relief. A CT-guided technique has also been described in the creation of lesions in the same area (62).

Percutaneous myelotomy is described by only four surgeons; the procedure has probably been performed in approximately 150 patients, although pain relief in large regions of the body has been reported in as many as 79% of patients with cancer. Hitchcock (46,47), Schvarcz (48), and Gildenberg and Hirshberg (49) described making a lesion at C-1, and Sourek (42,43 and 44) made lesions both at C-1 and at T-8 to T-10. Coagulation of the high spinal central gray matter produces dramatic changes in sensation and pain relief over variable but widespread regions of the trunk and extremities. In this technique, only a single lesion is made in the center of the spinal cord at a segment just above the highest level of the painful areas. A single lesion is made at the thoracolumbar junction of the spinal cord (so-called *punctate midline myelotomy*) for the most common use of this procedure—pelvic visceral pain from rectal or uterine cancer (63). Follow-up times and areas of sensory loss have been variable, and the duration of pain relief is not clear.

Despite the well-documented shortcomings, there are certainly some rewarding clinical results. These come in cancer patients with pain in the pelvis, perineum, and/or both lower extremities. Good pain relief without significant analgesia is also occasionally seen (64). In combined series, total relief of pain or total cessation of analgesics was initially reported in 92% of 175 patients, most of whom had cancer pain. This rate, however, dropped to 59% at last follow-up or death in the cancer pain patients. There has been great variance in these results, however, between different series, possibly because of differences in technique, especially the depth of the sectioning.

Wertheimer and Lecuire (39), who applied myelotomy on a large scale nearly 40 years ago, initially stated that myelotomy provided satisfactory pain relief in most patients with bilateral pain in the lower half of the body. The same clinical material was subsequently reanalyzed by Dargent and colleagues (40), who concluded that myelotomy was effective only for the management of vaginal and visceral pain, whereas rectal pain and lower limb pain were not significantly influenced. Later, Sourek (42,43 and 44) and Broager (50) reported good results for the relief of lower limb pain, whereas Cook and Kawakami (51) and Lippert and associates (52) did not succeed in relieving lower limb or spinal pain. As for the pain located in the upper part of the body, Lembcke (41) and Cook and Kawakami (51) reported satisfactory results, whereas Sourek's (42,43 and 44) experience was disappointing.

With stereotaxic cervical procedures, Hitchcock (46,47) and Schvarcz (48) succeeded in most patients irrespective of the location of pain. Between these two series, 100 patients were treated. Follow-up until death or for up to 5 years indicated that approximately 70% of patients had satisfactory pain relief. Papo and Luongo (53), however, obtained only short-lasting relief with a cervical procedure (superficial splitting and deep coagulation) regardless of the type and location of pain, which always recurred in patients who survived longer than 2–3 months.

Sunder-Plassmann and Grunert (45) claimed that 91% of their patients were pain-free after midline myelotomy; 26% remained pain-free until their deaths or for the duration of follow-up, which lasted up to 4 years. Others believe that late pain recurrence as a result of a falling sensory level is rare (65). Myelotomy is a procedure confined to selected patients (66). All the published series have contained small numbers of patients.

Complications have been reported in 5–10% of the reported cases. Most surgeons agree that the typical open longitudinal midline myelotomy produces a temporary loss of pain and temperature sensation in a girdle area that corresponds to the region of the cord incision. How long this unexplained sensory loss persists is unclear. Postoperative mortality has been low (0–3%) in most recent series. Rarely, a dysesthetic or radicular pain of mild severity might occur at the top end of the area of pain relief (65). Other side effects include hyperesthesia, diminished proprioception, paresis or incoordination of gait, and motor and sphincter disturbances (64).

Although myelotomy remains a useful procedure, caution should be exercised with regard to recommending myelotomy as the initial procedure for the relief of cancer pain. This procedure can be useful for the relief of bilateral pelvic and perineal pain because the other surgical alternative is bilateral cordotomy, which carries increased risk of bladder dysfunction. Epidural and intrathecal narcotics have unquestionably greatly reduced the numbers of patients who need ablative surgery for cancer pain. For the management of noncancer pain, open myelotomy is difficult to accept. So few surgeons have reported on C-1 radiofrequency myelotomy that it is impossible to adequately evaluate this variant, which can have a different anatomical substrate from the low thoracic myelotomy. Using the present understanding of the anatomy and physiology of mesial spinal cord systems, myelotomy techniques can be chosen but should be coupled with objective assessments of side effects and effects on different aspects of the pain (67). Present data strongly suggest that this is an effective procedure, albeit for a limited subset of cancer patients with

intractable pain that is either bilateral or midline, especially located in the pelvis.

DORSAL ROOT ENTRY ZONE LESIONS

The DREZ operation entails making a series of lesions aimed at the substantia gelatinosa Rolandi and the surrounding fiber tracts. This operation was conceived and first used by Nashold and coworkers (68) in 1976 in a patient with severe pain secondary to brachial plexus avulsion. That patient has been reported to be free of pain ever since. By 1989 the Nashold group had done a total of 550 operations for various conditions (personal communication to Bonica, 1989). Almost 500 additional operations have been reported by other authors. Although Nashold and associates have the most extensive experience with this operation, many other neurosurgeons are performing this ablative procedure. The data published to date permit us to make some inferences regarding its efficacy.

This operation involves the destruction of dorsal horn neurons and perhaps of the axons traveling in juxtaposition to the gray matter, particularly those segments that correspond to the patient's reported area of pain. The detailed anatomy of the human dorsal horn is not discussed in this chapter. Rather, this chapter contains only a brief anatomical review relevant to this operation. The dorsal horn can be segmented on a cytoarchitectural basis into six laminae (Rexed's laminae). The five most superficial are clearly involved in the transmission of nociceptive information from the periphery and can play an essential role in some deafferentation or central pain states.

Not only are the synaptic connections from peripheral nociceptors localized in laminae I–V, but also studies have demonstrated major concentrations of opiate receptors, substance P, and other biologically active peptides in these regions. Indeed, many believe that the “gate,” as described by Wall and Melzack (69), resides in this region of the spinal cord. The combination of classic neurophysiology and modern pharmacology points to this region as being critical in the processing of sensory information. In 1967, Loeser and Ward (70) reported that neurons in the dorsal horn become hyperactive when deafferentated. Nashold and coworkers (68) subsequently designed an operation to destroy the dorsal horn in patients with deafferentating lesions and severe pain. Since initial successes have led to increasing use of this procedure, it has been almost exclusively used for pain states characterized by an injury to the nervous system referred to in this book as *deafferentation pain* and thought to have a peripheral-central pain mechanism; others have used the term *central pain*.

Few, if any, traditional surgical procedures have a significant chance of alleviating the pain that follows deafferentation (71). Certainly, rhizotomy, cordotomy, myelotomy, or sympathectomy is unlikely to produce long-term pain relief. DREZ lesions appear to be remarkably effective in brachial plexus avulsion and are reasonably effective for the relief of postparaplegic pain, postamputation pain, and postherpetic neuralgia and for a small number of miscellaneous neuropathies and myelopathies.

Brachial plexus avulsion, other brachial plexus destructive lesions, sacral root avulsion, and postparaplegic pain are diagnoses that have been considered as most appropriate for treatment by DREZ lesions. The procedure has also been used, although with a lower success rate, in the treatment of phantom limb pain, stump pain, postthoracotomy pain, postherpetic neuralgia, peripheral mononeuropathy, spinal cord tumor, multiple sclerosis, causalgia, and postrhizotomy pain. Specific predictive factors to indicate a favorable outcome are being developed.

The indications for consideration of DREZ lesions as a mechanism for the treatment of chronic pain include an established diagnosis and failure of medical-pharmacological management. In addition, it is important the patient has an understanding of alternative strategies, risks, and potential benefits. As previously mentioned, the diagnoses listed above are those that have thus far been considered to be appropriate for DREZ lesions. The number of patients treated, however, is currently limited in some of these diagnostic groups.

Contraindications relate to the patient's general health and ability to withstand a major surgical procedure, including such factors as infection, resistance to wound healing, blood and coagulation problems, and poor cardiopulmonary status. Patients who have a significant emotional component to their pain are rarely good surgical candidates, although the ravages of chronic pain can alter patients' judgment and emotions.

DREZ lesions are performed under general anesthesia and require a laminectomy over each segment to be lesioned. For brachial plexus avulsion involving C-5 to T-1 dorsal roots, it is necessary to do a C-4 to T-1 laminectomy (Fig. 7-6).

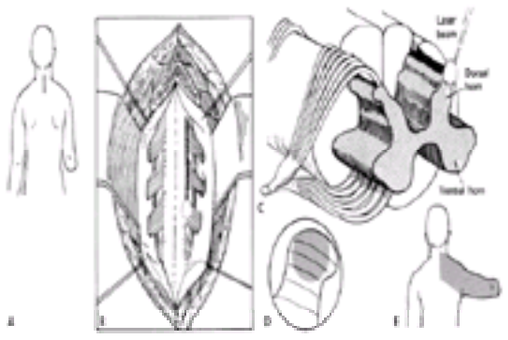

FIGURE 7-6. A: Site of C-5–T-1 dorsal root entry zone (DREZ) lesions. **B,C:** Production of DREZ lesion using carbon dioxide laser. **B:** After a laminectomy of T-1, the dura is opened, and the dorsolateral sulcus is identified. The pial vessels are coagulated and a continuous lesion made in the dorsolateral sulcus to destroy the DREZ. **C:** After the laser is used, a microprobe is inserted into the dorsal horn to verify its destruction. **D:** Extent of lesion in dorsal horn. **E:** Analgesia produced by right C-5–T-1 DREZ lesions. (From Garber JE, Hassenbusch SJ. Neurosurgical operations on the spinal cord. In: Loeser JD, ed. *Bonica's management of pain*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 2001, with permission.)

The postoperative course is usually benign; many patients have transient dorsal column or pyramidal tract dysfunction, but few have permanent deficits. It is presently unclear which method of destroying the dorsal horn is safest and most effective.

A major concern with regard to the placement of DREZ lesions is proper localization for placement of these lesions. The dorsolateral sulcus is varyingly discernible; when the dorsal roots have been avulsed, the dorsolateral region can be densely adherent to the arachnoid or to the dura. The dorsal horn is obliquely oriented and the electrode, knife, or laser beam must be angled or the spinal cord rotated to create the desired lesion and avoid damage to the pyramidal tract or the dorsal column. When roots have been avulsed or the spinal cord damaged, it is helpful to expose the levels rostral and, when feasible, caudal to the proposed operative area so that normal dorsal roots can be visualized and the dorsolateral sulcus can be identified. Evoked potentials can also be used to localize the superficial tracts in the spinal cord and assist in the placement of lesions (72).

The most common and most successful application of DREZ lesions is for the relief of the pain of brachial plexus avulsion. This traumatic disaster is most common in young men who ride motorcycles. Nashold's first patient suffered from this injury. An overall 83% success rate has been reported, with many follow-ups of longer than 5 years (68,73,74,75,76,77,78,79,80,81,82,83 and 84). A few patients with sacral root avulsions have been included in these series. No other diagnosis has as high a likelihood of success, and no other operation is as likely to relieve this type of deafferentation pain.

Postparaplegic and postquadriplegic pain is relieved by DREZ lesions (73,75,76,78,84,85 and 86). The long-term success rate is 54%, but the duration of follow-up has been variable. Some of the reported patients had drainage of posttraumatic syringomyelia at the same time; it is unclear if DREZ lesions alone are responsible for their pain relief. It is puzzling that distal spinal cordectomy does not often relieve this type of pain but that DREZ lesions are sometimes effective. It should be recognized that this is not radicular pain, nor is it the pain associated with osseous instability that can occur with traumatic injury to the vertebral column. Although cordotomy is sometimes effective for this type of pain, the long-term results do not approach those obtained with DREZ lesions.

Another type of central pain that has responded to DREZ lesions is postamputation pain (75,78,79,83,84,87,88). Within this category are two different types of pain syndromes: stump pain and phantom limb pain (88,89). The overall results for postamputation pain are 39% success in a group of 28 patients. In the series of Saris et al., phantom limb pain was highly likely to respond (six of nine patients), whereas stump pain was never relieved (zero of six patients) (88). When phantom limb pain and stump pain were both present, good results were noted in two of seven patients, but only the phantom pain responded regularly. None of the other reports clearly discriminated between phantom limb pain and stump pain. Because of the aforementioned failures, DREZ lesion is not highly recommended for stump pain.

In the earlier reports on the use of DREZ lesion for postherpetic neuralgia, Nashold and associates (86,87,90) reported that 10 of 17 patients (59%) had good pain relief

accompanied by a complication rate of 35%. In patients who had postherpetic pain for 6 months to 11 years and were followed 6 months to 6 years postoperatively, 29 (91%) had immediate relief. At 6 months, however, the figure dropped to 17 (53%), and at 18 months and thereafter only eight (25%) had persistent relief of postherpetic neuralgia involving the spinal nerves (81). Thirty-one patients with various myelopathies and neuropathies have also been treated with DREZ lesions (71,72,91,92). Approximately two-thirds had good results, with follow-ups of 6–19 months and a complication rate of 10–20%.

Nashold and associates (93,94) reported the use of DREZ lesions on the subnucleus caudalis for the treatment of severe postherpetic neuralgia and other severe intractable facial pain. After laminectomy of the C-1 to C-3 vertebrae and a small suboccipital craniectomy, the lesion is made to extend from the upper dorsal rootlet of C-2 to the tuberculum cinereum, slightly rostral to the level of the obex and the fourth ventricle. Production of DREZ lesions in the subnucleus caudalis also entails destruction of the descending trigeminal tract; the anatomical correlate of pain relief is unclear (88,93).

Since 1989, there have been at least 46 reported operations for facial pain using a two-electrode technique for subnucleus caudalis DREZ lesions. The overall pain relief was noted as “excellent” in 34% of patients and good in another 40%. The best results were obtained in patients with postherpetic pain involving one or more divisions of the trigeminal nerve (95). Pain resulting from facial trauma or dental surgery was not improved. In general, deafferentation pain responds to lesioning, but pain of a peripheral origin does not.

As more reports continue to be published regarding DREZ lesions, clear indications become more apparent for DREZ lesions in the management of chronic pain. The DREZ lesion is the only operation that was specifically designed to treat central and deafferentation pain. It is widely recognized that all standard ablative neurosurgical procedures are much more effective against pain associated with nociception (especially cancer pain) than they are against peripheral-central pain states. It remains unclear whether DREZ lesions are useful in patients with cancer pain; dorsal rhizotomy seems to be a less formidable operation for denervation of the painful area. The results of rhizotomy are variable, however, and it remains unclear whether the addition of ganglionectomy can improve them. Perhaps DREZ lesions will be effective in this type of pain.

More than any other ablative procedure, use of DREZ lesions can achieve variable results because of differences in lesion placement. It is not known how many segments above or below the level of injury the lesions should be made. Patients who have failed to obtain good pain relief might continue to suffer because the lesions did not extend far enough rostrally or caudally, yet the failure to relieve pain is ascribed to a deficiency of the operation itself. The poor results that sometimes follow DREZ lesions could be caused by failure of the surgeon to destroy the necessary amount of tissue or could be a result of inherent shortcomings in the operation as a concept (74).

ASSESSMENT AND MANAGEMENT OF CANCER-RELATED FATIGUE

CHRISTINE A. MIASKOWSKI
RUSSELL K. PORTENOY

Fatigue is among the most common symptom experienced by patients with cancer. In fact, the prevalence of fatigue ranges from 70–100% in patients receiving cancer treatment (1,2,3,4 and 5). Fatigue is often identified by patients as a major impediment to function and quality of life.

Although recognized by clinicians as a significant clinical problem, there is a striking lack of empirical research on fatigue. The epidemiology is poorly defined, and the range of clinical presentations remains anecdotal. The possibility of discrete fatigue syndromes linked to specific predisposing factors or potential etiologies, and described by unique phenomenologies and pathophysiologies, has not been explored. Indeed, there are very few data available to confirm the importance of any particular etiology, and pathophysiological mechanisms for cancer-related fatigue are entirely conjectural. Perhaps most important, there have been almost no clinical trials of putative therapies for fatigue. Treatment, when it is offered, is based largely on extrapolation of data from other clinical settings and anecdotal experience.

The obvious complexity of fatigue in the medically ill, combined with the lack of research, complicates efforts to define and characterize the symptom and offer clinical guidelines for assessment and management. Nonetheless, it is important to begin this process and thereby increase the visibility of fatigue as a clinical problem and the willingness of clinicians to explore therapeutic options. In this regard, an abundant theoretical literature can be heuristic (6,7,8,9,10,11,12,13,14,15 and 16).

DEFINITION OF FATIGUE

Fatigue is a symptom and, as such, is inherently subjective. No clear consensus exists about the nature or duration of the phenomena that would warrant the diagnosis of a fatigue syndrome or the utility of functional impact as a defining characteristic. Although clinicians generally appreciate that the differentiation between the “normal” fatigue experienced commonly by the population at large and clinical fatigue associated with a disease or its therapy requires specific criteria related to phenomenology, severity, duration, or impact, none of these potential criteria has been evaluated sufficiently to determine a definition on empirical grounds. Indeed, one definition suggests that fatigue is a feeling of weariness, tiredness, or lack of energy that varies in degree, frequency, and duration (2).

Recently, a multidisciplinary panel of clinicians and researchers convened by the National Comprehensive Cancer Network developed practice guidelines for cancer-related fatigue. The Fatigue Practice Guidelines Panel defined cancer-related fatigue as “an unusual, persistent, subjective sense of tiredness related to cancer or cancer treatment that interferes with usual functioning” (17). In addition, cancer-related fatigue was accepted as a diagnosis in the *International Classification of Diseases, 10th Revision, Clinical Modification*. Fatigue may be classified as a multidimensional phenomenon that develops over time, diminishing energy, mental capacity, and the psychological condition of cancer patients (Table 8-1) (18).

The following symptoms have been present every day or nearly every day during the same 2-wk period in the past month:
- Significant fatigue, diminished energy, or increased need to rest, disproportionate to any recent change in activity level

Plus five (or more) of the following:
- Complaints of generalized weakness or limb heaviness
- Diminished concentration or attention
- Decreased motivation or interest in engaging in usual activities
- Insomnia or hypersomnia
- Experience of sleep as unrefreshing or nonrestorative
- Perceived need to struggle to overcome inactivity
- Marked emotional reactivity (e.g., sadness, frustration, or irritability) to feeling fatigued
- Difficulty completing daily tasks attributed to feeling fatigued
- Perceived problems with short-term memory
- Postexertional malaise lasting several hours

The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

There is evidence from the history, physical examination, or laboratory findings that the symptoms are the consequence of cancer or cancer-related therapy.

The symptoms are not primarily a consequence of comorbid psychiatric disorders such as major depression, somatization disorder, somatoform disorder, or delirium.

Adapted from Cella D, Peterman A, Passik S, et al. Progress toward guidelines for the management of fatigue. Oncology 1998;12(3A):369–377; with permission.

TABLE 8-1. CRITERIA FOR CANCER-RELATED FATIGUE

EPIDEMIOLOGY OF CANCER-RELATED FATIGUE

Although there are obvious problems in performing valid surveys of a symptom that is yet poorly defined clinically, an abundance of observations in the cancer population together affirm that fatigue is both extremely prevalent and protean in its presentation. The current data are very limited, however, and there continues to be little known about the factors that may predispose to fatigue or produce it, the comorbidities that may influence its expression, and the impact it has on the quality of life of cancer patients.

Among those with metastatic disease, the overall prevalence rate for the complaints of diminished energy or fatigue has been reported to exceed 75% (19,20,21,22,23 and 24). A cross-sectional survey of 151 patients with ovarian cancer that evaluated symptom prevalence and characteristics (19) observed that fatigue during the past week was reported by 69% and that approximately one-half of those who experienced it described it as highly distressing.

A recent population-based survey of 419 randomly selected cancer patients, 31% of whom had been diagnosed during the past year, revealed that 78% experienced fatigue (defined as debilitating tiredness or loss of energy at least once each week) (25). Two-thirds of these patients reported that the symptom “significantly” (31%) or “somewhat” (39%) affected daily routine.

Some surveys have linked the occurrence of fatigue to specific antineoplastic therapies (5,7,15,16,26,27,28,29 and 30). The prevalence rates from these surveys must be viewed as tentative because of methodological concerns, including the use of nonvalidated assessment techniques in some and, in most cases, the inability to control for a variety of intercurrent phenomena such as other treatments, changes in the disease, and new-onset medical or psychosocial problems. Nonetheless, these surveys suggest that fatigue can occur after surgery, chemotherapy, radiotherapy, and immuno-therapy. Prevalence rates as high as 96% have been reported in association with chemotherapy and radiotherapy (7), and severe fatigue has been described as a near constant phenomenon associated with some of the biological response modifiers, such as interferon-a and interleukin-2 (15,16,30). A relationship between the timing of treatment and the course of fatigue has been observed in several studies (5,29), providing perhaps the strongest evidence of a causative role for the treatment.

Fatigue has been anecdotally associated with many other potential etiological factors (Table 8-2), but little is known about the incidence and prevalence of the symptom when these factors exist. Although there is good evidence, for example, that fatigue can be caused by anemia (31), little is known about the relationship between the extent or rate of hemoglobin loss and the development of fatigue. Fatigue also has been associated with many types of major organ dysfunctions, including severe

cardiac or pulmonary diseases, renal failure, or hepatic failure. Hypothyroidism and adrenal insufficiency, even if relatively mild, may also be etiologically important. Neuromuscular disorders, such as polyneuropathy or Eaton-Lambert syndrome, are also associated with fatigue. More commonly, fatigue is associated with a sleep disorder, systemic infection, the use of centrally acting drugs such as opioids, poor nutrition, or cachexia. It is possible that these factors, too, are involved in the pathogenesis of fatigue. Finally, there is a well-recognized association between fatigue and major depression.

Medical/physical conditions
Associated with the underlying disease itself
Associated with treatment for the disease
Chemotherapy
Radiotherapy
Surgery
Biological response modifiers
Associated with intercurrent systemic disorders
Anemia
Infection
Pulmonary disorders
Hepatic failure
Heart failure
Renal insufficiency
Malnutrition
Neuromuscular disorders
Dehydration or electrolyte disturbances
Associated with sleep disorders
Associated with immobility and lack of exercise
Associated with chronic pain
Associated with the use of centrally acting drugs (e.g., opioids)
Psychosocial factors
Associated with anxiety disorders
Associated with depressive disorders
Stress-related
Related to environmental reinforcers

TABLE 8-2. POSSIBLE PREDISPOSING FACTORS OR ETIOLOGIES OF CANCER-RELATED FATIGUE

Systematic surveys that could confirm the importance of these anecdotal associations have not been performed. Consequently, neither the nature of these relationships nor their importance relative to each other is known. Their utility in developing a therapeutic strategy (see “Management of Fatigue”) underscores the need for more research.

The relationships between fatigue and other patient characteristics, including demographics and psychosocial factors, also have been explored very little and there are no reliable conclusions. Older age, more advanced disease, and combined modality therapy have been associated with fatigue in one survey (27), and psychological distress was associated in another (5). There continues to be a need for systematic prospective surveys that can confirm and expand these observations.

There are many parallels between cancer and other incurable, progressive diseases, such as acquired immunodeficiency syndrome (AIDS). There is little information about the epidemiology of fatigue in these other disorders. A recent study of 427 ambulatory patients with AIDS (32) suggests the importance of such research. The prevalence of fatigue was 54%, and there were strong associations found between the occurrence of fatigue and the number of AIDS-related physical symptoms, current treatment for human immunodeficiency virus–related medical disorders, anemia, and pain. In this study, AIDS patients with fatigue were also observed to have relatively poorer physical functioning and quality of life and relatively greater psychological distress than those who reported no fatigue.

PATHOGENESIS OF FATIGUE

The mechanisms that precipitate or sustain fatigue in the cancer population are not known. The diversity of factors that may predispose to fatigue, cause it directly, or influence its expression, combined with the equally complex phenomenology of the symptom, suggest that it is not one disorder with a single mechanism. Rather, it is more likely that the fatigue associated with cancer or other medical illnesses actually represents a final common pathway to which many mechanisms may potentially contribute (6,8,9,11,12,13 and 14).

On theoretical grounds, it may be proposed that some fatigue is caused by abnormalities in energy metabolism related to increased need, decreased substrate, or the abnormal production of substances that impair intermediate metabolism or the normal functioning of muscles. Increased need, for example, could be associated with the hypermetabolic state that can accompany tumor growth, infection, fever, or surgery. Decreased substrate may account for the fatigue associated with anemia, hypoxemia of any cause, or poor nutrition.

Based on limited studies of muscle function in cancer patients, it has been suggested that some fatigue could be related to abnormal accumulation of muscle metabolites, such as lactate (33). There is no evidence linking this mechanism to fatigue, however, and if it were to occur, it could still reflect an epiphenomenon related to more fundamental disruption in metabolic activity. The mechanisms that have been most intensively studied involve the production of cytokines, such as tumor necrosis factor and others. There is good evidence that these compounds play a role in the cachexia experienced by some patients with cancer or AIDS (34). The link between cachexia and fatigue observed in the clinical setting, combined with the fatigue that often accompanies the exogenous administration of the biological response modifiers when used as cancer therapy, suggests that similar mechanisms may be involved in the pathogenesis of at least some types of fatigue (35). At the present time, however, there is no direct evidence that any cytokine is causally related to the occurrence of fatigue. Measurement of these and other biochemical factors concurrent with systematic symptom assessment is needed to confirm the relationship.

Other mechanisms for fatigue probably exist as well. Changes in the efficiency of neuromuscular functioning could occur as a direct result of neurological diseases, such as peripheral neuropathy, and result in fatigue. It is interesting to speculate that the fatigue sometimes reported in association with immobility and lack of exercise may also be due to reduced efficiency of neuromuscular functioning.

A sleep disorder could possibly cause disturbed arousal mechanisms, or equally plausible, be an indicator of a disorder of arousal. These disorders could be primary or related to metabolic disturbances or the use of centrally acting drugs. In a recent study (36), the relationships between daytime inactivity and nighttime restlessness and cancer-related fatigue were evaluated in 72 women who were undergoing the first of three cycles of chemotherapy after surgery for stage I/II breast cancer. Women who were less active during the day and who had more nighttime awakenings consistently reported higher levels of cancer-related fatigue at the midpoints of each chemotherapy cycle. In addition, the number of awakenings had the strongest association with the severity of fatigue. Additional work is warranted to determine the exact role that sleep disturbance and/or activity intolerance plays in the development of cancer-related fatigue.

Finally, it may be useful to postulate a mechanism of fatigue that may be specifically related to an affective disorder. The improvement in fatigue often noted by patients who were successfully treated for a major depression provides some support for this speculation.

Ultimately, it may be possible to assess the fatigue reported by a patient with cancer and infer from this assessment the nature of the underlying mechanism(s). This approach may in turn provide new avenues for therapies targeted to the specific mechanisms involved. A great deal more research is needed before this goal can be attained.

ASSESSMENT OF FATIGUE

Fatigue is a subjective, multidimensional symptom associated with a broad spectrum of physiological disorders. Detailed characterization of the symptom, combined with an understanding of the most likely etiological factors, is needed to fashion a therapeutic strategy that aims to minimize or reverse the likely causes and provide whatever symptomatic therapies are practicable. From this perspective, fatigue is similar to other prevalent symptoms in the cancer population (37). The clinical literature on symptom assessment is most developed for cancer pain, and the guidelines that have been developed for pain assessment offer important lessons for the assessment of fatigue.

Assessment of Fatigue Characteristics

The comprehensive assessment of fatigue begins with a detailed description of its phenomenology and the elaboration of hypotheses concerning etiology and pathogenesis. This information is acquired through the history, physical examination, and review of laboratory and imaging studies.

As noted, fatigue is multidimensional. Some of the dimensions that could be used to characterize fatigue are like those that could be applied to any other symptom, such as severity or associated distress. Other dimensions, however, are unique to this symptom and reflect the complexity incorporated into the definition of this phenomenon (Table 8-1).

As discussed previously, patients may describe fatigue in terms that relate to lack of vitality, muscular weakness, dysphoric mood, somnolence, or impaired cognitive functioning. Commonly, the description will focus on several disturbances. The history should clarify the spectrum of complaints and attempt to characterize features associated with each component. In some cases, this information will suggest an approach to therapy. For example, a patient may report a sense of diminished energy

throughout the day and somnolence in the morning. If the latter symptom can be related to a nighttime medication, such as an antidepressant, a treatment strategy could be developed that would first address the morning symptoms by changing the drug regimen and then attempt to manage whatever residual fatigue remained.

The distinction between acute fatigue and chronic fatigue is clinically relevant. Acute fatigue has a recent onset and is anticipated to end in the near future. Chronic fatigue may be defined as fatigue that persists for a period of weeks and is not anticipated to remit soon. Although there is obvious imprecision in this distinction, it is important in therapeutic decision making. A patient who is perceived to have chronic fatigue typically warrants a more intensive assessment and an approach to management focused on long-term as well as short-term goals.

Other temporal features, such as onset and course, are also clinically relevant. Fluctuation in the levels of fatigue that is linked to a discrete event, such as the administration of an antineoplastic therapy, is strong evidence of causation.

Information about factors that exacerbate or relieve fatigue should be specifically queried. Like the course over time, this information may suggest an etiology or pathophysiological mechanism or may be therapeutically relevant.

In clinical practice, the assessment of fatigue must always include an evaluation of severity. This assessment can be accomplished using a verbal rating scale (none, mild, moderate, severe) or an 11-point numeric rating scale (where 0 equals “no fatigue” and 10 equals “the worst fatigue imaginable”). The clinician should adopt one scale and use it consistently over time. The patient should be given a specific frame of reference when responding. For example, the patient might be asked to indicate the level of fatigue on average during the past week. The clinician can choose a different frame of reference, if this is desired, as long as the same instructions are given whenever the patient is evaluated.

Instruments for the Assessment of Fatigue

Unidimensional fatigue measurement typically focuses on severity (Fig. 8-1). In addition to the common four- or five-point verbal rating scales and numeric scales, visual analog scales (also called a *linear analog scale assessment*) may be used. The linear analog scale is typically a 100-mm line anchored on the ends with disparate word descriptors (e.g., “no fatigue” and “worst fatigue imaginable”). The psychometrics of a linear analog and a numeric scale have been evaluated in a medically ill population (38). Verbal rating scales and numeric scales have been incorporated into many symptom checklists (39,40 and 41).

FIGURE 8-1. Examples of unidimensional measures of fatigue severity. ECOG, Eastern Cooperative Oncology Group.

Other types of unidimensional scales have been used to assess fatigue severity. The validated quality-of-life measure created for the European Organisation for Research and Treatment of Cancer, the European Organisation for Research and Treatment of Cancer Quality of Life Questionnaire C30, has a subscale for fatigue that may be used independently (42). The three items in this subscale (Were you tired? Have you felt weak? Did you need a rest?) are graded on four-point verbal rating scales, and the sum provides the global score. The nine-item Fatigue Severity Scale (43) and the vigor/fatigue subscale of the Profile of Mood States (44) also measure global fatigue severity. An older scale, the Pearson-Byars Fatigue Checklist, has been used in studies of cancer patients but was validated in a healthy population and has been supplanted by newer measures (45).

Multidimensional fatigue questionnaires provide information about a range of characteristics other than intensity (46). There are now many validated instruments of this type (Table 8-3) (43,47,48,49,50,51,52,53,54 and 55).

Piper Fatigue Scale (47)
Lee Fatigue Scale (48)
Fatigue Assessment Questionnaire (49)
Functional Assessment of Cancer Therapy—Anemia/Fatigue (50)
Fatigue Symptom Inventory (51)
Brief Fatigue Inventory (52)
Cancer Fatigue Scale (53)
Schwartz Cancer Fatigue Scale (54)
Multidimensional Fatigue Inventory (55)

TABLE 8-3. MULTIDIMENSIONAL FATIGUE QUESTIONNAIRES

There are advantages and disadvantages in selecting a multidimensional assessment instrument. Most important, multidimensional assessment allows analyses that potentially clarify the nature of a fatigue syndrome or the type of response that occurs after an intervention. For example, a multidimensional instrument could help clarify the extent to which an intervention such as epoetin alfa affects fatigue in general, the cognitive component of fatigue, or mood.

There also may be disadvantages. Although all of the validated multidimensional assessment questionnaires have been developed in the cancer population, there has been no validation in other populations and no studies to determine the extent to which the different instruments measure similar constructs in the same population. Without these data, there is a possibility that the information collected during a study may not reflect validly on the population or scientific question. Each questionnaire covers a differing set of domains, and investigators must review a measure carefully before assuming that it addresses the issues relevant to the specific study. For example, many questionnaires do not assess sleep disturbance, mood disturbance, or cognitive impairment, and some do not evaluate fatigue-associated distress, temporal characteristics (e.g., onset, duration, fluctuation, course), or factors that worsen or relieve the fatigue.

To complement a multidimensional questionnaire, specific items can be developed, or additional validated questionnaires can be added to the questionnaire packet. The use of single items is simpler, but must be recognized as face valid only.

Other Fatigue-Related Evaluation

Identification of factors that may be contributing to the fatigue can suggest the use of a specific primary therapy directed to the etiology itself. All patients should undergo a medical and neurological examination and an evaluation of psychological status. Most patients should be screened for hematological or metabolic disturbances that may be relevant. The degree to which this and other types of laboratory or radiographic evaluation is pursued must be decided on a case-by-case basis. An extensive and costly evaluation that may be burdensome to the patient is justified only when the etiology is uncertain and the findings of the evaluation could lead to a change in therapy.

Assessment of Related Constructs

The occurrence of fatigue in the context of a progressive medical illness obligates the clinician to assess the symptom in a broader context. Chronic cancer-related fatigue cannot be addressed clinically without an understanding of the patient's overall quality of life, symptom distress, and the goals of care. These constructs constantly inform decision making.

Quality of life is itself a subjective, multidimensional construct that reflects the overall perception of well-being. It is related to the experience of suffering. The most relevant dimensions that contribute to quality of life or the degree of suffering pertain to physical, psychological, social, and existential or spiritual concerns (54,55). To fully characterize the impact of fatigue, the assessment should attempt to discern the degree to which this symptom contributes to impairment in quality of life and, concurrently, identify other factors that may be equally or more important. These factors may include other symptoms, progressive physical decline, independent psychological disorders, social isolation, financial concerns, spiritual distress, or others. This larger assessment allows the development of a therapeutic strategy that should be more likely to yield improved quality of life, or reduced suffering, than one focused entirely on a single symptom.

In assessing physical and psychological concerns, it is important to recognize that most cancer patients experience multiple symptoms concurrently (19,20). Studies have generally demonstrated that pain, fatigue, and psychological distress are the most prevalent symptoms across varied cancer populations. The construct of global symptom distress has been useful to characterize overall symptom burden (39,40 and 41), and in some situations, it is useful to consider symptom distress as the critical issue when addressing an impairment in quality of life. Patients who report fatigue should always be queried about the presence of other symptoms.

The issues encountered in the assessment of fatigue may also be clarified by another construct, the goals of care. At any point during the course of the disease, the patient, the patient's family, and clinicians may emphasize one or more of the major goals in this setting: (a) to cure or prolong life, (b) to maintain function, or (c) to provide comfort. The assessment of the goals of care derives from both the patient's desires and knowledge of the medical realities. Lack of clarity or disagreement about the goals of care can skew the assessment process and undermine the relationship with the patient and family. To avoid these problems, ongoing assessment of the goals of care and communication with the patient and family about these goals must be considered among the most important and challenging aspects of patient care.

MANAGEMENT OF FATIGUE

The comprehensive assessment of the patient with cancer-related fatigue allows the development of a strategy that attempts to ameliorate this symptom while addressing the therapeutic requirements posed by the disease itself and the need to provide other elements in the broader approach to palliative care. In some cases, therapy for fatigue should be aggressively pursued, whereas in others, interventions for fatigue can be subordinated to other therapeutic imperatives. These priorities should be developed collaboratively with the patient.

An algorithm for the treatment of fatigue has been developed based on the limited existing data and clinical experience (Fig. 8-2A and Fig. 8-2B) (56). After setting realistic expectations, the fundamentals include decisions about treatment for potential contributing causes and decisions about a variety of symptomatic therapies, both pharmacological and nonpharmacological.

FIGURE 8-2. A, B: Algorithm proposed for the treatment of cancer-related fatigue. Hgb, hemoglobin. (Adapted from Portenoy RK, Itri LM. Cancer-related fatigue: guidelines for evaluation and management. *Oncologist* 1999;4:1–10, with permission.)

Establishing Realistic Expectations

Education of the patient about the nature of fatigue, the options for therapy, and the anticipated results is an essential component of any therapeutic approach to fatigue (see Patient Education). In some situations, such as fatigue associated with advanced disease and organ failure, there are limited expectations for reversal of the symptom and this should be explained to the patient as part of a plan to improve adaptation. If there is reason to believe that the fatigue will be transitory, this information alone can sometimes suffice as therapy.

Primary Interventions

Interventions for fatigue can involve primary management of factors that are believed to be causally related, symptomatic interventions, or both. Although the range of factors associated with fatigue (Table 8-2) offers many opportunities for primary interventions, the decision to pursue a specific therapy is often difficult. None of these interventions has been studied as primary treatments for fatigue. The assessment of fatigue frequently reveals many potential factors, and their relative importance is often unclear. In the medically frail, interventions must be undertaken cautiously. The trial-and-error process of manipulating first one and then another contributing factor can be time-consuming and frustrating for the patient. Some of the potential causes for fatigue, such as the use of centrally acting drugs, are extremely prevalent, and it is often difficult to justify efforts to alter these factors when there is risk in doing so and they are so commonly used without the complication of fatigue.

Some primary interventions pose relatively little burden for the patient. The threshold for implementing these interventions is low. For example, all patients who complain of fatigue should undergo review of the drug regimen. Centrally acting drugs that are not essential should be eliminated or reduced. Polypharmacy is extremely common, particularly in the setting of advanced cancer, and there is often a tendency to continue drugs that have questionable benefit due to concerns about worsening symptoms if they are stopped. The experience of fatigue shifts the therapeutic index and clearly justifies a trial of dose reduction, at the least. The drugs that are usually considered in this case include antiemetics, hypnotics or anxiolytics, antihistamines (H_1 or H_2 blockers), and analgesics. If pain is controlled with an opioid, the experience of distressing fatigue often justifies cautious dose reduction (e.g., 25% of the total daily dose) to determine whether fatigue improves without worsening pain.

The threshold for intervening in an effort to reduce physical inactivity, insomnia, some metabolic abnormalities, or depressed mood is also usually low. The suggestion of exercise, if possible, and nonpharmacological therapy for a sleep disorder are often accepted enthusiastically by patients (see the section Symptomatic Therapy: Nonpharmacological Approaches). The use of a hypnotic can be useful but clearly requires careful monitoring. If sleep duration increases but the patient perceives it to be nonrestorative, the desired goal has not been achieved. As might be expected, the use of a centrally acting hypnotic may worsen daytime fatigue.

Fatigue can be associated with varied metabolic disturbances. Some, such as the metabolic derangements associated with renal failure, may not be treatable in the context of the overall disease. Others, such as dehydration, hypercalcemia, hypothyroidism, hypocortisolism, or hypoxia, can be managed at little risk. Interventions to improve these disturbances may be warranted in the overall approach to the fatigued patient.

A trial of an antidepressant in a fatigued patient with major depression is strongly indicated. More challenging is the decision to implement antidepressant therapy in the patient who has dysphoric mood but is not anhedonic and lacks other psychological criteria for the diagnosis of major depression. Although there are some risks with this therapy, most clinicians perceive that a treatment trial is warranted with any significant degree of depressed mood, particularly if there are other targets for the drug, such as anxiety or pain. In the setting of fatigue, the use of a relatively less sedating antidepressant, such as one of the serotonin-selective reuptake inhibitors, is appropriate. Bupropion or one of the secondary amine tricyclic antidepressants, such as desipramine, are alternatives to this class.

Recent evidence suggests that anemia may be a major factor in cancer-related fatigue. Anecdotally, transfusion therapy for severe anemia is often associated with substantial improvement in fatigue. Treatment with recombinant human erythropoietin offers another approach to this problem. In three randomized, placebo-controlled trials that enrolled a total of 413 patients, patients who were treated with erythropoietin for 8–12 weeks and experienced an increase in hematocrit of ³6% demonstrated significantly improved energy level, daily activities, and overall quality of life (57). The quality-of-life scores improved approximately 24% from baseline values. An open-label study of 2349 patients undergoing cytotoxic chemotherapy at >500 community oncology practices (31) demonstrated that erythropoietin treatment for up to 16 weeks was associated with significant increases in energy level, activities, and overall quality of life. These changes were correlated with the improvement in hemoglobin and not tumor response.

In a more recent study of 2370 patients with nonmyeloid cancers who were receiving chemotherapy (58), the effectiveness of administering erythropoietin as an adjunct to chemotherapy was evaluated in a prospective fashion. Patients received erythropoietin, 10,000 units three times weekly, which could be increased to 20,000 units three times weekly depending on the hemoglobin response at 4 weeks. Patients who experienced an improvement of >10 points in their overall quality of life demonstrated a 20–25% reduction in their levels of fatigue as measured by the FACT-An questionnaire.

These data are encouraging and suggest that patients with significant fatigue and hemoglobin levels that are not usually considered problematic (a level £12) should be considered for a trial of erythropoietin. Further studies are needed to illuminate the association between varying degrees of anemia and fatigue and clarify the extent to which hemoglobin must rise to obtain symptomatic benefit. Although erythropoietin is a relatively safe therapy, it is extremely expensive and is difficult to justify if either the fatigue or the anemia is mild, life expectancy is short, or there are other treatable factors that appear to be major contributors to the fatigue.

Symptomatic Therapy: Pharmacological Approaches

Although pharmacological therapy for fatigue associated with medical illness has not been evaluated in controlled studies, there is evidence supporting the use of several drug classes for this indication. The utility of the psychostimulants has been suggested in studies of methylphenidate and pemoline (59,60). There is a substantial clinical experience with these drugs in the treatment of opioid-related cognitive impairment (59) and depression in the elderly and medically ill (61,62,63 and 64). Although the evidence that psycho-stimulants can improve cancer-related fatigue is not conclusive, there is a favorable enough anecdotal experience to warrant a trial in patients who lack contraindications.

In the cancer population, the largest experience is with methylphenidate. Dextroamphetamine, pemoline, and modafinil have also been used anecdotally. There have been no controlled comparisons of these drugs and clinical experience suggests that the response to one does not necessary predict responses to the others. For this reason, sequential trials may be valuable to identify the most useful drug.

Pemoline is a novel psychostimulant with relatively less sympathomimetic activity than the other psychostimulants. This drug is available in a chewable formulation that can be absorbed through the buccal mucosa and may be useful in patients who are unable to swallow or absorb oral drugs. There is, however, a very small risk of severe hepatotoxicity from pemoline that has not been reported with the other psychostimulants (65). This risk may justify the use of methylphenidate as the first-line psychostimulant for most patients.

The potential toxicities associated with the psychostimulants include anorexia; insomnia; anxiety, confusion, and other organic brain syndromes; tremor; and tachycardia. These effects can be particularly problematic in the medically ill, who may be predisposed to the same symptoms for other reasons. Relative contraindications include preexisting anorexia, severe insomnia, anxiety or agitation (particularly if associated with paranoid ideation), and significant heart disease. To ensure safety, dose escalation of the psychostimulants should be undertaken cautiously, and at intervals long enough to evaluate the full gamut of potential toxicities.

In medically fragile patients, the initial dose of methylphenidate is usually 2.5–5.0 mg once or twice daily. This dose is gradually escalated until favorable effects occur or toxicity supervenes. Most patients require low doses; doses above 60 mg per day are very uncommon. Effects sometimes wane over time, a change that could reflect tolerance or progression of the underlying cause of the fatigue, and dose escalation may be needed to maintain effects. The risk of toxicity increases with the dose, however, and the ability to regain lost efficacy may be limited. The starting doses for dextroamphetamine and pemoline are 2.5–5.0 mg and 18.75 mg, respectively, once or twice daily, and modafinil usually initiated at a dose of 100–200 mg in the morning.

The use of low-dose corticosteroids as a treatment for fatigue has also been supported empirically (66,67). This treatment is usually considered in the population with advanced disease and multiple symptoms. There have been no comparative trials of the different agents in this class. Therapy is usually undertaken with dexamethasone, 1–2 mg twice daily, or prednisone, 5–10 mg twice daily.

Amantadine has been used for the treatment of fatigue due to multiple sclerosis for many years (59). There is no experience with this drug in populations with other diseases. Nonetheless, amantadine has relatively low toxicity, and an empiric trial may be warranted in selected patients with refractory fatigue associated with other diseases.

As noted previously, a therapeutic trial with an antidepressant drug is clearly appropriate if fatigue is related to a clinical depression and an antidepressant that is relatively less likely to be sedating, such as one of the serotonin-specific reuptake inhibitors, secondary amine tricyclics, or bupropion, would be preferred. Some patients appear to experience increased energy disproportionate to any clear effect on mood during treatment with one of these drugs. Theoretically, these “activating” effects could be used to treat fatigue. There have been no clinical trials of these drugs with fatigue as an end point, however, and the potential benefit of these drugs in nondepressed patients remains to be studied. In the absence of any data, an empiric trial would be warranted only in cases of severe fatigue refractory to other measures.

Symptomatic Therapy: Nonpharmacological Approaches

As noted, all patients with distressing fatigue require education to set realistic expectations. This communication is the simplest of the diverse nonpharmacological approaches that can be used to manage this symptom. Although there have been empirical evaluations of these nonpharmacological therapies, anecdotal experience suggests that several types of interventions may be useful (Table 8-4). Studies are needed to evaluate the effectiveness of these techniques.

Patient education
Exercise
Modification of activity and rest patterns
Stress management and cognitive therapies
Adequate nutrition and hydration

TABLE 8-4. NONPHARMACOLOGICAL INTERVENTIONS TO MANAGE FATIGUE

Patient preferences must be considered in developing a nonpharmacological strategy for fatigue. Participation is unlikely unless the patient perceives a substantial chance of benefit and only modest burden. More than one type of nonpharmacological intervention may be useful depending on the etiology of the fatigue.

Patient Education

Patient education that contains both procedural and sensory information has been shown to be effective in reducing pain and improving outcomes (68,69,70,71 and 72). Inadequate information may lead to needless anxiety. As noted previously, the fatigued patient should receive information about the nature of the symptom, the options for therapy, and the expected outcomes. Many patients assume that the problem reflects worsening of the disease and information about alternative explanations, if any are identified, can be very reassuring. There are large individual differences in patients' preferences for information, and the effort to educate should be provided

that is appropriate to the patient's educational level and readiness to learn.

As part of the educational process, patients may find it beneficial to keep a diary of their fatigue. The diary may help clinicians and patients discern a pattern to the fatigue and monitor its severity. This information may be useful in developing a management plan that modifies specific activities and incorporates appropriate periods of rest.

Exercise

Of the nonpharmacological interventions for cancer-related fatigue, exercise has the strongest evidence of a therapeutic benefit (72,73). Five studies have been published (74,75,76,77,78 and 79) that evaluated the effects of exercise on fatigue in cancer patients who were receiving treatment. According to Mock (73), all of these studies demonstrated significantly lower levels of fatigue in patients who exercised compared with controls. However, data that would allow the selection of the most appropriate exercise program for patients with various types of cancer or cancer treatments are not available.

Some general principles should be followed when prescribing exercise for a cancer patient. The exercise prescription should be individualized and consider such factors as the patient's age, gender, physical condition, and any inter-current medical conditions that may affect the individual's ability to exercise. Anecdotally, the type of exercise that appears to be most beneficial in ameliorating fatigue is exercise that involves rhythmic and repetitive movement of large muscle groups. This effect is achieved through walking, cycling, or swimming. An exercise program should be initiated gradually and patients should not exercise to the point of exhaustion. Exercise needs to be done for several days out of the week for beneficial effects to occur.

Contraindications to low-intensity exercise include cardiac abnormalities, recurrent or unexplained pain, onset of nausea with exercise, extreme fatigability, or cyanosis. A referral to an exercise physiologist may be warranted to have a more thorough evaluation and a specific exercise prescription developed for each individual patient.

Modification of Activity and Rest Patterns

The use of a diary to assess fatigue may identify specific activities that are associated with increased levels of fatigue. This information can facilitate a plan to modify, schedule, or pace these activities throughout the day. Brief, scheduled rest periods may help to reduce fatigue. Naps should be allowed only during the day because a period of sleep in the late afternoon or evening may interfere with the patient's ability to sleep at night.

One of the most important interventions in the area of activity and rest pattern modification is an assessment for sleep disturbances and patient education about basic sleep hygiene principles. Again, education about sleep hygiene principles should be tailored to the individual patient. One of the fundamental principles is the establishment of a specific bedtime and wake time. A specific wake time appears to be particularly important in maintaining a normal sleep-wake rhythm. An additional strategy is the establishment of routine procedures before sleep. For example, patients may read a book or watch television before falling asleep (80).

Exercise on a consistent basis tends to improve sleep and promote deeper sleep. If exercise is also used, it should be performed at least 6 hours before bedtime. Intense exercise raises the body temperature for at least 6 hours and it appears preferable for this period to pass before sleep.

Additional sleep hygiene measures include reduced environmental stimuli (e.g., loud noises, light) and the use of diversional activities (e.g., music, massage) to promote sleep. Patients also should be instructed to avoid stimulants (e.g., caffeine, nicotine, steroids, methylphenidate) and central nervous system depressants (e.g., alcohol) before sleep (80).

Stress Management and Cognitive Therapies

Anxiety, difficulties in coping with cancer or its treatment, or sleep disturbances are some of the factors that may contribute to the development of fatigue. These factors may be ameliorated using stress-reduction techniques or cognitive therapies (e.g., relaxation therapy, hypnosis, guided imagery, distraction). Research has demonstrated that distraction (e.g., gardening, listening to music, taking quiet walks) may be effective in reducing the symptom, particularly for patients with fatigue associated with deficits in attention (81,82). A referral to a psychiatrist or a psychologist for counseling and training in stress management techniques or cognitive therapies may be warranted in some patients.

Adequate Nutrition and Hydration

Cancer and its treatment can interfere with dietary intake. Fatigued individuals also may underestimate the amount of food and fluid they ingest. To aggressively manage fatigue, patients' weight, hydration status, and electrolyte balance should be monitored and maintained to the extent possible. Regular exercise may improve appetite and increase nutritional intake. Referral to a dietitian for dietary planning and suggestions for nutritional supplements may be beneficial if one of the causes of fatigue is inadequate food or fluid intake.

CONCLUSION

Despite the high prevalence and distress associated with fatigue, there has been little recognition of this symptom as an important issue for research and clinical guideline development. At the present time, relatively little is known about its epidemiology, etiologies, and management. There is no definitive information about the types of mechanisms that may produce fatigue in discrete populations.

With burgeoning interest in palliative care, it is likely that increasing attention will focus on the problem of fatigue. Extensive research is needed before the symptom will be adequately characterized in terms of phenomenology, pathogenesis, and management.

FEVER AND SWEATS

JAMES F. CLEARY

TEMPERATURE AND ASSOCIATED SYMPTOMS

Temperature has long been used in clinical medicine and was included in the cardinal signs of inflammation described as “tumor, rubor, dolor and fevor.” The measurement of temperature by thermometer, in the sublingual, subaxillary or rectal locations, is not a clinical skill practiced regularly by doctors. In most cases, temperature is recorded by other health workers or by patients themselves. Normal body temperature is considered to be 37°C, the average core temperature for an adult population.

Temperature is tightly controlled within a narrow range in each individual. Fever is defined as any elevation in core body temperature above the normal and results from the upregulation of body temperature. More commonly, a temperature greater that 38°C is considered a clinically significant fever. In oncological practice and many clinical studies, a significant fever is defined as single temperature reading greater than 38.5°C or three readings (at least an hour apart) of more than 38°C. The term *fever* (or pyrexia) *of unknown origin,*, FUO (PUO), is used commonly and often incorrectly in the daily practice of medicine. An FUO is defined as an illness lasting at least 3 weeks with a fever higher than 38°C on more than one occasion and which lacks a definitive diagnosis after 1 week of evaluation in a hospital (1).

Fever is often accompanied by other symptoms, including sweating and rigors. Sweating, when it accompanies fever, is a cooling response by the body in which heat is released from the body as it evaporates water on the skin's surface. Rigors and shivering also contribute to temperature control and are rapid muscle spasms designed to increase heat production within the body. For adult humans and most large mammals, shivering is the major means of increased heat production in response to a cold environment. Nonshivering thermogenesis, a process involving heat production in brown adipose tissue, is important in the temperature control of infants.

CONTROL OF TEMPERATURE

It is proposed that core body temperature is controlled by neurological mechanisms centered at the anterior hypothalamus. The onset of fever in patients results from an elevation of the body's regulated setpoint temperature through a resetting of the temperature “gauge” in the hypothalamus (2). This may be caused by various drugs or by endogenous pyrogens. As a result of the reset hypothalamic temperature, the body increases the core body temperature to this new level (Fig. 9-1) through shivering or nonshivering thermogenesis. The continued presence of pyrogen at the hypothalamus results in the maintenance of this higher temperature. Eventually, either as a result of a decrease in the quantity of pyrogen or the administration of an antipyretic, the hypothalamic temperature is reset back to a lower or normal level. The core body temperature is therefore lowered through sweating. This control mechanism may be suppressed in patients administered steroids or antiinflammatory agents. Older patients may not be able to mount the anticipated febrile response.

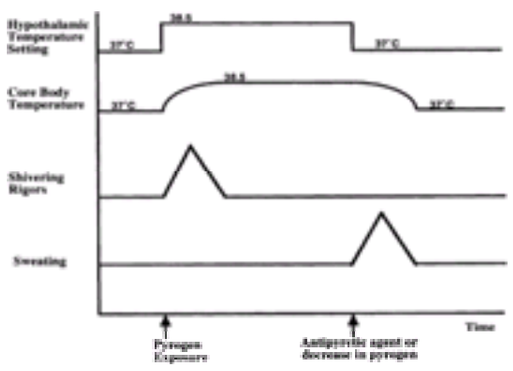

FIGURE 9-1. Physiological mechanisms associated with fever and accompanying symptoms. (Adapted from Boulant JA. Thermoregulation. In: Mackowiak P, ed. *Fever: basic mechanisms and management*. New York: Raven Press, 1991:1–22, with permission.)

The endogenous pyrogens that are responsible for the onset of fever are largely derived from monocytes and macrophages. These cells, as a result of challenge by either endotoxin or ineffective sources, release tumor necrosis factor (TNF) and interleukin-1 b(IL-1b). Their production is part of the complex cascade that results in the stimulation of other cytokines, such as interleukin-6 (IL-6), interleukin-8 (IL-8), and changes in prostaglandin metabolism. Serum levels of IL-6 and IL-8 have been found to correlate with core body temperature in febrile neutropenic patients (3). The ultimate end point of this cascade is the activation of granulocytes, monocytes, and endothelial cells. While fever appears to be associated with enhanced function of the immune system, it must nonetheless be noted that a direct connection between such phenomena and a beneficial effect of fever on outcome of infections has not been established. Fever, in fact, may be deleterious in the setting of autoimmune disorders or infections (4).

ETIOLOGY OF FEVER IN CANCER PATIENTS

Fever is commonly seen in cancer patients, both in those with and without infection. The wide range of etiologies of fever in cancer patients will be considered in relation to the pathophysiology of fever in these patients.

Tumor

Fever associated with tumor is believed to be associated with the release of pyrogens, either directly from a tumor or from stimulation of immunological mechanisms by the tumor, that cause an elevation in temperature through action on the anterior hypothalamus. The classical association of fever to particular tumor diagnoses relates more to tumors associated with a diagnosis of FUO (Table 9-1). In the combined results of six studies documenting the etiology of FUO, 23% of adults meeting the

defined diagnosis were found to have malignancy as the cause (c.f., 8% of children) (5). In another study of 111 elderly (age >65 years) patients with FUO, 26 had associated malignancy with 15 patients diagnosed with lymphoma and 4 with renal cell carcinoma (6). Almost 7000 cancer patients with fever were reviewed by Klastersky et al., and only 47 (0.7%) fit the diagnostic criteria for an FUO (7). Twenty-seven of the 47 had leukemia or lymphoma, with disease rather than infection being the cause of the fever in only 11. Tumor was responsible for fever in seven patients with widespread metastatic carcinomas; in six of these, large liver metastases were present.

Hodgkin's disease
Lymphoma
Leukemia
Renal cell carcinoma
Myxoma
Osteogenic sarcoma

TABLE 9-1. TUMORS CLASSICALLY ASSOCIATED WITH FEVER

Hodgkin's disease has classically been associated with the Pel Epstein fever (Fig. 9-2), where a patient experiences 3–10-day cycles of fever alternating with periods of normal temperature (8). Although the presence of fever is an important prognostic indicator in patients with Hodgkin's disease, there has been some discussion (9) about the value of Pel Epstein fever as a diagnostic tool particularly because the original description of the Pel Epstein fever was made in two patients who were subsequently found, on pathological review, not to have Hodgkin's disease.

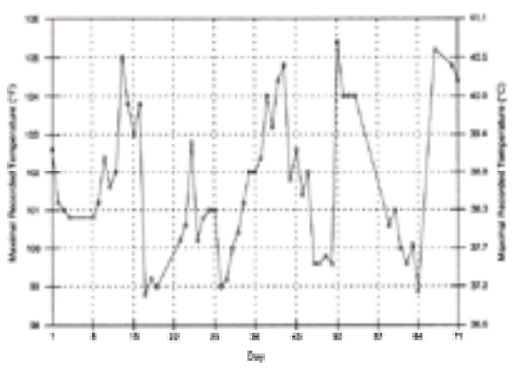

FIGURE 9-2. A 50-year-old man had fever, night sweats, and nonproductive cough for 10 weeks. He took antipyretic medications during the febrile periods. His wife recorded his temperatures, shown above, on 56 of the 71 days. Biopsy of a rapidly enlarging cervical lymph node revealed nodular sclerosing Hodgkin's lymphoma. The patient's fevers and other symptoms promptly disappeared after the first cycle of doxorubicin, bleomycin, vinblastine, and dacarbazine. [From Good GR, Dinubile MJ. Images in clinical medicine. Cyclic fever in Hodgkin's disease (Pel-Ebstein fever). *N Engl J Med* 1995;332:436, with permission.]

Although classical teaching is that fever is associated with particular tumors, fever also occurs in many of the more common cancers (Table 9-2). Forty-one percent of those who underwent autopsy had evidence of infection as an explanation of their fever (10). The incidence of infection among the autopsied patients was 50% for acute leukemia, 75% in lymphoma patients, and 80% in those with chronic lymphocytic leukemia. Infection was only found in a third of those with chronic myeloid leukemia, 17% with Hodgkin's disease, and 15% of patients with lung cancer.

Primary site	Number of patients observed	Number of patients with fever without associated infection	
		Number	%
Stomach	1498	573	41
Kidney	208	39	19
Colon and rectum	113	75	66
Liver and gallbladder	98	43	44
Uterus	81	19	36
Squamous skin cancer	41	20	49
Esophagus	20	7	35
Breast	48	16	33
Lung	17	8	47
Small bowel	17	1	6
Prostate	11	7	64
Bladder	10	6	60
Bone	10	7	70

TABLE 9-2. INCIDENCE OF FEVER WITHOUT EVIDENCE OF INFECTION AT AUTOPSY IN PATIENTS OF DIFFERENT PRIMARY TUMOR TYPES

Infection (Including the Neutropenic)

While infection and fever can be a common presentation in cancer patients, it is of particular concern in neutropenic patients. Neutropenia, defined as a peripheral blood neutrophil count of less than 500/µl, results from either increased destruction or decreased production of white blood cells. Decreased production by the bone marrow may result from either disease involving the marrow or from myelosuppression by chemotherapy. The cause of fever is not identified in some 60–70% of neutropenic patients (11). Risk factors for the development of fever in the setting of neutropenia have been identified and include a rapid decrease in the neutrophil count and a protracted neutropenia of less than 500 cells/µl for greater than 10 days (12). Twenty percent of patients with 1 week of chemotherapy-induced neutropenia develop a fever and the rate of infection increases with lengthening periods of neutropenia. Other factors that may alter the risk of the neutropenic patient include phagocyte function, the status of the patient's immune system, and alterations in the physical defense barriers of the body (e.g., mucositis).

Fever and neutropenia in cancer patients are associated with a high risk of medical complications with a death rate ranging from 4–12%. Twenty-one percent of patients with febrile neutropenia at the Dana Farber Cancer Center developed serious medical complications (13). The investigators identified four risk groups for febrile neutropenic patients. Group 1 were inpatients at the time of onset of fever; group 2, outpatients who developed significant comorbidity within 24 hours of presentation; group 3, outpatients with uncontrolled cancer but without serious concurrent comorbidity; and group 4, outpatients without serious concurrent comorbidity and whose cancer was well controlled. The model was validated in 444 patients with febrile neutropenia, of whom 36% had a significant comorbidity, 27% had serious medical complications, and 8% died. Group 1 had the greatest risk and group 4 had little risk in relation to medical complications and risk (Table 9-3).

Patient group	Number of patients	Multiple complications (%)	Deaths (%)
Group I	258	51 (19)	25 (9)
Group II	43	3 (7)	5 (12)
Group III	29	3 (10)	4 (14)
Group IV	134	0 (0)	0 (0)
All patients	444	57 (13)	34 (8)

[a]Risk groups are defined in text.
From Talcott JA, Siegel RD, Finberg R, et al. Risk assessment in cancer patients with fever and neutropenia: a prospective, two-center validation of a prediction rule. J Clin Oncol 1992;10:316–322, with permission.

TABLE 9-3. INCIDENCE OF MULTIPLE MEDICAL COMPLICATIONS AND MORTALITY IN FEBRILE NEUTROPENIC PATIENTS AS DEFINED BY RISK [a]

An important component of this study was the identification within 24 hours of onset of fever of those patients at low risk of medical complication. These low-risk patients were indeed at risk of developing medical complications (5%). But they were either transient and asymptomatic or were heralded by at least 7 days of medical deterioration and were thus readily detectable by appropriate follow-up. Two additional risk factors—a latency period of less than 10 days from the time of chemotherapy administration to the onset of fever, and neutropenia and age greater than 40—correlated with the occurrence of more frequent complications. Mucositis was associated with decreased risk of medical complications, suggesting that infection associated with mucositis may be responsive to antibiotics. The identification of a causative organism or positive blood cultures was not associated with increased risk.

In a multinational study, a risk-index score was developed to “stage” those patients with febrile neutropenia (14). Predictive factors included blood pressure, presence of chronic obstructive pulmonary disease or solid tumor, previous fungal infection in patients with hematological malignancies, outpatient status, status of hydration, and age in relation to 60 years. On the validation set, a Multinational Association for Supportive Care in Cancer risk-index score ^{3} to 21 identified low-risk patients with a positive predictive value of 91%, specificity of 68%, and sensitivity of 71%. In a further population, the risk index accurately identified patients at low risk for complications. This risk index may be useful in the selection of patients for studies that test strategies to treat febrile neutropenia.

Based on a number of retrospective studies, similar definitions of low risk have been applied to pediatric patients with fever and neutropenia (15). Low risk included evidence of bone marrow recovery in culturenegative patients who were afebrile for at least 24 hours and who had no other reason to continue intravenous antibiotics in the hospital. The control of any localized infection and the patient's ability to return promptly in the event of fever or other complications were also necessary. In a prospective study of 70 patients who met the above criteria and who were discharged home with neutropenia, none was readmitted with fever. All seven patients who were inadvertently discharged without evidence of marrow recovery were readmitted with recurrence of fever. Neutropenic children with positive cultures were also assessed to identify risk factors for bacteremia (16). Of the cases of bacteremia, 92.5% occurred in those whose cancer was not controlled, were less than 1 year of age, were less than 10 days past their last chemotherapy, and who had no evidence of marrow recovery.

Organisms (Bacteriology)

A basic understanding of the classification and sensitivities of the different organisms is essential to the understanding of infection in cancer patients. Over time there have been changes in the underlying organisms associated with febrile neutropenia as evidenced by progressive studies by the EORTC group (17). Gram-negative organisms were the leading cause of infection in febrile neutropenic patients, but their incidence has decreased from 71% of identified causative organisms during the 1973–1978 period to 31% during the 1989–1991 period. Infection by one of these gram-negative organisms—*Pseudomonas aeruginosa*— has been a driving force in the selection of antibiotics. However, the incidence of pseudomonas infection has also decreased over the last few years as reflected by an incidence of only 0.1% of febrile neutropenic cases at the National Cancer Institute (18). The incidence of gram-positive organisms has increased from 29% during the 1973–1978 period to 69% during the 1989–1991 period, requiring a review in treatment regimens used in febrile neutropenic patients. The incidence of both acute and chronic fungal infections has also increased, with up to 33% of febrile neutropenic patients not responding to a week of antibiotic therapy, having a systemic fungal (*Candida* or *Aspergillosis*) infection (19).

Location

Infections can occur throughout the body and need to be sought carefully with history and examination. Collapse, consolidation, and superimposed infection may develop behind an obstructing bronchial tumor. Aspiration pneumonia may occur in those with esophageal tumor either secondary to an obstruction or as a result of a tracheoesophageal fistula.

The gastrointestinal system is the most common site of indigent organisms causing infection in neutropenic patients. *Clostridium difficile* infection may present with fever and diarrhea and must be considered in those who are already taking antibiotics. Fungal and viral infections of the esophagus need to be suspected in those with dysphagia and odynophagia. Anaerobic infections may be a factor in severe mucositis or gingivitis and in those patients with perianal discomfort. Spontaneous bacterial peritonitis may be a cause of fever in patients with ascites. A urinary catheter will increase the risk of urinary tract infection as does the presence of obstruction, but the presence of asymptomatic bacteriuria in a nonneutropenic cancer patient is not usually an indication for antibiotic treatment.

Central nervous system infections can be difficult to diagnose and usually require lumbar puncture to confirm. Infection is the most common complication of Ommaya reservoirs, used to administer intraventricular chemotherapy, and is more likely to occur in those with previous radiotherapy or in whom repeated surgical procedures have been necessary (20). Most infections are due to *Staphylococcus epidermidis* and usually can be successfully treated with antibiotics (21).

Particular attention to sites of recent surgery is important in assessing infection. Surgical collections may include infected hematomas that develop following surgery. The skin is also a common site of infection that may range from infected decubitus ulcers to herpes zoster infections. The use of catheters in oncology has created another portal for the introduction of infection in cancer patients. Of a total of 322 indwelling devices placed in 274 cancer patients by a single surgeon, device-related sepsis occurred in 28 of 209 patients (13%) with catheters and 6 of 113 patients (5%) with subcutaneous ports (22). Triple lumen catheters were associated with a higher rate of thrombosis but not of infection. The complications of 1630 venous access devices for long-term use in 1431 consecutive patients with cancer were reviewed (23). Of the catheters inserted, 341 of 788 (43%) had at least one device-related infection compared with 57 of 680 (8%) of the completely implanted ports (p = .001). The number of infections per 1000 device days was 2.77 for catheters compared with 0.21 for ports (p = .001). The predominant organisms isolated in catheter-related bacteremia were gram-negative bacilli (55%) compared with gram-positive cocci (65.5%) in port-related bacteremia. Patients with solid tumors were less likely to have device-related infectious morbidity compared with patients with hematological cancers.

Transfusion-Related

Blood products, administered extensively to cancer patients, may be associated with febrile reactions. The incidence of side effects following the administration of over 100,000 units of red blood cells to more than 25,000 cancer patients over a 4-year period was retrospectively reviewed (24). Of all transfused units, 0.3% had a transfusion-associated reaction; 51.3% were febrile nonhemolytic, and 36.7% were allergic urticarial reactions. Only 17 hemolytic reactions (4 immediate, 13 delayed) were documented. The incidence of transfusion-related side effects was significantly lower in this study than that reported in the noncancer population. Infection may also be a source of fever in patients receiving blood products. The Canadian Red Cross (25) estimated that the true positive rate of bacterial contamination of platelet concentrate units was between 4.4 and 10.7 per 10,000 units and recommended screening of all such units. The percentage of those patients developing bacteremia or septicemia from infected units was not discussed.

Thrombosis

Trousseau's self diagnosis of gastric cancer on the basis of venous thrombosis is a reminder that cancer patients are at particular risk of thrombosis. Deep-vein thrombosis may present with fever and, given the uncertainty of clinical diagnosis, investigation may be necessary in the “at risk” patient. Pelvic thrombophlebitis may sometimes occur after pelvic surgery and, if septic, may manifest with either low- or high-grade fever. Pulmonary embolus also needs to be considered in the differential diagnosis of fever in cancer patients. Of 97 patients with confirmed pulmonary embolus in the Urokinase PE Trial, 17 had associated malignancy (26). Of those with confirmed malignancy, 54% had a fever greater than 37.5°C and 19.6% had a fever greater than 38°C. Fortyone percent of the cancer patients had associated sweating. Pulmonary infarction, with the primary signs of tachypnea, tachycardia, and fever, may be a presentation of pulmonary thrombi. Other thrombotic syndromes, such as cerebral venous thrombosis, although associated with fever, are not common in the setting of malignancy.

Hemorrhage

Gastrointestinal bleeding may present with fever and should be considered in the differential diagnosis of a patient with low-grade fever and sweats. However, in a major review of fever in cancer patients (10), serious hemorrhage was followed by fever in a minority of cases; the usual sequence has been that of hemorrhage in an already febrile patient.

Drugs

Drug-associated fever is an illdefined syndrome in which fever is the predominant manifestation of an adverse drug reaction. It is normally a diagnosis of exclusion (27). The drugs commonly associated with fever are antibiotics, cardiovascular drugs, central nervous system drugs (e.g., phenytoin), cytotoxics, and immune therapy (either as biological response modifiers or growth factors). Antimicrobial agents were responsible for 46 of 148 drug-related fevers in a review of the experience of two hospitals in Texas and the United Kingdom with a mean lag time from initiation of treatment to onset of fever of 21 days (median, 8 days). For 11 cases of cytotoxic-induced fever, the mean lag time was 6.0 days with a median of 0.5 days. Shaking chills were more common with the administration of cytotoxic-associated fever than with other drugs (28).

Cytotoxics

There is a diverse range of cytotoxic drugs whose administration is associated with fever (Table 9-4). The febrile response to bleomycin was described in the original phase 1 studies (29) and characteristically occurs 3–5 hours after injection. It is more common after intravenous than after intramuscular injection. It is seen in approximately 25% of patients administered the drug. The fever becomes less frequent with repeated injections. An anaphylactic reaction manifested by hyperpyrexia, shock, hypotension, urticaria, and wheezing occurs in 1% of patients administered bleomycin (30). Fever following the administration of cisplatin was also reported in early clinical trials (31). Streptozocin administration may result in fever associated with chills, as can cytarabine and etoposide. Fever can occur after the administration of 5-fluorouracil and high-dose methotrexate. Confusion concerning the etiology of a fever arises more commonly in the situation of intensive chemotherapy regimens where neutropenic patients may be administered cytotoxic agents that cause fever. Awareness of the symptoms produced by the different agents assists in discerning the etiology of the fever.

Bleomycin	Mustine
Cisplatin	Mithramycin
Cytarabine	Streptozocin
Cyclophosphamide	Thiotepa
Etoposide	Vinblastine
5-Fluorouracil	Vincristine
Methotrexate	

TABLE 9-4. CYTOTOXIC AGENTS ASSOCIATED WITH FEVER AFTER ADMINISTRATION

Antibiotics

The antibiotics commonly associated with fever are the penicillins, cephalosporins, and amphotericin. In 50 patients administered at least 100 mg of amphotericin B over a minimum of 3 days, fever was experienced by 34% and chills by 56%, with rates of 2.6 and 3.5 mean episodes per patient per treatment course, respectively (32). In patients who had received 20 mg or more of amphotericin-B per day for at least 10 consecutive days, shivering was noted to occur first at the test dose, with the percentage of patients who shivered increasing with each successive dose and peaking at the fifth therapeutic dose (33).

Opioids

The intravenous injection of morphine is often associated with sweating, and vasodilatation, but not necessarily associated with fever. Fever may occur as a result of the interaction between pethidine and monoamine oxidase inhibitor, an interaction to be avoided. Drug withdrawal is associated with a syndrome that includes fever and needs to be suspected in febrile cancer patients in whom opioids have been suddenly stopped. Withdrawal from benzodiazepines may also be associated with fever.

Biological Therapy

Interferons (IFN) are associated with the development of fever (34). Partially purified IFN administered at low doses intramuscularly induces a fever (38–40°C) within 6 hours that persists for some 4–8 hours. More severe side effects are seen when the drug is administered intravenously, intrathecally, or in patients older than 65 years of age. The use of the highly purified recombinant DNA IFN induces similar side effects. IFN at doses of 50–120 MU results in a sharp febrile response with severe rigors, peripheral cyanosis, vasoconstriction, nausea and vomiting, severe muscle aches, and headaches. In those receiving IFN daily, the febrile response and accompanying symptoms usually decrease in intensity and disappear in 7–10 days. Fever, however, persists with intermittent (nondaily) injections producing a fever that peaks at 6–12 hours and tends to last longer than the normal 4–8 hours. The administration of other biological factors is associated with the onset of fever (e.g., tumor necrosis factor). The administration of growth factors is associated with the onset of fever although the incidence following granulocyte colony-stimulating factor (G-CSF) is very low. Fever occurs much more commonly following granulocyte mac rophage colony-stimulating factor (GM-CSF) administration than with G-CSF administration.

Graft-versus-Host Disease

Chronic graft-versus-host disease is very much like that of a systemic collagen vascular disease and may be associated with infection, with or without the presence of fever. Acute graft-versus-host disease is associated with fever. Infection is also common.

Radiation-Induced Fever

Patients receiving radiotherapy alone may present with fever some hours after the initial treatment. Acute radiation pneumonitis may develop 2–3 months after completion of radiation therapy. A high spiking fever may be part of the syndrome that consists of dyspnea and an unproductive cough. Lung biopsy may be necessary to establish the diagnosis.

Other Diseases

Other diseases that may cause fever may coexist in cancer patients (e.g., systemic lupus erythematosus and rheumatoid arthritis). Careful review of past medical history and current symptoms is essential.

DIAGNOSIS

The classical teaching that history provides 95% of the diagnosis is certainly true when it comes to the symptoms of fever in oncology patients. Following the physical examination, the use of diagnostic aids is related very much to the relevant history. Although two-thirds of neutropenic patients do not have an identifiable cause of their fever, culture of relevant body fluids is still essential. However, routine surveillance cultures in patients with neutropenia, prior to the development of fever, are not cost productive (35). While a CXR may not be indicated in symptomatic patients presenting with febrile neutropenia (36), a recent CXR may be an important baseline in a

patient without respiratory symptoms or signs who is likely to have a prolonged period of neutropenia.

The diagnosis of fever due to the cancer itself can be confirmed with the use of naproxen (37). The proponents of “the naproxen test” state that it does not result in a decrease in temperature in those with infection. The successful treatment of “neoplastic” fever in 21 cancer patients was demonstrated with 15 responding to a dose of 250 mg/ day, while others responded following an increase in the dose of naproxen administered. The true sensitivity and specificity of this test is uncertain, but the authors stress that infectious fever and noninfectious fever due to drug toxicity, allergic reaction, and adrenal insufficiency need to be excluded before considering the diagnosis as “neoplastic fever.”

TREATMENT

Primary to any treatment of fever in cancer patients is the treatment of underlying cause of fever. Antibiotics should not be used to control fever in nonneutropenic patients in the absence of evidence of infection, but nonsteroidal antiinflammatory drugs may be useful in the treatment of fever associated with infection.

Physical cooling (e.g., through sponging) alone is likely to be uncomfortable for febrile patients and should be reserved for those in a hot and humid environment that may impede evaporative heat loss or for those with defective heat loss mechanisms (38). Sponging, when it does take place, should be with tepid water because the use of cold water will induce shivering, which increases patient discomfort and causes an elevation in temperature (39).

Agents that lower body temperature (antipyretics) primarily comprise three groups:

1. Pure antipyretics that do not work in the absence of pyrogen, and at usual therapeutic doses do not affect normal temperature (e.g., acetaminophen)
2. Agents that cause hypothermia in afebrile subjects by directly impairing thermoregulatory function
3. Those that are antipyretic in lower doses and cause hypothermia in higher doses (e.g., chlorpromazine)

Only salicylates, acetaminophen, and ibuprofen have been approved for antipyretic use in the United States, and none of these agents is likely to cause hypothermia in normothermic patients. Aspirin is not recommended for use in children because of the risk of Reye's syndrome, a disease process that results in liver failure (40). Aspirin has been the standard of reference in nearly two-thirds of clinical comparisons of antipyretic activity, but only one comparison of aspirin has been performed in cancer patients (41). Patients with low-grade fever each received doses of aspirin and placebo in random order. No useful conclusions could be drawn, as the mean reduction in temperature for the 600 mg of aspirin was only 0.3°C, not statistically significant from placebo.

In children, acetaminophen has a dose-response effect with doses of 5, 10, and 20 mg/kg bringing about a reduction in temperature of 0.3°C, 1.6°C, and 2.5°C, respectively, after 3 hours (38). Aspirin and acetaminophen appear equally effective at approximately 10 mg/kg. Ibuprofen, 0.5 mg/kg, is about as effective as 10 mg/kg aspirin and 12.5 mg/kg acetaminophen and probably lasts longer. Indomethacin has been reported to be more effective than these three compounds in limiting febrile responses to IFN (42) but is not approved for antipyretic use in the United States. Indomethacin (75 mg), naproxen (500 mg), and diclofenac sodium (75 mg) have been found to be equally effective in the management of paraneoplastic fever (43). Steroids may be useful in treating fever, acting in the same manner as nonsteroidal antiinflammatory drugs. Steroids may be particularly effective in patients who are imminently dying.

Treatment of Infection

The treatment of fever in a nonneutropenic oncology patient is not in itself a medical emergency. Shock associated with such a patient may well make it an emergency. A thorough review of the history and examination and the performance of the appropriate tests should guide both the timing and the type of treatment initiated.

The presence of fever in an immunocompromised patient is a medical emergency and empirical therapy should be initiated as soon as possible. Patients at risk of neutropenia should be instructed to record their temperature and to report the presence of fever to health care staff. An overall schema for the use of antimicrobial agents in neutropenic patients with unexplained fever is presented in Figure 9-3. Antibiotic recommendations by The Infectious Diseases Society of America Consensus Statement on Febrile Neutropenia (44) will be considered together with more recent studies on the choice of antibiotics in febrile neutropenia. The decision as to which antibiotic regimen to use rests with each institution and must take into consideration local experience and infection trends.

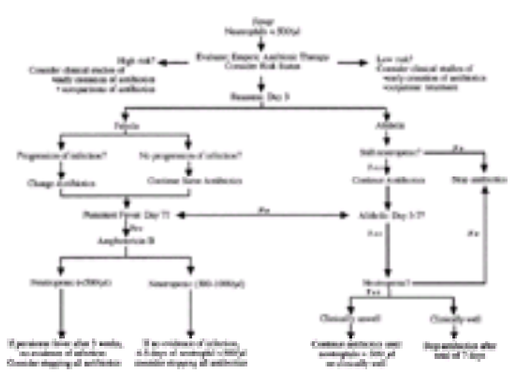

FIGURE 9-3. Clinical approach to the treatment of patients with febrile neutropenia.

The initial choice of antibiotic regimens is most commonly with an aminoglycoside and antipseudomonal beta lactam. These regimes have been extensively used and are particularly recommended for those at high risk of *Pseudomonas* infection, including cancer patients with severe mucositis and those known to be colonized with the organism. Given the nephro- and ototoxicity associated with aminoglycosides, serum concentrations of these drugs should be monitored regularly. Such a two-drug regimen is considered to be as effective as the combination of a third generation cephalosporins with an antipseudomonal beta lactam such as piperacillin. While safe, these latter regimens are expensive, open to resistance, and may not provide adequate coverage of staphylococcal infections. The addition of vancomycin to either of the above regimens provides additional coverage against staphylococcal infections and, if used initially, results in fewer incidences of treatment failure. Other studies have shown no difference in mortality and morbidity rates in those patients in whom vancomycin was added at a later date.

The use of monotherapy was not strongly supported by the committee (44). While initial results of such therapy were good, modification has been required often enough for combination therapy to be preferred as initial therapy. The panel recommended that monotherapy be considered in those at low risk of infection (brief period of neutropenia prior to fever and with neutrophil counts between 500 and 1000/μl) and that these patients be closely monitored. A meta-analysis has subsequently been performed on 13 studies that compared ceftazidime monotherapy with different combination therapies (45). No difference in treatment failure was found, and there was no difference in outcome when febrile and bacteremic episodes were considered independently. Similar percentages of modifications for monotherapy and combination therapy were made. In a more recent multicenter, randomized, controlled trial of the treatment of 876 febrile, neutropenic episodes in 696 patients (46), single-agent ceftazidime was found to be safer than piperacillin and tobramycin combined, while having similar effectiveness (62.7% vs. 61.1%; $p > .2$). Infectious mortality was 6% for ceftazidime and 8% for the combination therapy; 38 episodes of superinfection developed in each group. An adverse event occurred in 8% of the episodes treated with ceftazidime compared with 20% with combination therapy ($p < .001$). Of note, 83% of the patients enrolled in the study were leukemia and transplant patients and often experienced profound and prolonged neutropenia.

The need to continually review a patient's clinical situation and therapy is essential. The consensus panel agreed that by day 3, a neutropenic patient who was either afebrile or had continuing fever but with no progression of the infective process, could continue on the same antibiotics. Antibiotics should be changed if fever persisted and there was progression of the infective process. Either vancomycin could be added at that stage (if not already in use) or monotherapy, in the form of a third-generation cephalosporin, could be commenced. If the patient remained both neutropenic and febrile after a week and was unlikely to have white cell recovery in the near future, amphotericin should be added (47). Antianaerobic therapy should be considered in those with persistent fever and severe oral mucositis, necrotizing gingivitis, or perianal tenderness.

The current duration of antibiotic treatment, where patients with febrile neutropenia have been admitted to hospital for antibiotic treatment until their neutropenia resolved, is based on the results of a 1979 study (48). Early stopping of antibiotics at day 7 in 17 patients with resolved fever but persistent neutropenia resulted in the recurrence of fever in seven patients, of whom two died. The consensus committee considered cessation of antibiotics in afebrile patients who were clinically well but with a neutrophil count of <500/μl. Although not strongly supported by scientific data, they considered that therapy could be stopped after 7 days provided that the

patient was carefully observed, mucous membranes and skin were intact, and no invasive procedures or ablative chemotherapy were imminent.

More recent studies have suggested that in patients at lower risk of complications, outpatient treatment and early stopping of antibiotics may be possible. Thirty febrile neutropenic patients, identified to be of low complication risk after 48 hours of inpatient intravenous treatment, were continued on the same antibiotics at home until neutropenia resolved (49). Four patients were readmitted with medical complications (hypotension, 3; acute renal failure, 1) and five others were readmitted for observation. Overall costs were similar for those treated at home and for those who were medically eligible for home treatment but who were treated in the hospital. The higher-than-expected cost of home treatment related to extended periods of neutropenia in these patients. Attempts have been made to shorten hospital stays by discontinuing intravenous antibiotics in blood culture–negative patients who remained clinically stable and afebrile after 48 hours of treatment (50). In a retrospective review of 134 admissions for neutropenic fever, the median duration of intravenous antibiotics decreased significantly from 7 days prior to institution of such a policy to 5 days (4,5 and 6) and 4 days (3,4 and 5) over the next two consecutive 6-month periods. The median duration of hospital stay decreased from 10 days to 7 days (5,6,7 and 8) and 6 days (5,6 and 7) over the same time periods. The authors concluded that intravenous antibiotics may be discontinued in patients who remain afebrile and clinically stable for 48 hours and who have negative blood cultures, resulting in a shorter duration of hospital stays with the potential for reduction in hospital costs.

Early stopping of antibiotics together with a selective decontamination regimen (neomycin, polymyxin, amphotericin, and pipemidic acid) was prospectively studied in 52 adult patients with hematological malignancies and a neutrophil count <500/µl (51). Patients experienced 77 febrile episodes while receiving the oral antibiotics and further treatment (either broadspectrum or disease-specific antibodies) was initiated only if clinical signs or microbiological culture results indicated an infection. Consequently, antibiotics were adjusted according to culture findings or discontinued if evidence of infection was lacking after 72–96 hours. For the 40 episodes without confirmed infection, the median duration of therapy was 3 days (range, 0–13 days) and the survival rate 100% with 15 receiving no additional antibiotics. For the 37 episodes with confirmed infection, the median duration of therapy was 12 days (range, 1–49 days, p <.0001) and the survival rate 85%. Broad-spectrum therapy was only used for the duration of neutropenia in 18% of the treated episodes, and none of the six deaths could be attributed to the withholding or stopping of broad-spectrum therapy. It was concluded that in febrile neutropenic patients on. this selective decontamination regimen, the standard prolonged administration of broad-spectrum antibiotics was not necessary. The authors recommended for this population that systemic antibiotics be discontinued after 3–5 days if infection is unlikely, that a narrower antibiotic spectrum be chosen according to the clinical situation, and that empirical antifungal treatment be considered after 7 days. Although very promising, the findings of this study need to be confirmed in randomized clinical trials before their widespread implementation.

The place of outpatient treatment of low-risk neutropenic patients was examined at the M. D. Anderson Cancer Center (52). Oral ciprofloxacin combined with clindamycin was as effective in the control of infection as was the combination of intravenous aztreonam and clindamycin. However, the oral regime was associated with increased renal toxicity that resulted in the early termination of the study. The authors recommended the development of better outpatient antibiotic regimens and urged caution as none of their patients had gramnegative bacteremias or pneumonias, a group that may be difficult to treat. Outpatient treatment was further studied in Pakistan, where 188 low-risk patients with febrile neutropenia were randomized to receive either inpatient or outpatient oral ofloxacin (53). The investigators had previously found oral ofloxacin to be as effective for inpatient care as their standard intravenous regimen (54). The patient group consisted of patients with both solid tumors and leukemias and excluded those in whom the duration of neutropenia was likely to exceed 7 days. Fever control was the same in both groups, with 78% of inpatient and 77% of outpatient fevers resolving without modification of the initial treatment. However, 21% of the outpatients required hospitalization. Mortality was 2% in those assigned inpatient treatment and 4% in outpatients, with one death occurring outside of hospital.

The oral administration of empirical, broad-spectrum antibiotics in low-risk patients was tested in a randomized, double-blind, placebo-controlled study of patients who had fever and neutropenia during chemotherapy for cancer (55). Hospitalized patients were randomized to receive either oral ciprofloxacin plus amoxicillin-clavulanate or intravenous ceftazidime. Of 116 episodes in each group, treatment was successful in 71% of episodes in the oral-therapy group and 67% of episodes in the intravenous-therapy group. Concerns have been raised as to the selection of patients in this study. However, this approach may be useful, but it should be limited to that subset of patients with low-risk factors who are not otherwise on quinolone prophylaxis and in whom close monitoring and surveillance can be performed. Those with an identifiable cause of infection should be treated with the appropriate antibiotics. The issue of limited treatment in low-risk groups needs to be more clearly defined and addressed in further clinical studies (Fig. 9-3).

In summary, for patients with fever who continue to have neutropenia for a week or more, broad-spectrum antibiotic therapy for the duration of the neutropenia along with empirical antifungal therapy in those who remain febrile is the current consensus. The use of narrow-spectrum agents or abbreviated courses of antibiotics in these patients is in need of further study as is their role in those patients at low risk of complications.

Vascular access devices often create a treatment dilemma in those with febrile neutropenia. These may be left in place in most patients, even if bacteremia is detected, and managed with antibiotic and local care (56). Catheters should be removed if they are nonpatent, associated with thrombosis, have evidence of septic emboli, or if there is a subcutaneous tunnel infection. Prompt removal of catheters is also indicated with *Candida spp.* fungemia and bacteremia due to *Bacillus spp*. or a bacteremia that persists for >48 hours after initiation of appropriate antibiotics.

Antiviral medications may be required in neutropenic as well as immunocompromised patients without neutropenia. However, the empirical use of antiviral drugs in the management of febrile neutropenia in patients without mucosal lesions or evidence of viral disease is not indicated. The recommended dose of acyclovir for the treatment of established herpes infections in the immunocompromised ranges from 5 mg/kg q8h i.v. for herpes simplex to 10–12 mg/kg q8h i.v. for herpes zoster.

Although popular throughout the 1970s and 1980s, granulocyte infusions use has faded in recent years, despite evidence of efficacy. In a review (57) of the use of granulocyte transfusions, this decline was related to the administration of ineffective doses of granulocytes. The author recommended that physicians assess the outcome of persistent febrile neutropenia in their own institutions and, if poor, the addition of granulocyte transfusions, at therapeutic doses ($2–3 \times 10^{10}$ PMN), may be useful along with other changes such as the use of different antibiotics. The use of G-CSF in the collection of white cells was also considered, but requires more work before its use is considered a standard treatment.

Treatment of Transfusion Reactions

Transfusion reactions can be prevented by filtering of blood products and also by premedication with an antihistamine. The use of erythropoietin in anemia associated with malignancy may reduce the need for blood transfusions, thus avoiding both transfusion reactions and a source of infection. The cost of such treatment needs to be considered carefully.

Treatment of Amphotericin-Related Febrile Reaction

For the prevention of amphotericin-related fever and rigors, 12.5–25.0 mg of intravenous meperidine is useful. However, slowing the rate of amphotericin may reduce toxicity. Amphotericin given over 45 minutes was much more toxic in relation to fever and rigors than the same dose given over 4 hours (58). Less meperidine was required for the control of symptoms in the 4-hour infusion arm. In another study, no difference was found between a 45-minute and 2-hour infusion (59). Other opioids may have the same effect on the treatment of these rigors.

PROPHYLAXIS

Prophylaxis, either in the form of antibiotics or other supportive treatment, may be useful in the prevention of febrile neutropenia.

Growth Factors

Hematological colony-stimulating factors (CSF) reduce treatment-associated myelosuppression by shortening the duration of neutropenia and by reducing the nadir of neutrophil counts. However, concern about their appropriate clinical use lead to the continued updating of guidelines from the American Society of Clinical Oncology (60). These guidelines, initially released in 1994, have resulted in a small improvement in the use of G-CSF (61). Two indications for the use of G-CSF administration were addressed; primary CSF use in those receiving their initial chemotherapy and secondary use in those who have previously had chemotherapy-induced neutropenia.

To assess a benefit in primary prevention, the incidence of Grade 4 neutropenia following CSF use in different randomized treatment protocols was considered. The incidence of neutropenia ranged from 0% in breast cancer patients receiving the combination of cyclophosphamide, doxorubicin, and 5-fluorouracil to 98% of 102 lung cancer patients administered cyclophosphamide, doxorubicin, and etoposide. G-CSF was found to significantly decrease the incidence of febrile neutropenia where the placebo group had an incidence of neutropenia greater than 40%. However, in these randomized CSF trials, no difference in infectious mortality, response rates, or survival between CSF- and placebotreated patients was documented. It was recommended that CSFs only be used with those protocols where the incidence of neutropenia was likely to be greater than 40% without their use. When less myelotoxic chemotherapy is planned, primary administration of CSFs should be reserved for those patients who are at high risk from neutropenic complications because of host- or disease-related factors. Individual cases should also be considered in patients at higher risk of chemotherapy- induced, infectious complications (e.g., extensive prior chemotherapy). Elderly patients tolerate chemotherapy as well as younger patients

and should not receive CSFs purely on the basis of age.

There were few studies concerning the secondary administration of CSFs available to the American Society of Clinical Oncology working group. If a patient has already experienced chemotherapy-induced neutropenia, then CSF can be used if there is proven benefit in maintaining the dose. It is important to remember that for primary use of CSF, there was no difference in infectious mortality, tumor response, or survival. In the absence of a reason to maintain chemotherapy dose, dose reduction should be considered, especially if other toxicities not responsive to CSFs are present. No evidence has been found to support the routine use of CSFs in febrile neutropenic patients, although those at particularly high risk may have some benefit. There has been no evidence to recommend the use of CSFs to increase chemotherapy dose intensity outside of clinical trials addressing this issue. CSFs may be useful for mobilizing peripheral blood stem cells, and they have a benefit in reducing the period of neutropenia in autologous and peripheral blood stem cell transplants. However, there was no indication for their use in patients receiving combined chemotherapy and radiotherapy. When used, the group recommended G-CSF dose of 5 µg/kg/day (GM-CSF, 250 µg/m^2/day), without dose escalation, administered 24–72 hours after chemotherapy until the neutrophil count is greater than 10,000/µl after the neutrophil nadir.

The implications, including cost, of the use of G-CSF in the treatment of small cell lung cancer at the University of Indiana were reviewed (62). The overall incidence of neutropenia was 18% in the 137 patients treated with standard chemotherapy and in whom dose reductions were allowed on subsequent courses. The estimated total cost of this treatment was approximated to be $192,000. There would have been more than a six-fold increase in cost ($1,200,000) if primary treatment of all patients with G-CSF had taken place. The cost of the secondary use of G-CSF in those with a previous episode of fever and neutropenia ($272,000) would have been less than twice that of not using growth factors at all. The authors concluded that the routine use of G-CSF in small cell lung cancer patients treated with standarddose chemotherapy was expensive and not associated with obvious therapeutic benefits or cost savings. They suggested that careful analysis of the incidence of infectious complications, rather than granulocyte nadir and duration, be performed.

Other Prophylactic Measures

Although total protected environments (involving laminar flow, the oral administration of nonabsorbable antibiotic, and cutaneous decontamination) reduce the incidence of infection, their use proved cumbersome and expensive, and they have largely been abandoned (18), particularly for those patients for whom the duration of neutropenia is likely to be short. Individual components of these regimens, however, continue to be used in many treatment protocols.

There have been mixed results from the oral administration of nonabsorbable drugs such as gentamycin, nystatin, and van comycin. The consensus panel could make no recommendation as to use of the drugs but agreed strongly that the use of aminoglycosides in this situation should be avoided. In a recent review, the use of nonabsorbable antibiotics without concurrent patient isolation was not recommended because of the unpalatability of the antibiotics, their cost, the emergence of resistant organisms, and the lack of constant efficacy (18).

The Infectious Diseases Consensus panel (44) recommended trimethoprim-sulfamethoxazole prophylaxis for afebrile, uninfected patients with profound neutropenia expected to persist for at least 1 week. This combination has a role in the prevention of *Pneumocystis* infections in transplant patients and has been used in protocols such as MACOP-B. Norfloxacin, an oral quinolone, has been found to reduce gramnegative infection when compared with Bactrim, but the possibility of the development of resistance prevented the Consensus group from recommending its routine use. The role of prophylactic ciprofloxacin in reducing the incidence of neutropenic fever in 88 consecutive men receiving intensive chemotherapy for germ cell tumors was reviewed. In total, 88 men received 429 courses of chemotherapy and prophylactic ciprofloxacin was prescribed for 168 courses. The incidence of fever in these patients was significantly reduced from 15% (20/131) to 5% (6/109) (p =.02) with prophylactic ciprofloxacin. Two patients, one of whom had received prophylactic ciprofloxacin, died of chest infections confirmed on postmortem. The results of this nonrandomized, retrospective study suggest that prophylactic ciprofloxacin, 250 mg twice a day, is effective in reducing the incidence of fever complicating neutropenia during chemotherapy for germ cell tumors. To be cost effective, however, it should be given only to neutropenic patients (63). Ciprofloxacin (750 mg twice a day) was found to be as safe and effective as trimethoprim-sulfamethoxazole (160 mg/800 mg twice a day) in the prevention of bacterial infections in 146 bone marrow transplant patients. However, ciprofloxacin was associated with a lower incidence of C. *difficile* enterocolitis and infections caused by gramnegative bacilli, indicating an advantage for its use in transplant patients (64). Prophylaxis also extends to antiviral medications. Acyclovir use decreases the incidence of herpetic gingivostomatitis in patients with neutropenia, and the administration of acyclovir decreases the incidence of cytomegalovirus pneumonitis in patients who have undergone bone marrow transplant.

ETHICAL CONSIDERATIONS OF TREATMENT OF INFECTIONS

There is no doubt that if the intention of treatment is to ensure the prolongation of survival, then treatment of the infective episode needs to be initiated. Dilemmas may arise in those patients in whom the intention of treatment is palliation. Antibiotics may make a patient feel more comfortable, but they may also prolong the dying process. A balance between the two should be assessed in each individual patient, factoring in particular factors such as prognosis and treatment goals.

Even if a patient is nearing death, indications for commencement of antibiotics may include convulsions or mental changes attributed to fever, extreme temperature (>40°C), extreme age (very young and very old), and a past history of adverse reaction to fever, marked subjective discomfort pronounced by patient, a prolonged high fever causing significant hypercatabolic state, and a reduced cardiac or pulmonary function to the extent that further tachycardia or tachypnea may be harmful. Further issues pertaining to this will be discussed in other chapters.

ANOREXIA/WEIGHT LOSS

AMINAH JATOI
CHARLES LAWRENCE LOPRINZI

Loss of weight and appetite predict a poor prognosis for cancer patients and spawn anguish for patients and their families. The Latin aphorism, *optimum condimentum fames* (“hunger's the best sauce”) alludes to hunger's reliability as an indicator of health and, at the same time, implies that unintentional loss of weight and appetite are associated with unfavorable health outcomes (1). Multiple clinical investigations have demonstrated that this adverse sign and symptom serves as a powerful predictive instrument in patients with cancer.

In the largest of these clinical investigations, DeWys and others retrospectively examined the records of 3047 cancer patients from 12 different Eastern Cooperative Oncology Group (ECOG) chemotherapy clinical trials (2). Patients had been evaluated for weight loss before trial participation. Loss of more than 5% of premorbid weight predicted a poor prognosis among patients with a variety of different tumor types, including lung cancer, breast cancer, gastrointestinal malignancies, and lymphoma. Even after adjusting for performance status, a strong association between weight loss and an early demise persisted. Weight loss was also associated with a trend towards lower chemotherapy response rates. Other large studies, including those that have used treatment modalities other than chemotherapy, also demonstrate a direct association between loss of weight and shortened survival (3,4). Along similar lines, but focusing on appetite, Chang recently reviewed the prognostic effect of this adverse symptom among cancer patients (5). He summarized several studies, including a multivariate analysis from the North Central Cancer Treatment Group, which examined patients with lung and gastrointestinal malignancies with a focus on physiological and psychological factors that might effect prognosis (6). A large number of these studies demonstrate that appetite loss also predicts a poor prognosis for cancer patients, thus adding to a growing body of literature that underscores this strong relationship between compromised nutritional status and an early demise.

The emotional impact of cancer-associated weight loss and anorexia may be just as strong as their negative prognostic impact. Peteet and others characterize this emotional impact in a paper entitled “Psychological Aspects of Artificial Feeding in Cancer Patients.” Relying on a series of case reports from which to draw conclusions on the psychological toll exacted by cancer-associated weight loss and anorexia, these investigators provide the following insights (7):

> For many, loss of appetite, weight, and body image are primary means by which cancer threatens their sense of self and autonomy. Inability to eat is often experienced as a failure of will. Similarly, for many families, feeding is a means of giving and caring, so that a patient's acceptance or rejection of food, especially in a time of family crisis, has pervasive implications for family relationships. Finally, for many persons, cachexia is closely associated with death from cancer, and with maintenance of health.

Such conclusions draw attention to the insidious but farreaching consequences of cancer-associated weight loss and anorexia.

Combining the above data on prognosis and emotional impact with studies on prevalence further enlarges the magnitude of the mortality and morbidity of cancer-associated anorexia and weight loss. In an ambulatory care setting, Tchekmedyian and others found that among 644 consecutive patients, approximately half had anorexia or weight loss of greater than 5% of premorbid weight (8). In a comprehensive prospective analysis of 1000 patients with advanced cancer about to enter a Hospice program, Walsh and others. found that 66% were experiencing anorexia (9). These prevalence rates might well become higher if gathered during the very final stages of life.

PATHOPHYSIOLOGY

Why are cancer-associated weight loss and anorexia associated with such devastating outcomes? The answer might rest in a more detailed understanding of events at the tissue level. Cancer patients who are losing weight waste both fat and lean tissue. With respect to loss of adipose tissue, many weight-losing cancer patients manifest a constellation of hyperglycemia, hypertriglyceridemia, and an exaggerated insulin response to glucose intake. Wasting of adipose tissue appears to be mediated by a lipid-mobilizing factor from the tumor (10). What is most striking about this wasting of body tissues, however, occurs within the lean tissue compartment. An excessive loss of lean tissue is a hallmark of cancer-associated weight loss and is not generally observed in other, more commonly discussed clinical settings (e.g., simple starvation). Cohn and others assessed body composition with tritiated water, prompt gamma neutron activation, and total body potassium among 50 cancer patients (11). They went on to make direct comparisons to age- and sex-matched controls. In contrast to the control group, weight-losing cancer patients manifested a dramatic loss of lean body tissue, most notably of skeletal muscle. Although this study did not include a direct comparison to starving but otherwise healthy controls, this pattern of lean tissue wasting stands in contrast to the relative preservation of lean tissue observed in starvation (12), in which lean tissue is relatively preserved, although the adipose compartment withers.

This phenomenon of lean tissue wasting carries grave potential consequences. Previous studies have observed that loss of weight and loss of performance status go hand-in-hand in cancer patients. In the study by DeWys and others, patients were also segregated by ECOG performance status (2). Patients with a worse performance status of 2–4, compared to a better performance status of 0–1, had higher rates of weight loss ($p < .01$ among 9 of 12 tumor types). In yet another ECOG study, Finkelstein and others found that a loss of >5% of premorbid weight was associated with greater debility (13). Thus, as cancer patients lose weight, they tend to manifest a decline in their ability to care for themselves and perform activities they formerly enjoyed. Furthermore, if we acknowledge that the lean tissue body compartment carries all the body's metabolic machinery, it becomes plausible that vital functions, such as respiration, blood circulation, bowel function, cognition, and ambulation, might become compromised when this body compartment erodes. It also becomes within grasp to speculate that weight loss—by means of lean tissue wasting—may in fact bear a cause and effect relationship when it comes to death from cancer. Early autopsy studies in patients with advanced cancer are often quoted to bolster this speculative cause and effect relationship: Anywhere between 1% and 20% of cancer patients had no discernible immediate cause of death other than “cachexia” at the time of their postmortem examination (14).

Because of these potential implications, recent studies have focused on identifying mediators of lean tissue wasting. Todorov and others have discovered a 24-kd proteoglycan from a tumor homogenate from the MAC16 tumor line (15) and have named this substance *proteolysis-inducing factor* (PIF). PIF appears to have direct proteolytic activity on muscle, and PIF antibodies prevent weight loss in animal models if given before PIF administration. Discovered in the urine of weight-losing cancer patients but not in the urine of weight-stable cancer patients or weight-losing noncancer patients, PIF also appears to be quite specific for cancer-associated wasting. In addition to this purported mediator of cancer-associated wasting, other mediators that appear to play an active role the syndrome of cancer-associated anorexia and weight loss include TNF-a, IL-b, IL-6, and ciliary neurotrophic factor (16,17,18,19,20 and 21). Previous animal studies have identified such cytokines in the setting of cancer-associated weight loss and have observed attenuation of cancer-associated anorexia and weight loss with administration of antibodies to these cytokines. Elucidating a potential pathway that might lead to muscle wasting in the cancer setting, Guttridge and others recently found that TNF-a's activation of NF-kappaB suppresses MyoD, a factor that is normally active in muscle repair (22). Although these investigators had not specifically examined cancer-associated wasting, identical or parallel mechanisms might ultimately prove responsible for the erosion of muscle tissue observed in cancer patients. Finally, several studies have implicated the ubiquitin-proteasome pathway in lean tissue wasting and have suggested that this pathway leads to wasting of muscle and perhaps other components of lean tissue in cancer (23,24). Baracos and others have suggested that the ubiquitin proteasome pathway might be responsible for as much as 80% of the muscle degradation that occurs in cancer-associated wasting (25).

In addition to direct erosion of lean tissue, other events perturb the balance of energy in cancer patients and predispose to weight loss. First, an increase in resting energy expenditure contributes to energy deficits. Elevations in resting energy expenditure have been observed in patients with lung cancer (even nonmetastatic non-small cell lung cancer) (26), hematological malignancies, and sarcomas (27,28,29 and 30). Gastrointestinal malignancies do not appear to predispose to this hypermetabolic effect. Although some investigators have suggested that this hypermetabolism may arise from underlying comorbidities such as ongoing infections or chronic obstructive pulmonary disease, many studies suggest that some cancers contribute single-handedly to this increase in metabolic rate. Recent studies have invoked uncoupling proteins as contributing to these metabolic aberrations. For example, Bing and others found that con centrations of mRNA for uncoupling protein-1

(UCP-1) were significantly increased in brown adipose tissue in a murine tumor model (31).

Second, previous studies suggest that cancer patients eat less. Theologides and others studied 39 cancer patients, 18 of whom had lost more than 10% of their body weight (32). Concurrently, all these patients reported a drop in their food intake of at least 300 kcal/day. This pioneering pilot study provides data to substantiate the hypothesis that amidst all the metabolic mayhem that occurs in the tumorbearing host, weight-losing cancer patients are, in fact, eating less. The etiology of this diminished food intake is multifactorial and might include cytokine-mediated anorexia, altered taste and nausea from antineoplastic treatment, depression, acquired food aversions, and compromised access to food due to increasing debility or hospitalization.

TREATMENT OPTIONS

Role of Caloric Supplementation

Caloric repletion might seem to be the most reasonable approach to the treatment of cancer-associated weight loss. As already discussed, in the setting of cancer, the host is plagued by energy deficits that arise from an increase in resting metabolism and poor oral intake. Hence, nutritional support, either in the form of enteral or parenteral nutrition, might compensate for such deficits. However, in advanced cancer patients, caloric supplementation rarely helps. For example, trials that have examined dietary counseling in chemotherapy patients with advanced cancer have not demonstrated favorable outcomes. Ovesen and others evaluated 105 patients who were being treated with chemotherapy for cancer (33). These investigators randomly assigned patients to receive either nutritional counseling or no nutritional counseling. Patients who received nutritional counseling consumed significantly more calories. However, direct comparisons between the two groups to assess outcomes such as tumor response rates, survival, and quality of life demonstrated no differences. Other, more aggressive measures aimed at caloric repletion have also been disappointing. A review of clinical trials that examined total parenteral nutrition in cancer patients with advanced disease led the American College of Physicians to issue a consensus statement in 1989 discouraging its use in patients undergoing chemotherapy (34). These recommendations remain unrevised today.

Although nutritional support—either in the form of parenteral or enteral nutrition—is generally discouraged in cancer patients, previous studies suggest a few circumstances in which its use can be justified. These include the following: (a) in patients undergoing stem cell or bone marrow transplantation; (b) perioperatively; and (c) during treatment for head and neck cancer. Studies that support the use of nutritional support in these settings, however, must be viewed in the context of other clinical trials, which have not shown clinical benefit with the use of parenteral nutrition.

First, nutritional support potentially may help patients in the setting of stem cell rescue after highdose chemotherapy. Weisdorf and others performed one of the earlier studies examining total parenteral nutrition in a study population of 137 patients, most of whom (93%) had cancer—mainly, acute leukemia (35). These investigators randomly assigned patients to receive either total parenteral nutrition or intravenous fluids, which consisted of a 5% dextrose solution. The majority of patients in the control arm crossed over to receive total parenteral nutrition because of malnutrition. Nonetheless, direct comparisons between the two study arms demonstrated that a number of clinical outcomes, including overall survival, were improved in patients initially assigned to the total parenteral nutrition arm. Although some might argue that transplantation has changed over the past decade to the point where patients engraft more quickly and are therefore less vulnerable to developing malnutrition, this study suggests that total parenteral nutrition might confer benefit when administered prophylactically.

Second, two studies suggest perioperative nutrition might benefit severely malnourished cancer patients. The first study is the Veteran Affairs Total Parenteral Nutrition Cooperative Group Trial, which examined 395 malnourished patients (36). Although not all of these patients had cancer, 65% did. Patients were randomly assigned to receive at least 7 days of total parenteral nutrition or no total parenteral nutrition. Twenty-four of these 395 patients were severely malnourished, as defined by their Nutrition Risk Index, a reasonable instrument designed to assess nutritional status. It was within this small subgroup that clinical benefit with total parenteral nutrition was observed. This subgroup manifested fewer noninfectious complications—such as anastomotic leak, bronchopleural fistula, and others—when compared to severely malnourished patients who did not receive nutrition support.

Before totally accepting the conclusions of this trial at face value, however, some aspects of the trial design merit discussion. The trial has been criticized because it included patients with mild to moderate malnutrition, and some nutritionists contend that only patients with severe malnutrition should have been included. It is important to point out, however, that these investigators had carried out subanalyses to examine potential differences between groups, and that these subanalyses had been planned *a priori* with respect to the trial's initiation. Admittedly, the conclusions of this trial would have been more compelling had the number of severely malnourished patients exceeded 24, but this small number speaks to the fact that relatively few severely malnourished patients are surgical candidates in the first place. Another concern is the lack of double-blinding. A valid criticism, this shortcoming is also difficult to surmount. Complete double-blinding when prescribing total parenteral nutrition administration is problematic, especially when one considers the metabolic aberrations, including hyperglycemia and electrolyte abnormalities, which must be managed. Working within such practical constraints, this study provides reasonable justification for administering total parenteral nutrition to severely malnourished patients immediately before surgery.

Couple the results of the Veteran Affairs Total Parenteral Nutrition Cooperative Group trial with the results of a trial by Fan and others (37), and one acquires further justification for considering total parenteral nutrition in severely malnourished patients in the perioperative setting. Fan and others studied 124 malnourished patients with hepatocellular carcinoma before surgery. Many of these patients were touted as being only mildly malnourished, as suggested by the fact that only 20% had sustained a loss of >10% of their premorbid weight; however, in the setting of liver disease, evidence of malnutrition can be occult. In this placebocontrolled trial, patients who were randomly assigned to receive total parenteral nutrition also experienced a decrease in postoperative morbidity and a reduction in the use of diuretics after surgery. However, similar to the Veteran Affairs Total Parenteral Nutrition Cooperative Group trial, a survival advantage with the use of total parenteral nutrition was not seen in this study.

Finally, although head and neck cancer patients may also benefit from nutritional supplementation, study results are far less convincing than the other two indications cited previously. Two small studies suggest that enteral feeding may lead to fewer treatment delays in patients receiving radiation for head and neck cancer and may improve functional ability several months after completion of therapy (38,39). Although these data are in large part exploratory in nature, they nonetheless provide some justification for aggressive oral nutrition in head and neck cancer patients during aggressive antineoplastic treatment.

Because not all groups of cancer patients have been formally studied with respect to implementation of adjunctive nutrition therapy, how do we decide when to use it? In our own medical oncology practice, we find that we use nutritional support sparingly, if not rarely. However, outside of the clinical settings discussed previously, one might be able to justify its use if patients meet both of the following criteria: (a) notably malnourished or at risk for becoming so during cancer treatment; and (b) diagnosed with a potentially curable malignancy or about to receive cancer treatment that may result in a long diseasefree period. Otherwise, in patients with advanced incurable cancer, there is no substantial justification for prescribing enteral or parenteral nutrition.

Patients with Advanced Incurable Cancer

To date, the most effective approach for treating cancer-associated anorexia and weight loss revolves around palliating anorexia. Several clinical trials have been unable to demonstrate survival advantages or improvement in global quality of life even with the use of state-of-the-art interventions aimed at palliating anorexia. Nonetheless, because dying cancer patients rank anorexia as their third most noxious symptom (9), an argument can be made for attempting to palliate it. In our own practice, we use a two-step approach before the initiation of orexigenic agents (Fig. 10-1). The first step involves predicting whether a patient is likely to receive palliation of anorexia as a result of antineoplastic therapy. A recent study by Geels and others underscores the importance of attempting to predict tumor response before treating anorexia with other maneuvers (40). These investigators assessed 300 patients who were about to receive chemotherapy for breast cancer. They found that 82% of patients who demonstrated a partial or complete response to therapy also manifested an improvement in anorexia. Thus, if a patient is likely to obtain tumor regression with antineoplastic treatment, we often forego other palliative measures to help with anorexia, saving them for later. The second step involves a frank discussion with patients and family members about eating goals. As pointed out earlier by Peteet and others, guilt often accompanies loss of appetite (7). If mealtime represents a time of “giving and caring,” then the cancer patient's inability to eat carries with it a mixture of failure and frustration for both the patient and family. We talk with patients and families about realistic expectations during meals and explain some of the reasons behind compromised oral intake in the cancer setting. After such discussions, patients and family members usually become more accepting of loss of appetite. If pharmacological manipulation of appetite is desired, they better understand the goals behind its use.

FIGURE 10-1. Algorithm of advanced cancer patient with loss of appetite.

A subgroup of patients ultimately opts for drug therapy to improve appetite. In sifting through the published literature to decide on the best agent to try, it is important to consider certain elements of clinical trial design that make clinical investigation in this field especially challenging. First, earlier studies have described a significant placebo effect, which may be as high as 40% with oral agents (41). It is conceivable that placebos administered by intravenous or subcutaneous methods may carry even higher response rates, as demonstrated by clinical studies in the noncancer setting (42). In view of such high "response rates" with placebo alone, it is important to evaluate phase II trials in cancer-associated anorexia with caution and to maintain placebo-controlled trials as the gold standard for efficacy. Second, because patients with advanced cancer and anorexia are ill, dropout rates in these trials are high. A common pitfall is to ignore dropouts and conclude that one treatment arm is more efficacious than another on the basis of a group of biased survivors. Although circumventing this pitfall is challenging, successful strategies include planning for large sample sizes and carefully stratifying patients on the basis of well-defined prognostic criteria. It is also important to include short but frequent assessments of appetite early in the trial to capture differences between study groups before the onset of further morbidity.

When such criteria are applied to "promising" agents, most are found to be no better than placebo, or even inferior to another agent. So-called "promising" agents that have fared well in pilot studies but not in large controlled trials include hydrazine sulfate, anabolic steroids, pentoxifylline, dronabinol, and cyproheptadine hydrochloride. First, because hydrazine sulfate inhibits gluconeogenesis, it seemed a reasonable choice for further clinical study among cancer patients with weight loss. However, at least two large clinical trials in cancer patients have shown that this agent is not effective in this setting (43,44). Moreover, hydrazine sulfate is associated with toxicity, and a fatal case report was recently published (45). Second, with respect to anabolic steroids, a recent trial by the North Central Cancer Treatment Group found that the androgen fluoxymesterone resulted in lower rates of weight gain than megestrol acetate or dexamethasone in patients with cancer-associated loss of appetite and weight (46). Third, pentoxifylline is a methylxanthine derivative that is thought to inhibit the production of TNF-a. Based on this purported mechanism, the North Central Cancer Treatment Group launched a randomized, placebo-controlled trial among patients with cancer-associated loss of appetite and weight, but found that this agent resulted in no improvement in either appetite or weight among this group of patients (47). Fourth, dronabinol has been touted as an effective agent for boosting appetite among AIDS patients, and placebo-controlled trials support its use in the setting of AIDS-related loss of appetite (48,49). However, a recently completed trial by the North Central Cancer Treatment Group did not find a similar effect among cancer patients (50). In the latter study, 469 evaluable cancer patients with loss of appetite or weight were randomly assigned to receive either megestrol acetate with placebo, dronabinol with placebo, or combination therapy. Megestrol acetate proved superior to dronabinol as an orexigenic agent, and combination therapy added nothing above and beyond megestrol acetate alone. Hence, there appears to be little role for dronabinol, as prescribed in this study, for the treatment of cancer-associated loss of appetite. Fifth, cyproheptadine hydrochloride, a histamine and serotonin antagonist, was also evaluated in a large placebocontrolled trial and was found to carry only minimal appetite stimulatory effects (51). In summary, these agents have, at best, limited use in the management of cancer-associated anorexia.

In contrast, two other classes of agents have proven themselves effective: progestational agents and corticosteroids. Both medroxyprogesterone acetate and megestrol acetate have been demonstrated to improve appetite in patients with cancer-associated anorexia; the latter having been more extensively studied. To our knowledge, 13 of 15 placebo-controlled trials have been published demonstrating that megestrol acetate improves appetite in the cancer setting (52). Despite these favorable orexigenic effects, however, it is important to underscore that this agent has not been shown to augment lean tissue, to improve global quality of life, or to advance survival. A direct dose–response effect occurs between megestrol acetate and appetite stimulation; this effect generally reaches a plateau at doses of beyond 800 mg/day (53). Because the oral suspension formulation carries better bioavailability, we normally begin with this formulation at a dose of 400 mg/day and increase to 600–800 mg/day over 2–4 weeks, should patients fail to derive an orexigenic effect. However, in the event that patients suffer a serious infection or trauma, we prescribe supplemental corticosteroids because of the potential for adrenal axis suppression.

Corticosteroids also work (54). Loprinzi and others recently compared megestrol acetate, dexamethasone, and fluoxymesterone for the treatment of cancer-associated anorexia (46). Although the anabolic agent, fluoxymesterone, was not effective, the other two agents were relatively comparable in efficacy at the doses prescribed. Dexamethasone, however, was associated with a worse side effect profile; for this reason, we recommend dexamethasone for cancer patients with a less favorable prognosis, because troublesome side effects such as myopathy are unlikely to occur in the short term. Dexamethasone is also a reasonable choice in patients at higher risk for thromboembolic phenomena and in those who require a less expensive orexigenic agent. Megestrol acetate is a reasonable choice for most other cancer patients who choose to try an orexigenic agent for anorexia.

New Agents

Thalidomide is a newly described appetite stimulant that deserves further investigation in this setting. A suppressor of TNF-a, thalidomide shows promise in phase II trials as a potential appetite stimulant and weight stabilizer among cancer patients. To our knowledge, phase III studies to investigate the primary end points of appetite, weight, or body composition have not been published in cancer patients. However, two phase II studies suggest that this agent should be further investigated (55,56). Eisen and others administered thalidomide, 100 mg/day orally, to 66 cancer patients. Although only three patients manifested tumor regression, 14 of 15 who completed quality of life questionnaires noted either stability or improvement in appetite. Similarly, Boasberg and others recently studied 15 weight-losing patients with metastatic cancer. They prescribed thalidomide, 100 mg p.o. q.h.s., but escalated the dose to 200 mg p.o. q.h.s. if treatment was well tolerated. Patients appeared to stabilize their weight. Of note, dose was an important aspect of both these trials. Whereas earlier thalidomide trials had administered high doses of thalidomide with high toxicity rates and severe toxicity grades, this regimen of continuous, relatively low-dose thalidomide appeared to be well tolerated, thus laying the groundwork for further investigation of this agent in this setting.

Adenosine triphosphate (ATP) also shows promise. Using this key energy source, Agteresch and others tried to attack the phenomenon of hypermetabolism in non–small cell lung cancer patients and advanced the hypothesis that ATP may attenuate weight loss. These investigators randomly assigned metastatic non-small cell lung cancer patients to ATP versus no ATP (57). Dropout rates in this study were high, which may have created selection bias between groups at the time of data analysis. Nonetheless, the ATP-treated group maintained weight and showed evidence of improved appetite in contrast to the control group. Because ATP requires intravenous administration, it may represent a cumbersome approach to a debilitating clinical problem. At the same time, however, these preliminary data suggest potential efficacy in the treatment of both anorexia and tissue wasting and suggest a need for further clinical investigation.

An omega-3 fatty acid derived from fish oil, EPA, appears to attenuate cancer-associated tissue wasting in preliminary clinical trials (58,59). Barber and others studied 20 patients with unresectable pancreatic cancer. All of these patients were losing weight, but after starting fish oil supplements, which contained 1.09 g of EPA, weight gain was observed over several weeks. Gogos and others studied 60 patients with advanced cancer in a placebo-controlled trial, which administered a fish oil–based supplement versus placebo (60). A slight survival advantage was observed in the group that received the supplement. Hussey and Tisdale and others suggest weight-sustaining mechanisms that may be at work. In an animal study, these investigators suggest that EPA may suppress PIF (61). An ongoing North Central Cancer Treatment Group is examining EPA versus megestrol acetate versus a combination of both agents to compare the effects of these treatments on appetite, weight, and body composition in patients with advanced cancer who have anorexia or weight loss.

Intriguing information has also been reported for ondansetron, a type 3 serotonergic receptor antagonist. This agent's remarkable ability to treat chemotherapy-induced nausea and vomiting has fostered interest in its potential role in the treatment of cancer-associated anorexia. In a phase II trial that examined 27 patients with advanced cancer and weight loss, Edelman and others prescribed ondansetron 8 mg twice a day (62). Patients were not receiving antineoplastic treatment. Although 20 evaluable patients continued to lose weight, appetite assessment with a 7-point hedonic scale suggested patients were enjoying food more after 1 month: 5.15 ± 0.9 compared to 5.49 ± 0.32 at baseline and 4 weeks, respectively (mean score ± standard error of the mean; $p = .04$). A large, placebo-controlled trial might clarify whether these promising results represent a true orexigenic effect.

Melatonin is another agent that has preliminary positive results for treatment of cancer-associated anorexia or weight loss. In a trial of 100 patients with metastatic cancer, Lissoni and others found that melatonin at an oral dose of 20 mg/day resulted in a significantly lower rate of weight loss when compared to placebo-treated patients (63). Mechanisms by which this agent might be working remain unknown, and confirmatory trials are necessary.

Because many mediators of cancer-associated weight loss, such as TNF-a, IL-b, and IL-6, also mediate inflammation, some clinical trials have focused on the use of nonsteroidal antiinflammatory agents. Cahlin and others found that tumor-bearing mice increased their food intake with indomethacin (64). In addition, mice with a genetic knockout of IL-6 ate more with indomethacin. Several small clinical studies suggest that ibuprofen abrogates the inflammatory response and results in modest weight gain (65,66). In contrast to these favorable results, however, McCarthy treated tumor-bearing mice with indomethacin but observed no improvement from a nutritional perspective (67). Thus, the role of nonsteroidal antiinflammatory agents in weight-losing cancer patients needs to be better defined.

Our improved understanding of some of the mechanisms that conspire to create this syndrome of cancer-associated anorexia and weight loss has recently led to some particularly novel approaches. The relationship between NF-kappaB and the upregulation of TNF-a, a cytokine implicated in cancer-associated anorexia and weight loss, was recently exploited by Kawamura and others (68). Having developed a double-stranded oligodeoxynucleotide that configured the ciselements of NF-kappaB, these investigators hypothesized that direct injection of this decoy into tumors would attenuate anorexia and weight loss. Tumor-bearing mice that received the decoy did not develop tumor regression, but there did appear to be a trend suggestive of increased food intake and weight stabilization. In contrast, tumor-bearing mice that received a scrambled decoy demonstrated a rapid nutritional decline. Results such as these require confirmation and suggest that this novel approach merits further investigation.

Along similar lines, Torelli and others explored the use of a dimeric, pegylated 55-kDa TNF receptor construct for purposes of palliating cancer-associated anorexia (69). These investigators used an animal model to test their hypothesis that TNF-a blockade would attenuate anorexia in this setting. Direct comparisons between animals that received this TNF-a inhibitor and those that received only vehicle demonstrated that cytokine blockade resulted in improved ad libitum food consumption. This effect appeared sustained over 8 days. Thus, this study, in addition to some of those cited above, suggests that TNF-a might be a worthwhile treatment target for cancer-associated anorexia and weight loss.

CONCLUSIONS

Recent novel therapies have generated new enthusiasm for tackling the frustrating but common problems of cancer-associated anorexia and weight loss. The mainstay of management continues to be a combination of counseling, appetite stimulants such as progestational agents and corticosteroids, and occasionally, nutritional support. However, our improved understanding of the pathophysiology of this syndrome has led to targeted therapies aimed at not only improving appetite but also augmenting lean tissue.

ORAL SENSATION AND CANCER

VALERIE B. DUFFY
KATHARINE FAST
LAURIE A. LUCCHINA
LINDA M. BARTOSHUK

Food has an immense impact on our quality of life. Eating, as with the preparation of meals, is often a social activity, and the consistent flavor of packaged cookies or a family recipe subtly reminds us of the few constants in our lives. It stands to reason, then, that changes in the food we know can have a profound effect on us, especially if they arrive at a particularly stressful time (e.g., after a cancer diagnosis or while undergoing treatment). Changes in a cancer patient's relationship to food can influence response to treatment: Diminishing appetite and multiplying aversions to necessary nourishment can compromise a patient's strength, morale, and chances of survival. This chapter aims to familiarize clinicians with the chemosensory mechanisms responsible for the perception of foods and beverages and the causes of dysfunction in these mechanisms. It also reviews reports associated with cancer and its related therapies. This helps the clinician determine whether a patient complaint represents an alteration in sensation per se or an alteration in the pleasure associated with eating food.

ORAL SENSATION: A REVIEW OF FUNCTION

Foods and beverages are perceived as a complex mixture of true taste, smell, and oral somatosensory (touch, temperature, and pain) sensations. These sensations function through separate neural pathways yet are tightly integrated to provide the composite sensation of food flavor. Alteration of one or more of these sensations can alter the composite flavor sensation, leading to an abnormal sensory experience and diminished enjoyment of eating.

True taste involves perceiving substances that impart salt, sweet, sour, and bitter sensations. Taste buds, clusters of receptor cells containing receptor sites for these compounds, are present on specific regions on the tongue, between the hard and soft palate and in the throat (Fig. 11-1). The elongated tips of the receptor cells contain taste receptor sites. These tips project into a space (taste pore) in which they come into contact with taste stimuli. On the tongue, taste buds are found in papillae. The fungiform papillae (which resemble small button mushrooms) are most densely distributed on the tip and edges of the tongue. The foliate papillae are on the edges at the base of the tongue. and the circumvallate papillae are circular structures arranged in an inverted V across the base of the tongue. Three cranial nerves innervate taste buds and route taste information to the medulla, the ventrobasal thalamus, and finally, to the cortex. The facial nerve VII innervates taste buds in the fungiform papilla through the chorda tympani branch and innervates taste buds on the palate through the greater superficial petrosal branch; the glos-sopharyngeal nerve IX innervates foliate (these may also be innervated by cranial nerve VII) and vallate papillae on the posterior tongue; and the vagus nerve X innervates taste buds in the throat. Incidentally, the taste map of our high school textbooks showing sweet perceived on the tip of the tongue, bitter on the back, etc., is incorrect; it stems from the mistranslation of a German thesis. In reality, all four taste qualities can be perceived on all areas of the tongue and palate in which there are taste buds (1).

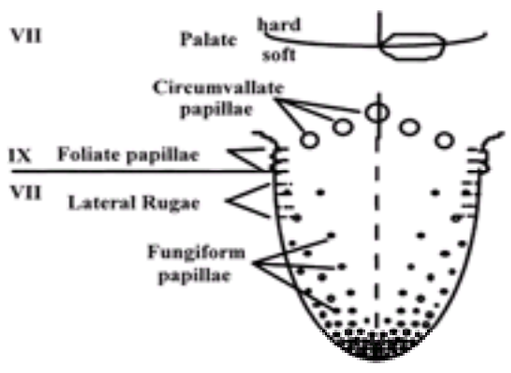

FIGURE 11-1. Drawing showing areas of cranial nerve innervation to taste buds within papillae on the tongue and to taste buds in between the hard and soft palate.

The sense of smell serves as a dual sensory system: We experience the aroma of foods through the nostrils and a substantial component of food flavor through the mouth (Fig. 11-2). Smelling through our nostrils can be passive, as when we breathe, or active, as when we concentrate odors by sniffing (i.e., orthonasal olfaction). Air enters the nostrils and moves up past the turbinate bones. A small sample of this air ultimately reaches the top of the nasal cavity, travels through a small opening called the olfactory cleft, and then contacts the olfactory receptors (located behind the bridge of the nose). The receptors for olfaction are found on the ciliated dendrites of olfactory fibers. Odors can also reach the olfactory receptors from the mouth, where active chewing and swallowing create a pressure gradient and push air from the mouth up behind the palate into the nose (retronasal olfaction). Whether orthonasal or retronasal in origin, once an odor reaches the olfactory receptors, it is carried by the olfactory nerve (cranial nerve I) through the cribriform plate to be distributed to the olfactory bulb.

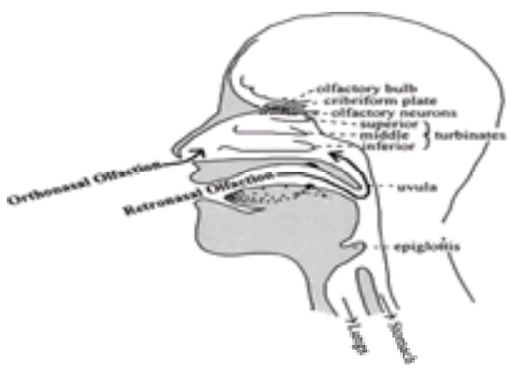

FIGURE 11-2. Drawing showing the two pathways to olfactory perception. Orthonasal olfaction occurs passively as we breathe, and retronasal olfaction occurs actively through mouth, tongue, and throat actions. Both pathways carry odors to olfactory receptors that sit behind the bridge of the nose.

Touch, temperature, and irritation or pain sensations from eating are mediated by the lingual branch of the trigeminal nerve on the anterior tongue and by the glossopharyngeal nerve (cranial nerve IX) on the posterior tongue.

The ability to perceive the taste and somatosensory sensations of foods and beverages varies normally with genetics. Genetic taste variation was discovered in the early half of this century (2). Some individuals (nontasters) are taste-blind to 6-n-propylthiouracil (PROP), whereas others find it bitter (tasters). Family studies (3) have shown that non-tasters carry two recessive alleles for the trait. More recently, Bartoshuk and colleagues (4,5) described two phenotypical subgroups among tasters: Supertasters taste the most intense bitterness from PROP and medium tasters less so. Supertasters may carry two dominant genes for the PROP trait (11) and perceive more intense taste sensations from many compounds (see reference 5 for a review). For example, supertasters perceive more than twice as much bitterness from black coffee as nontasters do (6). This could have implications for cancer therapies: Supertasters could experience more bitterness from chemotherapeutic medications than do nontasters, even if delivered intravenously (see the section Chemotherapy and Taste). Anatomical studies show that supertasters have the most fungiform papillae (and thus the most taste buds) (4,7). Because taste buds are innervated by fibers that carry touch and pain (8), super-tasters also perceive the most intense textural sensations from foods (e.g., creamy or viscous sensations from fat in foods) (7,9) and the greatest burn from oral irritants (e.g., black pepper, chili pepper, alcohol, carbonation). Greater pain innervation suggests that supertasters would also perceive greater pain from oral lesions. The gene for PROP tasting appears to reside on chromosome 5, with a related region on chromosome 7 (10).

Changes in sex hormone levels in females may influence sensory intensity or affective response to tastants and odorants.During childbearing years, variability in taste (12) and olfactory perception (13) are associated with menstruation and pregnancy. It may be that these senses, particularly taste, are upregulated during childbearing years to support a healthy pregnancy. For example, the perceived bitterness of quinine hydrochloride increases in the first trimester of pregnancy (14). Because poisons are often bitter, enhanced bitter perception could hinder maternal ingestion of substances harmful to fetal development. During menopause, taste— particularly bitterness (15), and possibly olfactory perception (16)—may be vulnerable to declines. Chemotherapeutic agents that alter sex hormone levels could change oral sensations by affecting taste and olfactory perception.

SOURCES AND POTENTIAL THERAPIES FOR ORAL SENSORY DISORDERS

Alterations in perception of food flavor through changes in taste, oral somatosensation, and retronasal olfaction can have a devastating effect on an individual. Living with chronic oral pain, a salty taste, or an inability to experience food flavor can obviously have tremendous impact on one's day-to-day life. Although these are extreme (but not uncommon) experiences, less severe dysfunction—such as heightened bitter intensity, diminished sweet perception, or faded flavors—can also reduce quality of life.

Taste Disorders

Taste is a remarkably robust sense; and ageusia, or total loss of taste, is rare (17). Interactions between the cranial nerves that mediate taste are responsible for some of this stability. This has been seen in clinical and experimental studies for interactions between cranial nerves VII and IX (18,19,20 and 21). Although the nerves responsible for taste sensation do not interact in the periphery, the areas to which they project within the brain appear to inhibit one another. For example, if one of the nerves is damaged, the inhibition produced by that nerve declines and taste responses from the other nerve are intensified. This intensification appears to compensate for taste lost from the damaged nerve (i.e., release of inhibition). Unilateral or bilateral insult to taste-related nerve(s) is detectable by applying tastants to the tongue and palate that correspond to cranial nerve innervation (18). For example, the chorda tympani branch of cranial nerve VII is vulnerable to viral (e.g., otitis media, influenza) and mechanical (e.g., head trauma, surgery) damage, leading to unilateral or bilateral losses of bitter taste on the anterior tongue (22). Taste may also be altered with medications (23). Some regional taste losses may not alter whole mouth taste perception (24) because the localization of taste sensations is controlled by the sense of touch (25). However, losses of chorda tympani taste may contribute to taste and oral sensory alterations.

One of the most disturbing taste alterations is dysgeusia, the presence of a chronic taste in the mouth (e.g., bitter, salty, metallic). In many cases, the dysgeusia results from an actual stimulus that has gained entry to the mouth (e.g., reflux, postnasal drip, infection, medications in saliva or gingival fluid). If a taste is not localized (i.e., it seems to come from all over in the mouth) and can be rinsed from the mouth even briefly, the taste may reflect an actual stimulus. Topical anesthesia of the mouth abolishes such sensations.

Dysgeusia can also reflect abnormal activity in a neural structure mediating taste. Taste sensations produced in this way are akin to phantom limb sensations and tinnitus; we call them *taste phantoms* (26). There is still much to be learned about taste phantoms, but what we have learned to date can provide some clues to their origin.

At least two types of taste phantoms can originate from the central nervous system. The first type results from direct stimulation of a neural structure. In one case, a prosthesis in the middle ear of a patient accidentally stretched the chorda tympani nerve, resulting in bitter and metallic taste sensations (27). Damage can also stimulate input. When a nerve is severed, the site of damage can produce a neural signal that is interpreted as taste sensation in the central nervous system. As recovery proceeds, a neuroma may form. Pressure on the neuroma can produce a continued neural signal. Phantoms of this type are usually intensified by topical anesthesia of the mouth. The topical anesthesia abolishes the taste input responsible for generating central inhibition; this releases inhibition on the phantom, making it intensify.

The second type of taste phantom results indirectly from the presence of inhibitory connections. Damage to one nerve releases inhibition of the other. This not only produces intensification of taste but also can produce taste sensations in the absence of any stimulus (i.e., taste phantoms). As yet, we do not know how such phantoms are produced centrally. One possibility is that spontaneous activity from uninjured sites becomes intensified enough by the release of inhibition to act as a stimulus. Such a possibility would explain why some release-of-inhibition phantoms are abolished when the area from which they seem to arise is topically anesthetized.

The uncertainties about the mechanisms of taste phantoms limit our ability to diagnose the source of every case of dysgeusia encountered in the clinic. However, we can conclude that if topical anesthesia of the mouth intensifies dysgeusia, it must originate in the nervous system (i.e., the dysgeusia can be classified as a taste phantom). Further, we should expect to find that dysgeusia in the presence of taste damage likely has neural origins as well. Dysgeusia produced in response to damaged nerves may diminish with regeneration of the nerves or mediation of the central processes that produce the phantom sensation. The average life of a taste receptor is 10 days but can extend to a month or more (28); thus, damaged taste buds are likely to regenerate, as are damaged neurons routing sensation to the brain. Phantom taste sensations (as well as phantom oral pain sensations) may respond to low doses of benzodiazepines, drugs that work on the central processing of taste (see description in the section Oral Pain).

Olfactory Disorders

Individuals can suffer from olfactory perception that is diminished (hyposmia), absent (anosmia), and distorted (parosmia), as well as olfactory sensations without an odor stimulus (phantosmia). Loss of olfaction can result from interference with conduction of odorants to receptors and damage to the neural structures mediating olfaction (29). Reports of hypersensitivity to odors do not appear to be associated with altered perception (30).

Much of the study of olfactory dysfunction involves how well odors are perceived through the nostrils (orthonasal olfaction). However, clinical evidence suggests that retronasal olfaction (perception of the odor component of food flavor through the mouth) may dissociate from orthonasal olfaction; this could have implications for oral sensation and sensory perception of foods and beverages.

Conductive damage includes all of those occasions in which the delivery of stimuli to the olfactory epithelium is impeded, whether through obstruction or swelling in the paranasal sinuses or interference with the mouth movements necessary to pump odors from mouth to nose. The olfactory nerve (cranial nerve I) can be damaged by viruses (especially from infection of the upper respiratory tract) as well as head trauma (31). Patients with upper respiratory infection-related olfactory loss (and head trauma) may exhibit parosmia (32). This occurrence may be similar to tinnitus and could potentially represent damage to the olfactory receptor cells (33). A less common but still prevalent cause of olfactory loss is repeated exposure to toxins (13). Degenerative diseases of the central nervous system (e.g., Alzheimer's or Parkinson's disease) (34) have olfactory dysfunction as a comorbidity. Olfactory perception also shows age-related declines (35). It is difficult, however, to distinguish olfactory losses associated with the aging process from those due to environmental insult.

Retronasal olfaction occurs naturally with eating and is tightly integrated with taste and touch sensations. Chewing and mouth movements warm and release olfactory volatiles from foods and beverages, and mouth and swallowing actions create sufficient intraoral pressure to pump volatiles to the olfactory receptors (36). Conditions that alter chewing, mouth, and swallowing movements can thus decrease retronasal perception, even if the olfactory system is intact (e.g., maxillary dentures) (37). Damage to touch sensations or chorda tympani taste may also impair retronasal olfaction. Historically, touch has been thought to help localize retronasal olfaction to

the mouth (38), but anecdotal and experimental evidence suggests that taste is necessary for full retronasal perception. Individuals with damage to taste, including those with damage after radiation therapy (39) or unilateral chorda tympani section during stapedectomy (24), report reduced retronasal olfactory sensations. Experimentally, unilateral anesthesia of the chorda tympani nerve reduces retronasal olfaction on the anesthetized side (40). It appears that both taste and touch sensations need to be intact to experience full retronasal olfaction. Retronasal olfaction and not orthonasal olfaction can be intact in subjects who have undergone a total laryngectomy (41,42). The laryngectomy interrupts the normal path of air traveling from the nose or mouth to the lungs and allows the individual to breathe through a stoma in the throat. Orthonasal olfaction is impaired because the air carrying odors does not pass through the nostrils during breathing; retronasal olfaction is intact because swallowing pumps the olfactory volatiles to the olfactory epithelium.

Olfactory neurons are capable of regeneration at all points between the receptor site and the central nervous system (43,44), although, as demonstrated with head trauma, the degree of regeneration may depend on the severity of damage (45), and perception may be blunted or distorted (46). Conductive losses may respond to therapies with topical steroids (47) or restoration of oral health to improve release and transport of odors from foods and beverages.

Oral Pain

Cancer and cancer therapies can cause oral pain, which impedes eating and the ability to obtain adequate nutrition. In this section, we discuss topical capsaicin as a potential treatment for the acute oral pain resulting from tissue damage. In addition, we discuss burning mouth syndrome, a chronic oral pain that appears to be central in origin (i.e., a phantom sensation). Cancer patients, because of the cancer or its therapies, may suffer from oral pain from lesions as well as from central sources.

Capsaicin, the active ingredient in chili peppers, produces a burning sensation when applied to the skin or mucous membranes, yet it desensitizes polymodal nociceptors if there is sufficient exposure, followed by removal of the capsaicin stimulus (48). Desensitization is particularly effective in the oral cavity (48,49) because capsaicin crosses the oral mucosa effectively (50). Capsaicin desensitization offers another benefit over topical anesthetics: Pain control can last much longer than results with topical anesthesia. In experimental studies with healthy subjects, complete recovery from capsaicin desensitization can take days (51). Capsaicin does not desensitize mechanoreceptors; thus, it does not produce the numbness that can make eating difficult.

The clinical utility of capsaicin as a topical analgesic depends on minimizing its burn and maximizing desensitization (52,53) as well as providing the analgesic in an acceptable form. Bone marrow transplant recipients, who have high risk of oral mucositis, report preferring nonviscous, room-temperature products with limited flavor (54). We have delivered capsaicin (via cayenne pepper) in a taffy candy (53); allowing patients to sample the candy to find the amount of cayenne pepper that provides a minimal burn before oral pain improves patient acceptance (55). Dietary use of capsaicin and taste genetics may influence the preferred level of capsaicin (supertasters, as already mentioned, experience more irritation from capsaicin) (56).

Patients can also apply capsaicin as diluted Tabasco sauce directly to lesions. Full strength Tabasco sauce is equivalent to 300 ppm capsaicin; this produces a very strong burn in someone who is not desensitized (individuals who use Tabasco sauce frequently report much lower burn). Diluting the Tabasco sauce 1:3 or 1:4 parts and applying this dilution to the lesion with a cotton-tipped swab for 30 seconds to 1 minute should produce sufficient exposure to desensitize the pain receptors and provide pain relief. The patient can try reapplication of the capsaicin as candy or directly to the lesion as needed. Subsequent applications may require less capsaicin to maintain the desensitization (57).

Oral pain in cancer patients, in some instances, may be similar to the oral pain of burning mouth syndrome (BMS). The severity of oral pain in BMS appears to be associated with genetic variation in taste and chorda tympani taste loss (58). Taste and oral pain (cranial nerve V) appears to show the same inhibitory interactions as seen between taste from cranial nerves VII and IX. Temporary anesthesia of the chorda tympani nerve can produce increases in the burn of capsaicin particular to genetic supertasters (59). Grushka and Bartoshuk (58) have suggested that BMS is an oral pain phantom in susceptible individuals. Genetic supertasters, defined by the density of fungiform papillae, report the most oral pain from BMS (60). Those who suffer from BMS show diminished or absent chorda tympani nerve taste (60). BMS also afflicts primarily postmenopausal women. The loss of bitterness associated with menopause (15) may act to release the inhibition on oral pain and increase the risk of BMS in susceptible individuals. There is some evidence that the oral pain of BMS may respond to benzodiazepines (58). The rationale for this treatment is that the oral pain is centrally mediated, and possibly controlled, through the trigeminal nucleus of the medulla. Taste appears to inhibit oral pain through gamma-aminobutyric acid (GABA). Clonazepam, a GABA receptor agonist, intensifies the inhibition produced by GABA, and thus can suppress the oral pain and taste phantoms. Low doses of clonazepam can diminish oral burn and dysgeusia in seven of ten patients treated (61,62). Cancer patients who suffer from oral pain that is not responsive to topical agents may benefit from drugs such as clonazepam, which act centrally.

PSYCHOPHYSICAL ISSUES IN THE STUDY OF TASTE AND CANCER

Anecdotal accounts from patients provide convincing evidence that eating can be a very unpleasant experience for many cancer patients. Gilda Radner describes her taste problems with chemotherapy in her book, *It's Always Something* (63):

> My taste buds were weird. Things tasted weird . . . eating was very unpleasant. I ate what I ordinarily wouldn't eat. I wanted cheeseburgers, cheese, and pickles. Lettuce and vegetables tasted like plastic. The highly salty, tasty things were good, but bland foods tasted like something they weren't and that was too strange. It was too weird when a carrot tasted like a ceramic kitchen magnet.

This provides a wonderful example of the difficulty in discerning the source of the alterations. For example, “lettuce and vegetables tasted like plastic” suggest an olfactory loss, yet Ms. Radner's ability to taste salt remained. “Eating was very unpleasant” could reflect a pure hedonic change or could reflect sensory abnormalities. If we are to provide relief to patients, we must document these changes with careful psychophysical testing. However, the psychophysical methods that can reveal real changes in the patient's chemosensory world are deceptive. They often look very simple but in reality require considerable skill both in execution and in interpretation. In the next sections of this chapter, we discuss the problems encountered in any psychophysical evaluation of abnormal sensory experience, review the cancer data with those problems in mind, and suggest appropriate study designs for future research. It should be noted that the best designs to determine whether an illness or therapy affects sensory experience is a prospective design in which each subject can be his or her own control. With such designs, patients can be tested before and after a given therapy. However, such designs are impractical when studying an illness. Therefore, the determination of whether cancer per se affects sensory experience is a much harder task than the determination of whether a particular therapy affects sensory experience. Obviously, in a clinical setting, an extensive psychophysical evaluation of each cancer patient is impractical. At the end of this chapter, we provide a brief list of suggestions that may help clinicians identify the source of food complaints.

THRESHOLD VERSUS SUPRATHRESHOLD EVALUATIONS

The threshold of a particular substance refers to the lowest concentration a subject can either detect or recognize. Threshold measurement seems a simple enough concept, but many experimental artifacts exist to plague accurate measurement, and some of the methods that have been used extensively in studies of taste and cancer are open to serious criticism. That aside, even when taste thresholds are measured with appropriate procedures (64,65 and 66), thresholds provide little information of value for cancer patients. Thresholds merely measure the bottom of the range and cannot demonstrate the actual effect of cancer or its therapies on a patient's taste world. The bottom of the range does not predict perceived intensities of foods and beverages because they are at higher concentrations (i.e., suprathreshold).

Figure 11-3 illustrates some dissociations between threshold and suprathreshold perception for sweet and bitter. We have selected these qualities because they are especially relevant to an explanation of the flaws in one of the most cited cancer papers (67). We discuss that paper in more detail later in this chapter. The two top panels show psychophysical functions for sucrose (i.e., perceived sweetness plotted against sucrose concentration). In both cases, the threshold (i.e., the approximate concentration at which sensation is zero) is elevated. The panel on the left shows taste loss associated with upper respiratory infection across the whole concentration range (68,69); this kind of change involves both a threshold shift and a reduction in perceived intensity. The right panel shows an elevated threshold (produced by adapting to sucrose), but no change in perceived intensity of the highest concentrations (65).

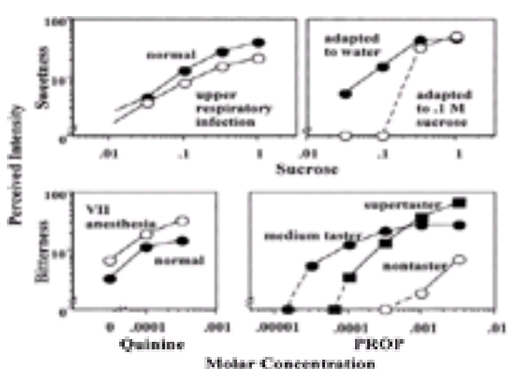

FIGURE 11-3. Psychophysical functions for sweet and bitter (see text for explanation). Upper left (68,69); upper right (65); lower left (20); lower right (22). PROP, 6-*n*-propylthiouracil.

The two bottom panels show psychophysical functions for the bitter compounds quinine and PROP. The panel on the left shows the results of a study in which quinine was swabbed onto a circumvallate papilla on one side of the tongue. The "normal" function shows the bitterness before anesthesia to the chorda tympani nerve on the contralateral side (20), and the "anesthesia" function shows the bitterness after anesthesia. Note that even water tasted bitter after the anesthesia, and that the bitterness of the quinine solutions was intensified. The panel on the right shows the thresholds and psychophysical functions for three individuals: a nontaster, a medium taster, and a supertaster of PROP. The thresholds for nontasters are clearly elevated above those for tasters (medium and super), and the suprathreshold intensities for nontasters are reduced below those of tasters; among tasters, thresholds do not completely predict how bitter PROP tastes at suprathreshold concentrations. Although individuals who taste PROP to be intensely bitter (i.e., supertasters) have lower PROP thresholds on average than those who taste PROP to be only moderately bitter (i.e., medium tasters), there are many reversals. The medium taster in the lower right panel actually has a lower threshold than the supertaster. These kinds of dissociations between threshold and suprathreshold intensity have been well documented in taste (65,70,71).

CANCER AND BITTER THRESHOLDS

DeWys and Walters (67) reported that cancer patients had high detection and recognition thresholds for the sweet taste of sucrose and that a subgroup of cancer patients had unusually low recognition thresholds for the bitter taste of urea. The authors stated, "The decreased taste symptom correlated with an elevated taste threshold for sweet (sucrose), and the symptom of meat aversion correlated with a lowered taste threshold for bitter (urea)." However, the conclusions are compromised by a miscalculated c^2 test (72). Correcting the statistical errors leads to the following corrected conclusions:

1. The sucrose detection and recognition thresholds were significantly elevated (although the c^2 reported for the recognition threshold, 59.4, should be 5.94).
2. The urea thresholds were *not* significantly lowered c^2 was reported to be 10.5, but the correct value is 1.05, which is not significant).
3. Patients with subjective taste loss did have significantly elevated sucrose recognition thresholds.
4. Patients with meat aversions did have significantly lowered urea recognition thresholds.

Gallagher and Tweedle (73) tested cancer patients before treatment and reported significantly lower urea thresholds, confirming the DeWys and Walters conclusion that we now know is incorrect. The data were not provided in the paper and, therefore, their Mannwhitney U tests cannot be checked. However, because means and standard errors were provided, we can calculate *t* tests. The *t* test for cancer patients versus controls was $t = 0.943$, which is clearly not significant. Thus, a second claim that cancer per se lowers urea thresholds does not appear to be correct.

Hall et al. (74) studied gastrointestinal (GI) cancer patients before treatment and reported (correctly) that a subgroup had urea thresholds lower than both noncancer GI patients and normal controls. However, GI noncancer patients had lower urea thresholds than the normal controls, casting doubt on any conclusions about cancer per se. Further, the patients with low urea thresholds did not have meat aversions. Other studies (75,76 and 77) found no differences between bitter thresholds in cancer patients who had not received chemotherapy or radiation therapy and control subjects. Bolze and colleagues (78) reported *elevated* thresholds for urea. In this study, cancer patients were significantly older than control subjects, and taste thresholds are known to rise with age. For this reason, we reanalyzed the data using only cancer patients and controls younger than 60 years of age. Urea thresholds were still elevated for cancer patients.

These studies do not support the conclusion that cancer lowers bitter recognition thresholds, rendering meat unpalatable because of its bitter components. However, even with the statistical errors, a few patients did have urea thresholds that were very low. These low thresholds raise additional issues regarding bitter thresholds that may be especially relevant to cancer patients. First, bitter dysgeusias have been reported by cancer patients, most often in connection with chemotherapy. The presence of a bitter dysgeusia could affect the measurement of bitter thresholds. For example, the Henkin threshold procedure (66,79) presents the patient with three drops, two of water and one containing the tastant. The concentration of tastant at which the subject consistently detects the correct drop is the detection threshold; the concentration at which the subject consistently selects the correct drop and provides the correct quality is the recognition threshold. Detection thresholds are generally lower than recognition thresholds. Weiffenbach (J. M. Weiffenbach, personal communication, 1998) has noted that if a patient has a chronic bitter taste in her or his mouth, the recognition threshold is the same as the detection threshold because all three drops taste bitter; thus, bitter thresholds appear reduced.

Another issue relevant to bitter taste and cancer is the suggestion that certain types of cancer are not randomly distributed among nontasters, medium tasters, and super-tasters of PROP. For example, Milunicová et al. (80) found fewer nontasters than expected among women with malignant tumors of the thyroid gland, breast, uterus, and ovary. If there is an association between type of cancer and type of PROP taster, it may be mediated through acceptance of bitter-tasting fruits and vegetables as well as bitter phytochemicals that are linked with cancer prevention (81). For example, PROP supertasters report less preference for cruciferous vegetables (81) and less frequent intake of green vegetables than do nontasters (82). If PROP tasting influences cancer risk through food preferences and intake, then we would expect to find variations in bitter taste thresholds across cancer patients.

Incidentally, food aversions are not explained by lowered bitter thresholds. Food aversions are far more likely to reflect bitter dysgeusia or conditioned aversions.

SELECTION OF APPROPRIATE CONTROLS FOR PATIENT-CONTROL DESIGNS

To match controls to patients, one must know all of the relevant variables affecting the illness. Any failure to do this renders the conclusions of the study suspect. Obviously, if we knew all of the relevant variables, the investigation at hand would probably be unnecessary; thus, we are virtually never certain that a patient-control study is adequate. However, at the very least, variables known to affect the measure under study must be controlled.

Taste and olfactory thresholds rise with age (83,84). As we noted with Bolze et al. (78), some taste thresholds were higher among cancer patients (tested before radiation therapy) than among controls; however, the patients were significantly older than the controls with which they were compared. A reanalysis of their data using only subjects younger than 60 years of age diminished the age difference, as well as the impact of some of the results. Bolze et al. measured detection and recognition thresholds for stimuli representing the four taste qualities (sweet, salty, sour, bitter); detection thresholds for sodium chloride (NaCl), hydrochloric acid (HCl), and urea (but not sucrose) were elevated, and recognition thresholds for HCl and urea were elevated. Our reanalysis showed significant elevations for the HCl recognition threshold and for both the urea detection and recognition thresholds.

The ability to taste varies genetically. To the best of our knowledge, no published paper on taste and cancer has attempted to control for this genetic variation. As we noted, some authors have suggested the possibility of connections between cancer and PROP tasting. Any such connections are especially important where patient-control studies claim lowered bitter thresholds.

Because the incidence of particular types of cancer is associated with risk factors (e.g., smoking, alcohol abuse), the impact of these risk factors on taste and smell must be considered in the selection of controls. In addition, effects of cancer on incidence of diseases like upper respiratory infections may also produce non–cancer-related differences between patients and controls.

LIMITATIONS ON THE SUPRATHRESHOLD TECHNIQUES USED TO COMPARE PATIENTS VERSUS CONTROLS

Suprathreshold scaling reflects the oral sensory world that is most relevant to everyday experiences such as eating and drinking. Suprathreshold scaling produces psychophysical functions that allow us to see how perceived intensity changes across the entire range of sensation from barely detectable (near-threshold) to the most intense sensations possible. This is the most important information but also the most difficult to obtain because we cannot share another person's experiences directly. We have reviewed this dilemma in the context of studies on aging (83) and genetic variation in taste (5,85); we briefly summarize that argument in the next section.

COMPARING SENSORY EXPERIENCES

How do we compare sensory experiences? We do so by finding a standard to which other sensations can be compared. One of the oldest methods is to use the adjectives on labeled selfrating scales (Likert, category, visual analog) as standards. For example, with the Natick 9-point category scale we tell subjects to apply numbers to their sensations, such that 1 = "very weak," 5 = "medium," and 9 = "very strong." These scales were originally used for measuring changes or differences within a person and are valid for such usage. But to make comparisons across subjects, we must assume that everyone applies these adjectives to their perceptions of intensity in the same way, so that if two people both call a stimulus very strong, they are perceiving the same absolute intensities. This is an incorrect assumption unless the adjectives are applied to a specific domain. This point was made by S. S. Stevens over 40 years ago: "Mice may be called large or small, and so may

elephants, and it is quite understandable when someone says it was a large mouse that ran up the trunk of the small elephant." If cancer patients and controls have different oral sensory worlds, the absolute intensities of the adjectives will be different; members of the group will stretch or compress the labeled scales to apply to the context of their oral sensation. This could minimize, reverse, or fail to detect the true oral sensory differences between cancer patients and controls.

Another way to find a standard is to use another sensory experience. For example, when we explore genetic variation in taste, we use the intensity of a sound as a standard. We essentially ask subjects to match the intensity of a taste to the intensity of a sound. We know that hearing varies, but we have no reason to believe that variations in hearing and taste are related. Thus, on average, we discover that supertasters match saturated PROP to a very loud sound, whereas nontasters match the same concentration to a very soft sound. The use of one sensory modality as a standard for variation in another is called *magnitude matching* (86). This method is usually used with the psychophysical method called *magnitude estimation* but is applicable to any suprathreshold scaling technique.

Research on oral sensory differences between PROP non-tasters and supertasters may provide insights on how to measure oral sensory differences between cancer patients or cancer patients and controls. Green and colleagues (87,88) empirically derived an adjective-labeled scale that has ratio properties. The labeled magnitude scale (LMS) has adjectives spaced such that distances along this scale are approximately logarithmic and essentially equivalent to magnitude estimates (i.e., if two stimuli produce responses of 8 and 4, respectively, the first stimulus is perceived to be twice as intense as the second). To avoid the relative meaning of the adjective on the scale, we propose that the top of the LMS be labeled as "strongest imaginable sensation of any kind" (85). This scale would therefore not be confined to a specific sensory modality but rather have meaning across all domains (Fig. 11-4). Preliminary findings reveal that use of the general LMS detects oral sensory differences among PROP taster groups and associations with dietary behaviors that have not previously been seen.

FIGURE 11-4. The general labeled magnitude scale (85,87,88) may provide a universal sensory ruler to obtain ratings of perceived sensory experience that are comparable across individuals (see the section in the text, Comparing Sensory Experiences). The scale contains descriptors that are used in everyday life, ranging from nothing at the very bottom to strongest imaginable sensation of any kind at the top. To obtain ratings of intensity, patients should read the descriptors of intensity, be instructed that the top of the scale is across any sensory domain, including experiences that may be painful, and indicate their rating of intensity at any location on the line.

Another psychophysical error is to give a standard to both patients and controls and tell them what rating the standard represents. This forces patients and controls to give the same ratings even if they are having very different experiences. The results, which will show no difference between patients and controls for the standard, are meaningless. This mistake is easy to make because the practice of providing a standard and assigning it a rating is common when individual differences are not important. Consider the following example: Ames et al. (89) studied the taste of NaCl and sucrose in patients with breast cancer using a method designed for studies related to food (90). The subjects were presented with a 15-cm horizontal line with the end points labeled "least salty/sweet" on the left and "most salty/sweet" on the right. Subjects were given the most extreme taste concentrations (e.g., 0.040 and 0.756 M NaCl and sucrose) and told that these corresponded to the labels. Subjects were then instructed to mark the line to indicate the perceived intensity of each sample. Note that if the cancer patients had perceived all tastants as weaker than the controls did, this would never have been revealed because cancer patients and controls alike were instructed to rate the top concentration at the most salty/sweet end of the scale. Not surprisingly, there were no differences between cancer patients and controls.

DISTINGUISHING HEDONIC FROM SENSORY ALTERATIONS

Taste and smell not only provide sensory information but also affect pleasure and displeasure. The hedonic attributes of taste and smell serve different functions. The affect of taste is hard-wired; newborns respond to sweet tastes with facial expressions suggesting pleasure, and to bitter tastes with facial expressions suggesting displeasure (91). On the other hand, the affect of olfaction appears to be largely (if not completely) learned. At 2 years of age, children do not appear to experience adult-like pleasure and displeasure from odors (92,93); by 3 years, their responses begin to resemble those of adults (94).

The affect of taste is relatively stable, but the affect of olfaction is quite labile. Simple exposure to an odorant can change its pleasantness (95). Pairing an odor with pleasurable experiences like sweet taste (96) or calories (97) can increase its pleasantness, and pairing an odor with nausea decreases its pleasantness (98). This latter phenomenon plays an important role in the formation of conditioned food aversions.

When patients say that food does not taste good, they may be referring to a genuine sensory alteration or to a hedonic change: Food tastes just as it always did, but that taste is no longer pleasant. It is important to question patients to be sure that the nature of the complaint is clear.

ORAL SENSORY ALTERATIONS ASSOCIATED WITH CANCER AND ITS RELATED THERAPIES

Most of the literature on oral sensory alterations is focused on taste. For that reason, the discussions in the next sections are also focused on taste. What is known about genuine cancer-related sensory alterations in olfaction is summarized later. Conditioned aversions, which reflect hedonic rather than sensory alterations, involve olfaction; these are discussed toward the end of this chapter.

REAL-WORLD TASTE EXPERIENCE AND CANCER

Tumors can obstruct chemoreceptor sites, interfere with neural transmission on the pathway between receptor site and the brain, and affect sensory processing in the brain itself. Several types of intracranial tumors are known to alter both taste and smell. Acoustic neuromas (also called *vestibular schwannomas*), which form on cranial nerve VIII, can produce taste loss if the tumor invades cranial nerves VII or IX (18).

There are two sources of evidence for meaningful taste loss in cancer patients, suprathreshold psychophysical studies and anecdotal reports. We have already discussed the study by Ames et al. (89) on breast cancer patients. Because these patients had only surgery (no chemotherapy or radiation therapy), they would have been appropriate to study. However, the results—that there were no effects of cancer per se—were produced by the misuse of the scaling method and have no relevance to cancer per se.

Mossman and Henkin (99) used a different suprathresh-old scaling method that can reveal differences between cancer patients and controls. The method used, forced scaling, asks subjects to rate the intensity of taste on a scale from 1 to 100, in which 100 equals the most intensely salty, sweet, sour, or bitter solution ever experienced. Patients with head and neck cancer rated taste intensities lower than control subjects did. Only one of the patients, however, was subjectively aware of any taste loss, which is hard to reconcile with the psychophysical data. This kind of method has a potential flaw for examining differences across groups. The subjects were asked to rate their sensations in comparison to their most intense taste experience. However, the most intense taste experience varies with genetic variation in taste. This means that differences between patients and controls may simply reflect genetic differences. Fortunately, this study also includes within-patient comparisons, which are discussed in the section on radiation therapy.

Anecdotal descriptions may offer insight into the status of taste function in cancer patients, but the anecdotes must contain sufficient information to ensure that the patient is reporting true taste changes. Bolze et al. (78) reported that 17% of their patients had subjective complaints of loss of taste or abnormal taste when initially interviewed, but did not describe how their questions were phrased. Kashima and Kalinowski (100) argue that taste function is frequently disturbed before treatment of laryngeal cancer. However, the phrasing of their questions is not included in their report, and they were dealing with patients who may also have experienced oral sensory alterations from some of the risk factors for this cancer (e.g., tobacco and alcohol use). Some reviews of cancer and taste assert that cancer damages taste (101), but the evidence turns out to be the untrustworthy threshold studies already discussed. Finally, some reports of alterations in taste perception are actually

assessments of changes in the palatability of foods (102). In conclusion, there is no good evidence for a general phenomenon of taste loss with cancer per se.

CHEMOTHERAPY AND TASTE

Cancer therapies often suppress tumor growth by interrupting the proliferative capacity of cancer cells and can have both a direct and indirect impact on taste, smell, and oral somatosensation. Tissues in the oral cavity are particularly susceptible to damage because they divide at a faster rate than tissues of other organs. Both chemotherapy and radiation therapy can damage chemosensory structures, disrupt saliva (103) and mucus production, and cause oral mucositis, xerostomia, and dental caries. Antiestrogen drugs, such as tamoxifen citrate, can alter the body's hormone production, which might diminish bitterness (12); chemotherapy drugs can also enter the mouth via gingival fluid (104) and saliva (105,106) and stimulate taste, tactile (107,108 and 109), and olfactory (110) sensations. The existence of venous taste was once exploited in the calculation of circulation time; compounds were injected into the blood-stream, and the length of time that passed before they were tasted in the mouth was used as a measure of circulation (111,112). These compounds stimulate taste receptors on the lower portions of the taste cells directly from blood without actually entering the mouth.

The effect of chemotherapy on a patient's experience with food can often be dramatic. One study demonstrated that over 80% of chemotherapy patients avoided food (113). Many reported taste alterations, as well as dry mouth, have been directly linked to drugs such as vinblastine sulfate, cisplatin, bleomycin sulfate, doxorubicin, or methotrexate (28,114). The worse the perceived taste alterations, the worse the reported distress and change in quality of life (114). A study by Soni and Chatterji (115) using electrogustometry (i.e., assessment of thresholds for electric taste) reported that 10% of the patients treated with bleomycin sulfate showed elevated thresholds (compared to control subjects), but that thresholds returned to normal within 10–12 weeks. This paper illustrates a point already made: Localized loss often fails to affect realworld perception. Electrogustometry uses a metal probe to stimulate the tongue. The probes are very small and so the stimulation is very localized. Soni and Chatterji reported that only one of five subjects who showed substantially elevated thresholds noticed any loss.

Two suprathreshold psychophysical studies have failed to find significant effects of chemotherapy. Trant et al. (116) used a 10-cm line labeled “no sweetness, sourness, saltiness, or bitterness” on the left and “extremely sweet, sour, salty, or bitter” on the right (subjects were allowed to extend the line if they chose). The intensity scores were not reduced in those patients receiving chemotherapy (compared to other cancer patients), but psychophysical limitations could have failed to detect differences. Mulder et al. (117) asked patients to rate taste intensities on a 7-point scale labeled with 0 = “no taste” and 7 = “extremely strong.” Patients were tested before chemotherapy and between the seventh and tenth days after the last day of nine courses of chemotherapy. Following chemotherapy, the lowest concentrations were rated stronger than before and the highest concentrations were rated lower than before, the most pronounced effect being on sweet. Note that this is a relatively subtle loss, yet Mulder et al. quote one of their patients as saying, “Everything tastes the same.”

The discrepancies between the results of these studies and patient anecdotes suggest several problems. Experimental designs may fail to capture the important effects of chemotherapy on taste. Prospective studies following individual patients may be necessary to identify the critical time at which taste loss occurs, as well as to identify the tumor sites and chemotherapeutic agents most likely to produce damage. New psychophysical methods for suprathreshold scaling are more sensitive than the methods previously in use (5,85). Finally, patient anecdotes, such as “everything tastes the same,” actually suggest olfactory losses, and the effects of chemotherapy on olfaction have been virtually ignored.

RADIATION THERAPY AND ORAL SENSATIONS

The anecdotal accounts of radiotherapy-induced disturbances are compelling. MacCarthy-Leventhal, a physician who underwent radiation for cancer of the pharynx in the 1950s (39), described both a “blindness of the mouth,” rendering food tasteless, and a “hallucinatory” taste, over-whelming all liquids. These descriptors suggest alterations of taste, retronasal olfaction, and possibly oral somatosensation. More recently, Chencharick and Mossman (118) reported perceived changes in food taste and use of sugar in head and neck cancer patients. Before radiation therapy, 25% of these patients reported “changes in taste” and that “foods taste bad,” whereas 80% reported such changes after treatment. More than half of these patients noticed an abnormal taste with high-protein foods (e.g., meat, eggs, dairy) and a quarter reported adding sugar to foods. Protein molecules are too large to stimulate taste or smell receptors directly. It is possible that dysgeusia is more apparent when eating high-protein foods. These foods require chewing that could release bitter-tasting compounds (from oral health problems or medications) into the mouth through the saliva. Centrally mediated phantoms may also be more noticeable when ingesting high-protein foods. Bonanni and Perazzi [(119) cited in Rubin and Casarett (120)] followed 50 patients for 1 month to 1 year and reported both suppressed and heightened taste sensations. This is particularly interesting because there are theoretical reasons to expect radiation therapy to be associated with heightened taste. Because radiation is directed to specific areas, one might expect some taste nerves to be affected more than others. Localized damage can lead to intensified taste sensations due to release of inhibition. It is also possible that high-protein foods “taste” bad because of impaired retronasal olfaction with altered taste and oral touch sensations due to radiation therapy.

The taste losses induced by radiation are not subtle. Taste loss can occur within 2–3 days after the therapy, before the observed degeneration of taste buds at approximately 7 days posttherapy (121). The number of taste buds degenerated is related to the size of radiation therapy. Radiation therapy may cause dissociation between thresholds and suprathreshold taste, as demonstrated in a 52-year-old woman undergoing radiation therapy for a tumor of the neck (65). This patient's taste recognition thresholds initially rose but returned to normal after approximately 60 days. Her suprathreshold functions flattened and did not recover. She lived in a pastel taste world despite normal thresholds. A study by Mossman and Henkin (99) made within-patient comparisons of taste function before, 2 weeks after, and 5 weeks after radiation therapy. The psychophysical functions for taste flattened steadily during this time. In a study of the longterm effects of radiotherapy (103), taste losses were still present up to 7 years after therapy. However, taste loss with radiation therapy is by no means universal. Schwartz et al. (122) found only mild impairment in patients tested at varying intervals after therapy (6 months to 19 years).

CANCER, CANCER THERAPIES, AND OLFACTION

The effects of cancer per se and chemotherapy on the sense of smell have received very little attention. This may reflect the common misunderstanding about the proper distinctions between taste and smell. Anecdotal accounts suggesting that food is flat with no taste actually imply olfactory loss as well as genuine taste loss, because a large part of the sensory input from food is olfactory (perceived retronasally). Cancer therapies that alter taste and oral touch could also impair retronasal olfaction, even if they do not alter functioning of the olfactory nerve (cranial nerve I). The effects of radiation therapy on olfaction have been documented by Doty and his colleagues (123,124) and Ophir et al. (125). In the study by Ophir et al., patients did not show complete recovery even 6 months after treatment. The influence of cancer and related therapies on olfaction deserves more attention.

CONDITIONED FOOD AVERSIONS

Garb and Stunkard (126) provided a classic picture of a conditioned aversion: If a person becomes sick after eating a specific food, he may develop an intense dislike (i.e., *aversion*) for that food, regardless of whether it was responsible for the illness. Conditioned aversions were used in the treatment of alcoholism as early as 1940 (127). Subsequently, conditioned aversions became of great interest to learning theorists (128,129). Conditioned aversions to foods form in the presence of nausea (98) and can occur even when an individual recognizes that the nausea was not caused by the food. Nausea is associated with both chemotherapy and radiation therapy, but may also be associated with the cancer itself. Bernstein (130) was the first to show that conditioned aversions could be produced by therapies for cancer and to suggest that these aversions might play a role in the loss of appetite in cancer patients.

The roles that taste and olfaction play in conditioned aversions are scientifically very interesting. In animals, conditioned aversions are believed to form better to taste than to olfactory stimuli. In humans, conditioned aversions are rarely (if ever) specific to sweet, salty, bitter, and sour, but form instead to the odors of the food perceived retronasally (131). Part of this apparent difference between the results in animal and human studies may relate to confusion over the proper distinctions between orthonasal olfaction, retronasal olfaction, and taste. Rozin (132) has suggested that the brain may treat olfactory input differently depending on whether its origin is orthonasal or retronasal, because orthonasal input provides information about the environment, whereas retronasal input provides information about what is in the mouth. To the best of our knowledge, the olfactory stimulation in animal studies is orthonasal. If these studies had used retronasal olfactory stimulation, we would expect that the conditioning would be greater to retronasal olfactory stimuli than to taste stimuli.

Broberg and Bernstein (133) used the properties of conditioned food aversions to provide a behavioral intervention that helps prevent aversions to important dietary items in cancer patients. Children were given either root beer or coconut Lifesavers candy before chemotherapy. The Lifesavers candy served as a scapegoat food. Aversions were formed to the scapegoat, preventing formation of aversions to other foods. Andresen et al. (134) compared novel and familiar scapegoats and found that the novel scapegoat was more effective. Mattes (135) demonstrated the efficacy of this procedure in a large population that included patients receiving radiation therapy (not tested in the previous studies).

One of the interesting features of conditioned food aversions is that some foods become aversive and others do not. Bartoshuk and Wolfe (L. M. Bartoshuk and J. M. Wolfe, unpublished data) demonstrated this with aversions formed in college students as the result of illness induced by consumption of alcoholic beverages. Of 61 alcohol-induced aversions, about half occurred when the subject consumed more than alcohol alone (e.g., vodka and orange juice, beer and buffalo wings). In these cases, about 40% of the time the aversion skipped the alcohol altogether and formed to the accompanying food or beverage. The rest of the time the aversion included the alcoholic beverage. Jacobsen et al. (136) studied the development of aversions to diet items over successive chemotherapy sessions in cancer patients. They

found that 46% of the patients developed aversions to at least one food at some time during treatment. They concluded that the number of aversions formed was probably limited by the familiarity of the foods (animal studies indicate that novel foods condition more easily). In addition, consumption of several foods may have protected individual items.

Although it is clear that nausea produces conditioned aversions (98,137,138), some aversions appear to form in cancer patients that cannot be closely associated with nausea (135,136,139,140).

PHANTOM SENSATIONS RESULTING FROM CHEMOTHERAPY OR RADIATION THERAPY

Some patients report bitter taste sensations during chemotherapy (107,108 and 109). Because medications tend to taste bitter, patients may be tasting their chemotherapeutic drugs. There are two routes by which these drugs might stimulate taste. First, the drugs may gain access to the mouth via saliva (105,106) or gingival fluid (104). Second, the drugs may be perceived directly from the blood-stream through venous taste (141,142) or olfactory (110) sensations.

Cancer therapies can produce salivary disorders (e.g., dry mouth) that abet tissue damage; insufficient saliva leaves tissues unprotected and open to infection, the products of which can be both tasted and smelled.

Nesse et al. (143) reported pseudohallucinations associated with chemotherapy. Some patients described a chemical odor that occurred when they thought about or viewed the clinic. Two patients described being able to taste their chemotherapeutic drugs while under treatment, and then tasting them again when thinking about them. Olfactory hallucinations can occur in normal individuals who have been exposed to intensely emotional experiences. Burstein (144) reported two such hallucinations related to posttraumatic stress disorder. A woman who had been in an automobile accident smelled gasoline while riding as a passenger in her husband's car, and a man who had been in a fire reported flashbacks in which he smelled smoke as he had in the fire.

RECOMMENDATIONS

Even without extensive psychophysical testing, clinicians can distinguish sensory from hedonic complaints and can obtain information about the source of dysfunctions. Table 11-1 summarizes steps to evaluate sources of oral sensory complaints. Identifying the complaint's source can provide insights into potential therapies. Strategies designed to improve dietary intake and nutritional status should be individualized, as illnesses and treatments affect patients differently, making the application of universal recommendations to improve the flavor of food unwise. Patients are likely to benefit from consultation with a registered dietitian. Strategies designed to prevent chemosensory dysfunction secondary to treatment (e.g., minimizing damage to taste and olfactory receptors with shielding during radiation therapy) should be adapted to the needs of the patient (28). The National Cancer Institute has published a booklet, *Eating Hints for Cancer Patients*, which provides useful recipes for cancer patients and their families. Finally, it is important to reduce the impact of conditioned aversions.Studies suggest that

TABLE 11-1. EVALUATING ORAL SENSORY COMPLAINTS

- Patients should be informed of the possibility of a food aversion occurring with treatment.
- Patients should avoid eating 4 hours before and after chemotherapy or bowel irradiation (28).
- Patients may ingest a novel-tasting but nutritionally unimportant food (scapegoat) shortly before irradiation or chemotherapy (133).
- If possible, patients should not consume nutritionally important foods until nausea ends (134).

DYSPHAGIA

STEVEN B. LEDER

The term *dysphagia* is derived from the Greek *dys* (with difficulty) and *phagia* (to eat). Passage of a food bolus from the oral cavity through the pharynx without penetration into the trachea constitutes a successful swallow. Dysphagia can occur due to disordered oropharyngeal swallowing or bolus penetration of the vocal folds and aspiration into the trachea and lungs.

When material penetrates the larynx and enters the airway below the level of the true vocal folds, aspiration has occurred. Aspiration can occur *before* the swallow (e.g., before triggering of the swallow reflex), *during* the swallow (e.g., due to poor laryngeal closure), or *after* the swallow (e.g., from residual material left supraglottically) (1).

Dysphagia results in higher health care costs due to increased length of hospitalization and the more expensive nature of nonoral feeding (2). Just as important, dysphagia impacts negatively on both eating and the activities associated with eating by restricting or preventing the normal act of swallowing (3,4,5,6,7 and 8).

Eating and life are bound together. Not only is eating one of life's greatest pleasures, but it is also necessary to sustain life itself. We eat for many reasons, including sustenance, satiety, and to satisfy hedonistic desires (3,4). Just as importantly, eating is integral to the social network of every society in the world (3,9). Annual feasts, seasonal celebrations, weekly meal planning, and daily treats help to define, order, and enrich a society's, a family's, and an individual's life (9,10,11,12,13 and 14). When an attendee at life's celebration cannot participate, the impact is immediate and significant (3,10). Inability to eat not only threatens biological survival but also represents a barrier to fully sharing life with one's family and society (4).

The impact of dysphagia on an individual's social, emotional, and psychological life and well-being has seldom been addressed in professional literature (15). A spousal report (16) discussed the importance of eating, for both the individual and his family, throughout the progression of neurological disease. When eating became impossible for patients, the family felt that even the smell of favorite foods brought pleasure and a sense of social connection and sharing between the patient and the family.

Only one scientific paper has dealt with eating and quality of life (4). It included an extensive discussion of the experiential meaning of eating, a theoretical framework that described dysphagia handicap and adaptiveness, outlined a model for understanding the dysphagic person's concealment of the disorder in the medical encounter, and proposed a strategy for professionals treating the disorder. Dysphagia intervention is intended to increase the patient's feelings of hope, security, and self-respect by focusing on adapting eating to the individual's psychosocial abilities and supporting the individual's feelings of hope for a meaningful life (4,17,18 and 19).

The adverse effects of both cancer and its treatment on swallowing are well known (20). Pretreatment dysphagia is caused by the tumor due to mass or neurological changes, which can lead to malnutrition and, at times, aspiration. Posttreatment dysphagia is caused by the treatment options, with surgery disrupting swallowing ability most significantly, but radiation therapy and chemotherapy, either alone or in conjunction with surgery, also contributing to the severity of dysphagia (20).

The purpose of this chapter is not only to discuss the anatomy and physiology of normal swallowing, etiologies of dysphagia, and diagnostic procedures, but to explore the importance of appropriate rehabilitation and psychosocial intervention with the patient and caregivers to foster an optimal supportive environment to either continue or reinstate the act of eating, with all its attendant social importance, into the daily life of the individual.

ANATOMY AND PHYSIOLOGY

Swallowing is a highly complex, sequential behavior with a number of interrelated and interdependent motor activity patterns that occur simultaneously and rapidly in a predetermined order. Successful swallowing is a function critical to a patient's emotional and psychosocial interactions (21), and it impacts directly on medical status due to the potential for aspiration pneumonia and other pulmonary complications (22,23 and 24).

It is not the purpose of this chapter to provide an extensive discussion of normal swallowing anatomy and physiology. A number of excellent sources are provided for a comprehensive discussion of this area [Miller (25,26), Logemann (1,27), Kennedy and Kent (28), Larson (29), Dodds (30), and Gelfand and Richter (31)]. However, a working understanding of normal swallowing anatomy and physiology is required before discussing the areas of disordered swallowing and dysphagia diagnostics and rehabilitation.

Figure 12-1 shows the anatomical structures involved in swallowing. Table 12-1 outlines basic swallowing response. The swallowing mechanism includes bony and cartilaginous support structures, striated and smooth muscle, and neural substrates. The act of swallowing shapes and moves a bolus from the oral cavity to the stomach by an ordered chain of events, commonly divided into the following four phases: oral preparatory phase, oral phase, pharyngeal phase, and esophageal phase. Dysphagia can occur during one or more of the four phases of swallowing.

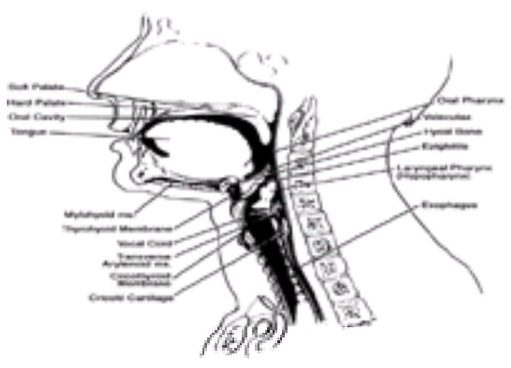

FIGURE 12-1. Sagittal view of the head and neck showing relevant musculoskeletal structures involved in swallowing. (From Kahrilas PJ. The anatomy and physiology of dysphagia. In: Gelfand DW, Richter JE, eds. *Dysphagia diagnosis and treatment*. New York: Igaku-Shoin Medical Publishers, 1989;11, with permission.).

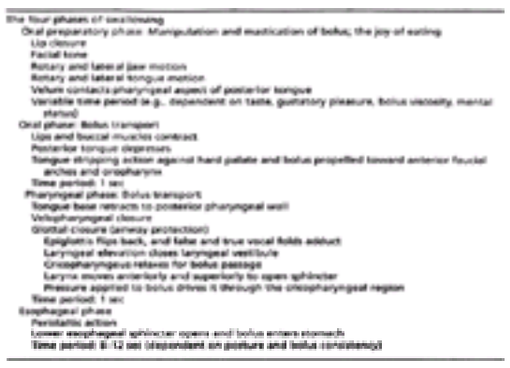


The four phases of swallowing
Oral preparatory phase: Mastication and mastication of bolus; the joy of eating
Lip closure
Facial tone
Rotary and lateral jaw motion
Rotary and lateral tongue motion
Velum contacts pharyngeal aspect of posterior tongue
Variable time period (e.g., dependent on taste, gustatory pleasure, bolus viscosity, mental state)
Oral phase: Bolus transport
Lips and buccal muscles contract
Posterior tongue depresses
Tongue stripping action against hard palate and bolus propelled toward anterior faucial arches and oropharynx
Time period: 1 sec
Pharyngeal phase: Bolus transport
Tongue base retracts to posterior pharyngeal wall
Velopharyngeal closure
Glottal closure (airway protection)
Epiglottis flips back, and false and true vocal folds adduct
Laryngeal elevation closes laryngeal vestibule
Cricopharyngeus relaxes for bolus passage
Larynx moves anteriorly and superiorly to open sphincter
Pressure applied to bolus drives it through the cricopharyngeal region
Time period: 1 sec
Esophageal phase
Peristaltic action
Lower esophageal sphincter opens and bolus enters stomach
Time period: 8–12 sec (dependent on posture and bolus consistency)

TABLE 12-1. BASIC SWALLOWING ANATOMY AND PHYSIOLOGY

Table 12-2 outlines the sensory and motor nerves (and their innervations) that are involved in swallowing. The neural control of swallowing involves four main components: efferent motor fibers of the cranial nerves and ansa cervicalis; afferent sensory fibers of the cranial nerves; cerebral and midbrain fibers that synapse with the brainstem swallowing centers; and the paired swallowing centers in the brainstem (30). The cranial and motor nerves and higher cerebral centers send input to the brainstem swallowing centers. The information is processed and, if the afferent neural input is appropriate, a swallow response is activated. The cranial nerves then carry the output signals to the muscles involved in swallowing.

Sense	Sensory area innervated	Cranial nerve	Motor area innervated
Touch	Soft palate, mouth, anterior ⅔ tongue, nasopharynx	V	–
		VII	Mastication muscles
		VII, VIII, C1–C2	Hyoid muscles
Taste	Anterior ⅔ tongue	VII	Facial muscles
Touch/taste	Posterior ⅓ tongue	IX	Stylopharyngeus, superior constrictor
Touch	Oro-hypopharynx	–	–
Touch	Tongue base, interior larynx	X	Palate,[a] pharynx,[b] larynx, esophagus
		XI	With X to larynx, pharynx, pharyngeal constrictors
Muscle[c]		XII	Intrinsic and extrinsic tongue muscles[c]
		C1–C2	Extrinsic tongue muscles[c]

[a]Except for tensor veli palatini innervated by V3.
[b]Except for stylopharyngeus innervated by IX.
[c]Except for glossopalatinus innervated by X.

TABLE 12-2. BASIC SENSORY AND MOTOR NERVES INVOLVED IN SWALLOWING

The exact nature of the neural circuitry that controls the oral, pharyngeal, and esophageal phases of swallowing is not fully known. Two theories, with the goal of explaining the neurological control mechanisms of swallowing, have been reported: the reflex chain hypothesis and the central pattern generator hypothesis (25). In the reflex chain hypothesis, a bolus moving in an anterior-to-posterior direction in the oral cavity and pharynx stimulates sensory receptors that sequentially trigger the next phase of swallowing. Swallowing occurs as a result of a chain of reflexes stimulated by and dependent on the previous response (i.e., the late oral phase starts the early pharyngeal phase of swallowing). In the central pattern generator hypothesis, sensory feedback does not influence swallowing behavior once a swallow has been started. The swallowing sequence is preprogrammed by the neurons in the medullary swallowing centers. Most likely, both theories play a role in the act of swallowing in that swallowing depends on a central pattern generator that is modified by, but not dependent on, feedback from sensory input (30).

ETIOLOGIES OF DYSPHAGIA

Head and Neck Cancer Surgery and Reconstruction

The act of swallowing, intermixed with respiration and speaking, is the most sophisticated coordination of voluntary and involuntary muscle action that exists in the animal kingdom (32). Dysphagia is a very common symptom in patients with head and neck cancer (33). Dysphagia is due to incoordination of the swallowing mechanism, obstruction, neurological changes, or pain caused by the tumor, and the combination of treatment modalities used [e.g., surgery for the resection of the cancer, external beam radiation therapy (EBRT), and chemotherapy]. Surgical resection of the oral, pharyngeal, laryngeal, or esophageal areas commonly results in varying degrees of dysphagia (1,32,34,35,36 and 37). The limiting factors relative to the type and severity of dysphagia are the number and amount of anatomical structures removed and the reconstructive procedure(s) used after the resection. In addition, patient motivation and the amount of individualized dysphagia rehabilitation impact on the rate of swallowing recovery (38).

The goal in the treatment of early tumors (stages I–II) is cure with surgical resection, EBRT, or both. Dysphagia rehabilitation is often not required in these patients, but when it is, the success rate for returning to a normal diet is excellent. The goal in the treatment of advanced tumors (stages III–IV) is locoregional control. This is accomplished by either organ preservation therapy [i.e., EBRT and chemotherapy (39,40,41,42,43 and 44)], with surgical salvage if necessary, or primary surgery followed by surgical reconstruction to allow for as much preservation of eating and speaking as possible. Organ preservation treatment may cause dysphagia due to mucositis, xerostomia, localized swelling, taste changes, and nausea. Surgical resection, however, often results in dysphagia, which may make eating very difficult (34). The patient's quality of life, dignity, and interpersonal relationships may become severely compromised, resulting in a reclusive behavior pattern and withdrawal from society (32).

Pretreatment Swallowing Function

To investigate outcomes of cancer treatment on swallowing, pretreatment baseline data on swallowing function are needed. Although early symptoms of head and neck cancer vary depending on site of lesion, dysphagia is often mentioned as a symptom of oral, pharyngeal, and laryngeal cancer. Little objective data, however, are available characterizing the swallow function in patients with head and neck cancer before treatment.

A multicenter database is currently evaluating the functional outcomes of swallowing in patients receiving speech pathology intervention after head and neck cancer treatment (45). This preliminary report outlines the rationale for the database and explores the complexities involved in obtaining reliable, long-term, accurate data collection in the head and neck cancer population. The goal is to obtain measures and predictors of “good functional outcomes” from mapping prospectively the path of rehabilitation of head and neck cancer patients.

Pauloski et al. (46) documented pretreatment swallowing function in 352 patients with various stages of oral, pharyngeal, and laryngeal cancer compared with a control group of age- and gender-matched subjects with normal swallow, and investigated the rate of patients' complaints of dysphagia before treatment. Head and neck cancer patients had significantly longer oral and pharyngeal transit times, greater amounts of oral and pharyngeal residue, shorter cricopharyngeal opening durations, and lower swallow efficiencies than controls. Swallow function worsened with increased tumor stage, and patients with oral and pharyngeal lesions had worse swallow function than patients with laryngeal lesions. However, despite these differences, the study population exhibited only a 4% aspiration rate, and in general, their swallows were efficient and highly functional before treatment. This is further reflected in the fact that 59% of patients had no complaint of difficulty swallowing before treatment.

Oropharyngeal Structure Resections and Consequences

Surgical resection(s) involving oral, pharyngeal, laryngeal, and esophageal structures commonly results in dysphagia. The actual functional deficits are dependent on the extent of the specific resection and the reconstructive procedure (36). New data, for example, have shown that patients with small resections of the oral tongue and tongue base had equal or better functional results with primary closure of the defect than with flap reconstruction (47). Additional data are needed to investigate the best method of closure for larger defects of the oral tongue and tongue base. Although this makes for a heterogeneous population (38), surgical resections nevertheless result in predictable patterns of dysphagia and aspiration risk (37). Common dysphagia symptoms are increased pooling of secretions, drooling, pocketing of food in the lateral and anterior sulci, difficulty with mastication, numbness, decreased temperature and pain sensation, and poor bolus control and transport.

Oral Cavity

Aspiration is not characteristic in patients with resections of the anterior tongue and floor of mouth, regardless of the type of closure (i.e., primary or flap). These patients have problems with the oral preparatory and oral phases of swallowing, but the pharyngeal phase is not disrupted, eliminating significant risk of aspiration (38).

However, resection of the lips, anterior tongue, and floor of mouth has social consequences for the individual. Drooling and bolus loss anteriorly make eating in public difficult and vigilance must be maintained to place the bolus posteriorly in the oral cavity to circumvent an anterior floor of mouth defect or loss of the tongue tip.

More extensive resections of the oral structures require a skin graft, tissue flap, or microvascular free flap. Generally, the larger the resection and subsequent reconstruction, the greater the probability of dysphagia and the higher the aspiration risk. McConnel et al. (48) compared three methods of oral reconstruction and found that the best method of reinstating masticatory and swallowing ability was intraoral skin grafting, followed by a myocutaneous flap and, last, a tongue flap. Microvascular free flaps have recently shown promise for oral cavity reconstructions that may surpass skin grafting (49).

Glossectomy

Total glossectomy results in a significant aspiration risk due to the obvious impairment of the oral preparatory and oral phases of swallowing and subsequent failure to trigger the swallowing reflex (50,51 and 52). When tumor is extensive and invades the preepiglottic space or the vallecula, it may be necessary to perform a total laryngectomy in conjunction with total glossectomy because of the high risk of life-threatening aspiration, especially in elderly and debilitated patients who are unable to tolerate the risk of recurrent aspiration (52).

Rehabilitation of the total glossectomy patient has focused on prosthetic management, with either a prosthetic tongue or palatal augmentation, to aid in deglutition and articulation (53,54 and 55).

Mandibulectomy

When cancer has invaded bone, a composite resection (i.e., glossectomy, mandibulectomy, and radical neck dissection) is performed for an en bloc resection. Oral preparatory and oral phases of swallowing are affected due to surgical changes in the muscles of the tongue and floor of mouth. Functional deficit is directly proportional to the amount of surgical resection, with the prognosis for prosthetic and functional rehabilitation better when more bone, musculature, and dentition are present postoperatively (56). When the anterior mandibular arch is resected, the genioglossus muscle, which composes the bulk of the tongue and suprahyoid laryngeal support, loses its insertion, resulting in drooling (57). If the mandible is cut, the inferior alveolar nerve, a sensory branch of V3, may be severed, resulting in ipsilateral anesthesia of mandibular dentition, alveolar ridge, labial alveolar mucosa, gingiva, skin, and mucous membrane of the lower lip, and skin of the chin; as well as reduced tactile sensation to the tongue. Bolus loss anteriorly and pocketing of food in the ipsilateral buccal sulcus often occur.

Palate: Hard and Soft

Palatal defects cause abnormalities in the oral preparatory and oral phases of swallowing. Hard palate defects are successfully handled with an obturator (58) that prevents food from entering the nose via the surgically created oronasal fistula. Soft palate defects are more difficult to solve, as the soft palate is a dynamic muscular structure. Resection often results in velopharyngeal insufficiency due to insufficient length for oronasal separation and neuromuscular deficits due to injury or severing of C-X. Lateral soft palate defects are more difficult to obturate than midline deficits (56). Both hard and soft palate defects and the obturator itself cause decreased sensation, which may impair oral function and result in dysphagia. More recent surgical restoration techniques have attempted to preserve sensation along with functional anatomical separation of the oral and nasal cavities by using nerve grafts and sensate flaps (49). Objective improvement in swallowing has not yet been demonstrated.

Pharynx and Esophagus

When the hypopharynx is involved with tumor, resection involves the pharynx and, by necessity, the larynx, secondary to life-threatening risk of aspiration. Reconstruction is undertaken by gastric pull-up, jejunal free flap with microvascular anastomosis, regional myocutaneous flap, colon interposition, or radial forearm free flap (37).

Similarly, if the tumor is extensive and involves the esophagus as well, a total pharyngolaryngoesophagectomy with gastric pull-up or jejunal interposition is necessary. Although aspiration cannot occur after these procedures, dysphagia can occur due to a fistula or, more likely, poor emptying of the gastric segment or jejunal graft because gravity must be relied on to transport material through a low-resistance tube. The patient presents with a “full” feeling at the base of tongue and oral regurgitation occurs if an upright posture is not maintained during and for at least an hour after eating (59).

Laryngectomy: Total and Partial

There are three distinct types of swallowing problems corresponding to total laryngectomy and partial laryngectomies (i.e., supraglottic and hemilaryngectomy). These are dysphagia secondary to pharyngeal or cricopharyngeal dysmotility (60), recurrent tumor, and benign stricture (61). Partial laryngectomies are performed to save at least one vocal fold for preservation of voice.

The incidence of dysphagia after total laryngectomy is highly variable, ranging from 10% to 58% (61,62 and 63). Dysphagia may be underestimated because retrospective analyses may not identify all patients with complaints of dysphagia (62) and because aspiration is eliminated by the surgical separation of the respiratory and digestive tracts. Nonetheless, total laryngectomy alters the swallowing mechanism because there can no longer be laryngeal elevation with the concomitant development of negative pressure in the pharyngoesophageal segment to aid in bolus propulsion. The laryngectomy therefore increases the propulsive pressure generated by the tongue (64). Fistulae may develop secondary to the increased swallowing pressures, especially due to increased mucosal edema in the immediate postoperative period.

It has been recommended that a cricopharyngeal myotomy be performed at the time of total laryngectomy to aid in bolus transit into and through the pharyngoesophageal segment (65). Also, hypopharyngeal stenosis is a relatively common occurrence after total laryngectomy (66) and is most likely due to the nature of the surgery rather than the site of the lesion (64). Dilatation is the most common therapy solution, but microvascular intestinal transfer grafts may be required.

Supraglottic laryngectomy involves resection, in the horizontal plane, of two of the three airway protective mechanisms, the epiglottis and aryepiglottic folds and false vocal folds (but not the true vocal folds), and often the hyoid bone, which provides skeletal support superiorly for the suspensory mechanism of the larynx (37,67). Supraglottic laryngectomy is organ-sparing surgery that places the patient at high risk for dysphagia and aspiration secondary to poor ability to protect the airway and reduced pharyngeal clearing resulting in aspiration after the swallow (67,68). Recovery of swallowing may take as little as 2 weeks, but some patients never regain functional swallowing. Although an overall failure rate between 8% and 20% was reported (37), the median number of days to resumption of successful oral intake was 106 (68).

Partial laryngectomy involves excision, in the vertical plane, of the aryepiglottic fold, false vocal fold, and true vocal fold unilaterally, sparing the epiglottis (37). Specific oncologic requirements may also necessitate resections involving the hyoid bone, arytenoid cartilage, superior laryngeal nerve, thyroid cartilage, or base of tongue, with concomitant increasing swallowing difficulties based on the extent of surgery.

Most patients exhibit some amount of aspiration in the short term after partial laryngectomy, ranging from 50% to 67% (37). Although life-threatening complications (e.g., pulmonary fibrosis, pneumonia, and lung abscess) can develop, most patients eventually regain the ability to eat by mouth after surgical resection, reconstruction,

and dysphagia rehabilitation (69,70).

Tracheotomy and Tracheotomy Tubes

Dysphagia has been shown to be a problem in both the head and neck cancer and tracheotomized populations. It appears that alterations in oral, pharyngeal, and laryngeal anatomy and physiology secondary to either the cancer and surgical resection and reconstruction or changes secondary to bypassing the upper airway with a tracheotomy place each of these populations at risk for various swallowing difficulties, including aspiration. When the populations overlap, as in patients with both head and neck cancer and a tracheotomy, the incidence of aspiration increases (33).

Tracheotomy has become one of the most frequently performed operations in otolaryngology head and neck surgery (71,72) due to the wide variety of conditions for which it is performed (e.g., acute airway obstruction secondary to infection or edema, chronic airway obstruction secondary to a mass or sleep apnea, respiratory difficulties requiring prolonged ventilatory support or to bypass the dead space of the upper airway, and chronic aspiration) (72). Despite such widespread use, the effect of a tracheotomy on the involved anatomical structures and their physiological relationships is not without consequences.

In humans, the two diverse and mutually exclusive functions of deglutition and respiration share the same anatomical structures in the upper aerodigestive tract. Swallowing is a highly complex activity requiring precise coordination between anatomical structures and the sequencing of physiological events occurring within a closed aerodigestive system. Tracheotomy inherently violates the closed aerodigestive system and alters the precise interrelated coordination involved in breathing and swallowing (71). Glottic reflexes have been shown to be less sensitive in experimental animals after tracheotomy (73,74).

Explanations as to the cause of aspiration after tracheotomy and placement of a tracheotomy tube include the following:

1. Fixation of the larynx, causing impaired mechanical ability of the supraglottic larynx to achieve closure and protect the airway by limiting the rostrocaudal excursion of the laryngotracheal complex (71,75,76 and 77)
2. Esophageal compression caused by a distended trachea secondary to an inflated tracheotomy tube cuff (78,79)
3. Desensitization of the larynx secondary to diversion of normal airflow through the tracheotomy (71,76)
4. Neurophysiological changes, specifically, adductor vocal fold dysfunction and a weakened closure response after long-term tracheotomy
5. Alterations in respiratory abductor function of the larynx secondary to bypassing the upper airway via tracheotomy (71,73,74)

Tracheotomy tube occlusion status, as it relates to prevalence of aspiration in head and neck cancer surgical patients, is unclear. A case study (75) reported that the presence of an open tracheotomy tube appeared to have an adverse effect on swallowing; on plugging and subsequent removal of the tube, the dysphagia resolved. Although tracheotomy caused neurophysiological changes in both abductor and adductor laryngeal responses, when the tracheotomy cannula was occluded for 3 minutes, some motor return was observed (71,74). Muz and colleagues reported on patients with tracheotomy and head and neck cancer. They found that aspiration increased when the tracheotomy tube was unoccluded (80) and that aspiration occurred twice as often with an unoccluded tube (33).

In contrast to these findings, when the occlusion status of the tracheotomy tube in head and neck cancer patients was altered, in no case did an early, postsurgical head and neck cancer subject aspirate first with an occluded tracheotomy tube and then not aspirate with an unoccluded tube or, conversely, not aspirate with an occluded tube and then aspirate when the tube was occluded (81). It was concluded, therefore, that short-term (i.e., approximately 5 minutes) tracheotomy tube occlusion status in early postsurgical head and neck cancer patients did not influence the prevalence of aspiration. It would be of great interest to investigate the impact of long-term tracheotomy use and tube occlusion in humans to determine whether tracheotomy tube occlusion alters the pattern of laryngeal reflexes.

There are a number of possible reasons for the disagreement regarding aspiration results between the early and late postsurgical cancer patients. First, a larger number of consecutive patients were used (81) than the observations reported previously (80). Second, any bias to finding aspiration was eliminated because no selection process determined referral for dysphagia evaluations (81) as was the case in a follow-up study (33). Third, early postsurgical patients (81) may exhibit dysphagia patterns that are different from those of late postsurgical patients (33,80) as a result of the length of time a tracheotomy tube is present, early postoperative edema, more impaired lingual and mandibular range of motion, and greater oropharyngeal sensitivity and pain. Fourth, it is also understood that physiological impairment of adductor laryngeal reflexes may not occur for 6–8 months after tracheotomy (74). Fifth, differences in the bolus volumes used, specifically 5 ml (81) and 10 ml in the scintigraphy studies (33,80), could have influenced aspiration results.

A Comment on Tracheotomy, Tracheotomy Tube Placement, and Aspiration Status

The reader may draw the conclusion from the preceding discussion dealing with aspiration, surgical tracheotomy, and tracheotomy tubes that the latter two variables are causal factors for the outcome (i.e., aspiration). This, however, may not be the case. A basic flaw in this literature is the lack of pretracheotomy swallowing assessment results. There is no way to tell who will receive a tracheotomy in the future, and therefore, once a tracheotomy is performed, the pretracheotomy swallow can, ipso facto, never be assessed. There are a number of reasons for this. Many patients are orally intubated before a scheduled tracheotomy, precluding a swallowing evaluation. Cancer surgery alters head and neck anatomy and physiology, predisposing these patients to increased aspiration risk with or without a concomitant tracheotomy. Finally, pretracheotomy swallowing evaluations done for elective tracheotomy (e.g., sleep apnea) are not routinely performed.

Recent research has shown that the pretracheotomy swallowing status of most patients who had a tracheotomy did not change. In other words, patients who aspirated before their tracheotomy continued to aspirate and patients who swallowed successfully before tracheotomy continued to do so after undergoing tracheotomy. No causal relationship between tracheotomy and aspiration status was exhibited. Rather than tracheotomy, the patient's medical status, neurological functioning, and head and neck cancer were the primary determinants of swallowing success (82).

External Beam Radiation Therapy

Although EBRT does not usually cause physiologically based swallowing problems, reduced oral and pharyngeal swallowing performance, as demonstrated by longer oral transit times, lower oropharyngeal swallow efficiency, increased pharyngeal residue, and reduced cricopharyngeal opening duration, have been reported (83). As is the case after surgery and reconstruction, a wide variety of oral complications contributing to poor oral intake can occur (84). Complications may become more prevalent when combined treatments are used (e.g., surgery with EBRT) whether given pre- or postoperatively (85). Some problems are temporary [e.g., mucositis, infections, odynophagia, trismus, and dysgeusia (86)] and resolve in the months after completion of EBRT. Other problems (e.g., xerostomia, dental caries, osteonecrosis, and tissue necrosis) may be permanent (87).

Chemotherapy

Similar to EBRT, chemotherapy does not usually cause physiologically based swallowing problems, but it does contribute to poor oral intake due to the emergence of taste changes (84). In addition, the cytotoxic effects of chemotherapeutic agents can cause mucositis, xerostomia, increased dental caries, nausea, vomiting, and dysgeusia. More severe complications can lead to life-threatening hemorrhage and infections, which are more likely to occur in a chemotherapy patient than in an EBRT patient (88).

COUNSELING

Preoperative counseling is often quite helpful, not so much to discuss the extent of the upcoming surgery but to prepare the patient for possible swallowing problems and, if they occur, to assure the patient that rehabilitation will be initiated before discharge from the hospital. The use of a nasogastric tube for nutritional maintenance immediately postoperatively and the possibility of a feeding gastrostomy tube if dysphagia persists are discussed. The patient is informed that swallowing diagnostics and rehabilitation will most likely begin before the nasogastric tube is discontinued. The different types of food consistencies (i.e., thin and thick liquid, puree, soft/moist solid, and hard/dry solid) are discussed, and the patient should understand that a diet may be restricted to one or more of the consistencies, depending on postoperative swallowing ability.

Postoperative counseling deals with long-term issues related to nutritional maintenance, type of food consistency (e.g., restriction to a blenderized diet), and the importance of following swallowing recommendations and therapy exercises after discharge from the hospital. If postoperative EBRT or chemotherapy is to be given, the patient is educated regarding possible consequences (i.e., xerostomia, localized edema, odynophagia with EBRT and mucositis and taste changes with chemotherapy), to decrease anxiety and concern should these side effects occur.

DIAGNOSTICS

Dysphagia diagnostics has three purposes:

1. To document if dysphagia and aspiration are present
2. To determine why dysphagia and aspiration occurred
3. To make recommendations for rehabilitation strategies (e.g., bolus consistencies, head positions, and swallowing techniques)

The bedside dysphagia evaluation (BDE), which follows a standardized protocol, examines the oral preparatory and oral phases of swallowing and can identify patients at risk for dysphagia (89). The accuracy of such predictions, however, was reported to range from 42% (90) to 66% (91). Despite such variable accuracy, the BDE is widely used in making the initial diagnosis of dysphagia and subsequent recommendations for oral feeding.

The videofluoroscopic swallowing study (VFSS) (92) uses a more extensive test protocol than the original modified barium swallow (2) and is the gold standard for diagnosing dysphagia and recommending rehabilitation. Performed in a fluoroscopy suite, it assesses all four phases of swallowing, and many studies over the past decade have shown it to have excellent sensitivity and specificity (89).

The flexible endoscopic evaluation of swallowing (FEES) (93,94) is a relatively new bedside procedure for assessing the pharyngeal phase of swallowing by using a flexible nasolaryngoscope for visualization of the pharynx and larynx on a video monitor. Objective information can be obtained regarding aspiration, safety of oral feeding, bolus consistency, and optimum positioning in patients for whom a BDE is inadequate or deemed unreliable, and when a VFSS is difficult or impossible to perform.

The relative advantages and disadvantages of the BDE, VFSS, and FEES diagnostic procedures are listed in Table 12-3.

	Advantages	Disadvantages
Bedside dysphagia evaluation	Ease of administration No equipment needed No transport needed Assess oral preparatory and oral phases Use different bolus consistencies Repeat as often as want Cost	Does not assess pharyngeal or esophageal phases Potential to miss "silent" aspirators Adequate mental status to follow directions
Videofluoroscopic swallowing study	Assess oral preparatory, oral, pharyngeal, and esophageal phases Objective assessment Use different bolus consistencies Team approach, speech-language pathologist and radiologist	Time limit due to X-irradiation exposure Must transport patient to fluoroscopy suite Adequate mental status to follow directions Cost
Fiberoptic endoscopic evaluation of swallowing	Direct view of pharynx, larynx, and vocal folds Objective assessment Use different bolus consistencies or saliva Cost Repeat as often as want No transport needed No time limit	Must tolerate transnasal endoscopy Difficult with agitated patient Trained endoscopist Initial setup cost: nasolaryngoscope, video camera, video recorder, TV monitor Only assesses pharyngeal phase

TABLE 12-3. RELATIVE ADVANTAGES AND DISADVANTAGES OF THE BEDSIDE DYSPHAGIA EVALUATION, VIDEOFLUOROSCOPIC SWALLOWING STUDY, AND FIBEROPTIC ENDOSCOPIC EVALUATION OF SWALLOWING PROCEDURES

DIAGNOSTICS WITH SPECIAL POPULATIONS

Tracheotomy Tubes

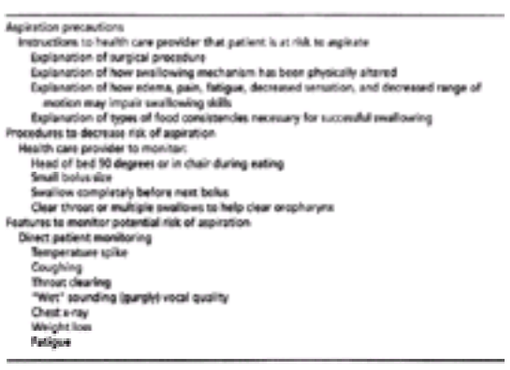
When assessing swallowing with a tracheotomized patient, the tracheotomy cuff should always be deflated. The reason for this is that an inflated cuff does not prevent aspiration but only delays its detection. Recent evidence has demonstrated that the occlusion status of the tracheotomy tube does not influence the prevalence of aspiration, but rather age (>65 years) and overall medical condition predispose the patient for aspiration (81,82,95,96). The deflated cuff allows for immediate identification of aspiration, by either coughing of a food bolus out the tracheotomy tube or evidence of food in the trachea after tracheal suctioning. An inflated tracheotomy cuff does not prevent aspiration (by definition, aspiration has occurred when the bolus is below the true vocal folds) and only delays evidence of aspiration for a short time (i.e., until the aspirated material that has collected just above the cuff migrates between the cuff and tracheal wall and enters the main stem bronchi and lungs).

Ventilator Dependency

Patients on ventilatory support can eat orally. However, because the tracheotomy cuff cannot be deflated, extra care must be taken during dysphagia diagnostics and subsequent rehabilitation. A careful BDE in conjunction with FEES should be capable of determining the swallowing ability and bolus consistency necessary for successful oral feeding.

RECOMMENDED ORAL FEEDING

Once the speech-language pathologist has reviewed the medical history, completed a physical assessment of the swallowing mechanism, and performed a diagnostic dysphagia evaluation, determination of type of oral feeding (if any) can be made. The speech-language pathologist then makes recommendations regarding food consistencies, rehabilitation techniques, aspiration precautions, and criteria for discontinuing oral feedings due to signs of aspiration (Table 12-4).



Aspiration precautions
Instructions to health care provider that patient is at risk to aspirate
Explanation of surgical procedure
Explanation of how swallowing mechanism has been physically altered
Explanation of how edema, pain, fatigue, decreased sensation, and decreased range of motion may impair swallowing skills
Explanation of types of food consistencies necessary for successful swallowing
Procedures to decrease risk of aspiration
Health care provider to monitor:
Head of bed 90 degrees or in chair during eating
Small bolus size
Swallow completely before next bolus
Clear throat or multiple swallows to help clear oropharynx
Features to monitor potential risk of aspiration
Direct patient monitoring
Temperature spike
Coughing
Throat clearing
"Wet" sounding (gurgly) vocal quality
Chest x-ray
Weight loss
Fatigue

TABLE 12-4. COMMON ASPIRATION PRECAUTIONS, PROCEDURES TO DECREASE RISK OF ASPIRATION, AND FEATURES TO MONITOR POTENTIAL ASPIRATION RISK FOR HEALTH CARE PROVIDERS

Individualized aspiration precautions, recommended techniques to improve dysphagia, and the steps to be followed for successful swallowing are often placed at the head of the bed on brightly colored paper so that all health care providers are alerted to the fact that a swallowing problem exists. As noted in the previous paragraph, Table 12-4 lists common aspiration precautions, procedures to decrease aspiration risk, and features that health care providers should be cognizant of when monitoring the dysphagic individual both during and after eating.

Specific indirect, direct, compensatory, and adaptive rehabilitative strategies are listed in Table 12-5. Indirect strategies do not use a food bolus, and the exercises are focused on improving range of motion and strength of the structures of the swallowing mechanism, from labial closure to airway protection. Direct strategies use a food bolus consistency and quantity that are safe for the patient and direct him or her regarding optimal bolus placement in the oral cavity and specific instructions regarding postures and positioning. Compensatory strategies encompass bolus consistency modifications and steps to be followed for a successful swallow. Adaptive strategies use devices to aid in successful swallowing by optimal bolus placement, manipulation, and transit in the oral cavity (see reference 97 for a detailed discussion of oral

and oropharyngeal prostheses used to rehabilitate and facilitate swallowing skills).

TABLE 12-5. INDIRECT, DIRECT, COMPENSATORY, AND ADAPTIVE REHABILITATION STRATEGIES FOR DYSPHAGIA

The following is an example of dysphagia rehabilitation for a patient with decreased lingual range of motion secondary to lingual resection. Indirect and direct dysphagia rehabilitation (Table 12-5) was attempted first, but lingual motion remained decreased and food pocketed in the left sulcus. The speech-language pathologist and maxillofacial prosthodontist collaborated on designing a prosthesis to aid in swallowing. The puree bolus consistency was placed on the right side of the oral cavity by a long-handled spoon, with the patient's head tilted to the right. The custom-made palatal prosthesis physically lowered the palatal vault to allow for tongue contact. More normal oral preparatory and oral phases of swallowing were thus achieved. The patient was instructed to swallow twice to clear any residual bolus from the oropharynx. This rehabilitation strategy resulted in a successful swallow.

SUPRAGLOTTIC SWALLOW

The supraglottic swallow is a technique with the goal of adducting the true vocal folds to protect the airway during swallowing. The technique can also be used by patients who have poor vocal fold adduction secondary to tumor involvement or surgical resection of the laryngeal branches of C-X (i.e., the superior laryngeal nerve and right and left recurrent laryngeal nerves), neurological insult, or partial laryngectomy (68). The supraglottic swallow is composed of the following five steps:

1. Adduct true vocal folds and hold breath (tense neck).
2. Swallow during breath hold.
3. Clear throat or cough vigorously immediately after the swallow; do not inhale at this time.
4. Adduct true vocal folds and hold breath again.
5. Swallow again during breath hold.

PHARYNGEAL AND ESOPHAGEAL PHASE DYSPHAGIA

There is no direct therapy to improve decreased pharyngeal wall motion or paralysis, cricopharyngeus dysfunction, or esophageal phase disorders. Pharyngeal phase problems that may indirectly benefit from rehabilitation are stimulation of the swallow reflex, reduced laryngeal closure, and paralysis by compensatory head positions. Other pharyngeal phase disorders [e.g., cervical osteophyte (98), scar tissue, and cricopharyngeus dysfunction (71,99)] are treated surgically. Esophageal phase disorders are treated both surgically and medically (99,100).

CONCLUSIONS

Successful eating and swallowing are prerequisites for a normal life. Not only does dysphagia impair the individual's quality of life, but if aspiration does occur, the consequence could be life-threatening pneumonia. The patient should be counseled that although the cancer or its treatment may cause dysphagia, there are intervention strategies available to make eating as pleasant and successful an experience as possible.

CHEMOTHERAPY-RELATED NAUSEA AND VOMITING

ANN M. BERGER
REBECCA A. CLARK-SNOW

NATURE OF THE PROBLEM

Chemotherapy-induced nausea and vomiting is one of the most feared effects of cancer treatment. The incidence and severity of nausea or vomiting in patients receiving chemotherapy varies depending on the type of chemotherapy given, dose, schedule, combinations of medications, and individual characteristics. Approximately 70–80% of all patients who receive chemotherapy experience nausea and vomiting (1,2). Anticipatory nausea and vomiting are experienced by approximately 10–44% of patients who receive chemotherapy (3,4,5 and 6).

The phenothiazines were the mainstay of antiemetic agents before the mid-1970s (7,8). Currently, there are many efficacious antiemetic regimens for the nausea and vomiting produced by chemotherapeutic agents (9). In a study conducted in 1983, cancer patients ranked nausea and vomiting as the first and second most severe side effects of chemotherapy, respectively (10). After the emergence of new antiemetic agents and alterations in chemotherapeutic regimens, patients' perceptions of the most severe side effects were modified. In a 1993 study, 155 cancer patients receiving chemotherapy reported that they experienced an average of 20 physical and psychosocial symptoms. Nausea was ranked as the most severe symptom and vomiting as the fifth (11). Therefore, nausea is also an important efficacy parameter when evaluating an antiemetic.

Use of these new antiemetic agents has decreased the incidence and severity of nausea and vomiting induced by chemotherapy. However, these agents have not totally prevented the problem. The consequences of not controlling nausea and vomiting induced by cancer treatment may lead to medical complications, a failure of the patient to comply with the cancer therapy and follow-up, and a diminished quality of life.

PATHOPHYSIOLOGY OF NAUSEA AND VOMITING

The precise mechanisms by which chemotherapy induces nausea and vomiting are unknown. However, it appears probable that different chemotherapeutic agents act at different sites and that some chemotherapeutic agents act at multiple sites (12). The fact that different chemotherapeutic agents cause nausea and vomiting by different mechanisms and that one chemotherapeutic agent may induce nausea and vomiting by more than one mechanism helps us to understand why there is no one antiemetic regimen that is effective all of the time.

Mechanisms by which chemotherapeutic agents cause nausea and vomiting are activation of the chemoreceptor trigger zone (CTZ) either directly or indirectly; peripheral stimulation of the gastrointestinal (GI) tract; vestibular mechanisms; cortical mechanisms; or alterations of taste and smell (Table 13-1). For the majority of the chemotherapeutic agents, the most common mechanism is thought to be activation of the CTZ.

Stimulation of chemoreceptor trigger zone
Peripheral mechanisms
Damage of gastrointestinal mucosa
Stimulation of gastrointestinal neurotransmitter receptors
Cortical mechanisms
Direct cerebral activation
Indirect (psychogenic) mechanisms
Vestibular mechanisms
Alterations of taste and smell

TABLE 13-1. MECHANISMS OF NAUSEA AND VOMITING AFTER CHEMOTHERAPY

The CTZ is located in the area postrema of the brain and can be reached by emetogenic chemicals via the cerebrospinal fluid or the blood. The thought is that the mechanisms of interaction between the CTZ and chemotherapy involve the release of various neurotransmitters that activate the vomiting center. Either one or a combination of these transmitters may induce vomiting. Some of the neurotransmitters located in the area postrema of the brain that may be excited and lead to emesis include dopamine, serotonin, histamine, norepinephrine, apomorphine, neurotensin, angiotensin II, vasoactive intestinal polypeptide, gastrin, vasopressin, thyrotropin-releasing hormone, leucine-enkephalin, and substance P (13). Other enzymes surround the CTZ, such as adenosine triphosphatase, monoamine oxidase, cholinesterase, and catecholamines. However, their role in chemotherapy-induced emesis is unknown.

Until recently, the neurotransmitter that appeared to be the most responsible for chemotherapy-induced nausea and vomiting was dopamine. Many effective antiemetics are dopamine antagonists that may bind specifically to the D_2 receptor. However, there is a high degree of variation in dopamine receptor binding affinity by these drugs (14). The action of some drugs that cause nausea and vomiting is affected very little or not at all by dopamine antagonists. It is known that not all the important receptors in the CTZ are dopaminergic, as the effect of dopamine antagonists is not equal to surgical ablation of the CTZ (15). It has also been noted that the degree of antiemetic activity of high-dose metoclopramide cannot be explained on the basis of dopamine blockade alone (16).

Histamine receptors are found in abundance in the CTZ. However, H_2 antagonists have no antiemetic activity. H_1 antagonists alleviate nausea and vomiting induced by vestibular disorder and motion sickness but not nausea and vomiting induced by chemotherapy (17,18).

Knowledge that opiate receptors are found in abundance in the CTZ, as well as the fact that narcotics have mixed emetic and antiemetic effects that are blocked by naloxone, and that naloxone has emetic properties, have led to the proposal of opiates or enkephalins as an antiemetic. High doses of naloxone augments emesis induced by chemotherapy, and low doses of narcotic may reduce emesis (19). Studies to date have shown that opiates can prevent chemotherapy-induced emesis in laboratory animals. However, both butorphanol and buprenorphine have not proven to be effective antiemetics in patients who received previous chemotherapy (20,21). One study by Lissoni et al. (22) did demonstrate that Fk-33-824 was more effective as an antiemetic in patients who received cisplatin; however, it was ineffective for patients receiving cyclophosphamide or epirubicin.

Edwards et al. (23) found that arginine vasopressin levels rise to a greater extent in patients who vomit when they receive chemotherapy as compared to those who do not vomit. It has been suggested that perhaps arginine vasopressin plays a role in nausea more than in the vomiting induced by chemotherapy. Dexamethasone, which is a known effective antiemetic, may work by reducing arginine vasopressin levels (24). Another mechanism of action of corticosteroids as antiemetics may be related

to modulation of prostaglandin release (25).

Some evidence suggests that although no one neurotransmitter is responsible for all chemotherapy-induced nausea and vomiting, it appears that serotonin and 5-hydroxytryptamine (5-HT) receptors are particularly important in the pathophysiology of acute vomiting, whereas others may be more important in the pathophysiology of nausea and delayed emesis. The role of the 5-HT type 3 (5-HT3) receptor in chemotherapy-induced emesis was recognized by examining the mechanism of action of high-dose metoclopramide in decreasing cisplatin-induced emesis. High-dose metoclopramide, unlike other D_2-receptor antagonists, has an exceptionally good capacity to decrease the emesis induced by cisplatin administration (26). It has been recognized that metoclopramide has pharmacological effects other than dopamine antagonism. Metoclopramide is a weak antagonist of peripheral 5-HT3 receptors (27) and can stimulate GI motility by increasing acetylcholine release from the cholinergic nerves of the GI tract (28). To test whether 5-HT3-receptor blockade would decrease cisplatin-induced emesis, Miner and Sanger (29) took a substituted benzamide, BRL 24924, which has stimulatory effects on the GI tract and is a 5-HT3-receptor blocker, and demonstrated decreased emesis in ferrets that received cisplatin. This study was repeated with a nonbenzamide, selective 5-HT3-receptor blocker MDL 72222, which has no GI-stimulating activity. The study revealed that cisplatin-induced emesis was totally blocked by this compound (30). The same conclusion was reached in another study using a different nonbenzamide, the selective 5-HT3 antagonist ICS 205-930 (31). These studies demonstrated the role of 5-HT3-receptor blockade in chemotherapy-induced emesis.

The precise mechanism of action of the 5-HT-receptor antagonists is unknown. However, they may have both a central and a peripheral effect. The GI tract contains 80% of the body's supply of serotonin. It has been suggested that perhaps chemotherapy administration causes release of serotonin from the enterochromaffin cells of the GI tract, which then stimulates emesis via both the vagus and greater splanchnic nerve as well as stimulating the area postrema of the brain. After cisplatin administration, there is an increase in urinary excretion of 5-hydroxyindoleacetic acid, the main metabolite of serotonin. This increase parallels the number of episodes of emesis (32). Studies have shown that the 5-HT3-receptor antagonists decrease emesis from several chemotherapeutic agents, including cisplatin, cyclophosphamide, and doxorubicin (33,34,35 and 36).

There has been new evidence regarding the potential role of substance P in emesis and new data about the use of neurokinin (NK1) antagonists in the management of emesis. Substance P, a neuropeptide found in the GI tract and the CTZ of the area postrema, exerts its emetic effects by binding to a specific neuroreceptor, NK1. A number of compounds that selectively block NK1 have been identified. These NK1 antagonists demonstrate a wide spectrum of antiemetic activity against numerous emetic stimuli in animal models, including several emetic stimuli that are not affected by serotonin and dopamine receptor antagonists. Studies in preclinical models have demonstrated that several NK1 antagonists have activity in the prevention of both acute and delayed cisplatin-induced nausea and vomiting. Two randomized double-blind studies have demonstrated that NK1 antagonists are beneficial in the prevention of delayed emesis (37,38). These agents may also provide additional benefit in the prevention of acute nausea and vomiting when combined with a 5-HT3 antagonist and dexamethasone.

The second most important mechanism whereby chemotherapy may induce emesis is peripheral effects that are thought to arise from the pharynx and the upper GI tract. Most likely, the chemotherapy does not directly stimulate the peripheral receptors. Rather, neurotransmitters probably are released as a result of local GI irritation or damage. GI-tract serotonin, dopamine, opiate, histamine, and cholinergic receptors are most likely involved in the emesis induced by chemotherapy. The peripheral effects may be abolished by vagotomy, indicating that impulses from the GI tract may reach the vomiting center via the vagus and sympathetic nerves (39).

Another mechanism that may be involved in chemotherapy-induced emesis could be the therapy's effect on the vestibular system. It is known that patients who have a history of motion sickness experience a greater severity, frequency, and duration of nausea and vomiting from chemotherapy than patients who do not experience motion sickness. The mechanism by which the vestibular system may lead to chemotherapy-induced emesis is unknown. However, it is postulated that sensory information that is received by the vestibular system is different from information that was expected (40).

Some investigators believe that taste changes induced by chemotherapy may lead to nausea and vomiting. Some chemotherapeutic agents, such as cisplatin or gallium nitrate, can lead to loss of taste sensation or to a metallic taste in the mouth. A study conducted with patients receiving chemotherapy for malignant melanoma revealed that patients developed a more intense sense of taste for sweet, bitter, sour, and salt. After chemotherapy, the patients rated the highest concentration of sweet as lower, and the patients' discrimination between highest and lowest concentrations of sour, bitter, and sweet was decreased (41). In another study of patients with breast carcinoma who received cyclophosphamide, methotrexate, and 5-fluorouracil, 36% reported a bitter taste in their mouth. One-third of the patients thought that the bitter taste caused vomiting (42). The exact mechanism by which taste is changed by chemotherapy is unknown. However, it is thought that while the drugs are in the plasma or saliva, they have a direct effect on the oral mucosa or taste buds. Changes in taste may contribute both to nausea and vomiting as well as to anorexia.

Finally, chemotherapy-induced emesis may be induced by direct or indirect effects on the cerebral cortex. Animal studies have shown that nitrogen mustard partially causes emesis via direct stimulation of the cerebral cortex (43). Studies demonstrate that the risk of nausea and vomiting is increased when a patient's roommate is experiencing nausea and vomiting. It is also known that the amount of sleep before receiving chemotherapy may influence whether a patient develops chemotherapy-induced emesis. In addition, large differences exist in the severity and incidence of nausea and vomiting from the same chemotherapeutic agents in different countries (44). These studies indicate that indirect psychological effects can mediate chemotherapy-induced nausea and vomiting.

Aside from there being more than one mechanism by which each chemotherapeutic agent may induce emesis, chemotherapy induces emesis in a manner different from that of other classic emetic agents. Drugs such as apomorphine, levodopa, digitalis, pilocarpine, nicotine, and morphine cause vomiting almost immediately. Nitrogen mustard also may lead to emesis immediately. However, most chemotherapeutic agents and radiotherapy require a latency period before emesis begins. Also, most chemotherapeutic agents do not induce emesis in a monophasic way, as do the classic emetic agents. Chemotherapeutic agents induce emesis with a delayed onset, and the emesis has multiphasic time courses (45). When managing chemotherapy-induced emesis, one should realize that there is most likely more than one mechanism involved, suggesting that there will not be one antiemetic regimen that will work for all patients all of the time.

EMETIC SYNDROMES

Patients undergoing therapy for the treatment and possible cure of cancer with chemotherapy often are faced with the distressing side effects of nausea and vomiting. Although advances in the 1990s have provided the clinician with an array of antiemetics and varied regimens, therapy-induced nausea and vomiting have yet to be totally eliminated. The goals of antiemetic therapy are as follows:

1. To achieve complete control in all settings
2. To provide maximum convenience for patients and staff
3. To eliminate potential side effects of the agents
4. To minimize the cost of treatment with antiemetic agents and drug administration

Five distinct but related emetic syndromes have been identified: acute chemotherapy-induced emesis, delayed emesis, breakthrough nausea and vomiting, refractory emesis, and anticipatory emesis. Traditionally, acute nausea and vomiting are defined as occurring within the first 24 hours after administration of chemotherapy. Delayed nausea and vomiting have been arbitrarily defined as occurring 24 hours after chemotherapy administration. More recent observations of the pattern of emesis indicate that delayed emesis may begin as early as 16 hours after chemotherapy administration and that serotonin may not be the primary mediator of symptoms for delayed emesis. Breakthrough nausea and vomiting are nausea and vomiting that occur despite preventive therapy. Rescue therapy is the treatment administered to patients who have not responded to the prophylactic regimens prescribed for acute or delayed nausea and vomiting. Refractory emesis occurs during subsequent cycles when antiemetic prophylaxis or rescues (or both) have failed in earlier cycles.

Anticipatory vomiting is a learned or conditioned response that typically occurs before, during, or after the administration of chemotherapy. Patients receiving one or a combination of several of the chemotherapy agents must receive an antiemetic regimen that is tailored to the individual pattern and emetic potential of each agent. For example, patients receiving a combination of high doses of intravenous cyclophosphamide and doxorubicin (Adriamycin) would require antiemetic coverage for the early onset of emesis usually seen with doxorubicin, as well as continued protection from cyclophosphamide-induced emesis that does not begin until 9–18 hours after the drug's administration (46). If patients are given the opportunity to receive the optimal antiemetic regimen during their initial course of chemotherapy, the likelihood of developing anticipatory emesis with subsequent cycles is greatly reduced. Other advantages for patients include increased tolerance of dose-intensified chemotherapeutic regimens. In addition, through the prevention of emesis, patients are able to achieve an enhanced quality of life at a particularly difficult time.

Two reports, one by Hesketh et al. (47) and an expert consensus by the American Society of Health-System Pharmacists, (48) contain new guidelines for the classification of the acute emetogenicity of chemotherapy into five levels (Table 13-2). When the agents are combined, ratings are based on the combined emetogenicity of the individual agents. An algorithm for defining the emetogenicity of combination chemotherapy has been developed (Table 13-3).

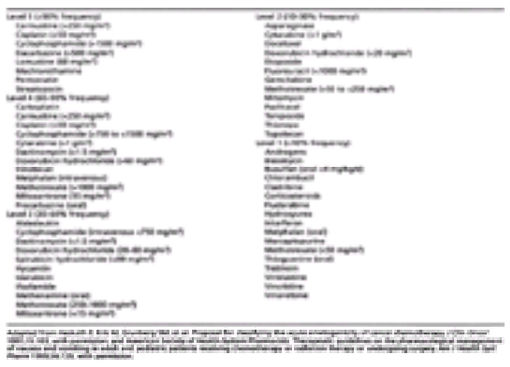

TABLE 13-2. EMETIC POTENTIAL OF CHEMOTHERAPEUTIC AGENTS

The most highly emetogenic agent in the chemotherapeutic combination must first be identified.
Level 1 chemotherapeutic agents do not contribute to the emetogenicity of the regimen.
Adding one or more level 2 chemotherapeutic agents increases the emetogenicity of the combination by one level greater than the most emetogenic agent in the combination.
Adding level 3 and 4 agents increases the emetogenicity of the combination by one level per agent.

Adapted from Hesketh P, Kris M, Grunberg SM, et al. Proposal for classifying the acute emetogenicity of cancer chemotherapy. *J Clin Oncol* 1997;15:103, with permission; and American Society of Health-System Pharmacists. Therapeutic guidelines on the pharmacological management of nausea and vomiting in adult and pediatric patients receiving chemotherapy or radiation therapy or undergoing surgery. *Am J Health Syst Pharm* 1999;56:729, with permission.

TABLE 13-3. RULES FOR IDENTIFYING THE EMETOGENICITY OF COMBINATION CHEMOTHERAPY

CONTROL OF EMESIS AND PATIENT CHARACTERISTICS

The methodology used in antiemetic studies has identified several useful patient characteristics and prognostic factors that may affect antiemetic control. These indicators become important for tailoring antiemetic regimens as well as designing antiemetic trials. Careful studies have defined previous experience with chemotherapy, alcohol intake history, age, and gender as influencing patient outcomes.

A patient's prior exposure to chemotherapy very often determines success or failure in controlling emesis with future treatment courses. Administration of the appropriate antiemetic during an initial course of chemotherapy can very often eliminate or significantly reduce the development of anticipatory emesis, in addition to decreasing the severity of delayed emesis.

Chronic and heavy alcohol usage—defined as more than 100 g of alcohol or five mixed drinks per day, whether in the past or currently—has been shown positively to affect the control of emesis. Ninety-three percent of patients in a prospective study who had a history of high alcohol intake were able to achieve a complete response, or no emesis, after receiving high doses of cisplatin with a combination antiemetic regimen (49). The hypothesis is that chemotherapy-induced emesis may be decreased in patients with a high alcohol intake because of “burnout” of the CTZ. Although emesis may be easier to control in this setting, patients nonetheless must receive an appropriate and effective antiemetic regimen. As a result, this prognostic factor has been incorporated in many prospective trials for stratification purposes.

Age as a prognostic factor cannot predict patient response to antiemetic therapy. Some studies have indicated better control in older patients, although others have reported little difference among various age groups. Age is, however, an important factor in determining the potential for the occurrence of acute dystonic reactions. Patients 30 years and younger are more prone to experience the acute dystonic reactions associated with the dopamine-receptor blocking agents, such as the phenothiazines, butyrophenones, and substituted benzamides. These side effects are usually characterized by trismus or torticollis. It is also important to remember that within this population of patients, chemotherapeutic agents that might necessitate antiemetics often are given over several consecutive days, increasing the possibility of the occurrence of acute dystonic reactions (50). A distinct advantage for the use of the serotonin or 5-HT3-blocking antiemetic agents is that they do not cause acute dystonic reactions, making them an especially beneficial treatment option for children and younger adults.

It has been difficult to explain the rationale for poorer control of emesis in some women receiving treatment for various malignancies. A possible explanation may be that women characteristically receive chemotherapeutic regimens that contain highly emetogenic agents, such as cisplatin and cyclophosphamide, usually given in combination, and are less likely than men to have a history of a high alcohol intake. Although these may be contributing factors, multivariate analyses in some larger studies have indicated that gender is an independent consideration that must be recognized in planning and analyzing clinical studies.

Other factors also have been reported possibly to affect the incidence of nausea and vomiting after chemotherapy. A patient may develop nausea and vomiting if he or she is anxious during the chemotherapy infusion, there is an expectation of severe side effects, or the patient's roommate is experiencing nausea and vomiting. Patients who are well motivated and have a good performance status may experience a decreased incidence of nausea and vomiting (51,52). Food intake before chemotherapy and the amount of sleep a patient has had may influence the degree of nausea and vomiting (53). Patients who are more likely to develop nausea and vomiting are those who have had severe emesis during pregnancy (54) and those who are prone to motion sickness (Table 13-4) (55,56).

Patient-specific factors
Previous emesis experience with chemotherapy
Alcohol intake
Age
Gender
Anxiety
Expectation of severe side effects
Roommate experiencing nausea and vomiting
Motivation level
Performance status
Food intake before chemotherapy
Amount of sleep before chemotherapy
Severe emesis during pregnancy
Motion sickness
Treatment-specific factors
Drug
Dose
Infusion rate

TABLE 13-4. FACTORS AFFECTING THE CONTROL AND INCIDENCE OF NAUSEA AND VOMITING AFTER CHEMOTHERAPY

ANTIEMETIC AGENTS

Most Active Agents

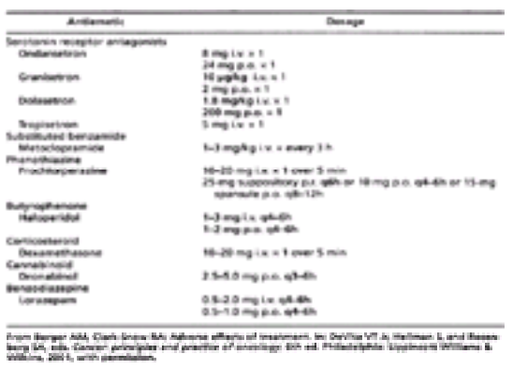
Antagonism of 5-HT3 is an important approach to controlling chemotherapy-induced emesis. Several agents are available that exert their efficacy in this manner. Metoclopramide, which was previously thought to block emesis by antagonism of a dopamine receptor ($D_2$3), probably works primarily via the 5-HT3 pathway at higher doses. This explains why higher doses of metoclopramide are more effective than lower doses (57). However, metoclopramide is not selective for the 5-HT3 pathway.

Several selective 5-HT3 antagonists are commercially available: dolasetron, granisetron, ondansetron, and tropisetron. Many multiple, randomized, well-controlled

studies have demonstrated that these agents have equivalent antiemetic activity and safety (58,59,60,61 and 62).

Nonetheless, some differences do exist among these agents. The differences are primarily in their structure and pharmacokinetic profile. However, to date none of these differences has been shown to be of clinical importance. All agents work by the identical mechanism: antagonism of the 5-HT3 receptor. All appear to accomplish this maximally, and differences among the relative potencies are unimportant at the recommended doses. There is no clear evidence that one of these agents will be effective when another is not. Half-lives in the serum vary from approximately 3–11 hours, but activity at the receptor appears to be similar in that single doses of all agents are equally effective. All agents have good bioavailability following oral administration; oral administration is as effective as is the intravenous route (63,64,65,66,67,68 and 69).

Controversy remains concerning the optimal dose of the serotonin antagonists. It appears that maximal benefit occurs once all relevant receptors are saturated. No matter what the emetic source, if the best results are to be achieved, an adequate dose should be given. Higher doses are not advantageous once all receptors have been saturated (70,71). In that these are very safe and well-tolerated agents, it has been difficult to define the best dose regimens. Different doses have been mandated in different countries. Several international consensus guidelines have been published, including those from the subcommittee for antiemetics of the Multinational Association of Supportive Care in Cancer, the American Association of Clinical Oncology, and the American Society of Health-System Pharmacists. As a general rule, the lowest adequately tested dose should be assumed to be the best dose in all settings (Table 13-5).



Antiemetic	Dosage
Serotonin receptor antagonists	
Ondansetron	8 mg i.v. × 1 24 mg p.o. × 1
Granisetron	10 μg/kg i.v. × 1 2 mg p.o. × 1
Dolasetron	1.8 mg/kg i.v. × 1 200 mg p.o. × 1
Tropisetron	5 mg i.v. × 1
Substituted benzamide	
Metoclopramide	1–3 mg/kg i.v. × every 3 h
Phenothiazine	
Prochlorperazine	10–20 mg i.v. × 1 over 5 min 25-mg suppository p.r. q8h or 10 mg p.o. q4-6h or 15-mg spansule p.o. q8-12h
Butyrophenone	
Haloperidol	1–3 mg i.v. q4-6h 1–2 mg p.o. q4-6h
Corticosteroid	
Dexamethasone	10–20 mg i.v. × 1 over 5 min
Cannabinoid	
Dronabinol	2.5–5.0 mg p.o. q3-6h
Benzodiazepine	
Lorazepam	0.5–2.0 mg i.v. q6-8h 0.5–1.0 mg p.o. q4-6h

TABLE 13-5. DOSES, SCHEDULES, AND CLASSES OF COMMONLY ADMINISTERED ANTIEMETICS

Although some debate persists concerning the best dose of ondansetron, the majority of trials have indicated that the lower dose (8 mg) is as effective as the higher and far more expensive dose of 32 mg (72,73). The latter dose was superior in only one trial (74). The lower granisetron dose of 10 mg/kg is as effective in all circumstances as four times the dosage (75,76). The same dose recommendations continue for single-agent or combination use.

The side effect profile of the 5-HT3 antagonists provides a distinct advantage over other antiemetics. Central nervous system effects, extrapyramidal reactions, and sedation are not observed with serotonin antagonists. This is particularly beneficial in younger patients. Common side effects include mild headaches usually not requiring treatment, transient transaminase elevations, and constipation (77,78,79 and 80).

As indicated, the antiemetic activity of metoclopramide is likely as a serotonin antagonist, although it has substantial dopamine antagonist action as well. This latter mechanism explains the potential for extrapyramidal reactions. Studies have shown that higher doses are more effective (81,82). A dose of 3 mg/kg given every 2 hours for two doses in a combination regimen with corticosteroids has been found to be effective (83,84). To date, metoclopramide appears to be at least as effective as serotonin antagonists in preventing delayed emesis and is far less expensive (85,86 and 87).

Corticosteroids are valuable antiemetics. Dexamethasone is the best studied of these agents, is available in oral and parenteral preparations, and, in most countries, is very inexpensive. Although the optimal dose has not been established, it appears that a single 20-mg dose before chemotherapy administration is adequate, with no clear indication that either higher or lower doses is preferred (88). The other steroid that has been studied and that can be used is methylprednisolone. Caution must be used when treating diabetic patients or others with poor tolerance for corticosteroids. However, the short recommended course makes these agents safe and easy to use. In preventing delayed emesis, adequate doses of corticosteroids currently are viewed as the starting point of treatment, with some studies showing advantage for metoclopramide combined with steroids (89,90 and 91).

Efficacy for corticosteroids has been clearly outlined for cisplatin-containing regimens as well as other types of chemotherapy with lesser emetic potential (92,93,94,95,96,97 and 98). The addition of a corticosteroid to 5-HT3 antagonists significantly improves antiemetic efficacy with each of the agents. This is seen with cisplatin chemotherapy (99,100) as well as with anthracyclines, cyclophosphamide, and carboplatin (101). Double-blind studies have shown that efficacy is raised for 40% or 50% of patients having complete control with single agents, and 75% or 85% of patients with a combination of 5-HT3 antagonist plus a corticosteroid (102,103 and 104). This has led most investigators to advise that a corticosteroid should be added whenever the emetic source is thought to warrant a serotonin antagonist, unless a clearly documented reason for not using a corticosteroid in that patient has been demonstrated.

Antiemetics of Lower Activity

Phenothiazines, butyrophenones, and cannabinoids all have some degree of antiemetic efficacy. In general, this efficacy is substantially lower than that seen with the serotonin antagonists (including high-dose metoclopramide), and the side effects are greater (105). When given intravenously, phenothiazines appear to be more active than when given by other routes, but are associated with hypotension (especially orthostatic), which can be severe. Oral forms of all three of these agents exhibit only modest activity. Thus, these agents are not highly recommended.

Several cannabinoids have been tested in chemotherapy-induced emesis and are of both historic and lay press interest. Semisynthetic agents, such as nabilone and levonantradol; tetrahydrocannabinol, the active agent in marijuana; and inhaled marijuana, all appear to be of low and equal efficacy, with frequent autonomic side effects including dry mouth, hypotension, and dizziness (106,107). Dronabinol may be useful as an adjuvant to other antiemetics.

Antianxiety agents, such as the benzodiazepine lorazepam, have little efficacy as single agents in carefully conducted trials (108). However, they function well against anxiety in the emotionally charged atmosphere of receiving chemotherapy, although they add only a minor antiemetic effect to more active agents (109). They should be regarded as adjuncts to antiemetics and, in that role, can be useful for many patients. Recommended doses range from 0.5–1.5 mg. It is not clear that there is any advantage in giving these agents parenterally rather than orally. Additionally, these drugs may be useful when given to patients with anticipatory emesis, starting 1 or more days before the next chemotherapy dosing. Side effects mainly concern sedation, which can be marked in some patients, especially if the drug is given intravenously (Table 13-5).

DELAYED EMESIS

With the identification of useful antiemetics for the treatment of the acute emetic syndrome, it became apparent in patients receiving high total doses of cisplatin that, despite good control of emesis during the initial 24 hours after therapy, delayed emesis became an issue. To date, the pathophysiology of this especially difficult problem remains unclear. What is known, however, is that delayed emesis is a phenomenon observed in as many as 80% of patients, typically occurring 24–72 hours after high doses of cisplatin (>100 mg/m^2) have been administered (110). Delayed emesis may also be seen in a substantial number of patients who receive as little as 50 mg/m^2 cisplatin or a chemotherapy combination including cyclophosphamide and an anthracycline.

Initial studies revealed that delayed emesis could be controlled with a regimen of metoclopramide and dexamethasone (Table 13-6). Because of the possibility of extrapyramidal side effects, such as anxiety, akathisia, restlessness, torticollis, or oculogyric crisis, with metoclopramide, the patient should routinely be given a supply of diphenhydramine that should be taken at the first sign of an extrapyramidal symptom. In the younger patient, diphenhydramine should be given prophylactically.

Begin 16–24 h after cisplatin:
Days 1, 2: Metoclopramide, 0.5 mg/kg p.o. q.i.d.
plus
Dexamethasone, 8 mg p.o. b.i.d.
Days 3, 4: Dexamethasone, 4 mg p.o. b.i.d.
1. Diphenhydramine should be given at the first sign of extrapyramidal symptoms and prophylactically to the young patient.
2. Regimen to be given for cisplatin, >50 mg/m^2, or combination chemotherapy with an anthracycline and cyclophosphamide.
3. Oral 5-HT3 antagonists can be substituted for metoclopramide.

5-HT3, 5-hydroxytryptamine type 3.

TABLE 13-6. RECOMMENDED REGIMEN FOR DELAYED EMESIS

Initial trials addressing the treatment of delayed emesis with the single-agent serotonin antagonist ondansetron were discouraging (111,112). Two randomized studies, one with ondansetron and one with granisetron, indicated efficacy of the serotonin antagonists for delayed emesis in patients receiving chemotherapy of intermediate emetogenicity (113,114).

As it is known from previous studies that a delayed antiemetic regimen with a substituted benzamide and dexamethasone controls the emesis, further research is needed to compare this standard regimen with a regimen of a serotonin antagonist and dexamethasone. One may need to differentiate between late-onset acute emesis (i.e., 18–48 hours after cyclophosphamide administration, for which oral granisetron and ondansetron have demonstrated benefit) versus true delayed emesis that is evident 2–7 days after cisplatin administration, for which the 5-HT3 antagonists may not have a large advantage over standard metoclopramide-based regimens. It is likely that the mechanism of action for delayed emesis is very different from that for acute chemotherapy-induced emesis, and perhaps serotonin is not involved at all. This should be addressed further in carefully controlled clinical trials, as the cost of the serotonin antagonists is far more than the cost of a substituted benzamide.

Another group of agents that have a potential role in the prevention of delayed nausea and vomiting are the NK1 antagonists. Substance P, which is found in the GI tract and the central nervous system and can produce vomiting when injected into ferrets, exerts its effects by binding to the neuroreceptor NK1. Hesketh et al. (115) reported on a randomized phase II study of the NK1-receptor antagonist CJ-11,974 in the control of cisplatin-induced emesis in 61 patients. This exploratory trial revealed that CJ-11,974 was superior to placebo in controlling delayed emesis and may provide additive benefit in acute emesis and nausea control when combined with a 5-HT3 antagonist and dexamethasone. In a multicenter, double-blind, placebo-controlled trial involving 159 patients who received a single dose of cisplatin, the NK1-receptor antagonist L-754,030 prevented delayed emesis and, in combination with granisetron plus dexamethasone, improved the prevention of acute emesis (116).

Other agents that may be of benefit in the treatment of delayed emesis include benzodiazepines, especially lorazepam and alprazolam; the H_2 blockers cimetidine and ranitidine; and omeprazole. Studies are currently under way on the use of cisapride, a potent gastric prokinetic agent that does not affect the D_2 receptors and, therefore, does not lead to adverse extrapyramidal effects.

ANTICIPATORY NAUSEA AND VOMITING

Anticipatory nausea and vomiting occurs approximately 24 hours before the patient begins chemotherapy. The symptoms may occur outside the hospital, in the clinic, when talking about chemotherapy, or when the patient perceives special tastes or odors.

Acute nausea and vomiting that occur with chemotherapy are thought to be secondary to the medication. The exact mechanism of posttreatment nausea and vomiting is unknown, though is most likely secondary to the chemotherapeutic agent itself. At times it may also involve a psychological mechanism. Anticipatory nausea and vomiting always involve a psychological mechanism in that episodes are triggered by events that are not secondary to the direct administration of the chemotherapeutic agent itself.

The prevalence of anticipatory nausea and vomiting is unclear, depending on the study cited and whether nausea and vomiting are analyzed separately. A review by Morrow and Dobkin (117) summarized 28 surveys that were carried out in North America since 1979. The prevalence of anticipatory nausea ranged anywhere from 14–63%, with a median of 33%. Many factors that appear to be associated with anticipatory nausea and vomiting have been studied (Table 13-7).

Severe postchemotherapy side effects
Schedule of chemotherapy
Numerous chemotherapy cycles
Chemotherapeutic agents with high emetogenic potential
Age
History of motion sickness
Anxiety
Depression
Taste and odors

TABLE 13-7. FACTORS ASSOCIATED WITH AN INCREASED INCIDENCE OF ANTICIPATORY NAUSEA AND VOMITING

Numerous studies have revealed a relationship between severe postchemotherapy side effects and the development of anticipatory nausea and vomiting (118,119,120 and 121). The schedule of chemotherapy also appears to be related to anticipatory symptoms. Anticipatory symptoms are related to the emetogenicity of the chemotherapeutic agents in most studies (122,123 and 124). They also are related to the length of chemotherapy, in that patients who receive chemotherapy for longer periods have a higher incidence of anticipatory symptoms (125,126 and 127).

Motion sickness is a risk factor for the development of postchemotherapy nausea and vomiting (128). Studies by Morrow (129) of 608 patients and another study (130) of 355 patients found a significant relationship between motion sickness and anticipatory nausea and vomiting. In some studies, age appears to be related to anticipatory symptoms; anticipatory nausea and vomiting occur more often in patients younger than 45–50 years old (131,132,133 and 134). Possibly, age is related to anticipatory symptoms because younger patients receive stronger emetogenic chemotherapeutic agents, which leads to increased postchemotherapy nausea and vomiting and, therefore, increased anticipatory nausea and vomiting. Another proposed explanation is that younger patients have a higher level of anxiety while receiving chemotherapy, which may lead to increases in anticipatory symptoms. Both of these explanations are plausible, though current data do not support either (135).

Other factors reported to be related to anticipatory nausea and vomiting include expectations. Those patients with anticipatory symptoms report the expectation of developing nausea and vomiting after chemotherapy (136,137). Type and stage of cancer also are related to anticipatory nausea and vomiting (138,139). Anticipatory symptoms have been found to be correlated with a patient's previous response of nausea and vomiting to other situations (140). It has been noted that patients with anticipatory nausea and vomiting have higher levels of depression (141). A relationship between anxiety and anticipatory nausea and vomiting has also been noted, (142,143) although insufficient evidence is available to indicate how anxiety is related to anticipatory symptoms (144).

Several retrospective reviews have indicated that taste and odors are related to anticipatory nausea and vomiting (145,146,147,148 and 149). Though a prospective study did not reveal any relationship among taste, odors, and anticipatory nausea and vomiting, Bovbjerg et al. (150) reported a study in which they administered a beverage to patients before they received chemotherapy. The investigators found a clear relationship between anticipatory nausea and a special taste. Blasco (151) suggested that taste and odors may be involved not only in anticipatory nausea and vomiting but perhaps with postchemotherapy nausea and vomiting. Indeed, the role of taste and smell is largely unknown. However, it may be involved in a spectrum of GI complaints experienced by the patient with cancer. Studies by Bernstein

(152) suggest that a learned food aversion develops to specific tastes or food and occurs because of an association of the food with unpleasant symptoms, such as nausea and vomiting. This food aversion could partially explain the anorexia associated with cancer.

Antiemetics used in the treatment of acute nausea and vomiting induced by chemotherapy are ineffective in treating anticipatory nausea and vomiting. Many studies have indicated that behavioral techniques are effective in reducing anxiety as well as reducing or eliminating anticipatory nausea and vomiting. Effective behavioral techniques include progressive relaxation with guided imagery, systematic desensitization, hypnosis, and cognitive and intentional distraction (153,154,155 and 156).

In one report in the literature, a lemon solution given to a patient before the receipt of chemotherapy masked taste sensations so that the patient experienced decreased anticipatory nausea and vomiting (157). It has also been suggested that benzodiazepines, especially lorazepam, may be helpful in treating anticipatory nausea and vomiting. However, no formal studies have established lorazepam's effectiveness in this situation.

RADIATION-INDUCED NAUSEA AND VOMITING

The etiology of radiation-induced emesis, like chemotherapy-induced emesis, is not completely understood. However, it is clear that it is a complex, multifactorial event. The incidence, severity, and onset of radiation-induced emesis appear to be related to the size of the radiation field, the dose per fraction, and the site of irradiation. Radiation-induced emesis occurs acutely in more than 90% of patients who receive total body irradiation for bone marrow transplantation, within 30–60 minutes in more than 80% of patients who receive single high-dose or large-field hemi-body irradiation (>500 cGy), and within 2–3 weeks in approximately 50% of patients who receive conventional fractionated radiotherapy (200 cGy per fraction) to the upper abdomen (158). Radiation-induced emesis also occurs in those patients who receive radiosurgery to the area postrema in excess of 350–400 cGy in a single dose. The emesis usually occurs between 1 and 12 hours after the radiosurgery.

The exact mechanism of radiation-induced emesis is thought to be due to a peripheral mechanism in the GI tract or a central mechanism involving the CTZ. It has been proposed that several substances, including dopamine, catecholamines, and prostaglandins, are released and stimulate afferent visceral fibers, an action that initiates sensory signals to the CTZ. As a result of both preclinical and clinical studies with serotonin antagonists, it has been suggested that serotonin may be released from enterochromaffin cells of the GI tract and may mediate emesis via mechanisms involving the 5-HT3 receptors, visceral afferent fibers, and the CTZ. This mechanism is most likely involved when radiation is applied to the upper abdomen, hemibody, or total body. Radiosurgery to the area postrema most likely induces emesis from the release of serotonin in the CTZ (159).

Clinical studies in the past using metoclopramide, nabilone (cannabinoid derivative), and chlorpromazine in the treatment of radiation-induced emesis revealed a response of 50–58% (160,161). In a nonplacebo trial with domperidone, a dopamine antagonist, a response of 82% was reported (162). A nonrandomized trial comparing ondansetron with other antiemetics reported response rates of 100% for ondansetron versus 43% for other antiemetics and 19% for no antiemetic treatment for patients who received middle to upper hemibody irradiation (163). A randomized study by Priestman et al. (164) of patients who received radiotherapy to the abdomen, pelvis, and thoracolumbar spine reported response rates of 45% for metoclopramide versus 97% for ondansetron. A randomized, double-blind, placebo-controlled evaluation revealed oral ondansetron to be an effective therapy for the prevention of emesis induced by total body irradiation (165). Ondansetron has been reported to be effective in radiotherapy-induced emesis in children (166) as well as for patients who receive radiosurgery to the area postrema (167).

Data are available from two double-blind, randomized studies concerning oral granisetron, 2 mg once daily, in radiation-induced nausea and vomiting. In a study involving patients undergoing fractionated, upperabdominal radiation, patients who received oral granisetron had a significantly longer median time to first emesis than did those who received placebo (35 days vs. 9 days, respectively) and a longer median time to first nausea (11 days vs. 1 day, respectively) (168). In another study of patients undergoing total body irradiation, patients treated with oral granisetron had significantly greater complete control as compared to the historical control group over the entire 4-day treatment period (22% vs. 0%, respectively) (169). Fauser et al. (170) reported on the use of oral dolasetron for the control of emesis during total body irradiation and high-dose cyclophosphamide in patients undergoing allogeneic bone marrow transplantation.

NAUSEA AND VOMITING SECONDARY TO COMORBID CONDITIONS

A number of comorbid conditions also may lead to nausea and vomiting, even though the majority of patients with cancer develop nausea and vomiting as a result of chemotherapy or radiotherapy (Table 13-8). Because the mechanism of the nausea and vomiting secondary to comorbid conditions is not usually well understood, it is difficult to know which antiemetics may be helpful. A study by Bruera et al. (171) revealed that controlled-release metoclopramide is safe and effective in managing chronic nausea in patients with advanced cancer. Future studies are needed to determine the optimal doses of metoclopramide as well as other antiemetics that may be used in drug combinations (e.g., metoclopramide plus corticosteroids) for the nausea and vomiting secondary to the malignancy itself.

COST AND BENEFIT OF ANTIEMETIC THERAPY

The important results of research that provide the medical community with additional chemotherapeutic choices and supportive care measures often translate into added health care costs for patients and families. With the increased use of expensive antiemetics and with managed care dictating the length of hospital stays, the emphasis is shifting to out-patient chemotherapy administration. The challenge for physicians becomes one of providing a treatment plan in which patients are offered state-of-the-art and cost-effective therapy. This can be accomplished by applying certain guidelines.

Specifically addressing 5-HT3 antagonist antiemetics and their associated cost, the choice among these agents should be made on the basis of acquisition costs and reimbursement differences. The 5-HT3 antagonists all have demonstrated equivalent efficacy and side effects. Therefore, once an effective dose has been established, there would be no advantage in exceeding this threshold dose. The 5-HT3 antagonist of lowest cost should be selected for administration. Single-dose regimens given in combination with a corticosteroid provide an effective and convenient alternative in antiemetic therapy. Regimens that take advantage of a completely oral route of administration are easy and convenient for patients and are likely to reduce nursing and pharmacy costs. However, prolonged use of oral serotonin antagonists should be avoided. Adherence by physicians and nurses to established doses and schedules of antiemetics and their appropriate use can be cost-effective measures for patients and institutions.

Nolte et al. (172) discussed guidelines developed by the Memorial Sloan-Kettering Cancer Center for the cost-effective use of 5-HT3 antagonists that resulted in substantial savings while treating more patients. The initial guidelines in 1993 were based on the premise that the dose of the intravenous 5-HT3 antagonist ondansetron, 8–32 mg, could be adjusted on the basis of emetogenic potential of the chemotherapeutic regimen schema proposed by Hesketh et al. (95). Cost savings were documented without affecting the quality of life. The guidelines were modified in 1994 to include granisetron, 10 mg/kg, for moderately or highly emetogenic chemotherapy. When oral granisetron tablets were approved in 1995 for the prevention of highly emetogenic chemotherapeutic regimens, the guidelines were further modified to incorporate the use of oral granisetron instead of intravenous 5-HT3 antagonists for moderately to highly emetogenic chemotherapy. Additional cost savings were realized while the quality of life of the patients was unaffected.

The use of an oral form of a 5-HT3 antagonist for highly emetogenic chemotherapy, when data from well-controlled trials demonstrate comparable efficacy to the intravenous formulation, appears to be cost-effective (173,174). One should take into consideration, when evaluating the results of these studies, whether a stringent efficacy end point was used. Some studies did not use “no nausea” as one of the criteria for a complete response. Because nausea was ranked as the most severe chemotherapy-related symptom according to a relatively recent survey, the effect of the agents on nausea should also be evaluated.

Economic considerations for the selection of antiemetic regimens should answer the following questions:

- Will the use of the regimens likely result in a reduced hospitalization?
- While receiving therapy, will patients be able to maintain their usual level of activity?
- Will nursing and pharmacy costs be reduced?
- Are there mandated restrictions on the use of an agent in hospital formularies and in clinical settings?
- Will the antiemetic regimen affect the patient's out-of-pocket expenses?

Extensive basic and clinical research has made it possible to control treatment-induced nausea and vomiting for most patients. With recognition and anticipation of nausea and vomiting, counseling of the patient and family, prophylactic intervention, flexibility in the therapeutic approach, and constant reassessment of the treatment plan, chemotherapy- and radiotherapy-induced nausea and vomiting can be managed effectively in 80–90% of patients. The progress made in the field of treatment-induced nausea and vomiting must be a paradigm for other symptoms faced by the cancer patient that lead to suffering and that affect the patient's quality of life.

CHRONIC NAUSEA AND VOMITING

EDUARDO BRUERA
CATHERINE SWEENEY

Chronic nausea and vomiting are common and trouble-some problems in patients with advanced cancer. The reported prevalence of these symptoms varies, depending on patient characteristics and the assessment methods used for diagnosing chronic nausea and vomiting. Fainsinger et al. reported that 71 out of 100 patients in a palliative care unit required treatment for nausea in the last week of life (1). Data from the National Hospice Study (2) showed that nausea and vomiting developed in 62% of terminal cancer patients with prevalence rates of 40% in the last 6 weeks of life with women and younger patients reporting higher rates. In a prospective study of 1635 cancer patients referred to a pain clinic, Grond et al. (2a) reported a prevalence of 27% for nausea and 20% for vomiting.

There is no standardized definition for chronic nausea. For research purposes it is often defined as nausea lasting for more than 4 weeks. In a population of patients with advanced cancer and short life expectancy this definition excludes many patients. For our purposes the presence of nausea for more than 1 week, in the absence of a well-identified, self-limiting cause (e.g., chemotherapy or radiotherapy) will be used. Chronic nausea is often multifactorial and requires chronic treatment.

The purpose of this chapter is to review the pathophysiology, causes, assessment, and management of chronic nausea.

PATHOPHYSIOLOGY

Much of what we know about nausea and vomiting is based on research in patients receiving chemotherapy or radiotherapy and in patients with postoperative nausea and vomiting (3,4 and 5). Chronic nausea in cancer patients has not been well researched. In this patient population, research is much more difficult because many factors are present that may contribute to the mechanism of emesis. As a result, research on mechanisms and management of acute chemotherapy or radiotherapy-induced nausea in which there are fewer contributing factors may not apply to the population of patients with chronic symptoms.

The pathophysiology of chronic nausea is complex with multiple mechanisms of emesis. A number of neural pathways and neurotransmitters are likely to be involved in the production of chronic nausea and vomiting. In addition the importance of different mechanisms are likely to vary between individual patients.

Vomiting Center

The vomiting center is located in the nucleus of the tractus solitarius and the reticular formation in the medulla. This center receives input from a number of areas within the brain and the gastrointestinal (GI) tract. Histamine and acetylcholine appear to be the predominant neurotransmitters in the vomiting center. The vomiting center then produces the vomiting reflex. Afferent emetic pathways and neurotransmitters are summarized in Figure 14-1.

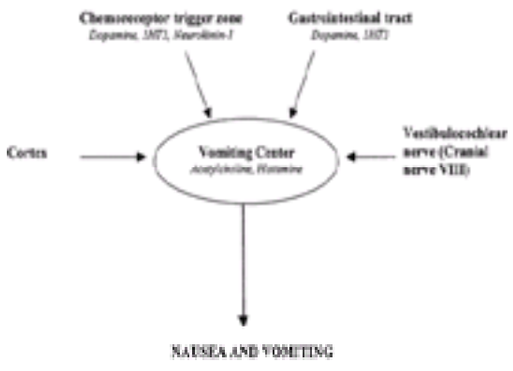

FIGURE 14-1. Afferent emetic pathways and neurotransmitters. 5HT3, 5-hydroxy-tryptamine type 3.

Chemoreceptor Trigger Zone

The chemoreceptor trigger zone (CTZ) is situated in the area postrema of the medulla. It samples cerebrospinal fluid and blood. Chemotherapeutic agents, metabolic products (e.g., uremia), opioids, and bacterial toxins produce nausea and vomiting by stimulating the CTZ. The CTZ initiates vomiting via the vomiting center. A neural pathway connects the two areas. The predominant neurotransmitters in this area are dopamine (D_2), serotonin (5-HT3), and neurokinin-1. The involvement of D_2 has been the basis for the use of drugs with antidopaminergic activity such as butyrophenones (haloperidol), phenothiazines, and metoclopramide. Serotonin antagonists and neurokinin-1-receptor antagonists are useful for the treatment of chemotherapy and radiotherapy-induced nausea.

Cortex

The cortex and other areas of the brain, such as the diencephalon and the limbic system, supply afferents to the vomiting center. Raised intracranial pressure, taste, smell, and anxiety can contribute to and stimulate vomiting. The brain cortex is also involved in emesis associated with thoughts, and visual or olfactory stimuli in patients receiving chemotherapy (6).

Vestibulocochlear Nerve

Motion can trigger nausea and vomiting. Opioids can alter the sensitivity of the vestibular center (7) resulting in nausea associated with movement. Motion stimulates receptors in the labyrinth. Impulses are then transmitted to the vestibular nucleus and onto the cerebellum, CTZ, and vomiting center. The frequency of nausea and vomiting is comparatively higher in ambulatory patients as compared to those confined to bed. The predominant neurotransmitters involved at this level are

acetylcholine and histamine. Anticholinergics and antihistamines are used for treatment.

Gastrointestinal Tract

The upper GI tract sends afferent impulses to the vomiting center via vagal and sympathetic stimulation. Stimulation of mechanoreceptors or chemoreceptors in the gut can cause nausea and vomiting. Gastrointestinal obstruction, gastric stasis, metastatic disease, bacterial toxins, drugs, chemotherapeutic agents, and irradiation can cause emesis in this way. In addition, stimulation of the glossopharyngeal or vagus nerves in the pharynx by sputum, candida, or mucosal lesions can cause nausea. Dopamine, acetylcholine, and 5-hydroxytryptamine are important neurotransmitters at the level of the upper GI tract.

CAUSES

Chronic nausea in advanced cancer patients is often multi-factorial. Figure 14-2 summarizes the common causes of chronic nausea in this patient population. In many patients the underlying cause or causes are difficult to determine.

FIGURE 14-2. Contributors to chronic nausea in patients with advanced cancer. NSAIDS, nonsteroidal antiinflammatory drugs.

Autonomic Failure

In some cancer patients chronic nausea is associated with the anorexia cachexia syndrome. In these patients autonomic failure is thought to be the most likely cause of chronic nausea (8). Autonomic failure causes gastroparesis, with resulting anorexia, nausea, and early satiety. In addition, other effects on the GI tract include diarrhea and constipation. Autonomic failure also has cardiovascular manifestations such as postural hypotension, syncope, and fixed heart rate.

Autonomic failure was originally described in patients with diabetes mellitus, neurological disorders, and chronic renal disease (8,9 and 10). More recently autonomic failure has been described in patients with advanced cancer. Kris et al. (11) reported delayed gastric emptying in 10 cancer patients who complained of chronic nausea and vomiting. Bruera et al. (12) looked at the incidence of cardiovascular autonomic insufficiency in 43 patients with advanced breast cancer and in 20 healthy controls matched for age and sex. Tests for autonomic failure were performed, and 52% of tests were abnormal in the patient group versus 7% in the control group. Autonomic failure in the cancer patient group was more common in those with poor performance status and malnutrition. In another study which included 5 patients with advanced cancer complaining of unexplained chronic nausea and anorexia, 16 out of 23 tests for autonomic function were abnormal, compared with none of 25 tests performed in five healthy adult controls (13). None of the five patients had clinical or laboratory evidence of disseminated disease to the abdomen or liver. All had normal endoscopy and barium meals with no evidence of mucosal injury. All five patients had severe gastroparesis (mean emptying time 192 ± 28 minutes) as compared to 5 controlled (mean emptying time 66 ± 5 minutes) when assessed with a gastric emptying scan. The differences between patients and controls were statistically significant; it was concluded that gastroparesis was the cause of chronic nausea and anorexia in these patients. There have been several other cases reported in the literature of autonomic dysfunction associated with lung and pancreatic cancers (14,15 and 16).

The cause of autonomic dysfunction in advanced cancer patients remains unclear and appears to be multifactorial. Malnutrition itself has been suggested as a cause of autonomic neuropathy (8). Jewish physicians in the Warsaw ghetto during World War II found that their starving patients were not able to increase their blood pressure with effort and had a constant tachycardia with no change upon standing up (17). Features of autonomic dysfunction have also been described in patients with anorexia nervosa. Studies on animals have suggested that fasting suppresses the activity of the sympathetic nervous system (18). There are isolated case reports suggesting autonomic dysfunction as a paraneoplastic manifestation of advanced cancer (19,20 and 21). Park et al. (20) reported a patient with bronchial carcinoma who showed postural hypotension and abnormal tests for autonomic dysfunction that disappeared after irradiation of the tumor. In a second report, a patient with small cell carcinoma of the lung developed intestinal obstruction and abnormal tests for autonomic dysfunction. An autopsy demonstrated degeneration of autonomic nerves without tumor involvement in the area. Antineuronal antibodies have been identified in patients with small cell lung carcinoma who demonstrated neurological signs consistent with autonomic neuropathy (22).

Another possible etiological factor in autonomic neuropathy in this patient population is direct tumor involvement (23). Cardiovascular autonomic neuropathy has been noted after the administration of chemotherapeutic agents such as vinca alkaloids (24). Drugs such as opioids, anticholinergics, antidepressants, and vasodilators may also have adverse effects on the autonomic nervous system. Many of these drugs are used in the management of cancer-related symptoms. Radiation damage to the autonomic ganglia is also a potential factor. Human immunodeficiency virus infection has also been noted to produce autonomic insufficiency (25).

Autonomic dysfunction is a frequent feature in patients with advanced cancer. It should be suspected in patients with unexplained tachycardia, poor performance status, chronic nausea, and malnutrition. Figure 14-3 summarizes the possible causes of autonomic dysfunction in advanced cancer patients.

FIGURE 14-3. Possible causes of autonomic dysfunction in advanced cancer patients.

Drugs

Opioids are one of the most common causes of chronic nausea in cancer patients. Opioid analgesia can cause nausea and vomiting in patients after initiation or increase in dose. This usually responds well to antiemetic medication and disappears spontaneously within the first 3 or 4 days of treatment (26,27). Some patients, particularly those receiving high doses of opioids, experience chronic and severe nausea (28).

Opioids cause chronic nausea by a number of mechanisms, including stimulation of the CTZ, gastroparesis, constipation, and by increasing sensitivity of the vestibular center (as discussed previously, see the section Vestibulocochlear Nerve) (7). The presence of opioid receptors in the CTZ in the area postrema is consistent with the observation of morphine and enkephalin-induced vomiting in the dog after local or systemic administration and the abolishment of this response after ablation of the

area postrema (29).

Chronic nausea has been associated with accumulation of active morphine metabolites such as morphine-6-glucuronide. Accumulation of morphine metabolites is more likely with higher doses of opioids but can occur even with lower doses, especially in patients with renal insufficiency (30).

Many other drugs can cause nausea. Nonsteroidal antiinflammatory drugs, antibiotics, and iron supplements can cause nausea irritation of the GI tract. Antibiotics may also cause nausea by a direct effect on the CTZ. Psychoactive medications including tricyclic antidepressants, selective 5-HT3 reuptake inhibitors, and phenothiazines can cause nausea.

Constipation

Constipation is common in patients with advanced cancer (31). Severe constipation can cause nausea and vomiting, abdominal pain, distention, urinary retention, and cognitive failure (32). There are many factors in advanced cancer patients that predispose to the development of constipation, including opioid analgesics, immobility, poor oral intake and dehydration, autonomic failure, and other medications. Constipation is often underdiagnosed in this patient population and should be suspected as a cause of nausea in all advanced cancer patients (33).

Bowel Obstruction

Bowel obstruction is a less common but important cause of nausea and vomiting. It has been reported to occur in 3% of all terminally ill cancer patients, and was found to be present in 15 of 100 consecutive patients admitted to a tertiary palliative care unit (34). Although acute complete bowel obstruction is easy to diagnose, the majority of advanced cancer patients tend to present with a less clear picture with a slow progression from partial to complete bowel obstruction. Some patients have only intermittent obstructive symptoms. These episodes of obstruction may be accompanied by nausea and vomiting.

ASSESSMENT

Because the causes of chronic nausea and vomiting are often multifactorial, the assessment in a given patient should be multidimensional, with awareness that these symptoms are dynamic processes and frequently change in intensity. There are a number of effective systems for assessing the intensity of nausea, such as visual analog scales, numerical scales, and verbal descriptors, but there is no “gold standard” for nausea assessment. As nausea is a subjective symptom, its expression varies from patient to patient and will depend on the individual patient's perception and other factors such as psychosocial issues. From a practical point of view this occasionally leads to a lack of correlation between the observed expression of nausea and the presumed pathophysiology of the underlying condition. It is also important to note that the term *nausea* may mean different things to different people and be used by some patients to describe other symptoms, including abdominal discomfort, pain, distention, or early satiety.

Once the intensity of nausea has been assessed, it is important to assess the symptom in the context of other symptoms such as pain, appetite, fatigue, depression, and anxiety. This multidimensional assessment allows formulation of a therapeutic strategy. An example of a validated multidimensional assessment tool is the Edmonton Symptom Assessment System (35,36) The system is based on visual analog scales that assess pain, nausea, anxiety, depression, appetite, shortness of breath, and sense of well being, among others. Tools such as this can be used to document the intensity of nausea initially, as a baseline assessment, and then on a regular basis, giving the examiner a sense of the therapeutic effect of the management. Such tools allow for a more reproducible assessment from the point of view of research and quality control.

A detailed history and physical examination is essential. It is important to clarify that the patient's expression of nausea does not describe a different symptom such as reflux. Intensity, frequency, exacerbating and relieving factors, onset, and duration of nausea should be documented. If there is coexistent vomiting, the nature of the vomiting should also be documented as the quantity of the vomitus can give a clue to the etiology. Large-volume emesis may indicate gastric outflow obstruction while small volume emesis may indicate gastric stasis. The extent to which the emesis interferes with oral intake should be noted, as large and frequent volume vomiting puts the patient at risk of rapid dehydration. A history of syncopal episodes or early satiety should alert the physician of the possibility of autonomic insufficiency.

The etiology of nausea may be related to the underlying cancer diagnosis. In patients with intraabdominal malignancies or metastases, bowel obstruction should be suspected. The stomach and duodenum can be compressed, causing the “squashed-stomach syndrome.” Symptoms and signs of raised intracranial pressure may indicate brain metastases.

A detailed medication history is essential. The use of drugs capable of causing nausea, such as opioids, anticholinergics, nonsteroidal antiinflammatories, and antibiotics, should be specifically noted. Other medical conditions, such as peptic ulcer disease and diabetes, should also be noted. Autonomic failure should be suspected in patients with diabetic neuropathy or chronic renal failure.

Constipation, as already discussed (see the section Constipation), is a common complication in advanced cancer patients and may cause or aggravate nausea. The frequency of bowel movements; feeling of abdominal distension; rectal soreness; oozing of stool; change in the amount of gases or stool passed recently; laxative use, type, and dose; and date of last bowel movement should be obtained. Unfortunately, clinical impression is likely to be quite unreliable and investigations, such as a plain abdominal x-ray, should be undertaken to help in the diagnosis (37). The use of a radiological constipation score may be necessary for adequate diagnosis in some patients, particularly those with cognitive failure. On a plain abdominal x-ray the abdomen is divided into four quadrants. Each quadrant is assessed for constipation: score, 0 = no stool; 1 = stool occupying <50% of the lumen; 2 = stool occupying >50% of the lumen; 3 = stool completely occupying the whole lumen of the colon. The total score of all quadrants is calculated and will range from 0–12. A score of 7/12 or greater is suggestive of severe constipation (33,37,38).

Physical examination may be helpful in identifying possible underlying causes. Table 14-1 summarizes possible findings on physical examination in patients with chronic nausea and vomiting.

General inspection
Cachexia or malnutrition; muscle wasting, skin fold thickness
Abdominal examination
Bowel obstruction; abdominal distention, increased bowel sounds
Abdominal masses or ascites
Constipation; abdominal fullness, including rectal examination
Neurological examination
Raised intracranial pressure; papilledema
Autonomic insufficiency; lying and standing blood pressure, absence of heart rate variation during Valsalva's maneuver

TABLE 14-1. POSSIBLE FINDINGS ON PHYSICAL EXAMINATION IN PATIENTS WITH CHRONIC NAUSEA AND VOMITING

Investigations to exclude renal impairment, hepatic failure, and other metabolic abnormalities such as hypercalcemia, hypokalemia, and hyponatremia should be undertaken. A computed tomography scan of the brain may be indicated where brain metastases are suspected. Abdominal x-rays may be useful in assessing nausea. A supine x-ray may indicate the presence of stool and fecal impaction. Erect or decubitus views may show air and fluid levels in the bowel, which is typical of bowel obstruction. Sophisticated investigations, such as gastric emptying scans, are probably not justified for the majority of patients.

MANAGEMENT

Appropriate management of chronic nausea and vomiting depends on a detailed assessment. The formulation of a management plan and decisions regarding the type of antiemetic medication to use depend on the postulated underlying cause or causes of the nausea. General support measures should be instituted. In addition, specific and symptomatic treatment should be undertaken as appropriate.

General Support Measures

General measures should address maintenance of good oral hygiene (poor oral hygiene can contribute to nausea), the creation of a comfortable environment for the patient, regular baths to prevent unpleasant body odors, and attention to diet. Small volumes of food at regular intervals should be considered for patients with early satiety associated with nausea.

Specific Treatment

In patients where an underlying cause or causes have been identified, there should be an attempt to correct these. Metabolic abnormalities should be corrected if this is possible. In situations where opioid toxicity is suspected, a change of opioids using equianalgesic doses can be expected to improve symptoms of nausea while maintaining pain control (39). Unnecessary medications should be discontinued. Aggressive bowel care, including cleansing enemas and regular laxatives, should be instituted when constipation or stool impaction is suspected. In some cases, such as in patients with brain metastases, symptom control may be attempted with radiation therapy or corticosteroids. If peptic ulcer disease is suspected, appropriate treatment should be instituted.

Symptomatic Treatment

Pharmacological Interventions

Many drugs with antiemetic properties are available for the treatment of chronic nausea and vomiting. Table 14-2 summarizes current and possible future agents.

Agent	Effects
Dopamine antagonists central action (e.g., metoclopramide, butyrophenone, phenothiazine)	Block dopamine at chemoreceptor trigger zone.
Dopamine antagonists peripheral action (e.g., metoclopramide, domperidone)	Promotility effects on gastrointestinal tract.
Anticholinergics (e.g., cyclizine, promethazine, dimenhydrinate)	Effects on vomiting center and vestibular apparatus.
Corticosteroids (e.g., dexamethasone)	Reduce raised intracranial pressure, other antiemetic effects not well understood. Also improve sensation of well-being and appetite.
5-HT3 antagonists (e.g., ondansetron, granisetron)	Block 5-HT3 (serotonin), useful in chemotherapy-induced and postoperative vomiting.
Progestational agents (e.g., megestrol acetate)	Unknown. Improve appetite, caloric intake, and nutritional variables in cancer cachexia.
Thalidomide	Centrally acting antiemetic effect. Other effects on improving appetite and sensation of well-being.
Cannabinoids	Central effects.
Neurokinin-1 antagonists (not yet licensed)	Central effects, antagonize substance P.
Octreotide	Reduced gastrointestinal secretions in patients with inoperable bowel obstruction.
Anticholinergic agents, e.g., hyoscine butylbromide	Reduced gastrointestinal secretions in patients with inoperable bowel obstruction.

5-HT3, 5-hydroxytryptamine type 3.

TABLE 14-2. ESTABLISHED AND EMERGING AGENTS FOR THE TREATMENT OF NAUSEA

Prokinetic Drugs

The initial pharmacological management of chronic nausea and vomiting in most patients should involve prokinetic drugs to normalize upper GI motility (40,41,42 and 43). Metoclopramide and domperidone are examples of prokinetic drugs. Metoclopramide has been established as an effective drug for treating delayed gastric emptying in patients who do not have cancer in a number of controlled clinical trials (43). Metoclopramide has also been demonstrated to be effective in reversing tumor-associated gastroparesis (11,42) and nausea associated with advanced cancer (28,40,44). Metoclopramide antagonizes D_2 both centrally in the CTZ and peripherally in the GI tract. In addition, it exhibits weak antagonism at the 5-HT3 receptor. In our experience metoclopramide is the drug of first choice for patients with chronic nausea (28). High doses of metoclopramide (1–2 mg/kg given up to 5 times in 24 hours) may produce 5-HT3 receptor blockade, which may in turn contribute to its antiemetic activity. However these high doses are frequently impractical. One problem with the administration of metoclopramide is its short elimination half-life, which necessitates frequent administration to provide optimal relief of nausea. Clinical trials support the view that sustained metoclopramide concentrations are required to suppress nausea and vomiting and possibly other GI symptoms associated with advanced cancer (28,45,46). As a result some patients require frequent administration or continuous infusions for optimal results (47). In a recent study, 26 cancer patients with a greater than 1-month history of dyspepsia were randomized to receive either controlled-release metoclopramide 40 mg 12 hourly or placebo for 4 days (40). Patients were then crossed over to the alternative treatment for another 4 days. On the last day of each treatment phase, nausea was significantly lower in the controlled-release metoclopramide group compared to placebo. Controlled-release metoclopramide was well tolerated and adverse events did not differ between treatments and placebo groups. In another study immediate-release metoclopramide 20 mg 6 hourly was compared to controlled-release metoclopramide 40 mg 12 hourly in patients with advanced cancer and chronic nausea. Nausea scores by day 3 of treatment were significantly lower for patients who received controlled release as compared to immediate-release metoclopramide (44). Metoclopramide occasionally causes acute dystonic reactions. These are more common in younger patients, especially in young men. Domperidone is another drug with antidopaminergic activity. However it does not readily cross the blood–brain barrier and acts primarily on the GI tract. Hence, it is less likely to cause central effects such as extrapyramidal reactions and sedation.

A standard therapeutic ladder for the management of chronic nausea in cancer patients based on metoclopramide has been developed. Table 14-3 summarizes this regimen. A retrospective assessment of this regimen in 98 terminally ill patients with nausea in a palliative care unit found that the majority of patients without bowel obstruction achieved excellent control of nausea using this regimen. Twenty-five patients (25%) required other antiemetics, 18 because of GI obstruction, three due to extrapyramidal side effects, and four for other reasons. These data suggest that nausea can be controlled in the majority of patients in this population.

Step 1	Metoclopramide, 10 mg p.o./s.c. q4h + 10 mg p.o./s.c. for rescue
	Poor response after at least 2 d of treatment (consistent complaint of nausea and >2 extra doses of metoclopramide per day), go to step 2; occasionally patients with severe emesis go to step 3
	Side effects or contraindication (bowel obstruction), go to step 4
Step 2	Metoclopramide (same dose as step 1) + dexamethasone, 10 mg p.o./s.c. b.i.d.
	Poor response after at least 2 d, go to step 3
	Side effects or contraindication, go to step 4
Step 3	Continuous subcutaneous infusion of metoclopramide (60–120 mg/d) + dexamethasone, 10 mg p.o./s.c. b.i.d.
	Poor response, go to step 4
Step 4	Other antiemetics (e.g., haloperidol, dimenhydrinate)

TABLE 14-3. A METOCLOPRAMIDE-BASED REGIMEN FOR TREATMENT OF CHRONIC NAUSEA

Other Centrally Acting Dopamine Antagonists

Phenothiazines (e.g., chlorpromazine) and butyrophenones (e.g., haloperidol) are effective antiemetics. They are D_2 antagonists and act centrally at the CTZ. They do not increase GI motility and are thus useful in patients with complete bowel obstruction (48). Phenothiazines are more sedating than butyrophenones and this effect limits their use in this patient population.

Antihistamines

Antihistamines (e.g., cyclizine, promethazine, and dimenhydrinate) are useful antiemetics particularly if a vestibular component to the nausea is suspected.

Corticosteroids

Corticosteroids have powerful nonspecific antiemetic effects that are not well understood. They can decrease peritumoral edema, thus reducing intracranial pressure, a known cause of nausea. Corticosteroids are beneficial in combination with other antiemetic agents such as 5-HT3 antagonists or metoclopramide in the prevention and management of acute chemotherapy-induced emesis (49,50). Corticosteroids are also useful in the management of other symptoms that may coexist with nausea in advanced cancer patients such as pain, anorexia, and asthenia (51,52 and 53).

Serotonin Antagonists

5-HT3 antagonists are widely used and researched for the prevention and management of acute chemotherapy-induced nausea and vomiting (49,54). There are case reports of nausea refractory to other treatments being effectively treated by 5-HT3 antagonists (55,56). However, no clinical trials have been published on the use of 5-HT3 antagonists in the management of chronic nausea.

Progestational Agents

Trials involving progestational agents in the treatment of hormone-responsive tumors found significant body weight gain with or without tumor response (57,58). This prompted studies of these drugs for the treatment of cancer cachexia. Megestrol acetate has been the most widely studied progestational agent in patients with advanced cancer. Several randomized controlled trials have shown that megestrol acetate can improve appetite, caloric intake, and nutritional variables in patients with cancer cachexia (59,60,61,62,63 and 64). Simons et al. (65) found improved appetite and possible reduction in nausea and vomiting in patients with advanced-stage, nonhormone-sensitive cancer treated with megestrol acetate (65). Loprinzi et al. (60), in a randomized, placebo-controlled trial of megestrol acetate involving 133 patients, reported a significantly reduced incidence of nausea and vomiting in patients receiving megestrol acetate. Reduced nausea has also been reported in other studies of megestrol acetate in cancer cachexia (61,62). Further research is needed to assess the potential role of progestational agents in the treatment of patients with chronic nausea.

Thalidomide

This drug was initially used during the 1950s as a mild anxiolytic, hypnotic, and antiemetic. Its antiemetic effects resulted in its use in the treatment of hyperemesis gravidarum (66,67), and was found to be effective in the symptomatic therapy of nausea and vomiting caused by malignant, nongastric neoplasms or by the administration of mechlorethamine (68). It was removed from the market after it was found to cause severe teratogenesis when administered to pregnant women. Its antiemetic effect is thought to be a central effect. In recent years there has been renewed interest in thalidomide, particularly for use in cancer patients. In addition to central antiemetic and sedative effects, thalidomide has immunomodulatory, antipyretic, anticachectic, and possible antiangiogenic, antidiaphoretic, and analgesic actions (69). This spectrum of potential effects makes it an interesting drug from a palliative care perspective. Bruera et al. (70) found that the administration of thalidomide 100 mg at night in 37 evaluable patients with advanced cancer and cachexia led to significant improvement in appetite, nausea, and sensation of well being. Further research is needed to evaluate the effects of thalidomide on chronic nausea.

Cannabinoids

Several studies have demonstrated the efficacy of dronabinol as an antiemetic agent for the treatment of chemotherapy-induced nausea and vomiting (71,72,73 and 74). A randomized controlled trial in 139 patients with acquired immunodeficiency syndrome cachexia comparing oral dronabinol 2.5 mg twice daily and placebo showed significant improvement in nausea, appetite, and mood but no body weight gain in those patients taking the drug (75). Side effects, such as somnolence, confusion, and perceptual disturbance, are common (73). The effects of cannabinoids in advanced cancer patients with chronic nausea have not been characterized. In this patient population who frequently have borderline cognitive impairment and are often receiving other medications, such as opioids and other psychoactive drugs, the incidence of side effects is likely to limit their use.

Neurokinin-1-Receptor Antagonists

The application of substance P to the nucleus tractus solitarii induces vomiting (76). The action of substance P is mediated through the neurokinin-1 receptor. Neurokinin-1-receptor antagonists have been found to inhibit cisplatin-induced emesis in animals (77,78). In a recent multicenter double-blind, placebo-controlled trial, 159 patients were randomized to one of three groups prior to receiving their first dose of cisplatin. All patients received granisetron and dexamethasone prior to cisplatin. Group 1 received an oral neurokinin-1-receptor antagonists (L-754,030) prior to cisplatin and on days 2–5 after cisplatin, group 2 received L-754,030 prior to cisplatin and placebo in days 2–5 afterwards, and group 3 received placebo before and on days 2–5 after cisplatin therapy. The neurokinin-1-receptor antagonist was found to prevent delayed emesis after treatment with cisplatin. It was also found to improve the prevention of acute cisplatin-induced emesis when combined with granisetron and dexamethasone as compared to placebo combined with granisetron and dexamethasone (79). No significant differences were observed in the incidence of adverse effects between the three groups. Hesketh et al. reported similar findings with another neurokinin-1-receptor antagonist (CJ-11,974) in patients receiving cisplatin. Improved control of delayed emesis and a possible additive benefit for prevention of acute emesis when combined with a 5-HT3 antagonist and dexamethasone were observed (80). Neurokinin-1-receptor antagonists have also been reported to be more effective than placebo in the treatment of established postoperative nausea and vomiting (81). The potential role of neurokinin-1-receptor antagonists in the treatment of chronic nausea and vomiting of cancer is currently unknown.

Octreotide and Anticholinergic Drugs

In patients with inoperable bowel obstruction, reduction of secretions has been achieved using anticholinergic agents (e.g., hyoscine butylbromide) (82) and octreotide (a somatostatin analogue) (83). Two recent randomized controlled trials have compared anticholinergic agents and octreotide. Mercadante et al. (84), in a study involving 18 patients, found that octreotide treatment produced a significantly reduced number of daily episodes of vomiting and intensity of nausea compared with hyoscine butylbromide. Lower levels of hydration were associated with nausea in both groups. Ripamonti et al. (85) looked at 17 patients who presented with inoperable bowel obstruction and a decompressive nasogastric tube. Patients were randomized to receive either octreotide 0.3 mg or scopolamine butylbromide 60 mg daily for 3 days by subcutaneous infusion. It was possible to remove the nasogastric tube in 13 of the 17 patients. Octreotide significantly reduced the amount of GI secretions at days 2 and 3 as compared to scopolamine butylbromide. Patients who received less parenteral hydration had significantly more nausea and drowsiness. The authors concluded that octreotide should be considered the first-choice drug when a rapid reduction in GI secretions is desired and that parenteral hydration over 500 ml/day may reduce nausea and drowsiness. Further studies are needed to identify the role that hydration plays in the etiology of nausea in this clinical situation.

Surgical Intervention

In patients with nausea and vomiting caused by intestinal obstruction, surgical procedures should be considered. Percutaneous gastrostomy for gastric outlet obstruction can greatly improve symptoms in some patients (34,86). Laparotomy for GI obstruction due to tumor or adhesions can abolish symptoms and improve life expectancy and quality. Surgery should be considered if a bypass procedure or excision of the obstructing lesion is possible and the patient's general physical condition suggests a life expectancy long enough to result in a likely benefit from surgery.

CONCLUSION

Chronic nausea and vomiting are common and distressing symptoms in patients with terminal cancer. These symptoms are likely to be due to several factors, including autonomic failure, opioid analgesics, metabolic abnormalities, constipation, and cachexia. Promotility agents (sometimes in combination with corticosteroids) are in most cases the drug of choice for management of chronic nausea and vomiting. Pharmacological agents, such as progestational drugs and thalidomide, need further evaluation of their potential beneficial effects in patients with chronic nausea. Despite significant ongoing research into acute chemotherapy-induced and postoperative emesis, research is lacking in chronic nausea. Drugs that have been found to be effective in acute vomiting, such as 5-HT3 and neurokinin-1-receptor antagonists, require further evaluation in advanced cancer patients with chronic nausea.

DIARRHEA, MALABSORPTION, AND CONSTIPATION

SEBASTIANO MERCADANTE

DIARRHEA

Diarrhea is commonly defined as an abnormal looseness of the stools (increased liquidity or decreased consistency). It occurs when the intestine does not complete absorption of electrolytes and water from luminal content. Although a practical definition of diarrhea is lacking, diarrhea is commonly diagnosed when an abnormal increase in daily stool weight, water content, and frequency, whether or not accompanied by urgency, perianal discomfort, or incontinence, is present (1).

Diarrhea is a common complication in the cancer population, occurring in 5–10% of patients with advanced disease (2,3 and 4). The consequences of diarrhea can be troublesome, and include loss of water, electrolytes, albumin, and failure to reach nutritional goals, declining immune function, and the risk of bedsores or systemic infection. Diarrhea also brings additional work for the nursing staff or family who have to prevent maceration and bedsores. Moreover, losses of comfort and dignity have to be considered.

Diarrhea principally induces dehydration. Several symptoms depend on dehydration, such as asthenia, anorexia, weight loss, and drowsiness, which limit the quality of life. Furthermore, it determines abnormal metabolic compartments influencing drug pharmacokinetics, blood renal flow, and acid-base balance, as well as hypokalemia and acidosis from massive potassium and bicarbonate loss (5).

Mechanisms

The presence in the lumen of unusual amounts of poorly absorbable, osmotically active solutes; intestinal ion secretion or inhibition of normal active ion absorption with or without exudation of mucus, blood, and protein from sites of inflammation; and deranged intestinal mobility constitute the principal mechanisms to produce diarrhea.

Osmotic Diarrhea

The ingestion of a poorly absorbable solute modifies the osmolarity of the luminal content and induces osmotic diarrhea (Table 15-1). The proximal small bowel is highly permeable to water; sodium and water influx across the duodenum rapidly adjust the osmolarity of luminal fluid toward that of plasma, secreting water even after the osmolarity values between luminal contents and plasma are similar. On the contrary, the mucosa of the ileum and colon has a low permeability to sodium and solutes. However, there is an efficient active ion transport mechanism that allows the reabsorption of electrolytes and water even against electrochemical gradients (1).

Carbohydrate malabsorption
Excessive ingestion of poorly absorbed carbohydrate
Magnesium-induced diarrhea
Laxatives containing poorly absorbable anions

TABLE 15-1. CAUSES OF OSMOTIC DIARRHEA

Carbohydrates and proteins are fermented by colonic bacteria and salvaged as short-chain fatty acids and gases. Anaerobic colonic flora are necessary for the fermentation of fiber into short-chain fatty acids and constitute the bulk of fecal mass. In the perioperative period, cancer patients may receive massive antibiotic therapy, able to suppress normal colonic metabolism, thus resulting in diarrhea (6). When large amounts of lactulose, an unabsorbable sugar in the small intestine, are ingested, the protective role of colonic bacteria may be exhausted, resulting in severe diarrhea. Fecal volume in carbohydrate-induced diarrhea is proportional to the osmotic force of the malabsorbed saccharide (7). Carbohydrate malabsorption may induce osmotic diarrhea. It is characterized by a low stool pH, due to the presence of short-chain fatty acids, a high content of carbohydrates, high stool osmolarity, and flatulence. In osmotic diarrhea caused by ingestion of magnesium, sulfate, and poorly absorbed salts, there will be a normal pH. Osmotic diarrhea commonly subsides as the patient fasts or stops ingesting poorly absorbable solutes laxatives. It is characterized by an osmotic gap in stool analysis, equivalent to the concentration of the osmotically active agents in fecal fluid that are causing diarrhea (1).

Secretory Diarrhea

An abnormal ion transport in intestinal epithelial cells, with a reduction in absorptive function or increase in secretion of epithelial cells, is observed in secretory diarrhea. Secretory diarrhea is rarely present as the sole mechanism and is often associated with other mechanisms (6).

Different from osmotic diarrhea, the anionic gap is small, eating does not markedly increase stool volume, and diarrhea usually persists during periods of fasting. Secretory diarrhea can result from bacterial toxins, or the presence of intraluminal secretagogues (such as bile acids or laxatives), circulating secretagogues (such as various hormones, drugs, and poisons), and other medical problems that compromise regulation of intestinal function, or reduce absorptive surface area (by disease or resection) (8). Secretagogues are substances stimulating the intestine to secrete fluid acting mostly via the enteric nervous system (9). Endocrine tumors may cause diarrhea via the release of secretagogue transmitters (10). Diarrhea is a common manifestation of a carcinoid syndrome, occurring in approximately 70% of patients. Intestinal secretion seems to be mediated by serotonin and substance P. In the Zollinger-Ellison syndrome, secretory diarrhea is the consequence of gastric hypersecretion caused by a high concentration of circulating gastrin, overwhelming the intestinal absorptive capacity. Severe diarrhea with hypergastrinemia due to lansoprazole rather than gastrinoma has been reported (11). In a medullary carcinoma of the thyroid, circulating calcitonin is the major mediator of intestinal secretion (1).

Malabsorption is often associated with diarrhea. Malabsorption due to bile salts rendered insoluble by the low intraluminal pH is often associated with this. Ileal resection or a postvagotomy state may result in watery diarrhea from the secretory effect of malabsorbed bile acids on colonic mucosa. Malabsorption due to lymphatic obstruction and fibrosis induced by the tumor may contribute to diarrhea (12) (see Malabsorption).

The cancer treatment–related diarrhea caused by acute graft-versus-host disease (GVHD) and chemotherapeutic agents (13), particularly fluoropyrimidines, paclitaxel, and irinotecan, significantly affects morbidity and mortality. Diarrhea is a significant consequence of colorectal chemotherapy, with the majority of patients experiencing grades 3 or 4 diarrhea and 56% of all patients also modifying their chemotherapy regimen (14). These agents cause acute damage to the intestinal mucosa, necrosis, and extensive inflammation of the bowel wall. Mucosal and submucosal factors, produced directly or indirectly by the inflamed intestine, stimulate secretion of intestinal fluid and electrolytes. Similar anatomical changes have been observed in patients with GVHD diarrhea, as well as with radiation enteritis (13).

Extensive necrosis of epithelial cells increases the risk of superinfection by opportunistic pathogens such as *Clostridium difficile*, *Clostridium perfringens*, *Bacillus cereus*, *Giardia lamblia*, *Cryptosporidium*, *Salmonella*, *Shigella*, *Campylobacter*, and *Rotavirus*. This risk is highest in patients who may be neutropenic or immunosuppressed. Bacterial enterotoxins or other infective agents induce secretion probably by a local nervous reflex mediated by enteroendo-crine cells or inflammation (1). The incidence of *C. difficile*-induced diarrhea is very high: 2.2% in patients receiving standard-dose regimens and 20% in patients receiving high-dose regimens (15,16 and 17).

Cancer patients who are immunocompromised or recently underwent surgery often are administered a long-term antibiotic therapy for resistant infections. These aggressive treatments, including ampicillin, clindamycin, or cephalosporins, may result in a disruption of the normal flora and overgrowth of pathogens. *C. difficile*, an anaerobic organism producing an enteric toxin, is the common cause of pseudomembranous enterocolitis, which presents itself as a severe microbial diarrhea (18). Other infectious agents include *C. perfringens*, *Staphylococcus aureus*, *Klebsiella oxytoca*, candida species, and salmonella species (17).

Some drugs, such as diuretics, caffeine, theophylline, antacids, antibiotics, and poorly absorbable laxative agents and osmotically active solutes, often chronically administered in a palliative care setting, may produce secretory diarrhea, mostly causing a reflex nervous secretion or directly activating secretory cellular mechanism (6).

Deranged Motility

When other measurable mechanisms are excluded, motility derangements should be suspected to be the cause of diarrhea. Even in the presence of a normal absorptive function of epithelial cells, defective motility may reduce the contact time between luminal contents and epithelial cells. This commonly occurs in cancer patients with postsurgical disorders, such as postgastrectomy dumping syndrome, postvagotomy, ileocecal valve resection, or neoplastic and chronic diseases, such as malignant carcinoid syndrome, medullary carcinoma of thyroid, and diabetes (19). The diabetic population can be affected by diarrhea as a result of severe neuropathy. The mechanism by which diabetic neuropathy causes dismobility is attributed to a sympathetic denervation of the bowel with a prevalence of cholinergic innervation (20). An iatrogenic autonomic neuropathy due to celiac plexus block, a procedure used to abolish visceral abdominal cancer pain, has been described. The sympathetic denervation of the bowel may leave a cholinergic innervation unopposed, leading to an increase in intestinal motility and diarrhea. This phenomenon is generally self-limiting (21).

An abnormal reduced mobility due to spinal cord damages may favor a bacterial overgrowth, which induces a deconjugation of bile acids in the small bowel and thereby causes diarrhea and steatorrhea. Diarrhea secondary to dysmotility disorders commonly subsides after a 1–2-day fast, determining a small stool volume and an osmolality in the range of 250–300 mOsm.

Assessment

The patient should be questioned in detail about dietary habits of food intolerance. The use of any prescription or antibiotics in the preceding few weeks should be noted. The assessment of concomitant diseases or previous surgical intervention can provide important clues about the etiology. Frequency, amounts, and consistency of the stools should be carefully obtained. When the stools are consistently large, light in color, watery or greasy, free of blood, or contain undigested food particles, the underlying disorder is likely to be in the small bowel or the proximal colon. But small stool diarrhea in which frequent but small quantities of feces, dark in color, often containing mucus or blood, pass in spite of a sense of urgency, is associated with a disorder of the left colon or rectum (1). These two patterns of diarrhea may occur simultaneously because of widespread inflammation. Fecal incontinence, change in stool caliber, rectal bleeding, and small, frequent, but otherwise normal stools have to be distinguished. Passage of nonbloody diarrheal fluid, pus, or exudates indicates an inflammatory or infectious disease. Diarrhea associated with excessive flatus and mushy stools suggests carbohydrate malabsorption. Intermittent diarrhea and constipation are frequent in diabetic neuropathy, as well as in irritable bowel syndrome or subobstructive disorders. Complaints of nocturnal diarrhea and fecal soiling are frequently reported by patients with autonomic neuropathy or anal sphincter dysfunction. From the clinical point of view, the suspicion of a partial obstruction should be raised in the case of sudden diarrhea after a period of constipation. Fecal impaction may cause apparent diarrhea because only liquids pass a partial obstruction. Therefore, alternating diarrhea and constipation suggests fixed colonic obstruction. Abdominal x-ray will help the diagnosis. The presence of a mass suggests a possible malignancy, especially if associated to hepatosplenomegaly (6). Rectal examination and abdominal palpation should be performed to look for fecal masses and to exclude fecal impaction and intestinal obstruction. Rectal involvement is probable in the presence of little or no stool in spite of a sense of rectal urgency, commonly named *tenesmus*.

Physical examination, laboratory findings, and signs and symptoms may reveal important clues to the cause of diarrhea, including abdominal mass, perianal fistula or abscess, signs of anemia, fever, postural hypotension, lymphadenopathy, neuropathy, hepatosplenomegaly, ascites, gaseous abdominal distention or lymphadenopathy, reduced anal sphincter tone, a rectal mass or impaction, fever, and deterioration of nutritional status. Symptoms of dumping syndrome after gastric surgery, such as early nausea, abdominal distention, weakness, and diarrhea after a meal followed by hypoglycemia, sweating, dizziness, and tachycardia, are typical. Secretory diarrhea combined with upper gastrointestinal symptoms caused by refractory peptic ulcer disease is suggestive of gastrin-secreting tumor. High circulating serotonin levels in carcinoid syndrome cause other effects besides diarrhea, including hypotension, sweating, flushing, palpitation, and wheeziness (1,6). Peripheral or autonomic neuropathy confirms the possible concomitant visceral neuropathy secondary to these diseases. The association of heat intolerance, palpitations, and weight loss suggests possible hyperthyroidism. Chronic bowel ischemia should be considered in the oldest patients with the clinical feature of diffuse atherosclerotic disease. Of course, the site of neoplasm and metastases is of paramount importance. The location of the tumor will be verified by computed tomography, magnetic resonance imaging scan, angiography, or laparoscopy. Intestinal dysmotility or bacterial overgrowth due to diabetes, neoplastic conditions, or postoperative conditions may be associated with diarrhea (6).

If feasible, collected diarrhea stool specimen should be submitted for qualitative study. Positive finding in either the stool guaiac or leukocyte test gives suspect to an exudative mechanism, as does happen in radiation colitis, colonic neoplasm, or infective diarrhea. Stool cultures for bacterial, fungal, and viral pathogens, as well as formal evaluation of the gastrointestinal tract should complete the initial assessment (1,13).

Watery diarrhea is generally sustained by infective agents and efforts should be made for this purpose. Gram's stain of stool can diagnose the presence of *Staphylococcus*, *Campylobacter*, or *Candida* infection. Multiple stool cultures should be obtained from patients with secretory diarrhea to rule out microorganisms producing enterotoxins, which stimulate intestinal secretion. The presence of a microorganism in the stools is diagnostic (1). Chemotherapy-induced diarrhea typically occurs 2–14 days after therapy. Incidence of delayed diarrhea has been reported as high as 80% with irinotecan (22). Number of stools per day, need for parenteral support or intensive care, nocturnal stools, and episodes of incontinence are common toxicity criteria to evaluate treatment-induced diarrhea.

Radiation colitis is probable in patients who have received pelvic radiation for malignancies of the urogenital tract and of the prostate (1). The need for primary prevention is becoming urgent because evidence is emerging that suggests the problem has an increasing frequency. The early acute syndrome, manifesting itself with diarrhea, is usually self-limiting and probably consequent to inflammatory reactions.

Osmotic diarrhea is associated with a reduction of stool content in sodium and potassium that produces an anion gap of more than 50 mmol/l, while secretory diarrhea, due, for example, to endocrine tumors presenting an active secretion of salts and water, is characterized by lower values (less than 50 mmol/l). Moreover, while osmotic diarrhea typically stops or reduces after fasting or stopping the drug previously used, secretory diarrhea persists in spite of fasting (1,6).

Treatment

Considering the different mechanisms involved in determining diarrhea in cancer patients, there are no broadly accepted treatment protocols. Current medication should be revised, considering the use of laxatives, antacids, theophylline preparations, central nervous system drugs, antiarrhythmics, and antibiotics.

Dietary advices are difficult to follow in cancer patients. A gluten-free diet can reduce abdominal cramping and bowel movement frequency in the presence of intestinal fermentation with bowel distention. Binders of osmotically active substances (kaolin-pectin) give a thicker consistency to loose stools, producing a viscous, colloidal, absorbent solution, but their antidiarrheal effectiveness is disputable. Apples without the peel are particularly rich in pectin. Other dietary advices include avoiding cold

meals, milk, vegetables rich in fibers, fatty meat and fish, coffee, and alcohol. Oral hydration solutions containing glucose, electrolytes, and water are the simplest and most common treatments. Complex carbohydrate rather than monomeric forms improves water and electrolyte absorption (22). However, clinical signs of dehydration, such as orthostatic hypotension, decreased skin turgor, and a dry mouth, suggest the need of intensive hydration by intravenous route, especially in patients suffering from nausea and vomiting in which oral therapy is ineffective (6).

Drugs for Radiation Enteritis

Cholestyramine has been favorably used in radiation-induced diarrhea. However, real progress will come from the prevention of radiation enteritis rather than from changes in its management. Aspirin has been reported effective in postradiotherapy diarrhea (23). The effects are attributed to the reduction of prostaglandin synthesis responsible for water and electrolyte secretion. Sucralfate has been shown to mitigate diarrhea after pelvic radiation therapy. However, recent controlled studies were not able to demonstrate significant benefits. Moreover, some gastrointestinal symptoms, such as fecal incontinence, need for protective clothing, and severity of nausea, were worse among patients taking sucralfate (24).

Silicate smectite has proven a promising drug in the prophylaxis of radiotherapy-induced diarrhea. Patients with a low, irradiated, small bowel volume show the greater benefit, with a delay in the development of diarrhea after irradiation of pelvis and the abdomen (25).

Steroids

Steroids may exert a positive effect on secretory diarrhea, probably due to their antiinflammatory activity. Cortico-steroids can be useful in reducing edema in intestinal pseudo-obstruction or in radiation-induced enteritis. Moreover, steroids can reduce hormone secretion in endocrine tumors, reduce the release and the effect of the inflammation mediators, and promote salts and water absorption acting on sodium pump and sodium-hydrogen exchange (1). They are also included in the pharmacological approach to GVHD-induced diarrhea (13). Budesonide, a topical active steroid, demonstrated a substantial activity in irinotecan and 5-fluorouracil–induced diarrhea after failure of loperamide treatment (26).

Antibiotics

Antibiotics, such as norfloxacin and amoxicillin-clavulanic acid, are effective in the treatment of bacterial overgrowth– related diarrhea (27). On the other hand, antibiotic-associated diarrhea (pseudomembranous enterocolitis) requires the discontinuation of antibiotics and the starting of either metronidazole or vancomycin (28). It often subsides spontaneously after stopping the antibiotics. Bismuth subsalicylate in doses of 30–60 ml every 30 minutes for eight doses may bring mild symptomatic relief in patients with acute infectious diarrhea with an unknown effect (29). Probiotic bacteria (i.e., live bacteria that survive passage through the gastrointestinal tract) may have beneficial effects on the host. In a recent review, probiotic bacteria consistently shortened the diarrheal phase of rotavirus infection, although the evidence for other viral or bacterial infections was less strong (30).

Other Drugs

Racecadotril, an enkephalinase inhibitor with antisecretory and antidiarrheal actions, has been found to be an effective and safe treatment for watery diarrhea, allowing for a reduction of oral rehydration, although no experience has been reported in cancer patients yet (31).

Clonidine, an a-2 agonist, has been reported useful in controlling diarrhea in diabetic patients or in patients with chronic idiopathic secretory diarrhea who present a reduced intestinal sympathetic tone and denervation supersensitivity. The increase of salts and water absorption is probably due to an interaction with enterocyte receptors and the suppression of secretory transmitter release. However, hypotension and sedation may limit the usefulness of clonidine in dehydrated or advanced cancer patients (5).

Opioids

Opioids are commonly used for their antidiarrheal properties. Opioid receptors are represented at different sites, including smooth muscle, myenteric plexus, spinal cord, and brain. Their activation influences intestinal motility and, as a consequence, secretion. Although a central action cannot be excluded, only peripheral mechanisms have been confirmed. Antidiarrheal effects can be obtained by both oral and parenteral opioids. Opioids increase ileocecal tone, decrease small intestine and colon peristalsis (increasing electrolyte and water absorption), impair the defecation reflex by inhibiting anorectal sphincteric relaxation, and diminish anorectal sensitivity to distention.

The contact time between intestinal mucosa and luminal contents is enhanced by the reduction of colonic propulsive activity, resulting in a greater fluid absorption (19).

Opioid-like agents, including codeine, morphine, diphenoxylate, and loperamide, represent the best known drugs for the symptomatic treatment of diarrhea. Loperamide is able to reduce ileal calcium fluxes, with an activity independent from the opioid effect, and does not cross the blood– brain barrier, whereas diphenoxylate rarely reaches significant opioid effects at a clinical dosage. Loperamide induces a long-lasting stimulation of colonic motility associated with a disorganization of cyclic motor activity, enhancing nonpropulsive contraction in the small intestine and the colon. The effects on the colon are probably mediated by a local mechanism. Loperamide shows the highest antidiarrheal/analgesic ratio among the opioidlike agents and proved to be the drug of choice due to its few adverse effects. The standard dose of loperamide is 4 mg followed by 2 mg after every unformed stool. The dosage should be titrated against the effect and higher doses, 2 mg every 2 hours have been recommended (up to 12 mg/day or more) in conjunction with chemotherapeutic agents associated with a high incidence of diarrhea (32). Loperamide-simethicone combination was significantly more effective than the drugs taken alone in the treatment of acute diarrhea with gas-related abdominal discomfort (33). However, the risk of producing paralytic ileus in the presence of continuous secretion should be considered as a life-threatening complication. Opioids may also cause a paradoxical diarrhea secondary to fecal impaction (19).

Octreotide

Refractory diarrhea that does not respond to specific therapy may present a challenging and serious clinical problem. Octreotide, an analogue of somatostatin with a more favorable pharmacokinetic profile, exerts a wide range of physiological effects on the gastrointestinal tract (5,34,35). Data from several clinical trials suggest that this antisecretory agent may be useful in the symptomatic treatment of diarrhea refractory to other medications. The mechanism by which octreotide produces these beneficial effects is probably multifactorial. It suppresses the secretion of many of the gut peptides implicated in the control of secretory and motor activity. Furthermore, it inhibits exocrine secretions from the stomach, pancreas, and small intestine, also facilitating water and electrolyte absorption (21). Octreotide has been found to control diarrhea due to carcinoid tumors, vipoma, gastrinoma, small cell lung cancer, as well as acquired immunodeficiency syndrome–related diarrhea (21,36), although hormonal responses to the somatostatin analogue do not always parallel clinical responses, probably because of the effects of cosecreted peptides. A dose-response effect of octreotide has been demonstrated (38,39). Octreotide seems to be an effective agent in the management of chemotherapy-related diarrhea and refractory GVHD-associated diarrhea (35,37,38,39,40,41,42 and 43). Finally, octreotide has been proven effective in the treatment of diarrhea induced by celiac plexus block, as well as diabetic diarrhea (21). Doses of 0.3–1.2 mg a day subcutaneously are commonly effective.

Long-acting, biodegradable, microsphere formulation of octreotide for monthly subcutaneous administration has been developed and could be evaluated for the prophylaxis of diarrhea in patients with a history of chemotherapy-induced diarrhea and in patients requiring high-dose chemotherapy or undergoing high-dose chemotherapy before autologous bone marrow cell transplantation.

MALABSORPTION

The term *malabsorption* refers to an ineffective absorption of breakdown products in the small intestine. Malabsorption may occur either because a disorder interferes with the digestion of food or directly with the absorption of nutrients. Different sequential stages of digestion and absorption may be affected in the cancer patient resulting in malabsorption. The series of events include the reduction of particle size, the solubilization of hydrophobic lipids and the enzymatic digestion of nutrients to small fragments, the absorption of the products of digestion across the intestinal cells, and the transport via lymphatics. The digestive and absorptive processes are inextricably linked.

Digestion

Pancreatic secretion of lipase, amylase, and proteases breaks down fat to monoglycerides and fatty acids, carbohydrates to mono- and disaccharides, and proteins to peptides and amino acids. Several processes have been recognized to facilitate the absorption of fat from the aqueous luminal environment, including emulsification, enzymatic hydrolysis, dispersion, diffusion, absorption, and intracellular metabolism. Triglycerides are emulsified together with phospholipids, bile salts, and mono- and diglycerides and dispersed into a variety of phases and particles. Lipid digestion by lingual lipase, active at low pH, begins in the mouth and in the stomach, promoting

emulsion stability and facilitating the action of pancreatic lipases. Gastric and pyloric motility further promote emulsification of lipids. This effect is amplified by bile salts and biliary phospholipids, which also influence the absorption of cholesterol and sterol vitamins. Lipolysis to fatty acids and monoglycerides is mediated by pancreatic lipases (6).

Protein digestion begins in the stomach. Acid denaturation prepares proteolysis. Proteolytic enzymes, endopeptidases activated by an acid environment, cleave the internal bonds of large proteins to form nonabsorbable peptides. Pancreatic peptidases convert proteins and polypeptides into amino acids and oligopeptides. After hormonal or neural stimulation, proenzymes are released by the pancreas. Enteropeptidases and trypsin activate a cascade of events that promote the activation of chymotrypsin, elastase, and carboxypeptidase A and B in the duodenum (44).

Pathophysiology

The hydrolysis of fat, protein, and carbohydrate by pancreatic enzymes, as well as solubilization of fat by bile salts, may be altered by several conditions (1,45). In such conditions, the intraluminal environment of the proximal small intestine resembles that of the colon. In pancreatic carcinoma or following pancreatic resection, decreased pancreatic enzymes and bicarbonate release may limit the digestion of fat and protein, leading to pancreatic insufficiency (46). These disorders may also be associated with malabsorption of fat-soluble vitamins. The Zollinger-Ellison syndrome is characterized by an extreme acid hypersecretion, causing a low luminal pH, inactivating pancreatic enzymes with consequent fat malabsorption. A decrease in intraluminal bile salts due to disruption of the enterohepatic circulation is also seen in patients with Zollinger-Ellison syndrome. Biliary tract obstruction, terminal ileal resection, or cholestatic liver disease result in decreased bile salts formation or delivery to the duodenum (47). Many postsurgical disorders have been associated with a marked proliferation of intraluminal microorganisms, including an afferent loop of a Billroth II partial gastrectomy, a surgical blind loop with end-to-side anastomosis, or a recirculating loop with side-to-side anastomosis. With limited small bowel resections, malabsorbed bile acids pass into the colon, decreasing water and electrolyte absorption, resulting in diarrhea. In massive small bowel resection, steatorrhea is caused by a diminished bile acid pool from increased intestinal bile salts loss, together with a loss of the absorptive intestinal surface and bacterial overgrowth (48).

Bacterial overgrowth competes with the human host for nutrients causing catabolism of carbohydrates by gram-negative aerobes, deconjugation of bile salts by anaerobes, and the binding of cobalamin by anaerobes. Causes of bacterial overgrowth include obstruction or strictures, autonomic neuropathy, and resection of the ileocecal valve. All of these conditions cause malabsorption by changing the intraluminal environment of the proximal small intestine so that it more closely resembles the colon (44).

Absorption

Absorption is the passage of these products of digestion from the lumen through the enterocyte to appear in the lymphatics or the portal vein. Several processes are involved in absorption. Active transport requires energy to move nutrients against a gradient, whereas passive diffusion allows nutrients to pass according to gradient differentials. Facilitated diffusion is an intermediate mechanism, similar to passive diffusion, but carrier-mediated and subject to competitive inhibition. Endocytosis is a process in which parts of a cell membrane engulf nutrients.

Carbohydrate absorption occurs as monosaccharides, predominantly in the proximal small intestine, although not all dietary carbohydrate is absorbed. The simple diffusion of monosaccharides across membranes is slow but important in the presence of high luminal concentrations of glucose. Specific active transport systems, especially via sodium-coupled transporters, mediate efficient transport of these substances when luminal concentrations of glucose are low. Monosaccharides may also enter enterocytes by facilitated diffusion. The uptake of lactose is limited by lactase activity. Xylose is not digested and has a low affinity for carriers. Some carbohydrates reach the colon and are fermented by bacteria into short-chain fatty acids with production of gases such as hydrogen and methane. Short-chain fatty acids are subsequently absorbed by colonic epithelial cells.

Fat products rapidly diffuse passively into enterocytes, with the rate of transfer depending on the chain length. Fatty acids and monoglycerides are metabolized into triglycerides and assembled with phospholipids and cholesterol esters into chylomicrons. Short- and medium-chain fatty acids have a less complex absorptive mechanism. They may be absorbed intact by passive diffusion or completely hydrolyzed, but they are not reesterified inside the enterocytes. Lipid absorption is highly efficient; only small amounts of lipids enter the colon. These may be absorbed by the colonic mucosa or undergo bacterial metabolism.

Bile salts are synthesized from cholesterol in the liver, conjugated with amino acids, secreted into the bile, and recycled back to the liver via the portal system. Minimal daily losses are balanced by hepatic synthesis. Passive diffusion and active transport are involved in bile salt transport in the small intestine to limit fecal loss. A certain amount of bile salt in the colonic lumen is essential for normal colonic function. In the colon, bile salts are not absorbed but they stimulate colonic motility and secretion of sodium chloride and water. In contrast, bile salt deficiency may cause constipation (6).

Amino acids are absorbed by enterocytes, oligopeptides are digested by the enterocyte, brush border by oligo- or dipeptidases. A specific transport mechanism exists for the intracellular transport of amino acids and dipeptides. Protein absorption is efficient and mainly occurs in the jejunum and ileum (44,45).

Pathophysiology

Abnormalities of the small intestinal mucosa or impairment of epithelial cell transport may be seen in radiation enteritis. The pathological changes from radiation enteritis occur in three phases. During and immediately after irradiation, abnormal epithelial cell proliferation, maturation, and inflammatory cell infiltration occur. An acute vasculopathy coincides in time with the period of maximal epithelial cell damage. Vascular changes may be progressive, even after the resolution of the acute epithelial changes. Subsequently, the intestinal mucosa regenerates to a variable extent depending on the vascular damage. Extensive fibrosis, strictures, and fistulae, with disruption of the mucosal surface, may develop resulting in a chronically inflamed bowel with impairment of mucosal function. Moreover, severe adhesions may develop between loops of intestine leading to the formation of fistulous tracts between adjacent bowel loops. Extensive mucosal damage, lymphatic obstruction, and bacterial overgrowth are the principal mechanisms of radiation-induced malabsorption (49).

A large surgical resection of the small intestine also reduces the epithelial surface area available for absorption. The extent and specific level of resection are predictive of severe malabsorption and short-bowel syndrome. Most patients with short-bowel syndrome either have a high jejunostomy with a residual jejunal length less than 100 cm or a jejunocolic anastomosis (45,48). The recovery from massive small bowel resection depends on the adaptive response of the remaining mucosa (50). Resection of more than 50% of the small intestine still results in significant malabsorption. The inclusion of the distal two thirds of the ileum and ileocecal sphincter in the resected section increases the risk of malabsorption. Preservation of the ileocecal sphincter is important because it may prevent small bowel contamination from colonic flora and may increase the transit time of the intraluminal content.

After intestinal resections, increased amount of bile salts reach the colon, promoting water and electrolyte secretion, unless liver production may compensate the losses, as it happens in limited resections. The consequent lack of solubilization of intraluminal fat will worsen the effects of bile salts on the colon mucosa. Enterostomy or intestinal fistulae may also result in a reduced absorption due to the loss of intestinal surface area. A vagotomy may increase the colonic content of bile acids due to an accelerated transit time. A diabetic neuropathy may result in intestinal dysmotility and bacterial overgrowth, and as a consequence, in malabsorption (6).

Lymphatic transport of chylomicrons and proteins is limited by lymphatic obstruction, leading to dilatation and potential rupture of intestinal lymphatic vessels, causing intestinal leakage of proteins, chylomicrons, and small lymphocytes. Localized ileal tumors, diffuse intestinal lymphomas, metastatic carcinoma, and metastatic carcinoid disease may all lead to lymphatic obstruction, fat malabsorption, and protein-losing enteropathy (6).

Assessment

Patients with malabsorption usually lose weight. If fats are not properly absorbed, the stools are light-colored, soft, bulky, and foul smelling. Such stool is called steatorrhea. Documentation of steatorrhea is the cornerstone of the diagnostic evaluation. Malabsorption can cause deficiencies of all nutrients or of proteins, fats, vitamins, or minerals selectively. Certain physical signs are frequently associated with specific deficiency states secondary to malabsorption, such as glossitis in folate or vitamin B_{12} deficiency, hyperkeratosis, ecchymoses, and hematuria due to fat-soluble vitamin deficiency (vitamins A and K). Anemia (chronic blood loss or malabsorption of iron, folate, or vitamin B_{12}), leukocytosis with eosinophilia, low serum levels or albumin, iron, cholesterol, and an extension of the prothrombin time are the most common laboratory findings in malabsorption (6,44). Impaired absorption of calcium and magnesium may induce weakness, paresthesias, and tetany. Osteopenia and bone pain, spontaneous fractures, and vertebral collapse may develop from vitamin D and calcium deficiency. Peripheral neuropathy may occur after gastric resection due to vitamin B_{12} deficiency. Weakness, severe weight loss, and fatigue result from caloric deprivation. In pancreatic carcinoma, floating, bulky, and malodorous stools and increased gas production are often associated with anorexia. Steatorrhea, peripheral lymphocytopenia, hypoalbuminemia, chylous ascites, and peripheral edema are the hallmarks of abnormalities of lymphatic transport. Symptoms of dumping syndrome after gastrectomy include early nausea, abdominal distention, weakness, and diarrhea after a meal, followed by hypoglycemia, sweating, dizziness, and tachycardia.

Other symptoms depend on the disorder that is causing the malabsorption. For example, an obstructed bile duct may cause jaundice; poor blood supply to the intestine

may cause abdominal pain.

Malabsorption is suspected when a person loses weight and has diarrhea and nutritional deficiencies despite eating well, although weight loss alone can have other causes in cancer patients.

Reviewing current drugs is important in the diagnostic evaluation. Colchicine, neomycin, and clindamycin are the most common drugs causing malabsorption, although the pathophysiologic mechanisms are unknown. Dietary phosphate absorption may be limited by use of aluminum-containing antacids, resulting in hypophosphatemia and hypercalciuria.

Laboratory tests can help confirm the diagnosis. Tests that directly measure fat in stool samples are the most reliable ones for diagnosing malabsorption of fat. Other laboratory tests can detect malabsorption of other specific substances, such as lactose or vitamin B_{12}. Undigested food fragments may mean that food passes through the intestine too rapidly.Such fragments also can indicate an anatomical abnormal intestinal pathway, such as a direct connection between the stomach and the large intestine that bypasses the small intestine. Small intestinal barium x-rays may define anatomical abnormalities after massive resection. Biochemical examination of the fecal material may give information about the origin of a fistula (pancreatic or enteric). Liver function tests and imaging of the liver or biliary tract may demonstrate parenchymal liver disease as a cause of decreased production of bile salts or a biliary tract obstruction.

Treatment

After assessing the causes of malabsorption, therapy should be directed to correct the deficiencies, including enzyme replacement, bicarbonate supplements, vitamins, calcium, magnesium, and iron. Pancreatic enzyme replacement along with a low-fat, high-protein diet is indicated in the case of malabsorption due to pancreatic insufficiency. The effectiveness of enzyme replacements is variable and, in part, depends on a high enough gastric pH to prevent their degradation in the stomach (51). Large doses of pancreatic extract are required with each meal. Sodium and bicarbonate, or anti-H_2 inhibitors and hydrogen pump inhibitors, are mainly added to raise the duodenal pH.

Fat intake should be strictly limited, especially in short-bowel syndrome. Medium-chain triglycerides may be substituted for long-chain triglycerides to improve fat absorption after a small intestinal resection, and they are useful in the presence of lymphatic obstruction because they do not require intestinal lymphatic transport (52).

For patients with prominent dumping, dietary modification comprising frequent small, dry meals that are high in protein and low in carbohydrates, along with ingestion of substances that prolong the absorption of carbohydrates, such as pectin, may be useful (5).

An aggressive approach should be reserved in the presence of severe malnutrition and dehydration, especially after surgery. Parenteral nutrition is strongly indicated in the immediate postoperative period after massive intestinal resection. The duration of parenteral nutrition is inversely proportional to the length of the remaining intestine. The weaning to oral nutrition depends on several variables including the preoperative nutritional state, the absorptive deficit, and the tolerance to oral intake. Oral feeding should be started as soon as possible, as adaptation of the remaining bowel to resection is facilitated by the early introduction of oral or enteral nutrients (53). Moreover, intraluminal nutrients stimulate trophic gastrointestinal hormones regulating mucosal repair. H_2-blocking agents may also favorably influence the rate of adaptation of remaining intestine after massive resection, possibly by a mucosal trophic effect improving nutrient absorption. Nutrients requiring minimal digestion for absorption should be chosen, such as commercial preparations containing simple sugars, amino acids, or oligopeptides, as well as medium-chain triglycerides. An excessive osmolar load should be avoided to prevent the occurrence of diarrhea. More complex food should be added gradually.

Vitamin B_{12} replacement is necessary after terminal ileal resection. H_2 blockers are used to treat the transient acid hypersecretion after extensive bowel resection or the acid hypersecretion state in patients with gastrinoma (Zollinger-Ellison syndrome) (44). Omeprazole inhibits the hydrogen-potassium proton pump and produces a greater antisecretory effect than that achieved by H_2-antagonist drugs alone. The use of cholestyramine should be carefully examined. It may be indicated in limited intestinal resections because it binds bile salts and prevents their irritant effects on the colon. However, in short-bowel syndrome after massive intestinal resection, it may reduce the bile salt pool, thus increasing fat malabsorption. The dose suggested is 4 g three times daily before meals. Aluminum hydroxide exerts similar effects.

Antibiotic-associated malnutrition requires discontinuation of any implicated antimicrobial agents. However, if there is stasis with bacterial overgrowth caused by impaired motility or stricture, such as in radiation enteritis or blind loop syndrome, broad-spectrum antibiotics should be administered. A 10-day course of a cephalosporin and metronidazole seems to be effective in suppressing the flora and correcting malabsorption. However, cyclic therapy may be needed (44).

In patients affected by malabsorption due to short-bowel syndrome, it is useful to reduce the intestinal output or the transit time. Codeine and loperamide can delay the transit time or reduce secretions (6). Somatostatin and, more recently, its derivative octreotide, have been used because of their ability to reduce gastric, pancreatic, and biliary secretions, as well as intestinal transit time. Octreotide possesses the same spectrum of effects as somatostatin but is more potent, has a long half-life, has less influence on insulin secretion than somatostatin, and, above all, can be administered by the subcutaneous route (21). Dosages from 0.2–0.6 mg daily have been advocated. It may reduce or shorten the use of parenteral administration in several postoperative conditions, such as enterocutaneous or pancreatic fistulae. Its use has been favorably reported in terminally ill patients (5). Reversal of a short segment of the bowel or construction of a recirculating loop have been advocated in patients with life-threatening malabsorption and uncontrolled weight loss. However, such operations may lead to stasis and bacterial overgrowth, and they may further compromise intestinal absorption. More often than not, these procedures fail to provide significant benefit (6).

CONSTIPATION

Constipation is extremely common in patients with cancer, especially in the advanced status of disease. Approximately 45% of hospice patients complain of constipation at admission (3,4,54). Constipation is defined in different ways as straining, hard stools, the desire but inability to defecate, infrequent stools, and abdominal discomfort. While stool weight and consistency are unreliable parameters because of the wide range in normal subjects (6), stool frequency is typically the most common parameter considered. A frequency of at least three bowel movements per week is viewed as an objective indicator of normality. In addition to causing discomfort, constipation affects daily living, nutritional intake, and socialization, thus compromising quality of life. Untreated constipation may progress to obstipation, which may potentially lead to life-threatening complications associated with bowel obstruction (55).

Pathophysiology

In cancer patients, constipation may be secondary to systemic diseases or those solely afflicting the gastrointestinal tract. It may be directly due to a cancer or to secondary effects of the cancer. Many drugs used by cancer patients may induce constipation. In Table 15-2, the most frequent causes of constipation are listed.

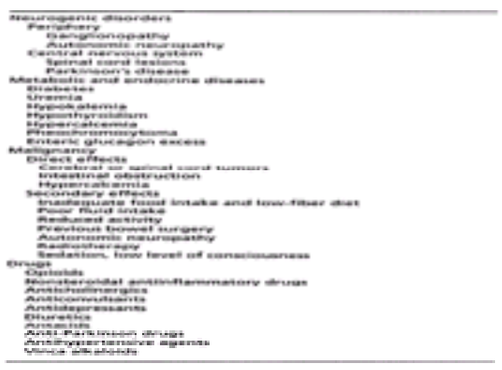

TABLE 15-2. CAUSES OF CONSTIPATION IN CANCER PATIENTS

Constipation is frequently noted by patients with various neurological disorders. A visceral neuropathy seems to be present in the majority of patients with severe slow-transit constipation. Disturbance in the extrinsic nerve supply to the colon has been found in these patients, along with a lack of inhibitory innervation of colonic circular muscle, and a diminished release of acetylcholine. Patients with advanced cancer frequently complain of gastrointestinal symptoms, including anorexia, chronic nausea, and early satiety—a symptom complex often associated with physical signs of an autonomic neuropathy. Autonomic neuropathy may also be manifested as severe constipation, including postural hypotension and resting tachycardia. It is a multifactorial syndrome, and malnutrition, decreased activity, diabetes, and drugs,

such as vinca alkaloids, opioids, and tricyclic antidepressants, are all possible causative factors (6).

Diabetic dysmotility has traditionally been thought to reflect a generalized autonomic neuropathy. However, secretions of gastrointestinal hormones may also be important. Decreased amounts of substance P in the rectal mucosa of constipated diabetic patients has been thought to contribute to the pathogenesis of diabetic constipation (56).

Peripheral neuropathy is a common complication of cancer chemotherapy. Patients receiving a high cumulative dose of vincristine or cisplatin seem to be at a significantly elevated risk for the development of long-term side effects (57). These drugs have been shown to cause symptoms of autonomic polyneuropathy with constipation, bladder atony, and hypotension. Whereas many reports describe acute neurological side effects during therapy, little is known about persistent and late damage to the peripheral nervous system. The long-term neurological side effects in patients with curable malignancies, such as Hodgkin's disease and testicular cancer, may be particularly troublesome.

Long-term denervation abolishes the normal pelvic floor muscle activity. This neurological impairment may be produced by nerve damage not only following chemotherapy, but also as a consequence of radiotherapy, pelvic surgery, compression, or invasion by neoplastic growth or during prolonged chronic opioid therapy. A loss of the normal rectal muscle tone is also a consequence of prolonged immobility often seen in debilitated cancer patients. Rectal sensation may be reduced and the rectal capacity to distention increased after vincristine treatment or as a consequence of neoplastic involvement of the pelvic sacral nerves (6). The rectosigmoid junction is a key area in the mechanism of constipation. Rectal outlet obstruction and failure of the puborectalis and anal sphincter muscles to relax are frequent findings in patients with neurological diseases with intractable constipation. Several mechanisms of constipation by outlet obstruction are possible, including a hyperactive rectosigmoid junction, an increased storage capacity of the rectum, spasticity, and hypertonicity of the anal canal with incoordination of the reflex between rectum and anus. Anismus is a spastic pelvic floor syndrome, recently termed *rectosphincteric dyssynergia*, for its similarity with vesicourethral dyssynergia. Similar extrinsic innervation of the bladder and the rectum has been observed, explaining why patients with severe slow-transit constipation often complain of urological symptoms.

The integrity of the spinal cord neurons is essential to maintain normal defecation. After spinal cord lesions above the lumbosacral area, incontinence is controlled but defecation is impaired. This is due to interruption of the cortical pathways, demonstrating the importance of supraspinal control of distal colonic function and defecation. Moreover, colonic response to a meal is reduced. However, appropriate stimuli may be sufficient to result in evacuation. In patients with damage to the cauda equina, transit time is prolonged and the rectoanal inhibitory reflex is weaker, offering little protection against fecal incontinence (19).

In cancer patients with Parkinson's disease, constipation is probably caused by the degeneration of the autonomic nervous system, particularly the myenteric plexus (58). Psychiatric and neurological diseases are frequently associated with colonic dysmotility (19).

Ogilvie's syndrome describes a variety of states with a similar clinical picture due to intrinsic defects in the intestinal smooth muscle, with a massive colonic dilatation in the absence of an obstruction or inflammatory process (59). Also termed as *pseudo-obstruction*, this syndrome can be categorized into those with myopathic and those with neuropathic features. Several conditions involving the intestinal smooth muscle are associated with colonic pseudo-obstruction, including endocrine and metabolic disorders, neurological diseases, nonoperative trauma, surgery, nonintestinal inflammatory processes, infections, malignancy, radiation therapy, drugs, and cardiovascular and respiratory diseases. Extensive damage to the submucosal and myenteric nerve plexus associated with lymphoid infiltrate has been observed as a specific disorder, different from other processes that produce intestinal pseudo-obstruction (60).

A large variety of metabolic disorders predispose to constipation. Of particular relevance to cancer patients are dehydration, hypercalcemia, hypokalemia, and uremia. Chronic dehydration can also result in dry stools that are difficult to expel. Many drugs induce constipation.

Many drugs with anticholinergic actions, antiemetics, and diuretics induce constipation. Patients treated with carbamazepine may develop severe constipation that is not dose related but is refractory to the concomitant use of oral laxatives, necessitating drug discontinuation (61). Selective 5-HT3-receptor antagonists cause constipation. They antagonize the ability of 5-HT to evoke cholinergically mediated contractions of the intestinal longitudinal muscle (62).

One of the most striking pharmacological features of opioids is their ability to cause constipation. Opioids cause constipation by binding to specific opioid receptors in the enteric and central nervous system. Opioid receptors have been identified on gut smooth muscle, suggesting that there is a local effect of opioid drugs, although central opioid effects cannot be excluded. Opioids affect the intestines by different mechanisms. Opioids augment the tone and nonpropulsive motility of both the ileum and the colon, thereby increasing transit time. Opioids desiccate the intraluminal content, either reducing secretion and increasing intestinal fluid absorption, with an indirect mechanism, possibly by tryptaminergic neurons in the myenteric plexus, resulting in the release of noradrenaline, which antagonize the secretory mechanism of the enterocytes, regulated by a-2 adrenoreceptors. Opioids may also suppress the release of the vasointestinal peptide, an inhibitory neurotransmitter. Vasointestinal peptide is a potent colonic secretagogue and an important inhibitor of smooth muscle contraction. Moreover, the prolonged bowel transit on its own may facilitate the increased intestinal absorption of fluid and electrolytes. Opioid use may lead to fecal impaction, spurious diarrhea, and bowel pseudo-obstruction, causing abdominal pain, nausea and vomiting, and interference with drug administration and absorption (19).

Oral morphine invariably causes constipation when used in repeated doses to treat cancer pain. Other common unwanted effects, such as sedation, nausea, and vomiting, tend to improve with continued use and often resolve completely. In contrast, it is commonly believed that opioid-induced constipation does not get better with repeated administration. However, long-term data suggest that a proportion of patients may become tolerant to the constipating effects of morphine with repeated administration (63). Other factors can contribute to slow intestinal transit, such as immobility, concomitant medications, disease-related factors, and so on. The importance of other factors for the development of constipation is demonstrated by the fact that approximately 50% of hospice patients not on opioids required regular oral laxatives (64). In another survey of patients admitted to hospice, 64% of patients not receiving opioid analgesia required laxatives.

The dose of laxative required seems to be significantly higher if an opioid is being taken than if not (65). Although there is no correlation between the dose of opioids and the dose of laxatives (63,64), an upward titration of laxatives in parallel to increasing doses of morphine has been observed (44). However, proportionally less laxative is required at a higher opioid dose. Approximate equivalents of laxatives and typical requirements of opioid therapy have been proposed, but there is clearly large individual patient variation (2).

Postoperative pain relief by both parenteral or intraspinal opioids is often associated with adynamic ileus. Gastric emptying and small bowel transit are inhibited. This is an important consideration for cancer patients undergoing surgical procedures in which the ileus is likely to be a severe problem. Epidural anesthesia with local anesthetics appears to disrupt gastrointestinal motility less than systemic opioids (6).

Assessment

There is evidence that the assessment and management of this symptom is frequently neglected by physicians and nurses. A minimal documentation on symptoms of constipation has been found in palliative care surveys (66). A careful history should be taken regarding the onset of constipation, bowel habits, and the use of laxatives. Patients who develop progressive constipation in the absence of any clear precipitating cause should be considered for an evaluation that may include determination of electrolytes and renal and hepatic function tests.

It is of paramount importance to first establish what the patient means by constipation: if stools are too small, too hard, too difficult to expel, too infrequent, or if patients have a feeling of incomplete evacuation after defecation. Impaction with overflow should be excluded by performing a rectal examination. Therefore, the first step is to completely evacuate the bowel. Multiple oil or saline enemas may be needed. Digital fragmentation is unpleasant, but may permit the great majority of fecal impactions in the rectum to be diagnosed. A pseudo-diarrhea in the presence of impaired anal sphincter function may be discovered. Gentle digital examination of the rectum may reveal a hard mass, a rectal tumor, rectal ulcers, an anal stenosis, anismus, or a lax anal sphincter. Patients with spinal cord lesions may have reduced sensation, but the anal tone is preserved, whereas patients with sacral nerve root infiltration will have a reduced anal tone. The examination of the abdomen may reveal fecal masses in the left iliac fossa. Fecal masses are usually not tender, are relatively mobile, and can be indented with pressure.

An abdominal radiograph may distinguish between constipation and obstruction. Examination after a barium meal may help to distinguish between paralytic ileus and mechanical obstruction. Barium studies may help reveal a small intestine motility dysfunction in chronic intestinal pseudo-obstruction. In visceral myopathy, intestinal contractions are infrequent, whereas with a visceral neuropathy, patients tend to have less distention and faster intestinal transit time due to uncoordinated contractions (59).

When constipation is due to ineffective colonic musculature, measurement of colonic transit time may be a useful tool to detect specific areas of the bowel that are not functioning properly. Pieces of radiopaque nasogastric tube are ingested and the progression of markers along the colon is observed by a daily radiograph until total expulsion. This study may demonstrate a delayed transit in the colon, a long storage of feces in the rectum, or a retrograde movement due to a distal spasm (67). A radiological constipation score has been proposed, assessing the amount of stool in each of the four abdominal quadrants (66).

Treatment

The management of constipation can be divided into general interventions and therapeutic measures. An extensive effort should be made to find a specific cause of constipation, and then treatment can be directed at that cause. Etiologic factors, such as physiologic consequences of cancer-associated debility, biochemical abnormalities, including hypercalcemia and hyperkalemia, and drug use, should be identified and reversed wherever possible. An adequate fluid intake is helpful to increase the stool water content (68).

Fluids, fruit juice, fruit, and bran are all recommended. However, fiber deficiency is unlikely to account for a lower stool weight, and there is no justification for the claim that treatment with bran can return stool output and transit time to normal. In far-advanced cancer patients, the use of high amounts of fiber is beyond the capacity of most patients (69). Moreover, dietary fiber seems to have no prophylactic value to prevent constipation in hospitalized patients. Fiber consumption may relatively decrease fluid intake, thus paradoxically worsening the situation (6).

As an unfavorable toilet environment, such as lack of privacy or inappropriate posture, may lead to constipation, patients should be provided privacy and appropriate facilities in the hospital setting.

When irreversible causes of constipation cannot be directly treated, symptomatic relief should be provided. Moreover, in spite of prophylaxis, most of these patients will require chronic laxatives, especially in the advanced stage of their disease or when treated with chronic opioid therapy. It is appropriate to begin prophylactic laxative treatment in patients with risk factors for constipation, including the elderly, those who are bedridden, or those requiring drugs known to cause constipation (70).

A low-rectal impaction should be removed manually. Appropriate sedation and analgesics are usually required to make this procedure comfortable. A more proximal mass can be broken by a sigmoidoscope or by delivering a pulsating stream of water against the stool. The use of enemas and rectal interventions is limited to the acute short-term management of more severe episodes. Therapeutic interventions for the management of constipation are based on the administration of laxatives, either orally or rectally. Laxatives are commonly used in advanced cancer patients. Sixty-two percent of patients admitted to hospice received laxatives regularly (64). Laxatives will promote active electrolyte secretion, decrease water and electrolyte absorption, increase intraluminal osmolarity, and increase hydrostatic pressure in the gut. Although laxatives can be divided into several groups, no agent acts purely to soften the stool or to stimulate peristalsis. Clinical criteria, responsiveness, acceptability, and the patient's preference should guide the selection of the drug. Table 15-3 outlines different medications useful for constipation.

Drug	Category	Comments
Docusate	Stool softener	Acts in 1–3 d, prevents hard stool formation, not together with mineral oil
Mineral oil	Lubricant	Useful in acute impaction
Senna	Contact	Acts on distal colon after conversion
Cascara	Contact	Dose-related colics
Bisacodyl	Contact	Effective within 12–24 h
Lactulose	Osmotic	Dose-related cramps, gaseous distention, effective after 2 d, useful in hepatic encephalopathy
Magnesium salts	Osmotic	Rapid evacuation, not in renal failure
Cisapride	Prokinetic	Mild laxative effect, anticholinergics may decrease cisapride's effects
Naloxone	Opioid antagonist	Possible withdrawal syndrome

TABLE 15-3. DIFFERENT MEDICATIONS USEFUL FOR CONSTIPATION

Laxatives

Patients with advanced cancer are likely to have chronic constipation and will need continuous laxative treatment. No data exist to guide the clinician or patient in the optimal choice of laxatives, as there have been no adequate comparative studies of long-term management of opioid-induced constipation. One of the main limitations of such trials is the lack of reliable clinical assessment tools. In a randomized, crossover clinical trial of laxatives in a hospice, lactulose/senna combination produced a significantly greater stool frequency than codanthramer in patients receiving opioids and reduced the usage of rectal measures, although the penalty for this achievement was an increased likelihood of diarrhea (71). In a comparative study conducted with the objective of determining treatment and cost efficiency for senna and lactulose in terminal cancer patients treated with opioids, no difference was found between the laxatives in defecation-free intervals or in days with defecation (72). In a recent systematic review, the use of docusate for constipation in palliative care has been found to be based on inadequate experimental evidence (73). In a study of healthy volunteers, in which constipation was induced by loperamide, a combination of stimulant and softening laxatives was most likely to maintain normal bowel function at the lowest dose and least adverse effects. Senna was associated with significantly more adverse effects than the other laxatives (74).

Bulk-Forming Agents

Bulk-forming agents are high-fiber foods containing polysaccharides or cellulose derivatives resistant to bacterial breakdown. These agents increase stool bulk and correct its consistency by increasing the mass and the water content of the stool. Evidence of their effect may take 24 hours or more. Their effectiveness and feasibility in the advanced cancer patient are doubtful, as they require the patients to drink extra fluids to prevent viscous mass formation.

Emollient Laxatives

Emollient laxatives are surfactant substances not adsorbed in the gut, acting as a detergent and facilitating the mixture of water and fat. They also promote water and electrolyte secretion. Stimulant laxatives are the most commonly used drugs to treat constipation. They are represented by the anthraquinone derivatives, such as senna, cascara, and danthron, and the diphenylmethane derivatives, such as bisacodyl and phenolphthalein. This class of drugs acts at the level of the colon and distal ileum by directly stimulating the myenteric plexus. Senna is converted to an active form by colonic bacteria. As a consequence, its site of action is primarily the colon. Danthron and the polyphenolic agents bisacodyl and sodium picosulfate undergo glucuronidation and are secreted in the bile. The enterohepatic circulation may prolong their effect. An increase in myoelectric colonic activity has been observed after administration of oral senna. Bisacodyl stimulates the mucosal nerve plexus, producing contractions of the entire colon and decreasing water absorption in the small and large intestine. Castor oil is metabolized into ricinoleic acid that has stimulant secretory properties and an effect on glucose absorption. All of these drugs may cause severe cramping. The cathartic action occurs within 1–3 days. Starting doses proposed are 15 mg daily of senna, 50 mg daily of danthron, or 10 mg daily of bisacodyl. Bisacodyl suppositories promote colonic peristalsis with a short onset due to the rapid conversion to its active metabolite by rectal flora. Docusate alone or in combination with danthron is most commonly used at doses of 100–300 mg every 8 hours. The effectiveness of docusate has been questioned (69).

Lubricant Laxatives

Lubricant laxatives are represented by mineral oil. It may be useful in management of transient acute constipation or fecal impaction, but has a little role in the management of chronic constipation. It lubricates the stool surface. Coated feces may pass more easily and colonic absorption of water is decreased. It may also decrease absorption of fat vitamins. Absorption of small amounts may cause foreign-body reactions in bowel lymphoid tissue. Liquid paraffin, 10 cm^3 day, may be given orally or rectally with an effect noted in 8–24 hours.

Hyperosmotic Agents

Hyperosmotic agents are not broken down or absorbed in the small bowel, drawing fluid into bowel lumen. Lactulose increases fecal weight and frequency but may result in bloating, colic, and flatulence, as well as electrolyte imbalances at high doses. Moreover, it is expensive in comparison to other preparations. The latency of action is 1–2 days. Starting doses are 15–20 ml twice a day. Saline laxatives exert an osmotic effect, increasing the intraluminal volume. They also appear to directly stimulate peristalsis and increase water secretion. The starting dose is 2–4 g daily. Magnesium, sulfate, phosphate, and citrate ions are the ingredients in saline laxatives. Saline laxatives usually produce results in a few hours. Their use may lead to electrolyte imbalances with accumulation of magnesium in patients with renal dysfunction or an excessive load of sodium in hypertensive patients. Moreover, their administration may result in an undesirable strong purgative effect. Administered rectally, they stimulate rectal peristalsis within 15 minutes. Repeated use of a phosphate enema may cause hypocalcemia and hyperphosphatemia or rectal gangrene in patients with hemorrhoids. Glycerin can be used rectally as an osmotic and lubricant agent.

Prokinetic Drugs

Cisapride is a prokinetic agent that appears to accelerate orocecal transit and to stimulate the colon. Cisapride enhances the release of acetylcholine from the myenteric nerve endings. It is devoid of the central antidopaminergic effects that limit the use of metoclopramide. It has been shown to correct impaired propulsion in the small bowel of patients with pseudo-obstruction. Suggested doses are in the range of 2.5–10 mg four times a day. Metoclopramide given by the subcutaneous route, but not by oral route, seems to be effective in narcotic bowel syndrome. Effects of metoclopramide are mediated by a central and peripheral antidopamine effect, and a stimulation of cholinergic receptors (19).

Opioid Antagonists and Opioid Therapy Modification

Opioid-induced constipation can be severe and refractory to therapy with conventional laxatives. Opioid concentration in the enteric nervous system correlates better with opioid-induced, prolonged, intestinal transit time than concentrations in the central nervous system (75,76). Naloxone is a competitive antagonist of opioid receptors inside and outside the central nervous system and, after systemic administration, it reverses both centrally and peripherally mediated opioid effects. There is now evidence that oral administration of naloxone can reverse opioid-induced constipation, without causing systemic opioid withdrawal in most patients. This route of administration theoretically allows selective blocking of intestinal opioid receptors without blocking the desired opioid effects, as long as hepatic first-pass capacity is not exceeded. The low systemic bioavailability due to marked hepatic first-pass metabolism allows for the low plasma levels and high enteric wall concentration (75). Oral administration of naloxone at a daily dose of approximately 20% of the daily morphine dose is capable of providing a clinical laxative effect without antagonizing opioid analgesia (77). In another study, the mean dose of naloxone was 17.5 mg/day. Adverse effects of short duration, including yawning, sweating, and shivering, were observed in approximately one-third of patients (78). While oral naloxone doses below 2–4 mg, or 10% or less of the morphine dose are mostly ineffective (78,79), opioid withdrawal may present. Reversal of analgesia does not seem to be an early symptom of systemic opioid antagonism (79).

In the former reports, the naloxone dose has been based on the preexisting morphine dose and expressed in percentages of daily morphine (75,76,77,78 and 79). However, the reaction to opioid antagonists seems to be proportional to the degree of opioid tolerance rather than to opioid concentration, and the risk of systemic withdrawal may increase if the same percentage relationship is used in patients with high opioid doses (80). It has been suggested that the initial dose of naloxone should not exceed 5 mg (75). Dose titration, beginning with a dose of 0.8 mg twice daily and doubling the dose every 2 to 3 days until favorable effects occur or adverse effects are experienced, independently of the preexisting morphine usage, may be a reasonable approach (75,81). Methylnaltrexone is an opioid antagonist that cannot penetrate the blood–brain barrier and has been shown to reverse morphine-induced delay of gastric emptying and intestinal transit time after intravenous infusion in volunteers (82). In a pilot study of subjects receiving chronic methadone therapy, low doses of intravenous methylnaltrexone effectively reversed chronic methadone-induced constipation and delay in gut transit time (83). It deserves future studies in cancer patients with opioid-associated constipation.

Constipation is an adverse effect that rarely requires modification of opioid therapy. However, there is a rationale in changing the route of administration. The use of a parenteral administration should result also in a change of the opioid concentration at intestinal receptors. However, in a retrospective study no difference in the doses of laxatives required to maintain regular bowel movements in patients receiving oral versus subcutaneous opioids was found (84).

Among opioids there may be differences in the analgesia/constipation ratio. Clinical studies have revealed that at doses of oral morphine and transdermal fentanyl that yield equivalent pain relief, constipation differs significantly between the two drugs (85,86,87 and 88). Although the majority of early studies were not randomized, different methodologies were used, and the analysis was performed while switching patients from oral morphine to transdermal fentanyl, more recent trials are remarkably consistent in that transdermal fentanyl causes less constipation than oral sustained-morphine at the same level of analgesia (89).

Differences in pharmacological profiles, in the affinity to opioid receptor and a higher exposure of opioid-binding receptors in the gastrointestinal tract following oral administration of morphine compared with transdermal administration of fentanyl, may offer an explanation for the clinically observed different constipation-inducing potentials of equipotent doses of morphine and fentanyl. The lipophilicity profile of fentanyl allows for the ease with which fentanyl penetrates the brain. As less opioid is required to produce a central analgesic effect, less opioid is available in the peripheral circulation to induce constipation. Experimental studies using a castor-oil–induced diarrhea model have shown a more favorable analgesia/constipation ratio of subcutaneous fentanyl as compared with oral morphine, although the difference was less pronounced with oral fentanyl. Considerably larger amounts of naloxone were needed to reverse the morphine than the fentanyl-induced antidiarrheal effects (90).

Methadone has a high oral bioavailability, a rapid and extensive distribution phase, followed by a slow elimination. The end of the distribution phase is at or below the minimum effective concentration necessary for an effect. This may result in limiting the continuous bathing of intestinal receptors. The high lipophilicity of methadone allows for the maintenance of a low plasma concentration with a relevant clinical effect. Constipation seems to be the symptom that mostly improves after opioid switching (91). This could be simply due to different tolerance of different opioid at the level of receptors located in the bowel. Moreover, different reports have shown that methadone therapy may cause less constipation than morphine (92,93). In a retrospective analysis, the laxative/opioid dose ratio was lower in patients receiving methadone than in patients on morphine (94).

Therapeutic Strategy

Local measures to soften fecal mass are necessary in case of rectal impaction. The short latency of action of rectal laxatives may be useful to remove hard feces impacted in the rectum. Glycerin suppositories or sorbitol enemas soften the stool by osmosis, also lubricating the rectum wall. Water penetration may be facilitated by a stool softener. Saline enemas cannot be regularly administered and should be used as a last resort if suppositories fail. Any patient requiring an enema should be reevaluated for a possible laxative dose titration.

Practical and economic consideration may influence the choice of drug according to the setting (home, hospital, hospice, or palliative care unit). While stimulant agents may cause painful colic, softener drugs may be useful in the presence of a hard stool. Peristaltic stimulants are indicated in patients unable to pass soft stool. Senna is the most useful drug in the presence of soft feces in the rectum. All patients commencing opioid analgesia should have a prophylactic laxative unless a contraindication exists, although periodic laxative-free intervals have been advocated for patients with a relatively long prognosis to avoid tolerance (70,81).

Laxative dose should usually be titrated according to the response and not according to the dose of opioids. The opioid dose increments do not determine laxative efficacy, indicating that constipating effect of opioids is not a function of dose. Combination therapy with different mechanisms may be more useful when higher doses of one laxative are required (72). In patients suspected of having intestinal obstruction, laxatives with a softening action may be tried (64). However, treatment should be immediately interrupted when transit stops. Patients with colostomies require the same treatment. Before using stimulating agents, an obstruction should be excluded in the absence of feces in a colostomy. Paraplegic patients often require regular manual evacuation. Glycerin and bisacodyl suppositories should be given in patients with cauda equina syndrome. They may also benefit from the use of cisapride. Opioid switching may be indicated in cases in which there are serious therapeutic difficulties in maintaining bowel transit. Opioid switching as well as the use of opioid antagonists should be carefully monitored.

BOWEL OBSTRUCTION

MATTHEW LUBLIN
DOUGLAS J. SCHWARTZENTRUBER

BACKGROUND

Abdominal symptoms in oncology patients are quite common. Opioids, chemotherapeutic agents, and tumor can lead to abdominal pain, constipation, and vomiting. These symptoms are frequent and can be confused with mechanical bowel obstruction. Bowel obstruction may be a primary presentation or secondary complication of a malignancy. Bowel obstruction can involve either the upper or lower gastrointestinal tract, and the site of obstruction determines management. Initial management is generally conservative and consists of hydration and nasogastric decompression. The decision to proceed with surgical intervention needs to be individualized to each patient. It is one of the more frequent reasons for emergency abdominal surgery in cancer patients (1,2).

Palliative management of bowel obstruction is often required in the oncology patient. Determining the course of palliative therapy can be challenging, and one must balance the individual patient's needs and desires with clinically sound judgment. Oncology patients can either be palliated medically or surgically. End-stage patients and patients who are not surgical candidates should receive medical palliation.

INCIDENCE

Upper gastrointestinal obstruction in the general population is more commonly caused by malignancy than ulcer disease, as a result of the introduction of proton pump inhibitors and H_2 blockers (3,4). Gastric carcinoma is the most common malignancy causing gastroduodenal obstruction, followed by pancreatic carcinoma (4). Obstruction is the initial presentation in 17.5% of patients with gastric cancer (5). Patients with pancreatic cancer initially present with upper gastrointestinal obstruction 6% of the time (6). After diagnosis, the incidence of gastroduodenal obstruction increases (7,8). In a review of 350 patients with pancreatic cancer, 25% of patients with unresectable disease developed gastroduodenal obstruction (6).

In contrast to gastroduodenal obstruction, small bowel obstruction in the general population is less commonly the result of malignancy. In a review of 238 patients with a diagnosis of small bowel obstruction, malignancy was the third most common cause of obstruction (7%) behind adhesions and hernia, accounting for 88% (9). The incidence of small bowel obstruction is much higher in the cancer population and is generally secondary to cancers arising at other sites. In a review of 518 patients with ovarian cancer, 127 patients (14%) developed intestinal obstruction (10). A direct correlation was reported between the stage of disease and the frequency of obstruction. In colorectal cancer, 41 of 472 (10%) patients developed small bowel obstruction after primary resection of their cancer (11).

Unlike small bowel obstruction, acute colonic obstruction in the general population is caused by primary malignancy of the colon in the majority of patients. Primary colorectal carcinoma was the cause of colon obstruction in 53% of 300 patients, whereas only 6% of obstructions were caused by extrinsic compression of the colon from metastases (12). In another study of 127 patients presenting with acute colonic obstruction, 99 (78%) were caused by primary colon cancer and 15 (12%) were caused by noncolonic carcinoma (13).

ETIOLOGY

In the majority of oncology patients, symptoms of nausea, vomiting, abdominal pain, and constipation are nonobstructive in origin. Certain chemotherapeutic agents cause nausea and vomiting as well as constipation. Vincristine sulfate may cause constipation or adynamic ileus. Forty-six percent of patients receiving vincristine sulfate, in one series, reported constipation, abdominal pain, or both (14). Nonchemotherapeutic agents (e.g., narcotic analgesics and anticholinergics) may lead to adynamic ileus. Also, patients with malignancy often are bedridden, inactive, malnourished, dehydrated, and have electrolyte imbalances. These states can lead to bowel dysmotility and the resultant clinical presentation may mimic mechanical bowel obstruction.

When present, mechanical bowel obstruction may involve the upper or lower gastrointestinal tract. The anatomical sites of obstruction in three combined series were small bowel (48%), colorectal (37%), both (4%), and gastroduodenal (11%) (15,16 and 17). Gastroduodenal obstruction is rarely benign in nature in the oncology patient. The obstruction may be secondary to a primary stomach cancer or by direct extension from kidney, pancreas, biliary, or colon carcinoma. Ovarian carcinoma can lead to gastroduodenal obstruction as well (18).

In contrast to gastroduodenal obstruction, a significant percentage of small bowel obstructions occurring in the cancer patient are benign. In the reviewed series, a median of 32% of small bowel obstructions were the result of benign processes such as adhesions from previous oncological operations (Table 16-1). However, the majority of small bowel obstructions (59–100%) were caused by recurrence of intraabdominal malignancy. Few patients present with primary small bowel tumors as the cause of obstruction (19). A primary small bowel tumor (adenocarcinoma, sarcoma, carcinoid, and lymphoma) should be suspected in patients with abdominal pain, weight loss, and occult gastrointestinal bleeding (20). Metastatic small bowel lesions should be considered in patients with these symptoms along with a history of cancer of the ovary, colon, stomach, pancreas, and breast, or melanoma.

TABLE 16-1. INTESTINAL OBSTRUCTION IN PATIENTS WITH A PREVIOUS DIAGNOSIS OF MALIGNANCY

Colorectal, ovarian (gynecological), and gastric are the most common (nearly three-fourths) sites of primary tumor in patients with subsequent small bowel obstruction (15,17,21,22,23,24,25,26,27,28 and 29). Less frequent are a variety of other intraabdominal and extraabdominal sites of tumor [e.g., pancreas (15,17,21,22,23,24 and 25), melanoma (21,22,30), breast (21,23,24), lung (21,22,23,24 and 25,31), and mesothelioma (22,23 and 24)]. Melanoma is the most common cause of malignant intussusception in the adult population (32). Thus, small bowel lesions may cause obstruction by their intraluminal occlusion, extraluminal compression, or by

intussusception (20,30,33).

Colorectal cancer can lead to obstruction of the colon as well as small bowel obstruction. Primary large bowel obstruction is most commonly caused by colon carcinoma (78% of patients) (13). Noncolonic malignancy (12%) and benign causes (10%) account for the rest. Approximately 15–20% of patients with colon carcinoma present with obstruction (34,35,36 and 37). Due to the increased diameter of the right-sided colon and the fecal consistency, left-sided colon cancer obstructs more readily than right-sided malignancies. Intussusception is an infrequent mechanism of obstruction in these patients (13,38). Ovarian and prostate carcinoma may obstruct the colon by peritoneal carcinomatosis or direct extension, respectively. Twelve percent of 379 patients with ovarian carcinoma developed rectosigmoid obstruction (39). Extraabdominal cancers, such as breast cancer metastases, may lead to large bowel obstruction (40).

As mentioned previously, not all bowel obstructions in cancer patients are mechanical in nature. A patient presenting clinically with obstructive symptoms may have intestinal dysmotility or pseudo-obstruction. The pathophysiology of pseudo-obstruction in the oncology patient has been attributed to denervation of the bowel and mesentery by carcinoma, metastatic infiltration of the celiac plexus, and paraneoplastic syndromes (41). Ogilvie's syndrome, classically described, specifically refers to pseudo-obstruction as a result of extraabdominal metastatic carcinoma invading the celiac plexus leading to sympathetic denervation (42). Small cell carcinoma of the lung, malignant thymoma, and retroperitoneal leiomyosarcoma have all been associated with intestinal pseudo-obstruction (41,43,44). These patients were all noted to be free of gastrointestinal involvement by their tumors at exploratory laparotomy despite obstructing symptoms. Recently, antibodies have been identified in small cell lung carcinoma that preferentially bind to neuronal elements in the small bowel (45).

DIAGNOSIS

After a careful history and physical examination are performed and blood is obtained for studies, patients admitted with obstructive symptoms (e.g., nausea, vomiting, constipation, crampy abdominal pain, and abdominal distention) should undergo radiographical evaluation with plain films of the abdomen (supine and upright) and chest. Patients with nondiagnostic plain abdominal films, atypical history or physical examination, or protracted courses without resolution of obstructive symptoms are candidates for further studies.

When a small bowel obstruction is suspected but not confirmed radiographically, abdominal computed tomography (CT) may be helpful. As many as 34% of patients with obstructive symptoms may have indeterminate or equivocal plain radiographs, resulting in delayed management (46). In this patient population, an abdominal CT scan is invaluable for diagnostic accuracy. In a recent study of 32 patients presenting with clinical suspicion of intestinal obstruction, abdominal CT had a higher sensitivity (93%) and specificity (100%) than plain radiographs (77% and 50%, respectively) in diagnosing obstruction (47). Therefore, an abdominal CT should be reserved for patients with an unclear diagnosis after plain films.

Upper gastrointestinal radiographic contrast studies with small bowel follow-through may be useful in further delineating a small bowel obstruction. Barium is generally more useful than water soluble contrast agents for identifying a distal obstruction because it does not become diluted by gastrointestinal secretions. If barium remains in the small bowel, it does not become inspissated because the small bowel lacks the water absorptive capacity of the colon. However, a disadvantage of barium studies is the need to cleanse the bowel of this agent before performing subsequent CT scans. Perhaps the greatest benefit of the upper gastrointestinal series is in patients with intermittent or partial small bowel obstruction.

For patients with suspected colonic obstruction, or both small and large bowel obstructions and no perforation, barium enema can be quite useful in determining the presence of large bowel obstruction. In 79 patients with suspected mechanical large bowel obstruction by plain abdominal radiograph, contrast enema confirmed the diagnosis in 50 patients (63%). However, one-third had free flow of contrast and were not obstructed (48). In another study, 35 of 99 patients (35%) with suspected mechanical large bowel obstruction by abdominal radiographs were found to be nonobstructed by contrast enema. In 11 of these 35 patients, colonic pseudo-obstruction was diagnosed (49). A barium enema should be terminated promptly if the fluoroscopist detects an obstructing lesion. The colon can absorb water from the barium, which then becomes inspissated above a partially obstructing lesion, making subsequent colonic cleansing very difficult.

MANAGEMENT OF MECHANICAL OBSTRUCTION

Overview

An algorithm describing the management of a suspected malignant mechanical bowel obstruction is presented in Figure 16-1. At initial presentation, a history, physical examination, and abdominal plain films should be routinely performed. Obstructed patients are usually dehydrated and have electrolyte imbalances due to persistent vomiting and the inability to tolerate oral liquids. All patients should be aggressively intravenously hydrated and given nothing by mouth. A nasogastric tube should be placed to relieve obstructive symptoms and electrolytes should be determined and corrected. Once the patient is adequately stabilized and hydrated, therapeutic strategies can be entertained.

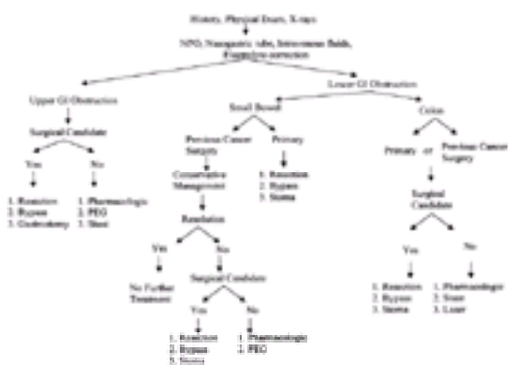

FIGURE 16-1. Management algorithm for malignant bowel obstruction. GI, gastrointestinal; NPO, nothing by mouth; PEG, percutaneous endoscopic gastrostomy.

When an upper gastrointestinal obstruction is diagnosed, the etiology is generally secondary to a malignancy. If the patient is able to tolerate an operation, a resection and anastomosis or a gastroduodenal bypass should be performed. If the patient is not a surgical candidate, pharmacological palliation or less invasive medical procedures can be offered.

In the setting of small bowel obstruction, patients with a previously resected malignancy may be managed with a trial of conservative therapy. If the obstruction resolves, no further treatment is warranted. If the obstruction persists for greater than 3–7 days, patients that are not surgical candidates are managed pharmacologically. Patients able to tolerate an operation should undergo an exploratory laparotomy with the intention of reestablishing gastrointestinal continuity. The procedure may involve enterolysis for benign obstruction, or resection, bypass, or a diverting ostomy for recurrent cancer.

In contrast to small bowel obstruction, mechanical colonic obstruction is not managed initially by a trial of conservative therapy. If the patient is able to tolerate an operation, a resection should be attempted when feasible. Patients with large tumor burden can be managed either by bypass or stoma creation. Patients unable to tolerate a surgical procedure can be managed pharmacologically or by less invasive laser therapy or stenting.

Initial Management

In the absence of fever, leukocytosis, or peritonitis, patients with obstructive symptoms deserve a trial of conservative therapy. Patients need to be monitored with serial physical examinations (preferably by the same clinician) and with daily abdominal radiographs. Such treatment in nonselected cases of partial small bowel obstruction may result in resolution of symptoms in up to 88% of patients (50). In the oncology patient, nasogastric decompression, intravenous hydration, and electrolyte replenishment results in spontaneous resolution of small bowel obstructions in 12–29% of patients (Table 16-1) in a mean of 3–7 days (24,25 and 26). Forty-one percent of patients (median) need to be readmitted for conservative or surgical management of recurrent obstruction (Table 16-1). Bowel strangulation and gangrene is rare in these circumstances (0–5%) (21,23,24 and 25,51), with the exception of one series, in which it occurred in 24% of patients (26). Preoperative recognition of bowel strangulation cannot be done reliably in patients with complete mechanical obstruction (52).

The choice of nasogastric tube or long intestinal tube (i.e., Miller-Abbott, Cantor, Baker) for decompression is individualized by the physician. Both tubes have been reported to have similar success in complete small bowel obstruction (53,54), although long tubes were associated with longer hospitalization (54). A recent randomized

study has failed to identify the superiority of one tube over the other (55). Partial small bowel obstruction has a higher success rate (88%) when treated with nasogastric decompression. A long tube yielded similar results as treatment with a nasogastric tube (50). The most common practice is to use the nasogastric tube because of its ease of placement and effectiveness in decompressing the upper gastrointestinal tract. Long tubes are more difficult to get into position (i.e., pass beyond the duodenum) but can be effective in decompressing the more distal bowel. They may be useful in delineating a site of obstruction by failing to pass beyond the obstructed point or serving as a port for instillation of radiographic contrast agents. Long tubes may also prove useful intraoperatively when faced with carcinomatosis and dense adhesions. Locating a suitable segment of small bowel for bypass may be facilitated by this tube.

Therefore, when managing patients with small bowel obstruction after oncologic surgery, an initial trial of conservative therapy is warranted in clinically stable patients. If the patient deteriorates or fails to improve after a clinically acceptable length of therapy, surgical therapy can be offered.

Surgical Management

Gastroduodenal

When patients present with gastroduodenal obstruction, the goal is to reestablish gastrointestinal continuity with curative intent or at least provide palliation. Surgical resection (if possible) or, alternatively, bypass should be undertaken. Only 15% of pancreatic patients are resectable for cure at time of diagnosis (56) and less than 20% of patients survive for more than 1 year after diagnosis (57). Therefore, palliative procedures are of primary importance in this patient population. Thirteen percent to 21% of patients with pancreatic cancer who do not undergo a gastrojejunostomy at initial exploration eventually do require a gastrojejunostomy for palliation of gastric outlet obstruction (8,56,58). Due to these findings, many favor prophylactic gastrojejunostomy at the time of initial exploration, once unresectability is determined (7,8,59). Palliation is not always achieved with gastrojejunostomy. Delayed gastric emptying may occur after the procedure, leading to significant postoperative morbidity (7,60,61). Recently, laparoscopic gastroenterostomy has been introduced for the treatment of gastroduodenal obstruction. The procedure can be performed safely with minimal operative times. Good palliation of nausea and vomiting can be expected (62,63).

Small Intestine

As many as one-third of cancer patients undergoing surgery for small bowel obstruction with a previous diagnosis of cancer may have adhesions or a benign cause of obstruction (Table 16-1). In this setting, operative success in resolving their symptoms is usually high. Still, the majority of obstructions in patients with a previous cancer diagnosis are tumorrelated (median, 74%). Forty-eight percent to 96% of patients (median, 79%) can be surgically relieved of their symptoms. A variety of surgical procedures have been performed to relieve the small bowel obstruction (Table 16-2). Bypass is the most commonly performed procedure, followed by stoma creation and then resection. Recurrent obstruction after successful surgical relief of symptoms occurs in 9–33% of patients (Table 16-1). Operative morbidity (median, 31%) and mortality (median, 16%) are high and reflect the generally ill nature of this patient population. Treatment options are similar for a small bowel obstruction caused by a primary small bowel tumor or an extraabdominal carcinoma with a metastasis to the small bowel. Patients should be managed by resection with primary anastomosis, when appropriate, or by bypass, if resection is not warranted or possible.

TABLE 16-2. SURGICAL PROCEDURES TO RELIEVE OBSTRUCTION IN CANCER PATIENTS

Colon

The surgical management of right-sided and transverse colonic obstruction secondary to a primary colonic malignancy is similar to small bowel obstruction. Right hemicolectomy for obstructing right colon lesions or extended right hemicolectomy for transverse colon lesions followed by primary anastomosis is generally considered safe in emergent conditions without preoperative bowel preparation (13,36,64,65). Obstructing carcinoma of the splenic flexure can be managed by extended right hemicolectomy and immediate anastomosis (64,65), although including these lesions in a left colon resection is also a valid option. The best approach is one individualized for the patient and comfortable to the surgeon.

The surgical management of obstructing left colon and sigmoid lesions is evolving from the traditional three-stage procedure to a two-stage procedure and, most recently, a single-stage procedure (36,64,66,67). The presence of peritoneal soiling or inflammation, the condition of the bowel, the stability of the patient, and ultimately the judgment and expertise of the surgeon will dictate the approach used. All three methods have a role that depends on the clinical setting. The three-stage procedure for lesions distal to the splenic flexure involves (a) creation of a proximal (transverse colon) decompressing colostomy, (b) elective resection of the lesion in the mechanically cleansed bowel and primary anastomosis, and (c) colostomy closure.

Presently, a two-stage procedure is the more common approach and consists of primary resection with the creation of a proximal end colostomy and Hartman pouch or mucous fistula (36). The second stage reestablishes bowel continuity. Retrospective data as well as one randomized study (68) support the use of a two-stage as opposed to a three-stage approach.

The most recent trend in treating obstructing left colon lesions has been a single-step segmental resection and primary anastomosis in selected patients (63,69,70,71,72,73,74,75 and 76). Currently, onestage procedures for obstructing left colon lesions are not advocated in the presence of fecal peritonitis, a large continuous pelvic abscess, or systemic sepsis (66). To accomplish a onestage procedure in highly selected populations and maintain a low incidence of anastomotic leak, a variety of approaches that allow mechanical bowel cleaning have been advocated. Preoperative techniques include endoscopic laser relief of obstruction (77), passage of a rectal tube over guidewire (78), colonic irrigation via long intestinal tube (79), and percutaneous colonic irrigation (80). Intraoperatively, a technique of intracolonic bypass with a silastic and latex tube has been described (81). Gaining popularity is intraoperative colonic irrigation as advocated by a variety of groups (63,69,70,71,72,73 and 74). The technique consists of proximal (cecal) infusion of saline and distal (above the obstruction) collection of luminal contents in a closed system. After resection and mechanical cleansing, a primary anastomosis is performed. The most aggressive approach of subtotal/total colectomy and ileocolonic/ileorectal anastomosis obviates the need of mechanical bowel cleansing (34,82,83 and 84). The subtotal colectomy can decrease the operative time and complexity associated with colonic irrigation. Any synchronous tumors are removed as well.

The first prospective randomized multicenter trial comparing subtotal colectomy to segmental resection after intraoperative irrigation was recently completed (85). Mortality and complication rates did not differ significantly between the two groups. However, patients undergoing subtotal colectomy reported increased bowel movement frequency and increased visits to their general practitioners for bowel problems.

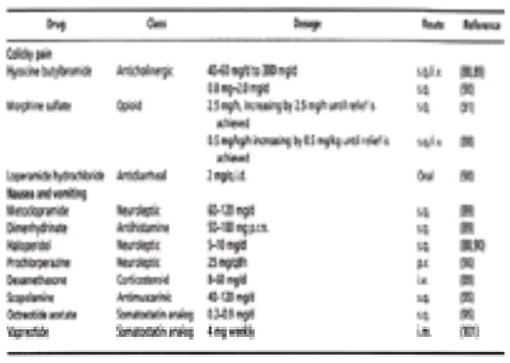
Curative resection for malignant colonic obstruction is not possible in all patients. Patients with unresectable disease, whether secondary to a primary, recurrence, or carcinomatous, may be palliated by bypass or stoma. For highrisk patients, a proximal diverting colostomy is still a viable alternative (86). Loop colostomies (independent of location) are generally easier to create and close than divided colostomies, and can be totally diverting (87).

Medical Management

Pharmacological

Pharmacological palliation is most often administered to end-stage cancer patients. The goal is to decrease symptoms associated with bowel obstruction. Therefore, pharmacological therapy should attempt to decrease abdominal pain, alleviate nausea and vomiting, reduce gastrointestinal secretions, and, at times, increase bowel motility. Hyoscine butylbromide and opioids (morphine sulfate) are the most frequently used agents to control colicky abdominal pain (Table 16-3) (88,89,90 and 91).

These agents may be delivered intravenously, rectally, or subcutaneously (92,93). Loperamide hydrochloride has also been used to relieve intestinal colic (90).



Drug	Class	Dosage	Route	Reference
Colicky pain				
Hyoscine butylbromide	Anticholinergic	40–60 mg/d to 300 mg/d	s.c./i.v.	[88,89]
		0.8 mg–2.0 mg/d	s.c.	[90]
Morphine sulfate	Opioid	2.5 mg/h, increasing by 2.5 mg/h until relief is achieved	s.c.	[91]
		0.5 mg/kg/h increasing by 0.5 mg/kg until relief is achieved	s.c./i.v.	[88]
Loperamide hydrochloride	Antidiarrheal	2 mg/q.i.d.	Oral	[90]
Nausea and vomiting				
Metoclopramide	Neuroleptic	60–120 mg/d	s.c.	[89]
Dimenhydrinate	Antihistamine	50–100 mg q.s.n.	s.c.	[89]
Haloperidol	Neuroleptic	5–10 mg/d	s.c.	[88,90]
Prochlorperazine	Neuroleptic	25 mg/q8h	p.r.	[90]
Dexamethasone	Corticosteroid	8–60 mg/d	i.v.	[89]
Scopolamine	Antimuscarinic	40–120 mg/d	s.c.	[95]
Octreotide acetate	Somatostatin analog	0.3–0.9 mg/d	s.c.	[95]
Vapreotide	Somatostatin analog	4 mg weekly	i.m.	[101]

TABLE 16-3. PALLIATIVE PHARMACOLOGICAL THERAPY

Emesis is controlled by a variety of different classes of pharmacological agents. Metoclopramide, dimenhydrinate, and haloperidol have all been administered subcutaneously to alleviate nausea and vomiting (88,89 and 90). Prochlorperazine (given rectally) and dexamethasone (given intravenously) have also been used (Table 16-3) (89,90).

For prophylaxis against crampy abdominal pain and nausea/vomiting, pharmacological agents have been employed that decrease gastrointestinal secretions. Hyoscine butylbromide, scopolamine, and octreotide acetate have all been used subcutaneously to successfully decrease gastrointestinal secretions (94,95). In one of these studies, the use of scopolamine or octreotide acetate led to the successful removal of nasogastric tubes in all 13 patients with end-stage cancer (95). Further, octreotide acetate may lead to a quicker resolution of symptoms related to bowel obstruction (95,96).

Continuous subcutaneous administration of octreotide acetate may reduce gastrointestinal secretions and control vomiting (97,98). Octreotide acetate exerts its effect by inhibiting the secretion of gastrointestinal enzymes, gastric acid, and water (98). Khoo and associates were the first to use octreotide acetate to palliate the symptoms of malignant bowel obstruction in 1992. Eighteen of 24 patients had a decrease in the amount of nasogastric tube aspirate and vomiting (99). Based on these results, octreotide acetate was used successfully to prevent the occurrence of complete bowel obstruction in two patients with partial bowel obstruction (100). Vapreotide, a new long-acting somatostatin analog, produces effects similar to octreotide acetate with weekly intramuscular administration (101).

Corticosteroids may have palliative effects because they are able to reduce the edema surrounding tumors (102). By reducing edema, steroids may lessen the extrinsic or intrinsic compression of the bowel lumen and relieve symptoms (102). A meta-analysis studying the use of corticosteroids and bowel obstruction could only conclude a trend towards the resolution of bowel obstruction at a dose range of 6–16 mg intravenously. Further study was recommended (103).

Optimal pharmacological management may permit the hydration of some terminally ill patients without the need for intravenous support. When the oral intake of fluids is contraindicated, the intravenous route may be used. Home care with intravenous hydration and pharmacological support has been successful in some series (104,105). However, intravenous access is often difficult in these patients. Hypodermoclysis is an option for hydration in terminally ill cancer patients. One liter of fluid can be administered subcutaneously in a safe and effective manner (106). Total parenteral nutrition is another option for hydration in this patient population. However, the risks from total parenteral nutrition are much greater than from simple hypodermoclysis (107).

Percutaneous Gastrostomy

When pharmacological management fails to control symptoms in patients that do not have surgical options, percutaneous endoscopic gastrostomy (PEG) may be an effective procedure to relieve symptoms of obstruction. PEG placement offers an alternative to nasogastric tube decompression and surgical gastrostomy when treating malignant upper gastrointestinal or small bowel obstructions. The PEG tube allows patients to resume oral intake and avoid nasogastric discomfort. In select patients with mostly gynecologic malignancies, palliation has been obtained successfully by PEG placement (108,109,110,111 and 112). In one study, 22 of 24 patients with advanced malignancies were able to tolerate liquids by mouth after PEG placement (5). Complications from PEG placement are mostly minor (e.g., superficial wound infections) (113). In addition, most patients can return home to continue palliative care (112,113).

Laser

Another palliative procedure less invasive than surgery for the relief of malignant bowel obstructions is endoscopic laser therapy. The laser has been used most frequently in select patients for left-sided colonic obstruction (77,114,115 and 116). The neodymiumyttrium aluminum garnet (Nd- YAG) laser is the most commonly used laser for palliation of symptoms. In a series of 117 patients treated with laser therapy for distal colonic obstruction, 89% of patients were successfully treated by initial endoscopic laser therapy. A mean number of seven sessions over a period of 7 months was needed to achieve long-term palliation in 65% of patients (116). Laser therapy has also been used concomitantly with metallic stents for distal colonic obstruction (117,118). After initial treatment of the obstruction with laser therapy, a metallic stent is inserted to increase colonic patency and decrease the need for repeated laser treatments (119). Obstructed patients with significant colorectal pain are best not treated by endoscopic laser therapy, as pain persists after treatment (116).

Stenting

Endoscopic metallic stenting is increasingly used for the management of upper gastrointestinal and left-sided colon obstruction. Whereas stenting for upper gastrointestinal obstruction is always palliative in nature, stenting for colorectal obstruction may be used as a bridge to definitive surgical treatment as well as palliation.

Most stents are placed radiographically in a similar fashion. The site of obstruction is visualized under fluoroscopy with an injection of radiologic contrast. Next, a guidewire is placed across the stricture with either endoscopic or fluoroscopic guidance or both. The self-expandable metal stent is then threaded over the guidewire and across the obstruction, and released into position. Once placed, repeat contrast injection is used to verify position and rule out perforation (120).

Endoscopically or fluoroscopically placed metallic stents have been used selectively for the treatment of malignant gastroduodenal obstructions (121,122 and 123). Gastroduodenal obstructions caused by pancreatic, gastric, and bile duct cancers, as well as lymphoma, have all been treated by metallic stenting (124,125 and 126). Upper gastrointestinal stents have been placed in the esophagus, stomach, duodenum, and across previous surgical anastomoses (124,127,128). Technical success in stent placement is greater than 90% in all series reviewed except one (Table 16-4). After successful stent placement, 85% or more of patients experience clinical improvement and are able to tolerate an oral solid or liquid diet. Major and minor complications related to the placement of the stents are uncommon. However, some stents migrate and obstruct over time. The average stent patency from four series with long-term follow-up was 67 days (121,124,128,129). Stent patency is difficult to determine in this patient population, as many patients expire before stent occlusion. It should be noted that stents are placed in a highly selected patient population and high success rates are due to retrospective analyses without prospective or randomized studies. Still, the stenting of malignant upper gastrointestinal obstructions remains an attractive, simple procedure to relieve vomiting and the inability to eat in selected patients.

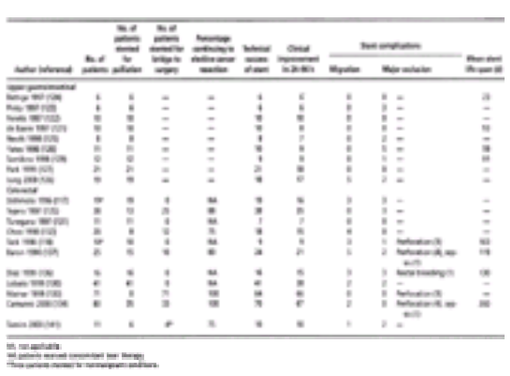


TABLE 16-4. USE OF PALLIATIVE STENTS IN BOWEL OBSTRUCTION

Stenting is more commonly performed for the resolution of malignant colorectal obstruction than upper gastrointestinal obstructions. In this setting, metallic wall stents may be employed for either palliation of obstruction in end-stage patients or as a bridge to further definitive surgical management (130,131 and 132). The use of preoperative stenting allows nonsurgical decompression of the colon and avoids an emergent colostomy. Decompression allows adequate bowel preparation and preoperative optimization. Further, metallic stents have been used after initial laser treatment to maintain colorectal patency (117,118 and 119). Successful placement of stents for either palliation or preoperative decompression is achieved in the vast majority of patients (Table 16-4). Once placed, obstructive symptoms are relieved in 87–100% of cases. Palliative stents are capable of maintaining patency for a mean of 103–200 days. When stents are placed for initial decompression as a bridge to definitive surgery, greater than 85% of patients are able to undergo definitive one- or two-stage surgical resection as evidenced in the three largest studies (133,134 and 135). Minor complications related to the stent placement itself include anorectal pain, bleeding, and tenesmus (117,133,136). Stenting can lead to perforation or sepsis at the time of the procedure itself or by stent migration (134,137). Once in place across the obstruction, stents may eventually migrate or occlude.

MANAGEMENT OF NONMECHANICAL OBSTRUCTION

Patients with malignancy may present with nonmechanical colonic obstruction during their course of disease. Colonic pseudo-obstruction has been managed both pharmacologically and by colonoscopic decompression. A mechanical obstruction must be excluded before the initiation of pharmacological management. Neostigmine has been used effectively to relieve colonic pseudo-obstruction in the nonmalignant setting (138). Further study is warranted to assess the efficiency of neostigmine in pseudo-obstruction associated with malignancy. Use of the prokinetic agent cisapride has also been studied for the treatment of nonmalignant pseudo-obstruction. Cisapride did improve symptoms related to obstruction, but results were similar to a placebo control (139).

Most patients with colonic pseudo-obstruction can be conservatively managed initially with a trial of bed rest, intravenous fluids, and pharmacological therapy. When symptoms worsen or risk of complication increases, colonoscopic decompression is warranted. Perforation from cecal dilatation is the most severe complication of colonic pseudoobstruction. Cecostomy was used in the past to prevent this complication. Successful decompression is now performed with colonoscopy. The majority (68%) of patients are effectively relieved of pseudo-obstruction by colonoscopy (140). If colonoscopy fails, either a right hemicolectomy or cecostomy should be performed for definitive management.

CONCLUSION

Mechanical bowel obstruction in cancer patients is managed initially with intravenous hydration and nasogastric tube placement and correction of electrolyte abnormalities. When possible, mechanical gastroduodenal and colonic obstruction should be treated surgically. Patients with small bowel obstruction should receive a trial of conservative therapy, which may lead to resolution of symptoms. The decision to proceed with surgical intervention in the small bowel ultimately needs to be individualized to each patient.

Palliative management of bowel obstructions, either medical or surgical, is often required in the oncology patient. Medical palliation by administration of a variety of pharmacological agents can control symptoms of nausea, vomiting, pain, and distention in patients who are not surgical candidates. Minimally invasive surgical procedures (e.g., percutaneous endoscopic gastrostomy, laser therapy, and stenting) may palliate symptoms without the need for pharmacological support.

DIAGNOSIS AND MANAGEMENT OF ASCITES

JAY R. THOMAS
CHARLES F. VON GUNTEN

EPIDEMIOLOGY

Ascites, the accumulation of fluid in the abdomen, is common in patients with certain types of end-stage cancer. Its formation may be a direct result of a malignant process or secondary to unrelated comorbidity. Because the pathophysiology of fluid collection varies, treatment strategies differ. Clinical distinction between the causes of ascites is therefore imperative.

Of all patients with ascites, approximately 80% have cirrhosis (1). Other causes of nonmalignant ascites are accounted for as follows: heart failure, 3%; tuberculosis, 2%; nephrogenic ascites related to hemodialysis, 1%; pancreatic disease, 1%; and miscellaneous entities such as hepatic vein thrombosis (Budd-Chiari syndrome), pericardial disease, and the nephrotic syndrome account for approximately 2% (1). Only 10% of patients who have ascites have a malignancy as the primary cause (1). In these patients, epithelial malignancies, particularly ovarian, endometrial, breast, colon, gastric, and pancreatic carcinomas, cause over 80% of malignant ascites. The remaining 20% are due to malignancies of unknown origin (2). In one study, Runyon has shown that 53.3% of malignant ascites is associated with peritoneal carcinomatosis, 13.3% is associated with massive liver metastases, 13.3% is associated with peritoneal carcinomatosis and massive liver metastases, 13.3% is associated with hepatocellular carcinoma with portal hypertension, and 6.7% is associated with chylous ascites (3).

In general, the presence of ascites portends a poor prognosis, regardless of the cause. Patients with nonmalignant ascites related to cirrhosis have a survival rate of approximately 50% at 2 years (1). The mean survival in patients with malignant ascites is generally less than 4 months (4). However, with ascites due to a malignancy that is relatively sensitive to chemotherapy, such as newly diagnosed ovarian cancer or lymphoma, the mean survival may improve significantly to 32 and 58 weeks, respectively (4).

PATHOPHYSIOLOGY

Nonmalignant Ascites

The mechanisms that lead to the development of ascites are many, and controversy exists regarding which factors are most important. The most common cause of nonmalignant ascites is cirrhosis of the liver. In cirrhotic ascites, abnormal sodium retention is mediated by various hormonal and neural mechanisms, similar to those responsible for excess fluid retention in congestive heart failure. A hemodynamic state exists where total blood volume is increased, cardiac output is increased, and systemic vascular resistance is low. Studies have implicated nitric oxide as one potential mediator of this arterial vasodilation (5). In response, the vasoconstrictors of the renin-angiotensin-aldosterone system and the sympathetic nervous system are activated. Although atrial natriuretic peptide levels are increased, there is reduced renal responsiveness (6). In addition, arginine vasopressin, a potent vasoconstrictor, is activated in a manner independent of the osmotic state (7). The net result is an increase in total body sodium and water. In conjunction with cirrhosis, which has caused increased hepatic venous and lymphatic resistance, severe portal hypertension ensues. The increase in hepatic venous sinusoidal and portal pressures causes the excess fluid volume to localize to the peritoneal cavity secondary to fluid transudation from the splanchnic capillary bed. Ascites accumulation is also exacerbated by diminished intravascular oncotic pressure, resulting from hypoalbuminemia due to decreased synthetic capacity of the cirrhotic liver.

Malignant Ascites

Malignant ascites arises via different pathophysiological mechanisms. In peritoneal carcinomatosis, tumor cells on the peritoneal surface of the abdominal cavity interfere with normal venous and lymphatic drainage, causing fluid to “leak” into the abdominal cavity. In addition to direct tumor involvement of the peritoneal surface, there is also evidence of indirect involvement mediated by humoral factors. Researchers have identified a vascular permeability factor that increases fluid leak from the peritoneal vasculature; vascular endothelial growth factor is a prime candidate for this activity (8). Portal pressures may also be raised by direct tumor invasion of the liver with resultant hepatic venous obstruction. The resultant portal hypertension leads to transudation of fluid across the splanchnic bed into the abdominal cavity. A final mechanism of ascites formation is due to lymphatic obstruction, commonly caused by lymphoma, resulting in chylous ascites.

DIAGNOSIS

History

Patients with ascites commonly notice an increase in abdominal girth, a sensation of fullness or bloating, and early satiety. Other useful historical features include recent weight gain or ankle swelling. Patients may describe vague, generalized abdominal discomfort or a feeling of heaviness with ambulation. They may also note indigestion, nausea, and vomiting due to delayed gastric emptying, esophageal reflux symptoms due to increased intraabdominal pressure, or protrusion of the umbilicus.

Physical Examination

Physical examination for ascites includes inspection for bulging flanks, percussion for flank dullness, a test for shifting dullness, and a test for a fluid wave. Jugular venous distention should also be assessed, as it may indicate a potentially reversible cardiac cause of ascites.

The abdominal flanks bulge when significant ascites is present due to the weight of abdominal free fluid. The examiner should look for bulging flanks when the patient is supine. The distinction between excess adipose tissue and ascites may be made by percussing the flanks to assess for dullness (Fig. 17-1). To detect flank dullness in the supine patient, approximately 1500 ml of fluid must be present (9).

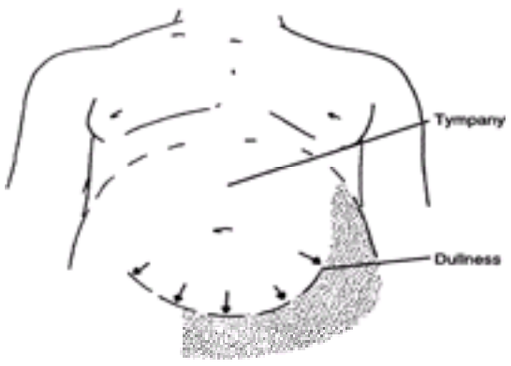

FIGURE 17-1. Shifting dullness.

If dullness to percussion is found, examination for shifting dullness is a useful maneuver. The flank is tapped, and a mark is made on the skin at the location where the tone changes. The patient is then turned partially toward the side that has been percussed. If the location of the dullness shifts upward toward the umbilicus, it is further evidence of intraabdominal ascites (Fig. 17-2).

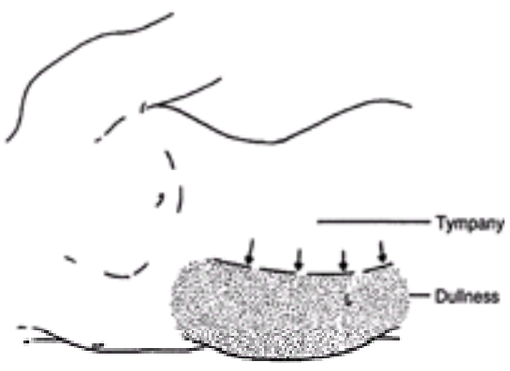

FIGURE 17-2. Tympany and dullness.

The elicitation of a fluid wave may also help to confirm the diagnosis. The test is performed by having an assistant place the medial edges of both hands firmly down the midline of the abdomen to block transmission of a wave through subcutaneous fat. The examiner places his/her hands on the flanks and then taps one flank sharply while simultaneously using the fingertips of the opposite hand to feel for an impulse transmitted through the ascites to the other flank. This test is 90% specific, but only 62% sensitive (10).

Several additional aspects of the physical examination may also be helpful. The liver may be ballotable if it is enlarged and ascites is present. If ascites is severe, the examiner may discern umbilical, abdominal, or inguinal hernias; scrotal or lower extremity edema; or abdominal wall venous engorgement. The umbilicus may be flattened or slightly protuberant. Two additional maneuvers that have been described for the physical diagnosis of ascites, the puddle sign and auscultatory percussion, are not recommended (10).

Several diagnostic tests may be useful, particularly if the physical examination is equivocal. A plain radiograph of the abdomen may demonstrate a hazy or ground-glass pattern. Ultrasonography or computed tomography of the abdomen readily identify as little as 100 ml of free fluid. These latter tests are most helpful in making the diagnosis when there is a relatively small amount of fluid, or when loculation is present.

Laboratory Abnormalities

A diagnostic paracentesis of 10–20 ml of fluid is useful to confirm the presence of ascites. More importantly, it is essential to help determine its cause. Identifying the cause has profound implications for what treatment is attempted.

To perform paracentesis, one of two locations is chosen. The first is a midline location 2 cm inferior to the umbilicus. This location is over the linea alba, which is typically avascular. The second is a location 2 cm superior and medial to the anterior iliac spine and lateral to the edge of the rectus sheath, avoiding entry into the inferior epigastric artery. Ultrasonography may be performed if the fluid is difficult to obtain, loculation is suspected, or surgical scarring is present. Previous surgery in the area of the procedure increases the possibility that the bowel may be adherent to the abdominal wall.

After careful cleansing and local anesthetizing, a 2-inch, 20-gauge angiocatheter is attached to a 20-ml syringe. To minimize the risk of leaking fluid after the procedure, the **Z** technique is performed. The skin is displaced 2 cm relative to the deep fascia. The needle is slowly advanced while a small amount of negative pressure is intermittently applied through the syringe until ascitic fluid is obtained. The intermittent pressure helps to avoid trapping omentum or bowel against the needle tip. After the necessary amount of fluid has been obtained, the needle is withdrawn. The fascial planes overlap to prevent fluid leakage, a common complication with a more direct approach.

The color of the fluid should be noted. A white milky fluid is characteristic of chylous ascites. Bloody fluid is almost always malignant in origin, although it may be due to abdominal tuberculosis. Initial bloody fluid that clears is more likely related to the trauma of the procedure.

The fluid should undergo cytologic analysis and determinations of cell count with differential and total protein concentrations. A Gram's stain with culture should be performed if infection is suspected. Inoculation of ascites directly into blood culture bottles increases the sensitivity of detecting infection up to 85% (11). Cytology is the most specific test to demonstrate that the ascites is due to malignancy. Cytology is approximately 97% sensitive with peritoneal carcinomatosis (3), but is not helpful in the detection of other types of malignant ascites. Therefore, the absence of malignant cells does not exclude malignancy as a cause. The cell count, particularly the absolute neutrophil count, is useful in the presumptive diagnosis of bacterial peritonitis. If the neutrophil count is greater than 250 cells/ml, bacterial peritonitis is presumed.

The total protein concentration has been used to classify ascites into the broad categories of exudate (total protein >25 g/l) or transudate (total protein <25 g/l). However, this classification system has limitations and sometimes fails to lead to optimal treatment. It has been superseded by the serum-ascites albumin gradient (SAAG). It is defined as the serum albumin concentration minus the ascitic fluid albumin concentration. The SAAG directly correlates with portal pressure (12). Patients with a SAAG of 1.1 g/dl or more have ascites that is due in part to increased portal pressures, with an accuracy of 97%. Patients with a SAAG less than 1.1 g/dl do not have portal hypertension, with an accuracy of 97% (13).

The superiority of the SAAG to the exudate/transudate characterization is shown by two examples. Cardiac ascites is associated with portal hypertension and would be expected to be transudative; however, the total protein levels in cardiac ascites are often exudative (13,14). Furthermore, ascites associated with spontaneous bacterial peritonitis (SBP) would be expected to be exudative consistent with an infection. However, SBP almost exclusively develops in low protein content ascites associated with portal hypertension, and total protein levels are typically in the transudative range (13).

MANAGEMENT

Overall goals for patient care should be considered before specific choices for managing ascites are made. The prognosis, expected response to management of the underlying conditions, and preferences for treatment should be established with the patient and family before any treatment plan is instituted. Each ascites treatment modality has associated burdens and benefits that deserve to be considered and discussed.

The discernment of the ascites as having a low or high SAAG is critical in determining the overall management plan. Ascites due to portal hypertension *is* in equilibrium with total body fluid. The most common cause of nonmalignant ascites, cirrhosis, falls within this category. Efforts to restrict salt and to affect fluid balance with diuretics are often successful. Malignant ascites may or may not be responsive to these efforts, depending on its cause. In peritoneal carcinomatosis and chylous ascites, the SAAG is low, there is no portal hypertension, and the ascites *is not* in equilibrium with total body fluid (15). Consequently, salt and fluid restriction and diuretics may be of little use. Their injudicious use may result in intravascular volume depletion, diminished renal perfusion, azotemia, hypotension, and fatigue (2). There are forms of malignant ascites with a high SAAG. For example, in cases of massive hepatic metastasis, portal hypertension is present. The resulting malignant ascites is responsive to salt restriction and diuretics (15). One exception to this rule is nephrotic syndrome in which the SAAG is low but the ascites is diuretic responsive (16). See Table 17-1 for a summary.

Cause of ascites	Serum-ascites albumin gradient	Typical diuretic response
Cirrhosis	High (≥1.1 g/dl)	Yes
Alcoholic hepatitis	High (≥1.1 g/dl)	Yes
Cardiac ascites	High (≥1.1 g/dl)	Yes
Fulminant hepatic failure	High (≥1.1 g/dl)	Yes
Budd-Chiari syndrome	High (≥1.1 g/dl)	Yes
Portal vein thrombosis	High (≥1.1 g/dl)	Yes
Veno-occlusive disease	High (≥1.1 g/dl)	Yes
Acute fatty liver of pregnancy	High (≥1.1 g/dl)	Yes
Myxedema	High (≥1.1 g/dl)	Yes
Tuberculosis (without cirrhosis)	Low (≤1.1 g/dl)	No
Pancreatic ascites (without cirrhosis)	Low (≤1.1 g/dl)	No
Biliary ascites (without cirrhosis)	Low (≤1.1 g/dl)	No
Nephrotic syndrome	Low (≤1.1 g/dl)	Yes
Serositis from connective tissue disease	Low (≤1.1 g/dl)	No
Bowel obstruction/infarction	Low (≤1.1 g/dl)	No
Mixed ascites (i.e., cirrhosis plus infection or cancer)	High (≥1.1 g/dl)	Yes
Peritoneal carcinomatosis	Low (≤1.1 g/dl)	No
Massive hepatic metastasis	High (≥1.1 g/dl)	Yes

TABLE 17-1. CAUSES OF ASCITES AND DIURETIC RESPONSIVENESS

Interventions for ascites management in the supportive or palliative care setting should generally be reserved for patients who are symptomatic. The following symptoms may spur the need for intervention when the ascites seems to be responsible for or contributing to

- Dyspnea
- Fatigue
- Anorexia or early satiety
- Nausea/vomiting
- Pain
- Diminished exercise tolerance

Dietary Management

The dietary management of ascites with a high SAAG begins with sodium restriction. Patients with cirrhosis may excrete as little as 5–10 mEq of sodium per day in their urine. Limiting sodium intake to 88 mmol or 2 g/day (equivalent to 5 g of sodium chloride per day) is an attainable goal for a motivated patient but does make food less palatable. Considering a patient's goals of care, it may be better to liberalize the sodium intake and control ascites through other methods.

Patients are also prone to develop dilutional hyponatremia. The management of this condition has typically been fluid restriction to 1 l/day. In the patient with advanced disease, when treatment goals are purely palliative, fluid restriction is usually intolerably burdensome. Judicious medical management may be less burdensome. For patients with cirrhotic ascites, serum sodium levels as low as 120 mmol/l are well tolerated and rarely dictate intervention (1).

Medical Management

For the majority of patients, the medical management of ascites is palliative. That is, the goal of therapy is to minimize symptoms and optimize quality of life without the expectation that the underlying cause can be reversed. *Systemic chemotherapy* may be an effective management strategy for patients with ascites due to a responsive malignancy (e.g., lymphoma, breast, or ovarian cancer). In addition to systemic chemotherapy, intraperitoneal treatment with chemotherapeutic and biological agents is being pursued. Intraperitoneal chemotherapy can deliver high doses to peritoneal sites with minimal systemic side effects. Phase III trials have been performed with ovarian and colon cancer. Alberts et al. showed that, in conjunction with intravenous cyclophosphamide, intraperitoneal cisplatin versus intravenous cisplatin significantly increased survival, to 49 months from 41 months (17). Vaillant et al. showed that a short period of intraperitoneal 5-fluorouracil after surgery for colon cancer decreased recurrence for stage II but not stage III (18). Biologically active agents have also been used intraperitoneally to treat malignant ascites. These include interferon (IFN)-a, IFN-b, IFN-g, tumor necrosis factor, and interleukin-2 (19). Early clinical trials have yielded mixed results. For example, tumor necrosis factor-a has yielded conflicting results with malignant ascites (20,21). To date, no phase III clinical trials have been performed. Thus, the overall efficacy and role of intraperitoneal chemotherapeutic and biological agents in both curative and palliative care remains to be determined.

Diuretic therapy is useful for some patients, particularly those whose ascites has a high SAAG. As with any drug therapy in the supportive care setting, the patient's symptoms should first be ascertained and the benefit versus the burden of therapy considered. The goal of diuretic therapy is to reduce extravascular fluid accumulation. Diuretic therapy should be directed to achieve a slow and gradual diuresis that does not exceed the capacity for mobilization of ascitic fluid. In the patient with ascites and edema, edema acts as a fluid reservoir to buffer the effects of a rapid contraction of plasma volume. Approximately 1 l/day (net) can safely be diuresed. In patients with ascites but without edema, diuresis may be achieved at the expense of the intravascular volume, leading to symptomatic orthostatic hypotension. In these patients, a more modest goal is to achieve net diuresis of 500 ml/day. Diuretics should not be administered with the goal to render the patient free of edema and ascites. Rather, only enough fluid should be mobilized to promote the patient's comfort. Overly aggressive diuretic therapy for ascites in a patient with nonmalignant ascites due to cirrhosis has been associated with the hepatorenal syndrome and death (22). There are no reports of hepatorenal syndrome associated with paracentesis for malignant ascites.

In patients with ascites for whom diuretics may be helpful, the renin-angiotensin-aldosterone system is activated. Therefore, the initial diuretic of choice for management is one that acts at the distal nephron to block the effect of increased aldosterone activity (23,24). Spironolactone, beginning with 100 mg/day and titrated up to effect or 400 mg/day, is often a useful agent with which to begin (Table 17-2). Given the long half-life of spironolactone, daily dosing is all that is needed. Spironolactone may cause painful gynecomastia (25). Amiloride hydrochloride, 10 mg/day, is an alternative. It is faster acting and does not cause gynecomastia. It can be titrated up to a dose of 40 mg/day. Because these diuretics are relatively potassium sparing, patients should be advised not to use salt substitutes, as these are usually preparations of potassium chloride. If patients have a suboptimal response despite maximal use of the distal diuretics, a loop diuretic may be added, beginning at low doses (e.g., furosemide, 40 mg orally daily). There is evidence to support the combined use of a distal tubule diuretic and a loop diuretic at the beginning of therapy (24). This combination may effect a more rapid diuresis while maintaining potassium homeostasis. A ratio of 100 mg of spironolactone to 40 mg of furosemide is recommended as a starting point (1). The ratio can be adjusted to maintain normokalemia. The dosages can be increased in parallel until the goals of therapy have been attained, up to a maximum of spironolactone, 400 mg/day, and furosemide, 160 mg/day, or until therapy is limited by side effects (1). If there is no response to this level of therapy, the ascites is considered refractory to diuretic therapy if the following are true: (a) salt intake is appropriately limited, and (b) nonsteroidal anti-inflammatory medications, which can affect glomerular filtration, are not being used.

Diuretic	Major site of action	Dosage range	Comments
Spironolactone	Distal tubule	100–400 mg/d	Long half-life; gynecomastia
Amiloride hydrochloride	Distal tubule	5–40 mg/d	–
Triamterene	Distal tubule	100–300 mg/d	–
Furosemide	Loop of Henle	40–160 mg/d	–
Ethacrynic acid	Loop of Henle	50–200 mg/d	Can be used for sulfa allergy

TABLE 17-2. DIURETICS

In the patient who has limited mobility, urinary tract outflow symptoms such as hesitancy and frequency, poor appetite, and poor oral intake, or who has difficulties related to polypharmacy, diuretic therapy may be excessively burdensome. Injudicious diuretic therapy can result in incontinence (with attendant self-esteem and skin care issues), sleep deprivation from frequent urination, fatigue from hyponatremia or hypokalemia, and falls from postural hypotension.

Patients with cirrhotic ascites with low protein content are at increased risk of SBP (26). This increased risk may be due to decreased opsonin levels in the ascites (27). Patients with SBP may be asymptomatic or may note fever, abdominal pain, nausea/vomiting, or mental status changes. Studies have indicated that antibiotic prophylaxis is effective in preventing SBP. Norfloxacin, 400 mg/day, ciprofloxacin, 750 mg/week, or one trimethoprim and sulfamethoxazole (Septra DS)/day Monday through Friday as primary prophylaxis significantly decrease the risk of developing SBP (28,29,30). Liver transplant protocols call for the routine use of SBP prophylaxis (31). Prophylaxis raises the concern of drug-resistant organisms. The long-term clinical significance remains unknown, but after 6 months on once a week ciprofloxacin there was no evidence of resistance (29). The use of prophylaxis in an individual case is dependent on the overall treatment goals and the disease context.

Therapeutic Paracentesis

Large-volume therapeutic paracentesis (³5 liters) with concurrent colloid infusion is a simple procedure and is associated with minimal morbidity or mortality (32,33). The symptom response is much faster than when diuretics are used alone. In the patient with refractory ascites it may be the only therapeutic modality that is effective. In fact, total paracentesis (mean, 10.7 liters) associated with colloid infusion has been shown to be safe (34). If the ascites is in equilibrium with the systemic circulation, as is the case with portal hypertension, there is a risk of hemodynamic compromise. Colloid plasma volume expansion (e.g., 6–8 g of albumin per liter of ascites removed) has been used to avoid this complication, but its use remains controversial. Ginès et al. (33) performed large-volume paracentesis with and without albumin. They demonstrated that without albumin, they could measure increases in blood urea nitrogen, plasma renin, and aldosterone, and decreases in plasma sodium, which were avoided by the infusion of intravenous albumin. Antillon and Runyon (35) argue that these laboratory value changes are asymptomatic and do not necessarily indicate increased morbidity or mortality. Kao et al. performed large-volume paracentesis (5 liters) on diureticresistant patients with tense ascites without the infusion of albumin and noted no significant hemodynamic compromise (36). Runyon argues that the discrepancy may be due to patient population differences. Further studies may elucidate under what circumstances colloid is and is not indicated. Although albumin is expensive, it is not known to cause harm. Practitioners may opt to use colloid for large-volume paracentesis until more definitive guidelines exist for ascites due to portal hypertension.

Surgical Procedures

Liver transplantation offers cure for a subset of patients with cirrhosis (31) and a subset of patients with small hepatocellular carcinoma (37).

Other surgical techniques offer palliation. Peritoneovenous shunts have been reported for management of malignant and nonmalignant ascites. They are placed surgically during a 30- to 60-minute procedure while the patient is under local anesthesia. Their purpose is to drain ascites from the peritoneal space via a one-way valve into the thoracic venous system. Unfortunately, the rate of complications is high, including shunt occlusion, heart failure due to fluid overload, infection, and disseminated intravascular coagulation. Stanley et al. (38) and Gines et al. (39) studied serial paracentesis compared with peritoneovenous shunts in patients with cirrhosis. There was no survival improvement and a high rate of complications with the peritoneovenous shunts. Similarly, Gough and Balderson (40) compared peritoneovenous shunts with nonoperative management in patients with malignant ascites. They found no difference in survival or quality of life. Thus, although there may be specific cases in which peritoneovenous shunting is advantageous in either nonmalignant or malignant ascites, serial paracentesis remains the first-line therapy.

Externally draining, implanted abdominal catheters may be beneficial for selected patients who require repeated large-volume paracentesis for comfort and whose prognosis warrants a surgical procedure. The catheter is surgically placed in the peritoneal cavity with an external drain, which can be accessed intermittently by physicians, nurses, or even trained family members (41). There are no comparative studies between these implanted catheters and serial paracentesis in patients with cirrhotic or malignant ascites. A study of 17 patients with an implanted catheter and abdominal carcinoma was complicated by two cases of cellulitis, one case of peritonitis, and eight cases of asymptomatic culture-positive ascites (42). With no guidance from the literature, use of implanted catheters must be individualized.

The transjugular intrahepatic portosystemic shunt (TIPS) is a procedure performed by interventional radiologists that creates a side-to-side shunt that effectively relieves portal hypertension. For patients with cirrhosis and refractory ascites with relatively good hepatic and renal function, TIPS is considered the treatment of choice. Rossle et al. showed that in comparison to serial large-volume paracentesis, TIPS led to a higher rate of ascites resolution and improved survival without transplantation and without an increase in the risk of hepatic encephalopathy (43). There was, however, almost a 40% rate of shunt malfunction. TIPS has also been employed in a few cases of malignant ascites associated with portal hypertension. In two cases of malignant portal and hepatic vein occlusion, TIPS improved ascites and quality of life (44). Whether to pursue any of the above invasive surgical procedures is dependent on the patient's goals and the disease context.

HICCUPS AND OTHER GASTROINTESTINAL SYMPTOMS

NABEEL SARHILL
FADE A. MAHMOUD
KRISTINE A. NELSON

To eat is human, to digest is divine. (Mark Twain)

Gastrointestinal (GI) symptoms are commonly seen in cancer patients, regardless of the disease site. These symptoms are experienced during the course of the illness or as a result of therapy. However, it should be remembered that many GI problems seen in cancer patients are also seen in those without cancer. In fact, some GI symptoms are very common, and although they do cause distress, they rarely represent life-threatening pathology. This presents a problem, as patients and physicians face the concern that every new symptom is related to the cancer. This chapter focuses primarily on GI symptoms as they relate to cancer and its treatment, but the reader is reminded that most GI symptoms are not directly due to the cancer.

HICCUPS

Definition/Incidence

Hiccup is a spasmodic, involuntary contraction of the inspiratory (external) intercostal muscles and the diaphragm associated with a strong, sudden inspiration and abrupt glottic closure. The inspiratory effort does not result in lung volume changes and there are minimal ventilatory effects (1,2).

Pathophysiology/Etiology

Hiccup is a primitive reflex that, unlike cough or gagging, has no known purpose. The reflex arch contains three parts. The afferent portion consists of branches of the vagus nerve, the phrenic nerve, and the sympathetic chain from T-6 to T-12. The central connection, or “hiccup center,” is located in the spinal cord between C-3 and C-5. The efferent limb is primarily the phrenic nerve with involvement of the efferents to the glottis and accessory muscles of respiration (3). Hiccups result from unilateral (usually left) or bilateral contraction of the diaphragm (one side is dominant)(4).

In addition to the neural pathways, numerous anatomical structures are involved in the mechanism of hiccup (epiglottis, larynx, hyoid muscles, superior constrictor of the pharynx, esophagus, stomach, diaphragm, and exterior intercostal, sternocleidomastoid, anterior serratis, and scalene muscles). Given this extensive list, it is not surprising that hiccup has been associated with many conditions affecting the central nervous system (CNS), thorax, mediastinum, and abdominal viscera, although a cause-and-effect relationship has not always been clear. One report listed over 100 causes, the most common being an overdistended stomach (5). Other common causes of hiccup include esophagogastric irritation, ileus, peridiaphragmatic irritation, general anesthesia, surgery, and excessive alcohol intake. Some cancer-related causes of persistent and intractable hiccup are listed in Table 18-1.

Intracranial neoplasms
Uremia
Alcohol
Hyponatremia, hypokalemia, hypocalcemia
Fever
Diaphragmatic irritation (diaphragmatic tumors, pericarditis)
Pleuritis
Esophageal obstruction
Pericarditis
Hepatomegaly
Subphrenic abscess
Esophageal cancer
Mediastinal tumors
Herpes zoster
Lung cancer
Gastric distention
Gastric cancer
Pancreatic cancer
Intraabdominal abscess
Bowel obstruction
Gastrointestinal hemorrhage
Short-acting barbiturates
Dexamethasone
Diazepam, chlordiazepoxide
Infection (meningitis)
Grief reaction
Psychosis

[a]A comprehensive list of the causes of hiccups can be found in Launois S, Bizec JL, Whitelaw WA, et al. Hiccups in adults: an overview. Eur Respir J 1993;6:563s–57s.

TABLE 18-1. CAUSES OF HICCUPS IN THE CANCER PATIENT[a]

Treatment/Management

Remedies for hiccup are numerous (6), although no single maneuver or medication is consistently effective. Management is usually aimed at inhibiting or interrupting the irritated reflex arc. Many folk remedies are variants of the Valsalva maneuver (expiring forcefully against a closed glottis). Presumably this inhibits an excitatory impulse to the diaphragm and intercostal muscles. Simple strategies include ocular compression, carotid sinus massage, traction on the tongue, ice water gargles, noxious odors or tastes, breath holding, rebreathing into a paper bag, gagging, drinking from a glass while holding a pencil between the teeth or while bending over head down, taking as many sips of fluid as rapidly as possible without breathing, ingesting granulated sugar, or inducing emesis. Although these measures have not been subjected to controlled clinical trials, most are worth a try. However, many are not practical for the oncology population, which may be too debilitated to tolerate even simple maneuvers (e.g., breath holding), much less dangerous ones (e.g., carotid massage). Many drugs have been advocated for the management of hiccups. The drugs most frequently used are prokinetic agents, such as metoclopramide (7), and sedatives, including most (if not all) of the benzodiazepines. The phenothiazine drugs are also widely used, most commonly chlorpromazine (8). Use of the anticonvulsants diphenylhydantoin (9), carbamazepine (10), and valproic acid (11) has been reported. Efficacy has been claimed for a variety of drugs that principally have a peripheral action [e.g., atropine sulfate (and other anticholinergic agents), edrophonium chloride, procainamide hydrochloride, and quinidine sulfate]. Amitriptyline hydrochloride (12) and methylphenidate hydrochloride (13) have been used, as well as the calcium channel blocker nifedipine (14) and the antispasticity agent baclofen (15), which acts on the spinal cord. Some of these seem to work some of the time, but none work consistently.

Various invasive methods have been tried. Gastric aspiration may be useful if overdistention of the stomach is a cause of hiccup. The insertion of a nasogastric tube may also serve a purpose by stimulating the pharynx or causing gagging (16). High-pressure oxygen inhalation has been tried. Percutaneous stimulation of the phrenic nerve has also been reported (17). A surgical approach consists of an attack on the phrenic nerve (by a crush technique), usually first attempted on the left. Regardless of treatment, in most cases, hiccups stop because of, or in spite of, therapeutic measures.

Clearly, many medications have been tried in the search for an effective treatment. However, a few drugs appear to be more effective than the rest (Table 18-2). Because gastric distention is the most common cause of hiccups in cancer, a treatment plan directed at decompression of the stomach should be the first intervention unless another cause can be clearly identified. Over-the-counter agents, including antacid and antiflatulence preparations, may provide relief. Chlorpromazine is advocated most frequently, but the side effects of hypotension and sedation make it less attractive in the oncology population. Haloperidol may be a better choice for those taking opioids (18).

Drug	Dose	Side effects
Metoclopramide	10 mg i.v. 10 mg p.o. 3-4 times daily	Extrapyramidal symptoms[a]
Chlorpromazine	25–50 mg i.v. infused slowly 25–50 mg p.o. 3 times daily	Sedation, hypotension
Haloperidol	1–5 mg p.o. 1–4 mg p.o. 3 times daily	Sedation, extrapyramidal symptoms
Baclofen	5 mg p.o. 15 mg every 3 days to max 60 mg	Sedation, confusion; less commonly, nausea and fatigue
Nifedipine	10 mg p.o. 3 times daily 10–20 mg p.o. 3 times daily	Hypotension, use with caution in patients with coronary artery disease

[a]More common in younger women.

TABLE 18-2. COMMONLY USED DRUGS IN THE TREATMENT OF HICCUPS

It is important to remember that hiccup in the cancer patient may be more than just an annoyance or signal pathology; it may exacerbate an already fragile condition by interfering with food intake, causing insomnia or exacerbating pain and other symptoms (19,20). For this reason, it may be advisable to pursue diagnosis and treatment more aggressively than in the general population.

DYSPEPSIA

Definition/Incidence

It has been said that dyspepsia defies definition. In 90 hospitalized patients asked to define indigestion, most linked it with psychological factors, feeding patterns, and bowel function, rather than physical illness (21). The international working party defines dyspepsia as episodic or persistent symptoms that include abdominal pain or discomfort, postprandial fullness, abdominal bloating, belching, early satiety, anorexia, nausea, vomiting, heartburn, and regurgitation. There is considerable overlap between this constellation of symptoms and those of gastroesophageal reflux disease (GERD), biliary tract disease, irritable bowel syndrome, and chronic pancreatitis. Dyspepsia is a recurrent problem, occurring more than six times per year in 6% of the population (22).

Pathophysiology/Etiology

Results of upper GI endoscopy in 3667 general medical patients with dyspepsia were as follows: normal (34%), gastroesophageal reflux (24%), inflammation (21%), ulcer (20%), and cancer (2%)(22). Dyspepsia is divided into two categories: organic dyspepsia and nonulcer dyspepsia. Patients in the first group have anatomical abnormalities definable by routine investigation (peptic ulcer disease and gastric cancer account for almost all cases). Patients in the second category have symptoms for which no focal lesion or systemic disease can be found. These patients can be placed in subcategories (Table 18-3) on the basis of their symptoms. However, the subcategories are not mutually exclusive; many of these patients have overlapping symptoms.

Classification	Symptoms	Treatment
Reflux-like	Heartburn, regurgitation without esophagitis	Antacid, H_2 blocker, proton pump inhibitor
Ulcer-like	Epigastric pain relieved by food and antacids, relapse and remission, without ulcer	Same
Dysmotility-like	Abdominal bloating, distention, early satiety, nausea, vomiting	Prokinetic agent, antiflatulence agent
Nonspecific	Symptoms do not fall into one of the three categories above	Start simple: antacid, antiflatulence agent (simethicone)

TABLE 18-3. CLASSIFICATION OF NONULCER DYSPEPSIA BY SYMPTOM TYPE AND THEIR TREATMENTS

Causes of dyspepsia in cancer include gastric cancer or lymphoma, gastritis secondary to radiotherapy/chemotherapy, gastric compression secondary to intraabdominal tumor, hepatomegaly, splenomegaly, ascites, gastric outlet obstruction due to tumor, or gastroparesis secondary to anticholinergic drugs, opioids, or autonomic nervous system dysfunction.

Management/Treatment

The management of dyspepsia should be directed at the cause, if organic. Treatment may be based on previous history (e.g., obstructing lesion responding to primary tumor treatment) or recent endoscopy findings. In nonulcer dyspepsia, treatment should be based on symptoms (Table 18-3).

PYROSIS

Definition/Incidence

Pyrosis is probably the most common GI complaint in the Western population. Surveys reveal that 33–44% complain of heartburn at least monthly and that 7–13% may have daily symptoms (23). Pyrosis is a retrosternal burning sensation that usually radiates proximally from the xiphoid process to the neck. It is caused by reflux of the gastric contents into the esophagus and is often precipitated by lying down or bending over, particularly after the ingestion of certain foods or large meals. Uncomplicated heartburn is usually relieved by antacids. The chronic or relapsing condition, GERD, can be a difficult problem to control, resulting in reflux esophagitis. Although there is no clear evidence that GERD is more common in those with cancer, certain conditions in this population may increase their risk, such as intraabdominal lesions, which increase pressure on the stomach.

Pathophysiology/Etiology

Several mechanisms are responsible for gastroesophageal reflex. The majority of episodes are due to transient relaxations of the lower esophageal sphincter (LES). Other factors that may contribute to GERD include transient increases in intraabdominal pressure, impaired clearance of acid from the esophagus because of diminished or absent peristalsis, and impaired salivary acid-neutralizing capacity.

The physiological mechanisms that produce heartburn are poorly understood. Although the reflux of gastric acid is most commonly associated with heartburn, the same symptom may be elicited by esophageal balloon distention. The correlation of discrete episodes of acid reflux and symptoms is poor. For example, postprandial gastroesophageal reflux is common in healthy people, but symptoms are rare. Symptoms must require more than esophageal contact with acid. Mucosal disruption with inflammation may be a contributory factor, but on endoscopy, the esophagus usually appears normal.

A number of foods, drugs, and neurohumoral factors reduce basal LES pressure, making patients prone to gastroesophageal reflux and heartburn (Table 18-4). Avoidance of these foods and medications often constitutes the initial treatment of GERD. Some common agents that increase the LES include a protein meal, bethanechol chloride, metoclopramide, and a-adrenergic agonists.

Low LES pressure	Direct mucosal irritant	Increased intraabdominal pressure	Others
Certain foods	Certain foods	Bending over	Supine position
Fats	Citrus products	Lifting	Lying on right side
Sugars	Tomato-based products	Straining at stool	Red wine
Chocolate	Spicy foods	Exercise	Emotions
Onions	Coffee		
Coffee	Medications		
Alcohol	Aspirin		
Cigarettes	Nonsteroidal anti-inflammatories		
Medications	Tetracycline		
Progesterone	Quinidine sulfate		
Theophylline	Potassium chloride tablets

Adrenergic agonists			
Adrenergic antagonists			
Diazepam			
Estrogens			
Mint, anise, dill			
Benzodiazepines			
Meperidine hydrochloride			
Nitrates			
Calcium channel blockers			

LES, lower esophageal sphincter.

TABLE 18-4. AGGRAVATING FACTORS FOR HEARTBURN

Many disorders cause epigastric or substernal pain similar to heartburn, making it important to determine the cause in each patient. Causes include collagen-vascular disorders, scleroderma, mixed connective tissue disorders, raised intraabdominal pressure, gastroparesis, nasogastric tube, prolonged recumbent position, persistent vomiting, pregnancy, hypothyroidism, Zollinger-Ellison syndrome, medications, and some surgical procedures (e.g., myotomy, esophagogastrectomy).

Heartburn is most frequently noted within 1 hour after eating, particularly after the largest meal of the day. Wine drinkers may have heartburn after hearty red wines but not after white wines. Lying down, especially after a late meal, causes heartburn within 1–2 hours; in contrast to peptic ulcer disease, heartburn does not awaken the person in the early morning. Heartburn may be accompanied by regurgitation, a bitter acidic fluid in the mouth that is common at night or when the patient bends over. The regurgitated material comes from the stomach and is yellow or green, which suggests the presence of bile. It is important to distinguish regurgitation from vomiting. The absence of nausea, retching, and abdominal contractions suggests regurgitation rather than vomiting. Furthermore, the regurgitation of bland material is atypical for acid reflux disease and suggests the presence of an esophageal motility disorder (i.e., achalasia) or delayed gastric emptying.

Treatment/Management

Initial treatment includes avoiding precipitating factors when possible, sleeping with head elevated, weight reduction (if feasible), and antacids. More aggressive therapy includes H_2 receptor blockers, sucralfate, or omeprazole (initial doses as for peptic ulcer; in unresponsive cases, higher than standard doses of H_2 receptor blockers may be effective). Agents that increase LES pressure and enhance gastric emptying may be helpful, such as metoclopramide. Long-term therapy is usually necessary.

EARLY SATIETY

Definition/Incidence

Early satiety is the desire to eat combined with an inability to consume more than an unusually small amount of food. This is in contrast to anorexia, in which there is a reduced desire to eat. Early satiety should be distinguished not only from anorexia, but also from nausea, bloating, postprandial filling, pyrosis, food aversion, and dyspepsia. However, all of these symptoms may be due to the same physiologic abnormality—delayed gastric emptying. Patients generally do not report this symptom unless questioned. The incidence of cancer-related early satiety varies from 13–62% depending on the study and population being evaluated (24,25,26 and 27).

Pathophysiology/Etiology

Satiety results from overlapping stimuli from the CNS and GI tract that affect food intake. The nutrients ingested and peptide hormones (insulin, glucagon, norepinephrinestimulating a_2-adrenergic receptors in the medial hypothalamus), along with serotonin and dopaminergic-/a-adrenergic receptors in the lateral hypothalamus, all affect satiety. Cholecystokinin may have primary effects on satiety. Exogenous administration of peptides like cholecystokinin and bombesin affect satiety both centrally and peripherally and inhibit feeding activity in animals.

Early satiety may be due to tumor encroachment on the GI tract, inappropriate satiety signals from oropharyngeal receptors, hyperglycemia, or gastric muscle atrophy. Another important cause appears to be reduced upper GI motility due to autonomic nervous system dysfunction, possibly a paraneoplastic syndrome (28). Tumor type and previous chemotherapy treatment have not been shown to affect the incidence of early satiety in cancer. However, those with taste aversions appear to have a higher incidence of early satiety than those without (29).

Treatment/Management

It is important to determine that early satiety is the reported symptom. If bloating, pyrosis, anorexia, or nausea not due to gastric status is present, it should be treated appropriately. If there is pressure on the stomach (“squashed stomach”), it should be reduced if possible, although in many cases it is not. Problems such as ascites may be amenable to paracentesis, which can provide temporary relief. Those with gastroduodenal ulcers should be treated with appropriate therapy (H_2 blocker, proton pump inhibitor, antibiotic). In patients with cicatrization at the pyloric outlet, balloon dilatation may afford relief for variable periods.

Patients with early satiety should be instructed to eat frequent, small meals, with the bulk of their daily intake consumed early, as gastric stasis increases as the day progresses. They should also be instructed to eat sitting up and avoid liquids at mealtimes, as this promotes gastric distention and the sense of fullness. Prokinetic agents (e.g., metoclopramide, domperidone) may be of particular value. The rationale for prokinetic agents in early satiety is based on the assumption that the symptom is due to delayed gastric emptying. Metoclopramide is the drug of choice in the United States (30). It is a dopamine antagonist that increases LES pressure

and enhances gastric antral contractility. It is generally well-tolerated orally, but extrapyramidal reactions, which appear to be more common in young women, do occur; insomnia (often noted to be “jumpy legs” on further questioning) and sedation have also been reported. Metoclopramide, 10 mg three times daily orally, is effective treatment for many and enhances food intake. The central effects of metoclopramide may have a direct effect on anorexia to improve appetite in addition to the peripheral effects on gastric contractility. The other prokinetic agents, cisapride and domperidone, are not available in the United States. Cisapride has been removed from the market due to drug interactions causing cardiac abnormalities. Domperidone, also a dopamine antagonist, does not cross the blood–brain barrier, hence its side effect profile is superior to metoclopramide; unfortunately, it has not yet been approved in the United States. Erythromycin is another prokinetic agent but is less useful in cancer-related gastroparesis as it causes gastric dumping, which is useful in acute gastric stasis (e.g., diabetic gastroparesis).

GASTROINTESTINAL HEMORRHAGE

Definition/Incidence

GI bleeding may originate at any site from the mouth to the anus. It can be occult or overt, with varying degrees of severity. A careful history and physical examination often suggest the site as well as the cause of the bleeding. Although controversial, most agree that 20% loss of circulating volume produces hemodynamic changes and greater than 30% produces shock with organ damage. In the debilitated cancer patient, the ability to tolerate a GI hemorrhage is compromised and the signs and symptoms may occur with far less blood loss.

The overall incidence of acute upper GI hemorrhage is 100 hospitalizations per 100,000 adults per year (31). In a study of over 15 million people there was an overall mortality rate of 14% (32). However, in patients younger than 60 years of age without malignancy or organ failure, the mortality was only 0.6%. In 800 admissions to a palliative home care program, the incidence of GI bleeding was 2.3%; those with liver cancer or hepatic metastases were at higher risk (33).

Pathophysiology/Etiology

GI bleeding can be multifactorial, and one should not assume that the tumor is the source of bleeding. In a general population of 2225 patients, duodenal ulcer (24%), gastric erosions (23%), and gastric ulcer (21%) accounted for the majority of the upper GI bleeding (34). In cancer, gastritis (36%), peptic or stress ulceration (26%), and tumor necrosis (23%) are the most common causes. Candida esophagitis, particularly during chemotherapy administration, Mallory-Weiss mucosal tears with significant bleeding in the setting of thrombocytopenia (35), and inflammatory conditions (e.g., radiation therapy) are less common (36). In the general population, 43% of lower GI bleeding is due to diverticulosis (37). Massive lower GI bleeding can be a late complication of the high-dose radiation therapy used for treatment of GI, gynecologic, or genitourinary cancer.

Other causes of bleeding in the cancer patient include thrombocytopenia and coagulopathies secondary to the disease or the treatment. Aggressive chemotherapy may cause stress-related ulceration of the mucosa or suppress bone marrow production. The incidence of GI perforation after chemotherapy is 10%; most are lymphoma patients. GI lymphomas are more common sources of tumor bleeding than other intraabdominal malignancies. Bleeding is the presenting symptom in 15–28% of patients, but only 3–4% have perforation (38). Hemorrhage has been reported in 27% of those receiving chemotherapy for unresected lymphoma. Resection before treatment may reduce the bleeding and perforation by 50%. Cytosine arabinoside can cause bowel necrosis, and hepatic arterial infusion of fluorodeoxyuridine may cause upper GI toxicity, resulting in gastritis and peptic ulcers. The initiation of chemotherapy has been reported to trigger or accelerate disseminated intravascular coagulation in lymphoma, presumably due to release of thromboplastin-like or other clot-promoting materials (39).

Medications may be responsible for GI bleeding. Drugs usually implicated are corticosteroids, nonsteroidal antiinflammatory drugs, and aspirin (40). Cephalosporins, streptomycin, isoniazid, penicillin, b-lactam, and amphotericin B may cause bleeding due to clotting factor inhibitors or impairing of platelet function.

Upper Gastrointestinal Bleeding—Diagnostic Evaluation

Hematemesis is the vomiting of blood, either bright red or dark, with a “coffee grounds” appearance. Melena is foul smelling stool with a coal black, sticky, tar-like appearance. Hematemesis and melena locates the source of bleeding as the nasopharynx, esophagus, stomach, duodenum, or, rarely, the proximal jejunum. Endoscopy is used to evaluate upper GI bleeding. Hemodynamically unstable patients should undergo emergent endoscopy, as they may benefit from both diagnosis and therapy (e.g., ligation for variceal bleeding).

Lower Gastrointestinal Bleeding—Diagnostic Evaluation

Hematochezia is the passage of red blood from the anus Blood from the distal colon, rectum, or anus is fresh and usually bright red, whereas blood from the proximal colon is likely to be darker. Bleeding from the cecum or ascending colon may appear black but is not as shiny or tar-like as melena. Early colonoscopy for the detection of lower lesions may be the first diagnostic step (41). However, when the bleeding is significant it is often difficult to identify the source. A technetium-99-labeled red cell scan may identify the general location of bleeding; however, results are variable. If the source remains unknown, the next step is typically angiography. It can detect the bleeding site as well as allow treatment with intraarterial infusion of vasopressin or embolization (42).

Treatment/Management

General

It is important to understand the status of the primary disease, the expected survival, and the potential for cure in patients with GI hemorrhage. The long-term survival rate is poor and patients should not be subjected to unnecessary tests and procedures in their final days. The goal is to determine the source of the hemorrhage, stop the bleeding, and prevent recurrence. Start with a quick assessment of the hemodynamic status including vital signs and postural blood pressure. A sudden increase in pulse or postural hypotension may be the first indication of bleeding. The hematocrit should be followed; however, it may take hours to equilibrate. Packed red blood cells should be transfused until the hematocrit is greater than 25%. A coagulopathy should initially be corrected with four units of fresh frozen plasma; thrombocytopenia below 50,000/mm^3 requires platelet transfusions.

Upper Gastrointestinal Bleeding Treatment

To prevent stress ulceration and recurrent bleeding several medications are now available, although there is no evidence they are of benefit in the immediate posttreatment period (Table 18-5) (43). Endotracheal intubation to prevent aspiration may be necessary with massive upper GI bleeding. Supportive measures with antacids, H_2-receptor blockers, and blood products control the bleeding in 60% of patients with gastritis or ulceration. Endoscopic control using heater probe, bicap, YAG laser, and other modalities may provide temporary control of bleeding ulceration or tumors. If medical management fails, surgery should be considered. The decision to operate should also be based on the patient's potential quality of life and disease prognosis, as surgery is associated with high morbidity and mortality (44).

Drug	Dose
Antacid	2 tablespoons high-potency liquid, after meals and with heartburn
H_2 blocker	Ranitidine hydrochloride 150 mg p.o. twice daily
	Famotidine, 40 mg, at bedtime
	Nizatidine, 150 mg, at bedtime (duodenal)/ 150 mg p.o. b.i.d. (gastric ulcer)
Proton pump inhibitor	Omeprazole, 20 mg p.o. daily
Sucralfate	1 g twice daily
Prokinetic	Metoclopramide, 5–15 mg p.o. 4 times daily

TABLE 18-5. DRUGS USED TO PREVENT RECURRENT UPPER GASTROINTESTINAL BLEEDING

Variceal bleeding may be treated with endoscopic sclerotherapy or variceal ligation. Medical management is less effective, but octreotide acetate, a long-acting synthetic analogue of somatostatin (50 to 100-µg i.v. bolus followed by an infusion at 25–50 µg/hour) may reduce portal hypertension in acute variceal hemorrhage.

Balloon tamponade may temporize bleeding until more definitive therapy is begun. However, it is associated with a high rate of complications and mortality. Splenorenal and portosystemic shunts control variceal bleeding in a very select group of patients (45).

Lower Gastrointestinal Bleeding—Treatment

For lower GI bleeding, colonoscopy, radionuclide imaging, or mesenteric angiography may be required to identify the source. However, it may be difficult to determine the source due to significant bleeding when performing colonoscopy. If the bleeding rate is greater than 1 ml/ minute, selective mesenteric arteriography is the best procedure to localize the source. When it is not possible to localize the source, subtotal colectomy should be performed. In poor-risk patients, therapy with selective infusion of vasopressin or embolization of the bleeding vessel can be performed, but there is a risk of bowel infarction (46).

The Dying Patient

GI hemorrhage may be a terminal event in advanced cancer, and the family and professional team should be prepared as this can be a very distressing time. Bleeding may occur very rapidly, and the patient will die immediately of asphyxiation (upper GI bleed) or a precipitous drop in blood pressure resulting in cardiac arrest due to massive lower GI bleed. GI hemorrhage prevented a peaceful death in 2% of patients in a study of 200 hospice patients (47). The key to successful symptom management in the final days, particularly in the home, is preparation. It is important to have a plan to control these symptoms. Neuroleptics are the drugs of choice to sedate patients who have catastrophic bleeds (e.g., chlorpromazine, 25 mg i.v. slow push or 50 mg p.r. can be used). Benzodiazepines may increase anxiety (48), and unless the patient is having pain, opioids should not be used, as they may cause restlessness, diaphoresis, and hallucinations (49). It is helpful to have dark sheets and towels available to camouflage the bleeding. Although symptoms can be managed well in most, poor preparation precludes a comfortable death.

BILIARY OBSTRUCTION

Definition/Incidence

Biliary obstruction is the blockage of the flow of bile resulting in increased pressure in the biliary system. Malignant obstruction can occur anywhere in the biliary tree, but it most often affects the extrahepatic biliary tree or liver hilum. The incidence in malignant disease varies depending on the etiology and stage of disease. Extrahepatic biliary obstruction is common in carcinoma of the head of the pancreas. Less common tumors are in the ampulla, bile duct, gall bladder, or liver. Cholangiocarcinoma, metastatic tumor, or enlarged lymphatic nodes are other causes of biliary obstruction (50).

Pathophysiology/Etiology

Normally, the hepatocyte secretes bile. Blocking the flow raises pressure in the biliary system rendering the hepatocyte unable to secrete more. The pressure needed to stop secretion is 300 mm of H_2O, but there is evidence of cholestasis with lesser pressure. A neural or hormonal mechanism may be responsible for cholestasis before the necessary biliary pressure is reached.

Treatment/Management

Patients usually present in the advanced stage of the disease and surgical resection is rarely possible. Patients with symptomatic biliary obstruction should be evaluated for some type of biliary bypass procedure (51). Although survival is often limited, the symptoms, particularly pruritus, are quite distressing and less amenable to other treatments. Open surgical procedures have not been shown to prolong survival and are associated with greater morbidity and mortality than endoscopically placed stents (52). Unless the patient is moribund, a stenting procedure should be considered, as it may offer dramatic relief.

Stent placement with biliary drainage results in decreased serum bilirubin, and symptoms of pruritus usually resolve within 24–48 hours. The duration of palliation afforded by stenting depends on the underlying disease and the type of stent used to relieve the obstruction (53).

There are two types of endoscopically placed stents: selfexpanding metallic stents (SEMS) and plastic stents. The major drawback of plastic stents is occlusion with bacterial biofilm. This results in occlusion and recurrence of jaundice and requires one or more stent changes in 30–60% of patients. In randomized trials comparing plastic stents to SEMS in malignant bile duct occlusion, SEMS provided longer patency rates but had no survival advantage. In a three-arm study comparing plastic stent left in place until dysfunction occurred versus plastic stent routinely changed every 3 months versus SEMS, an initial success rate of 97% was obtained. The plastic stent not routinely changed had the poorest complication-free survival rate. The SEMS were the most cost-effective when life expectancy was greater than 6 months (54,55,56 and 57).

The method to control symptoms associated with biliary obstruction depends on the performance status of the patient, tumor type, and local professional expertise. It is important to remember that patients may appear gravely ill due to infection and obstruction, yet may improve dramatically with antibiotics and a procedure to relieve the obstruction.

HEPATIC FAILURE

Definition/Incidence

Hepatic failure is the severe inability of the liver to function normally, as evidenced by jaundice and abnormal plasma levels of ammonia, bilirubin, alkaline phosphatase, glutamic oxaloacetic transaminase, lactic dehydrogenase, and reversal of the albumin/globulin ratio. It quickly leads to failure of other organs. The hallmark of acute hepatic failure is hepatic encephalopathy and coagulopathy (58).

Pathophysiology/Etiology

Most hepatic failure, regardless of cause, results from massive coagulative necrosis of hepatocytes. Viral hepatitis accounts for approximately 70%, and drug ingestion (primarily acetaminophen) accounts for the majority of the remaining 30%. Malignant causes are associated with metastatic gastric carcinoma, carcinoid, breast cancer, small cell lung cancer, melanoma, leukemia, and lymphoma. Hepatic failure may be the presenting sign of malignancy in some cases (59). Sinusoidal obstruction with subsequent ischemia has been reported in metastatic liver disease. Occlusion of hepatic venous outflow may occur in the setting of intensive chemotherapy or bone marrow transplantation or recrudescence of hepatitis B virus after treatment.

Clinical Manifestations

Regardless of the cause, hepatic failure begins with nausea and malaise. It proceeds to accumulation of ammonia as a result of diminished urea formation, hepatic encephalopathy, cerebral edema, prolonged prothrombin time, rapidly rising bilirubin, metabolic changes, GI bleeding, sepsis, respiratory failure, renal failure, and cardiovascular collapse (60).

Hepatic Encephalopathy

Hepatic encephalopathy is a complex neuropsychiatric syndrome characterized by cognitive changes, fluctuating neurological signs, and electroencephalographic changes. In severe cases, irreversible coma and death occur (61,62). It results from severe hepatocellular dysfunction or intrahepatic and extrahepatic shunting of portal venous blood into the systemic circulation bypassing the liver. Toxic substances are not detoxified by the liver; this leads to metabolic abnormalities in the CNS. Most patients have elevated blood ammonia levels (63). Cognitive changes are due to excessive concentrations of gamma-aminobutyric acid. The role of endogenous benzodiazepine agonists is unclear but may contribute to hepatic encephalopathy (64). A partial response has been observed in some after administration of a benzodiazepine antagonist (flumazenil) (65). The most common predisposing factor is GI bleeding, which leads to an increase in ammonia production. Hypokalemic alkalosis, hypoxia, CNS-depressing drugs (e.g., barbiturates, benzodiazepines), and acute infection may also trigger hepatic encephalopathy (66,67).

Reversal of the sleep/wake cycle is among the earliest signs of encephalopathy. Mood disturbances, confusion, alterations in personality, deterioration in self-care and handwriting, and daytime somnolence also are seen. The diagnosis of hepatic encephalopathy is usually one of exclusion (68). There are no diagnostic liver function test abnormalities, although an elevated serum ammonia level is highly suggestive of the diagnosis (69). It is sometimes difficult to distinguish hepatic encephalopathy from other forms of delirium.

Portal Hypertension

Tumor burden may compress the hepatic blood vessels; this can result in portal hypertension, which causes collateral vessels in the esophagus and the stomach to become enlarged and tortuous (varices). Bleeding of the varices is likely because the liver is unable to synthesize vitamin K and clotting factors. Procedures to reduce the pressure include (a) a portal-systemic shunt, and (b) b-adrenergic blockade (e.g., propranolol hydrochloride), if not contraindicated (70).

Spontaneous Bacterial Peritonitis

Spontaneous bacterial peritonitis occurs with ascites without an obvious primary source of infection. The ascitic fluid has low concentrations of opsonic proteins, which normally provide protection against bacteria. Paracentesis reveals cloudy fluid with a white cell count >500 cells/µl (>250 polymorphonuclear leukocytes). Common isolates are E. *coli* and pneumococci and, to a lesser extent, anaerobes. Empirical therapy with i.v. cefotaxime sodium (2 g every 8 hours for at least 5 days) and an aminoglycoside should be initiated if clinically appropriate (69).

Hepatorenal Syndrome

Hepatorenal syndrome is a disorder characterized by worsening azotemia, oliguria, hyponatremia, low urinary sodium, and hypotension, with structurally intact kidneys. It is diagnosed only in the absence of identifiable causes of renal dysfunction. Treatment is usually ineffective. Some patients with hypotension and decreased plasma volume may respond to volume expansion, but care must be taken to rehydrate slowly to avoid variceal bleeding (71).

Treatment/Management

Whenever possible, the inciting agent should be treated or eliminated. There is little role for liver transplant in the cancer patient. For most, treatment of the underlying disease provides the best method to reverse the process of hepatic failure. It may be useful to review adverse prognostic indicators in hepatic encephalophy (Table 18-6) before embarking on the intensive, supportive therapy necessary in those who survive.

Indicator	Value
Age	<10 yr, >40 yr
Cause	Idiosyncratic drug reaction, halothane, non-A, non-B hepatitis
Jaundice	>7 d before onset of encephalopathy
Bilirubin	>300 µmol/l (18 mg/dl)
Prothrombin time	>100 sec
Factor V level	<20%
Clinical status	Respiratory failure
	Rapid reduction in liver size
	Coma

TABLE 18-6. ADVERSE PROGNOSTIC INDICATORS IN HEPATIC FAILURE

Stenting biliary obstructions may provide relief of jaundice and pruritus. Paracentesis helps control symptomatic ascites. Neuropsychiatric symptoms are distressing and should be controlled with appropriate medications. Flumazenil, a short-acting benzodiazepine antagonist, may have a role in management of hepatic encephalopathy (65). Reducing oral protein intake in advanced cancer is rarely necessary. Administering lactulose, a nonabsorbable laxative sugar, may help. The initial dose is 30–50 ml every hour until diarrhea occurs; thereafter the dose is adjusted (15–30 ml three times daily) so that the patient has two to four soft stools daily (69).

In the terminal state, it may be appropriate to allow a deteriorating level of consciousness to progress and to forgo treatment. The neuropsychiatric symptoms are controlled with neuroleptics (if hallucinating, chlorpromazine 50–200 mg every 2–3 hours) or with diazepam (if agitated). The goal is to relieve distress without concern for the adverse effect of major tranquilizers on the mental status.

TENESMUS

Definition/Incidence

Tenesmus is a painful spasm of the anal sphincter with an urgent sensation of the need to defecate and involuntary straining, but little, if any, bowel movement. Patients complain of an abnormally frequent desire to defecate and a sensation that evacuation is incomplete. Rectal pain is not commonly caused by organic lesions, which more frequently result in tenesmus. It is a distressing, difficult to control problem. In the cancer patient it occurs most commonly in cancer of the rectum or after pelvic radiation.

Pathophysiology/Etiology

Tenesmus is thought to be a motility disorder of the rectum, with decreased compliance and high-amplitude pressure waves in the rectal wall. This results in an increased sensitivity to distention of the rectum. Rectal causes of tenesmus include impacted feces, carcinoma, rectal prolapse, rectal polyps, adenoma, hemorrhoids, fissure, proctitis, foreign body, abscess, and hemorrhoids. Infectious causes include *Shigell*a, *Campylobacte*r, and *Clostridium difficil*e.

In the patient with rectal cancer, tenesmus is usually an ominous sign, indicating circumferential growth or ulceration involving the sphincter muscle. Tenesmus typically occurs in the morning on arising and subsides as the day progresses. Accompanying perineal or buttock pain suggests involvement of the sacral nerve plexus. Patients presenting with this symptom complex are unlikely to be candidates for sphincter-saving procedures. Tenesmus can also be caused by damage from radiation therapy (acute and late effect) for rectal cancer or other pelvic structures (e.g., cervix, prostate, bladder, testes).

Treatment/Management

Treatment is based on the cause and is variably effective. Infectious causes should be treated with appropriate antibiotics. Radiation-induced tenesmus is a difficult problem. Symptoms usually resolve spontaneously within 2–6 months (72). Tenesmus and rectal bleeding have been treated with oral sulfasalazine combined with steroid enemas or sucralfate enemas (2 g in 20 ml of tap water) (73).

Among patients with rectal cancer, curative intent pelvic exenteration effectively controlled pain and tenesmus in 89% and palliative intent in 67% (74). However, this is a procedure associated with significant morbidity and should not be performed for the sole purpose of controlling pain. Radiotherapy may also provide symptomatic relief, but again, the primary purpose is to control the disease; it may be most useful in those who have not received chemotherapy (75). Metal expandable stents have been used successfully and are associated with little morbidity but may migrate (76). Lumbar sympathectomy produced complete relief of tenesmus in 10 of 12 patients with cancers in the pelvic region. Duration of relief was 3 days to 7 months (mean, 53 days). In this small series, the only complication was transient hypotension responding to intravenous fluids (77); however, mild, reversible bruising and stiffness at the needle insertion site often occur. Up to 20% of patients have limb pain, which develops after a 10- to 14-day latent period and spontaneously resolves after a few weeks. Major neurological deficits are uncommon when lumbar sympathectomy is performed by experienced pain practitioners, making lumbar sympathectomy one of the most important treatment modality currently available.

A general treatment plan should include a laxative and stool softener unless diarrhea is the prominent symptom, in which case an obstructing lesion should be ruled out. Care should be taken when prescribing roughage in those with previous radiation, as the bowel/rectal wall can be traumatized. Dexamethasone (4–16 mg daily) may provide some relief through its anti-inflammatory actions. The calcium channel antagonist nifedipine (10–20 mg two to three times daily) may help to relieve spasms. Epidural opioids and local anesthetics may also be helpful. Systemic opioids should be tried but are less effective, as in other forms of neuropathic pain. Traditional neuropathic pain treatment such as tricyclic antidepressants (e.g., amitriptyline hydrochloride) should be used with caution, as one of the main side effects is

constipation.

CONCLUSIONS

Because GI symptoms are so common in the general, healthy population it may be more difficult to evaluate them in those with cancer. Common symptoms may be disease-related or comorbidity unrelated to the cancer. Both may represent potentially life-threatening problems, and yet the decision to treat may not be clear if based on management guidelines for the general population. Decisions regarding treatment must be evaluated with an understanding of the goals of therapy, potential quality of life, and life expectancy. Consultation with GI specialists and ongoing communication with the patient and family help to provide the framework in which to make these often difficult decisions.

ORAL MANIFESTATIONS AND COMPLICATIONS OF CANCER THERAPY

IAN M. ZLOTOLOW
ANN M. BERGER

GENERAL STRATEGIES

In 2002, a projected 1.2 million people in the United States will have been diagnosed with cancer (excluding skin cancers). Regardless of therapy (i.e., surgery, radiation therapy, and/or chemotherapy), recognition of the preexisting dental status is paramount for eliminating or decreasing the sequela of cancer treatment to the oral cavity. Many treatments have an effect on the normal and adjacent hard and soft oral tissues. As the cancer treatment becomes more intensified or complex in nature, the morbidity to the oral cavity must be taken into consideration.

Oral sequelae vary from patient to patient and have different stages and intensities, even with the same modality of treatment and stage of disease. Patient compliance and basic understanding of both short- and long-term effects of therapy is essential to alleviate potential problems. It is imperative for the patient's dentist to be familiar with the medical therapy and outcome expectations. Pretreatment dental assessment should be completed and addressed before cancer treatment to reduce morbidity.

Generally, surgical resections of any anatomical oral or pharyngeal structure compromises oral function. Many resections (i.e., soft palate, tongue, hard palate, mandible, or any combination of these) can be alleviated by means of intervention with maxillofacial prosthetics. Maxillofacial prosthetics restore function and cosmesis, with some limitations.

Chemotherapeutic toxicity can present with oral manifestations, which include mucosal ulcerations, local infection, and a wide range of oral discomfort.

Radiation therapy for head and neck cancers has a range of sequela in the oral cavity. This includes caries, mucositis, trismus, xerostomia, osteoradionecrosis (ORN), and secondary oral and fungal infections. All of these can be minimized—and many prevented—with pretreatment intervention.

Pretreatment strategies and intervention can decrease the risk of many oral complications. Regardless of treatment modality, comprehensive oral evaluation must include clinical and radiographical surveys to identify possible sources of dental infection and to eliminate ongoing caries, symptomatic periapical lesions, calculus, plaque, and clinical periodontal disease (including pericoronitis).

It is recommended that any patient anticipating intense chemotherapy or head and neck radiation therapy undergo dental screening at least 2 weeks before commencement of cancer therapy. This generally allows for proper healing of extraction sites (10–14 days), recovery of soft tissue manipulations, and restoration of teeth, all of which are critical in maintaining an overall integral mucosal continuity during treatment (1).

The dental assessment and subsequent treatment rendered should correlate to the overall prognosis of the tumor. Consultation with the referring physician is paramount to dental treatment strategies and decision-making.

One of the most important areas of concern in the mouth, which affects each cancer patient regardless of cancer treatment modality, is lack of or poor oral hygiene. It is advisable to perform a thorough root planing, scaling, and prophylaxis before commencement of any cancer treatment modality, with the exception of visible tumor if at the site of anticipated dental manipulation. These procedures reduce the incidence of oral complications by eliminating bacteria that could lead to local or systemic septicemia. The dentist must also be aware of the patient's total white blood cell count, absolute granulocyte count, and platelet count if the patient has received chemotherapy or is anticipating intense chemotherapy or bone marrow or stem cell transplant, especially if the patient requires dental extractions, oral biopsies, or periodontal surgery.

It is also important for the dentist, in the pretreatment stage, to establish baseline data to which subsequent examinations and treatment can be compared. These pretreatment strategies include eliminating or reducing periodontal disease, dental caries, defective restorations, ill-fitting prostheses, and third molar pathology; improving oral hygiene; and maintaining an intact and normal condition of all mucous membranes.

Patient and family education, counseling, and motivation are critical to the success of preventive strategies. The dentist has a monumental role and can contribute to an improved quality of life of the patient, especially if initiated in a pretreatment time frame. Minimization and oral manifestations of cancer treatment is a major concern for both dentists and physicians.

DIRECT STOMATOTOXICITY

Normally, cells of the mouth undergo rapid renewal over a 7-to 14-day cycle. Both chemotherapy and radiotherapy interfere with cellular mitosis and reduce the regenerative ability of the oral mucosa. Cancer chemotherapeutic drugs that produce direct stomatotoxicity include the alkylating agents, antimetabolites, natural products, and other synthetic agents (e.g., hydroxyurea and procarbazine hydrochloride) (2). Typical sequelae of these cytotoxic agents include epithelial hyperplasia, collagen and glandular degeneration, and epithelial dysplasia (3). Mucositis is an inevitable side effect of irradiation. The severity of the mucositis depends on the type of ionizing radiation, the volume of irradiated tissue, the dose per day, and the cumulative dose. As the mucositis becomes more severe, pseudomembranes and ulcerations develop. Poor nutritional status further interferes with mucosal regeneration by decreasing cellular migration and renewal (4).

Direct stomatotoxicity usually is seen 5–7 days after the administration of chemotherapy or radiotherapy. In the nonmyelosuppressed patient, oral lesions heal within 2–3 weeks (5). The nonkeratinized mucosa is most affected. The most common sites include the labial, buccal, and soft palate mucosa, as well as the floor of the mouth and the ventral surface of the tongue. Clinically, mucositis presents with multiple complex symptoms: The condition begins with asymptomatic redness and erythema and progresses through solitary, white, elevated desquamative patches (which are slightly painful to contact pressure) to large, contiguous, pseudomembranous, acutely painful lesions with associated dysphagia and decreased oral intake. Histopathologically, edema of the rete pegs is noted, along with vascular changes that demonstrate a thickening of the tunica intima and concomitant reduction in the size of the lumen and destruction of the elastic and muscle fibers of the vessel walls. The loss of basement membrane epithelial cells exposes the underlying connective tissue stroma with its associated innervation, which, as the mucosal lesions enlarge, contributes to increasing pain levels. Oral infections, which may be due to bacteria, viruses, or fungal organisms, can further exacerbate the mucositis and may lead to systemic infections. If the patient develops both severe mucositis and thrombocytopenia, oral bleeding may occur and may be very difficult to treat.

PATHOPHYSIOLOGY OF MUCOSITIS

Sonis et al. (6) proposed a hypothesis as to the mechanisms of the development and healing of mucositis. The hypothesis is based on both animal and clinical data, although it remains speculative to some degree. It describes mucositis as a complex biological process that occurs in four phases: (a) the inflammatory or vascular phase, (b) the epithelial phase, (c) the ulcerative or bacteriologic phase, and (d) the healing phase (Table 19-1). Each phase is interdependent and is a consequence of the effect of the chemotherapy or radiotherapy on the epithelium (as well as actions mediated by cytokines), the status of the patient's bone marrow, and the oral bacterial flora (6).

Phase 1: Inflammatory or vascular phase, d 0
Phase 2: Epithelial phase, d 4–5
Phase 3: Ulcerative or bacteriologic phase, d 6–12
Phase 4: Healing phase, d 12–16

Adapted from Sonis ST. Mucositis as a biological process: a new hypothesis for the development of chemotherapy-induced stomatotoxicity. *Oral Oncol* 1998;34(1):39, with permission.

TABLE 19-1. FOUR PHASES IN THE DEVELOPMENT OF MUCOSITIS

Phase I: Inflammatory or Vascular Phase

Cytokines such as tumor necrosis factor-a, interleukin (IL-1), and perhaps IL-6 are released from the epithelial tissue and adjacent connective tissue shortly after the administration of chemotherapy or radiotherapy. Most likely, the initiating event in the development of mucositis is local tissue damage caused by the cytokines. Additional concentrations of cytotoxic drugs in the mucosa may result from the increased vascularity caused by IL-1. Increased submucosal vascularity also occurs during this phase.

Phase 2: Epithelial Phase

Reduced epithelial renewal, with atrophy and ulceration, occurs as a result of both radiotherapy and chemotherapy, particularly with drugs affecting the S-phase of the cell cycle, whereby the impact is on dividing cells of the oral basal epithelium. The atrophy and ulceration that occurs is most likely exacerbated by locally produced cytokines as well as functional trauma. The first two phases usually occur from days 0–5 of therapy.

Phase 3: Ulcerative or Bacteriologic Phase

The most complex and symptomatic phase is phase 3, during which localized areas of erosion often become covered with a fibrinous pseudomembrane. This phase usually coincides with the patient's period of maximum neutropenia. Secondary bacterial colonization involving some gram-negative organisms occurs, and the gram-negative organisms provide a source of endotoxin, which stimulates further cytokine release from the connective tissue around the cells. The patient's condition is exacerbated by the cytokines as well as the nitric oxide that is released. This phase usually occurs from days 6–12 of therapy.

Phase 4: Healing Phase

The final phase usually consists of renewal in epithelial proliferation and differentiation, with normalization of the patient's peripheral white blood cell count and reestablishment of the local microbial flora. The healing phase usually takes place from days 12–16.

RISK FACTORS

Both direct and indirect factors appear to contribute to oropharyngeal mucositis. Direct factors include the chemotherapeutic agent, dosage, and schedule (Table 19-2); the total dose and days of radiotherapy; mucosal damage from such problems as ill-fitting dental prostheses, periodontal disease, microbial flora, and salivary gland dysfunction; and patient susceptibility. Indirect factors include myelosuppression, immunosuppression, reduced secretory IgA, and bacterial, viral, or fungal infections.

Anthracyclines
Daunorubicin
Doxorubicin
Epirubicin hydrochloride
Alkylating agents
Cyclophosphamide
Busulfan
Procarbazine hydrochloride
Thiotepa
Mechlorethamine hydrochloride
Taxanes
Docetaxel
Paclitaxel
Vinca alkaloids
Vinblastine sulfate
Vincristine sulfate
Vinorelbine tartrate
Antimetabolites
Methotrexate
5-Fluorouracil
Hydroxyurea
Cytosine arabinoside
Mercaptopurine
Thioguanine
Antitumor antibiotics
Actinomycin D
Bleomycin sulfate
Mithramycin
Mitomycin
Amsacrine

TABLE 19-2. CHEMOTHERAPEUTIC AGENTS COMMONLY PRODUCING MUCOSITIS

A variety of patient-related factors have potential for affecting the development of mucositis after chemotherapy. It has been suggested that the repair of ill-fitting prostheses, extraction of offending teeth, elimination of periodontal disease, and effective oral hygiene can reduce the incidence and severity of mucositis. A patient might develop more severe mucositis if his or her nutrition is poor, through impairment of mucosal regeneration. Xerostomia that develops as a result of irradiation or drug use contributes significantly to the development of oral mucositis. Drugs that can result in xerostomia include antidepressants, opiates, antihypertensives, antihistamines, diuretics, and sedatives. Although both alcohol and tobacco can impair salivary function, it has been suggested that tobacco is associated with a decreased incidence of chemotherapy-induced stomatitis (7). One recent study involving 332 outpatients receiving chemotherapy revealed no significant differences in the incidence of mucositis between patients who wore dental appliances, had a history of oral lesions and a history of smoking, and practiced different oral hygiene regimens, and those patients who did not (8). These findings suggest that the risk factors for the development of chemotherapyinduced mucositis are many and complicated, and that further research is needed.

Reports on the effects of age on chemotherapy-induced mucositis development are conflicting. In general, younger patients are at increased risk for developing mucositis (7). Recent reports look at gender differences and the risk of mucositis. A meta-analysis of six North Central Cancer Treatment Group (NCCTG) trials involving 731 patients (402 men and 329 women) revealed that women reported stomatitis more often, and of greater severity, than men (9). In a pilot project using capsaicin for treating mucositis, data analysis revealed that women had a higher level of pain secondary to oral mucositis. It is also known that women are “supertasters” when tested with chemical relative phenylthiocarbamide/6-n-propyl-thiouracil; possibly, individuals who are supertasters and who therefore have more taste buds experience increased stomatitis (Table 19-3) (10,11).

Direct factors
Age
Gender
Preexisting dental hygiene
Nutritional status
Oral care during treatment
Radiation: dose, schedule
Chemotherapy: drug, dose, schedule
Xerostomia
Indirect factors
Myelosuppression
Immunosuppression
Reduced secretory IgA
Infections: bacterial, viral, fungal

TABLE 19-3. RISK FACTORS CONTRIBUTING TO MUCOSITIS

ASSESSMENT OF THE ORAL MUCOSA

A mucositis grading system allows the physician to assess mucositis severity in terms of both pain and the patient's ability to maintain adequate nutrition, so that a treatment plan can be appropriately constructed. Many different grading systems exist, most of which are based on two or more clinical parameters, including erythema, pain, and problems with eating (Table 19-4). An example of a common grading system is that proposed by the National Cancer Institute, which uses a numbering scale from 0 to 4. Grade 0 indicates no mucositis; grade 1, the presence of painless ulcers, erythema, or mild soreness; grade 2, the presence of painful erythema, edema, or ulcers that do not interfere with the patient's ability to eat; and grade 4, symptoms so severe that the patient requires parenteral or enteral support (12).

Grade	Criteria
0	Mouth pink No bleeding Mucosa moist No edema or infection No limitation to eating or drinking
1	Slightly increased redness of mouth 1–4 oral lesions Thinning of mucosa No bleeding or infection Mucosa moist Mild discomfort, burning sensation Possible avoidance of hot, harsh, or spicy foods
2	Moderate increase in mouth redness More than 4 discrete oral lesions, not coalescing Mucosa bleeds with manipulation Mucosa slightly drier Saliva slightly thicker Moderate edema White or yellow patches, infection present Eating of only bland, soft foods Avoidance of hot, spicy, or acidic liquids Moderate continual pain, necessitating intermittent, usually topical analgesics
3	Severe redness throughout oral cavity Multiple confluent ulcers Possible tonal denudation of oral cavity Marked xerostomia Severe edema White, yellow, or purulent patches Inability to eat or drink Inability to swallow saliva Severe, constant pain, necessitating systemic analgesia

Adapted from Western Cooperative for Cancer Nursing Research. Development of a staging system for chemotherapy-induced stomatitis. Cancer Nurs 1981;4:103, with permission.

TABLE 19-4. MUCOSITIS GRADING

Recently, new scoring systems have been developed for the assessment of oral mucositis. Sonis et al. (13) reported on a scale that uses an objective measure of mucositis, evaluating ulceration and pseudomembrane formation and erythema. Subjective outcomes of mouth pain, ability to swallow, and function were measured. Analgesia use for mouth sensitivity was also recorded. In the study that was conducted in nine centers, there was high interobserver correlation, with objective mucositis scores demonstrating strong correlation with symptoms.

At the 1989 National Institutes of Health consensus conference on oral complications of cancer therapy, clinicians and researchers agreed that effective prevention of mucositis requires a comprehensive patient examination to identify potentially complicating oral disease before the cancer therapy begins (14). Significant problems that must be corrected include poor oral hygiene, periapical pathology, third molar pathology, periodontal disease, dental caries, defective restorations, orthodontic appliances, ill-fitting prostheses, and other potential sources of infection. Bacterial and fungal surveillance cultures are not necessary, but prophylactic use of acyclovir should be considered in patients who are seropositive and at high risk for reactivating herpes simplex viral infection, such as those who undergo bone marrow transplant or who have prolonged and pronounced myelosuppression. If a diagnosis is made of a fungal, viral, or bacterial infection along with the mucosal lesions, prompt treatment is necessary to avoid the risk of systemic infection.

REMEDIES FOR THE PREVENTION AND TREATMENT OF MUCOSITIS

A standardized approach for the prevention and treatment of chemotherapy- and radiotherapy-induced mucositis is essential, although the efficacy and safety of most of the regimens have not been established. The prophylactic measures usually used for the prevention of mucositis include chlorhexidine gluconate (Peridex), saline rinses, sodium bicarbonate rinses, acyclovir, amphotericin B, and ice. Regimens commonly used for the treatment of mucositis and the associated pain include a local anesthetic such as lidocaine or dyclonine hydrochloride, magnesium-based antacids (Maalox, Mylanta), diphenhydramine hydrochloride (Benadryl), nystatin, or sucralfate. These agents are used either alone or in different combinations that compose a mouthwash. Other agents used less commonly include kaolin-pectin (Kaopectate), allopurinol, vitamin E, beta-carotene, chamomile (Kamillosan) liquid, aspirin, antiprostaglandins, prostaglandins, MGI 209 (marketed as Oratect Gel), silver nitrate, and antibiotics. Oral and sometimes parenteral narcotics are used to relieve the pain caused by mucositis. A new method that uses capsaicin for such pain relief is currently being studied.

Direct Cytoprotectants

Sucralfate

Sucralfate, an aluminum salt of sucrose orasulfate that has been used successfully to treat gastrointestinal ulceration, has been tested as a rinse for the prevention and treatment of mucositis. Sucralfate's mechanism of action appears to be the formation of an ionic bond to proteins in an ulcer site, thereby creating a protective barrier (15). Additionally, evidence points to an increase in the local production of prostaglandin E2 (PGE2), which results in an increase in mucosal blood flow, mucus production, mitotic activity, and surface migration of cells (16,17).

Anecdotal experience suggests that sucralfate might be useful in the prevention and treatment of chemotherapyinduced mucositis; however, data from the studies are conflicting. Solomon (18) reported a 55% objective response rate in patients receiving chemotherapy (19 patients), which was defined as a decrease in one grade on the Cancer and Leukemia Group B scale of oral toxicity. In 1984 and 1985, Ferraro and Mattern (19,20) reported encouraging results in the use of sucralfate for chemotherapy-induced mucositis. Two randomized, double-blind clinical trials also have evaluated sucralfate for the prevention of chemotherapy-induced mucositis. Pfeiffer et al. (21) found a significant reduction in edema, erythema, erosion, and ulceration in 23 of 40 evaluable patients receiving cisplatin and continuous infusion with 5-fluorouracil (5-FU) with or without bleomycin sulfate. Patients preferred sucralfate, although this preference failed to reach statistical significance. Ten of the patients did not complete the study, as the swishing of the sucralfate and the placebo aggravated chemotherapy-induced nausea. The authors suggested that, to help overcome this problem, the solution should have a neutral taste and should not be swallowed after swishing. In contrast, results from a similarly designed study, in which patients receiving remission-induction chemotherapy for acute nonlymphocytic leukemia were treated with sucralfate for mucositis, did not support the amelioration of mucositis (22). The latter study also concluded that chronic administration of the sucralfate suspension had no effect on the incidence of gastrointestinal bleeding and ulceration. The authors did note that some patients reported pain relief from sucralfate (22). A phase III study of sucralfate suspension versus placebo, recently completed by the NCCTG, revealed that in the 50 patients who developed stomatitis, the sucralfate suspensions provided no beneficial reduction in the duration or severity of 5-FU–induced mucositis (23). In addition, the sucralfate induced considerable additional gastrointestinal toxicity.

Sucralfate has also been tested in patients receiving radiotherapy. One study compared 21 patients who received standard oral care to the head and neck with 24 patients who received sucralfate suspension four times daily (24). Results revealed a significant difference in mucosal edema, pain, dysphagia, and weight loss in those patients receiving sucralfate. In a pilot study done by Pfeiffer et al. (25), sequential patients who received radiotherapy to the head and neck received sucralfate at the onset of mucositis. The majority of patients had a decrease in pain after sucralfate use. A doubleblind, placebo-controlled study with sucralfate in 33 patients who received irradiation to the head and neck reported no statistically significant differences in mucositis; however, the sucralfate group reported less oral pain and, in these

patients, other topical and systemic analgesics were started later in the course of radiation (26).

A prospective double-blind study compared the effectiveness of sucralfate suspension to that of diphenhydramine hydrochloride syrup plus kaolin-pectin on radiotherapyinduced mucositis. Data on perceived pain, helpfulness of mouth rinses, weekly mucositis grade, weight change, and interruption of therapy were collected daily. Analysis of the two groups revealed no statistically significant differences between them. A retrospective comparison of a group of 15 patients who had not used daily oral rinses with the preceding two groups suggested that the use of a daily oral rinse with a mouth-coating agent may result in less pain, may reduce weight loss, and may help to prevent interruption of radiotherapy because of severe mucositis (27).

Prostaglandins, Antiprostaglandins, and Nonsteroidal Agents

Prostaglandins are a family of naturally occurring eicosanoids, some of which have known cytoprotective activity. Dinoprostone, or PGE2, has been reported to be beneficial in healing both gastric ulcers and chronic leg ulcers (28,29). Pilot studies revealed the need for controlled clinical trials. In a pilot study undertaken by Kuhrer et al. (30), five patients received topical dinoprostone for chemotherapy-induced mucositis. Four of the five patients reported pain relief, with healing of the ulcers within 3–7 days. Kuhrer's group then tested the prophylactic efficacy of dinoprostone by applying it topically to one patient who was receiving chemotherapy and had developed previous episodes of mucositis, as well as to two other patients receiving total body irradiation (30). Only one of the patients who had received the dinoprostone and total body irradiation developed mucositis.

In a nonblinded study, ten patients who were receiving 5-FU and mitomycin with concomitant radiation for oral carcinomas were treated by Porteder et al. (31) with dinoprostone four times daily during treatment. The control group consisted of 14 patients who were receiving identical treatment. Eight of the ten patients who received dinoprostone were evaluable, and none developed severe mucositis, as compared with six episodes in the control arm.

A third pilot study conducted with 15 patients who received radiotherapy of the head and neck found that an inflammatory reaction in the vicinity of the tumor could be detected in only five patients treated with topically applied PGE2; none of the patients developed any bullous or desquamating inflammatory lesions (32). A double-blind, placebo-controlled study of PGE2 in 60 patients undergoing bone marrow transplant revealed no significant differences in the incidence, severity, or duration of mucositis. It. was noted that the incidence of herpes simplex virus was higher in those on the PGE2 arm; among those patients who developed herpes simplex virus, there was an increase in the severity of the mucositis (33).

Benzydamine is a nonsteroidal anti-inflammatory drug with analgesic, anesthetic, anti-inflammatory, and antimicrobial properties. Epstein and Stevenson-Moore (34) found, in a double-blind, placebo-controlled trial, that benzydamine produced statistically significant relief of pain from radiation-induced mucositis. Positive responses to benzydamine were reported in at least two other studies (35,36). The study conducted by Epstein and Stevenson-Moore (34) revealed not only a trend toward reduction in pain, but also a statistically significant reduction in the total area of ulceration, as well as the size of the ulcer. Another study demonstrated that when indomethacin, an antiprostaglandin, was given orally, it reduced the severity and delayed the onset of mucositis induced by radiotherapy (37).

Corticosteroids

No placebo-controlled studies of the use of corticosteroids for chemotherapy-induced mucositis have been reported, although two reports have focused on pilot work conducted with patients who received radiotherapy. Abdelaal et al.(38) reported the use of a betamethasone and water mouthwash in five patients receiving radiotherapy, whose mucosa remained virtually ulcer-free and who did not report any pain. The proposed mechanism of action of the steroid mouthwash was inhibition of leukotriene and prostaglandin production. Another pilot study compared 21 patients receiving radiotherapy, who used an oral rinse consisting of hydrocortisone in combination with nystatin, tetracycline, and diphenhydramine hydrochloride, with patients using a placebo rinse. Although only 12 of the 21 patients were evaluable by the end of the radiotherapy cycles, there was a statistically significant difference in mucositis and a trend toward a reduction in pain. No patients in the treatment group needed to interrupt the radiotherapeutic regimen, whereas three patients in the control group needed to interrupt their radiotherapeutic care (39).

Vitamins and Other Antioxidants

Vitamins in pharmacological doses have been used to treat mucositis. Vitamin E has been tested in chemotherapyinduced mucositis because it can stabilize cellular membranes and may improve herpetic gingivitis, possibly through antioxidant activity (40,41 and 42). The efficacy of vitamin E was demonstrated by Wadleigh et al. (43) in a randomized, double-blind, placebo-controlled study. Eighteen patients receiving chemotherapy were randomized to receive a topical application of vitamin E or a placebo. In the vitamin E-treated group, six of nine patients had complete resolution of their mucositis within 4 days of initiating therapy, whereas in the placebo group only one of nine had resolution of the lesions during the 5-day study period. This difference was statistically significant (43). Because both sucralfate and vitamin E provide some effectiveness in mucositis, a phase III study of sucralfate versus vitamin E for treatment-induced mucositis is currently under way.

Other antioxidants that have been used clinically include vitamin C and glutathione. Another antioxidant tested in a pilot study, azelastine hydrochloride, has been used in many allergic diseases and has been shown to be effective in the treatment of aphthous ulcers in Behçet's disease. Osaki et al. (44) reported on a study involving 63 patients who had head and neck tumors and received a combination of radiotherapy and concomitant chemotherapy. Twenty-six patients received regimen 1, which consisted of vitamins C and E and glutathione, whereas 37 patients received regimen 2, which consisted of everything in regimen 1 plus azelastine. At the completion of treatment, 21 of the patients in the azelastine arm remained at grade 1 or 2 mucositis, with six patients having grade 3 mucositis and ten having grade 4 mucositis. In the control group, grade 3 or 4 mucositis was induced in 6 and 15 patients, respectively, with only two patients having grade 1 mucositis and two having grade 2 mucositis. The azelastine was shown to suppress neutrophil respiratory burst both *in vivo* and *in vitro*, as well as suppressing cytokine release from lymphocytes. The authors concluded that a regimen including azelastine, which suppresses reactive oxygen production and stabilizes cell membranes, might be useful for the prophylaxis of mucositis due to chemoradiotherapy (44).

Beta-carotene, a vitamin A precursor with known effects on cellular differentiation, has been used for mucositis induced by radiation. Beta-carotene has been shown to produce regression of oral leukoplakia lesions (45). Mills (46) reported on the use of beta-carotene in treatment-induced mucositis. Ten patients receiving radiation interspersed with two cycles of chemotherapy were given beta-carotene 250 mg/day for the first 3 weeks of therapy, and then 75 mg/day for the last 5 weeks of therapy. The control group consisted of ten patients with oral cancer who were receiving identical treatment, but without the beta-carotene. At the end of treatment, there was a statistically significant difference in grade 3 to 4 mucositis in the beta-carotene group; there was no difference in grades 1 and 2 mucositis (46).

Silver Nitrate

Silver nitrate, a caustic agent, has been tested in radiationinduced mucositis. Because silver nitrate is known to stimulate cell division when it is applied to normal mucosa, it was thought that if it were applied before cytotoxic therapy, it might enhance repair and replacement of mucosa that was damaged by cytotoxic therapy. Maciejewski et al. (47) reported on 16 patients who received radiotherapy to bilateral opposing fields. Silver nitrate 2% was applied to the left side of the oral mucosa three times daily for 5 days before radiotherapy and during the first 2 days of radiotherapy. The right side of the oral mucosa was unpainted and served as the control. The study revealed significantly less severe mucositis and a decrease in duration of mucositis on the mucosa that was treated with silver nitrate (47). A second trial failed to confirm these results (48). Silver nitrate has not been formally evaluated in the treatment of chemotherapy-induced mucositis.

Miscellaneous Cytoprotectants

An uncontrolled study involving 98 patients with different malignancies who were receiving different medical regimens of either chemotherapy or radiotherapy reported that Kamil-losan liquid taken before and after the development of mucositis helped to prevent and decrease the duration of mucositis (49). In a placebo-controlled trial conducted by NCCTG, patients were randomized to receive chamomile or placebo, along with an established oral cryotherapy regimen. This study revealed that chamomile mouthwash did not reduce stomatitis associated with 5-FU chemotherapy (50).

Oshitani et al. (51) reported on the use of topical sodium alginate, an agent that has been shown to promote healing of esophageal and gastric mucosa, in radiation-induced mucositis. Thirty-nine patients with mucositis were randomized to receive either sodium alginate or placebo. Those who received sodium alginate had a reduction in both mucosal erosions and pain (51). Other topical agents used clinically for treatmentinduced mucositis include Kaopectate, diphenhydramine hydrochloride (Benadryl), saline, sodium bicarbonate, and gentian violet. Although these agents are used clinically for treatment-induced mucositis, no controlled clinical trials have yet established their efficacy.

Indirect Cytoprotectants

Hematological Growth Factors

Hematological growth factors currently are standard in the treatment of patients receiving high-dose chemotherapy. The effect of the hematological growth factors on decreasing the depth and duration of chemotherapy-induced neutropenia is well established. Lieschke et al. (52) examined the levels of neutrophil count and assessed

whether oral neutrophil count correlated with oral mucositis. In the study, the researchers found that the oral neutrophil count, similar to circulating systemic neutrophils, diminished to undetectable levels but recovered earlier than did the systemic circulating neutrophils. In those patients receiving granulocyte colony-stimulating factor (G-CSF), the mean cumulative mucositis score was less than that in patients who did not receive G-CSF (52).

Gabrilove et al. (53) reported on 27 patients receiving methotrexate, vinblastine sulfate, doxorubicin, and cisplatin for bladder carcinoma, along with escalating doses of G-CSF. The patients received the G-CSF on their first cycle of chemotherapy but did not receive it on their second cycle. Significantly less mucositis was seen during the cycle in which the patients received the G-CSF. In this study, a bias may have been inherent, as there is perhaps cumulative chemotherapeutic toxicity such that with each cycle of chemotherapy, the severity of mucositis increases.

Bronchud et al. (54) treated 17 patients with breast or ovarian carcinoma who were receiving escalating doses of doxorubicin with G-CSF support. In this study, the G-CSF did not prevent severe mucositis. In a fourth study using G-CSF, 41 patients receiving chemotherapy for non-Hodgkin's lymphoma received G-CSF, whereas 39 received chemotherapy without G-CSF. In those patients who did not receive G-CSF, the main cause of treatment delay was neutropenia, whereas in those patients who did receive G-CSF, the main cause of treatment delay was mucositis (55).

In a small prospective study, patients who received platinum, infused 5-FU, and leucovorin calcium plus granulocyte-macrophage colony-stimulating factor (GM-CSF) had a decreased incidence of grade 3 mucositis (56). In a study comparing patients undergoing bone marrow transplantation in whom GM-CSF was used to historical controls, recovery of neutrophils was more rapid in the GM-CSF group; however, there was no difference in the severity of mucositis, nor in duration of hospitalization (57). At this time, the use of CSFs in the prevention or treatment of mucositis is investigational.

The effect of other biologically active factors on mucositis development is currently being studied. *In vitro* studies have shown that epidermal growth factor (EGF) not only is present in saliva but also has the ability to affect growth, cell differentiation, and cell migration (58,59). It is known that EGF induces chemotaxis of oral epithelial cells, indicating that it may be important in maintaining the integrity of the oral epithelium, especially in wound healing. Patients with peptic ulcers have been shown to have significantly lower levels of EGF in their saliva, suggesting that EGF may be involved in either protection or repair (60). In an animal study in which the animals received either 5-FU with an infusion of EGF for 7 and 15 days or a placebo, the animals that received the EGF experienced increased mucosal breakdown. The results of the study indicate that chemotherapy-induced mucositis depends on the rate of epithelial cell growth. The timing of administration of the EGF in relation to the chemotherapy may determine whether the patient develops increased oral toxicity or repair of the mucosa (61). In a study conducted by Sonis et al. (62), hamsters received EGF versus placebo using four different treatment schedules. In this study, delayed exposure to EGF delayed the onset of mucositis, but it had no beneficial effects on the duration or severity of mucositis.

Tumor growth factor-b3 (TGF-b3) is an inhibitor of epithelial cell growth. In a study using Syrian hamsters done by Sonis et al. (63), the topical application of TGF-b3 resulted in a decrease in the severity and duration of chemotherapy-induced mucositis. In another study performed by Spijkervet and Sonis (64) with Syrian hamsters, the topical application of TGF-b3 significantly reduced the severity and duration of ulcerative mucositis induced by 5-FU. In animal experiments, IL-1 and IL-11 demonstrated a cytoprotective effect (65,66 and 67).

Antimicrobials

Many conflicting studies have been published on the use of chlorhexidine gluconate mouthwash for both alleviating mucositis and reducing oral colonization by gram-positive, gram-negative, and *Candida* species in patients receiving radiotherapy, chemotherapy, or bone marrow transplantation. In 1990, Ferretti et al. (68) demonstrated in a randomized, controlled trial that prophylactic chlorhexidine gluconate mouthwash reduces oral mucositis and microbial burden in cancer patients receiving chemotherapy. The majority of studies since that time have not demonstrated a reduction in mucositis in patients receiving intensive chemotherapy and using chlorhexidine gluconate mouthwash (69,70 and 71). However, Weisdorf et al. (70) and Epstein et al. (71) did demonstrate a reduction in oral colonization by Candida species and oral candidiasis. Ferretti et al. (72) found that the use of chlorhexidine gluconate rinse for the prevention of mucositis was not effective, although there was a reduction in streptococcal counts. Spijkervet et al. (73), in a placebo-controlled, double-blind study, revealed that the colonization index of viridans *streptococci* was reduced after 5 weeks of chlorhexidine gluconate treatment, although such therapy did not decrease the colonization of *Candida* species, *Streptococcus faecalis*, *staphylococci*, *Enterobacteriaceae*, *Pseudomonadineae*, and *Acinetobacter* species, and there was no difference in the development and severity of mucositis. A recent randomized, doubleblind study comparing chlorhexidine gluconate mouthwash to placebo in 25 patients receiving radiotherapy revealed that there was a trend toward more mucositis as well as mouthwash-induced discomfort, taste alteration, and teeth staining in the chlorhexidine gluconate arm (74). The overall statistical data led to the conclusion that chlorhexidine gluconate may result in improved oral hygiene, but the discomfort of using the rinse negates its minimal benefits.

The endotoxins of aerobic gram-negative bacilli are implicated in the etiology of mucositis. A study by Spij-kervet et al. (75) postulated that lozenges containing 2-mg polymyxin E, 1.8-mg tobramycin, and 10-mg amphotericin B (PTA) four times daily on the oropharyngeal flora would mediate and control mucositis. These researchers compared 15 irradiated patients using PTA and two other groups of 15 patients each, one of which was using 0.1% chlorhexidine gluconate and the other of which was using placebo. In the selectively decontaminated group, the severity and extent of mucositis was significantly reduced as compared with that in the chlorhexidine gluconate and placebo groups ($p<.05$). Clinically, all patients in the lozenge group showed erythema only, whereas 80% of both the placebo and chlorhexidine gluconate rinse patients experienced severe mucositis with extended pseudomembranes from the third week of irradiation. No nasogastric tube feedings were needed in the PTA group, as compared to 30% of patients in the other groups (75). The potential role of PTA lozenges remains to be clarified.

IB-367, a broad-spectrum antimicrobial peptide found in porcine leukocytes, was tested in a hamster model (76). The results indicated that mucositis scores were significantly lower in hamsters given topical IB-367, as compared to those receiving placebo. Although further study is needed, IB-367 might improve clinical outcomes in patients at risk for the development of mucositis (76). Another antimicrobial, nystatin suspension, has been studied in the prophylaxis of candidiasis in leukemia and bone marrow transplantation patients. The majority of publications do not support the use of nystatin (77,78,79,80,81,82,83 and 84).

Pharmacological Modulation

Another agent that has been evaluated for the prevention and treatment of oral mucositis induced by 5-FU chemotherapy is allopurinol. The rationale for allopurinol mouthwash was based on data that systemic allopurinol was able to decrease 5-FU–induced toxicity by inhibiting the enzyme orotidylate decarboxylase and formation of the metabolites of fluorodeoxyuridine monophosphate and fluorouridine (85).Two pilot studies support the use of allopurinol for oral mucositis. The study by Clark and Selvin (86) revealed that allopurinol mouthwash substantially decreased the incidence and severity of mucositis in six patients who received bolus 5-FU chemotherapy. Another pilot study, involving 16 patients receiving 5-day intravenous 5-FU infusions and using allopurinol mouthwashes four to six times daily, also found that the allopurinol alleviated the mucositis in all patients (87). After the success of these pilot studies, the use of allopurinol became routine medical practice in many institutions. The efficacy of allopurinol was tested by the NCCTG and the Mayo Clinic in a randomized, doubleblind clinical trial. Seventy-five patients were assigned to receive allopurinol mouthwash or placebo while they received their first 5-day course of 5-FU with or without leucovorin calcium. This study demonstrated no protective effect against 5-FU–induced mucositis by the allopurinol regimen (88).

Leucovorin calcium has been used in combination with methotrexate to help decrease the oral mucositis that occurs with methotrexate. In a pilot study involving 19 patients who received edatrexate for non-small cell lung carcinoma, less mucositis was seen than was anticipated (89). There is. decreased mucositis when reduced folates are given systemically after methotrexate administration (90). In a small crossover study, administration of leucovorin calciumhyaluronidase mouthwashes did not reduce the severity of mucositis induced by high-dose methotrexate (91).

Glutamine administration in animal studies has been shown to lead to a reduction in both morbidity and mortality of animals who have received a variety of chemotherapeutic agents, including methotrexate. The glutamine both preserved the morphological structure of the gastrointestinal tract and reduced the incidence of bacteremia (92,93). In a randomized trial of 28 patients with gastrointestinal cancers who received 5-FU and folinic acid, no effect on oral mucositis was seen in the group who also received 16 g glutamine daily for 8 days as compared to the group who received a placebo. The authors concluded that perhaps both the dose and duration of exposure to the glutamine were not sufficient to show a decrease in mucositis (94).

According to laboratory data, another agent that protects host tissues selectively from 5-FU's toxic effects without loss of antitumor effect is uridine (95). A study was conducted involving 29 patients with advanced malignancies who received N-phosphoracetyl-disodium l-aspartic acid and methotrexate, each at 250 mg/m^2 , followed 24 hours later by increasing doses of 5-FU (600 to 750 mg/m^2), with a leucovorin calcium rescue and uridine rescue for a 72-hour infusion. The uridine allowed dose escalation of 5-FU to 750 mg/m^2, with a decrease in all toxicities of the 5-FU except mucositis, which remained as the only significant chemotherapy-induced toxic effect (96). Perhaps additional studies with oral uridine will reveal a reduction of the toxicity from mucositis.

A pilot study using propantheline bromide, an anticholinergic agent that causes xerostomia, was performed to test whether the incidence of mucositis could be reduced when patients received etoposide (97). It was hypothesized that the mucosal toxicity might be related to salivary excretion of etoposide after its systemic administration. Propantheline bromide or placebo was given to 12 patients. The results revealed a decrease in the incidence and severity of mucositis in the patients who received the propantheline bromide (97).

Cryotherapy

Cryotherapy, in the form of ice chips and flavored ice pops, has been used to prevent mucositis. The NCCTG and the Mayo Clinic undertook a controlled, randomized trial of oral cryotherapy for preventing 5-FU–induced mucositis and found that cryotherapy is helpful in reducing the severity of 5-FU–induced mucositis (98,99). After this study had been completed, another was undertaken in which patients were randomized to receive 30 minutes versus 60 minutes of cryotherapy (100). A total of 178 evaluable patients were studied. Both cryotherapy groups had similar degrees of mucositis. The conclusion was to continue to recommend the use of 30 minutes of oral cryotherapy for patients receiving bolus-intensive courses of 5-FU–based chemotherapy (100). An additional study, conducted after the original study reported by the NCCTG and the Mayo Clinic, confirmed that oral cryotherapy can reduce 5-FU– induced mucositis (101).

Laser

Laser as a palliative methodology for mucositis has only recently begun to be investigated. The potential for lesion and pain control using laser was initially studied in an animal model. In a study of four groups of animals having a mucosal lesion, three groups received impulse laser exposure from 60 to 600 pulses, and one group remained untreated (102). The only group that demonstrated more rapid resolution of the mucosal lesion (14 versus 21–25 days) was the group that received the 600 pulsed exposures.

A preliminary report revealed that laser may be beneficial in reducing the severity and duration of mucositis. A study involving 20 patients with different cancers and chemotherapeutic protocols (who served as the controls) and 16 patients who received laser therapy (composing the treatment group) revealed reduced duration of the mucosal lesions, from a mean of 19.3 days in the control arm to 8.1 days, in the treatment arm (103). At this time, double-blind, randomized trials are needed to verify these earlier reports.

Anesthetic Cocktails

Several anesthetic cocktails, made up of agents such as viscous lidocaine (Xylocaine) or dyclonine hydrochloride, have been used with some success (104). The anesthetic agents do relieve the patient's pain; however, this relief is only temporary and also prevents taste perception, which can further interfere with food intake. Other analgesics and mucosal coating agents that can control pain include kaolin-pectin, diphenhydramine hydrochloride, and dental anesthetics such as Orabase and Oratect Gel. In a prospective, double-blind study involving 18 patients, viscous lidocaine with cocaine 1%, dyclonine hydrochloride 1%, kaolin-pectin solution, diphenhydramine hydrochloride, and saline solution were compared with a placebo. The dyclonine hydrochloride 1% provided the most pain relief, whereas dyclonine hydrochloride with viscous lidocaine and cocaine 1% provided the longest pain relief (105). Although clinicians use many of the topical agents, little experimental evidence exists to establish the efficacy of many of them (106).

Capsaicin

Capsaicin, the active ingredient in chili peppers, is a remedy that has been used for many different pain syndromes through the years and that may prove beneficial for mucositis pain induced by chemotherapy and radiotherapy. Several studies support the medical efficacy of locally applied capsaicin in a cream vehicle in neuropathic pain syndromes. A large, multicenter trial involving 277 patients demonstrated that topically applied capsaicin used for up to 8 weeks significantly reduced pain and improved quality of life in both postherpetic neuralgia and diabetic neuropathy (107,108 and 109). Other neuropathic pain syndromes for which capsaicin has been shown to be effective include postmastectomy pain (110), stump pain (111), trigeminal neuralgia (112), reflex sympathetic dystrophy (113), and Guillain-Barré syndrome (114). Topical capsaicin has also been shown to decrease the pain associated with rheumatoid and osteoarthritis (115), and intranasal capsaicin spray has been shown to reduce the pain associated with cluster headaches (116). Topical capsaicin has been shown to improve the rate of reepithelialization of wound healing in minipigs; thus, it may prove to be efficacious in wound healing in humans (117).

In a pilot project, capsaicin in a candy vehicle (cayenne pepper candy) was given to patients with therapy-induced mucositis. Patients were instructed to allow the candy to dissolve in the mouth without chewing it. After the candy had dissolved, the burn produced by the candy was allowed to fade. The patients rated their pain before and after eating the candy. The reduction in pain was highly statistically significant (10,11). A double-blind, placebo-controlled study is under way to test the efficacy of oral capsaicin for pain control.

Narcotics

Many of the agents previously mentioned may have some value in preventing mucositis or palliating the pain; however, very few controlled clinical trials have established their efficacy. At present, no standard treatment has been defined for the prevention or treatment of mucositis. When mucositis is severe and interferes with nutritional intake and quality of life, it is appropriate to use any of the treatments that have already been cited, as well as oral, transmucosal, or if necessary, parenteral narcotics. Currently, a study is under way to investigate the usefulness of transmucosal fentanyl (Actiq) in the treatment of mucositis (Table 19-5). A recent article also reported on the successful use of topical opioids (morphine sulfate 0.08% gel, prepared with taste supplements) in treating mucositis in a patient who was terminally ill (118). To discover an efficacious treatment, it is essential to continue studies of the treatments already available and to develop any promising new approaches.

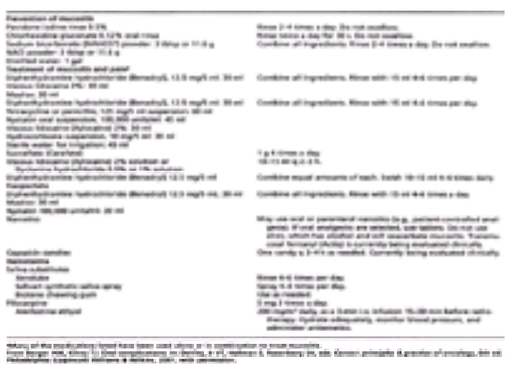

TABLE 19-5. FORMULARY OF COMMON REMEDIES FOR ORAL COMPLICATIONS

HEAD AND NECK RADIOTHERAPY—PRETHERAPY DENTAL EVALUATION AND INTERVENTION

Both short- and long-term effects of therapeutic radiation therapy to the head and neck regions involve the oral cavity. These changes can lead to mucositis, xerostomia, radiation caries, loss of taste, trismus, and possibly radionecrosis (119). The oral sequelae may cause substantial problems during and after radiation therapy. Acute incidents of focal infection (e.g., periodontal or periapical infection) and severe mucositis occasionally may necessitate an adjustment or an interruption of the radiation therapy schedule. Most preventive procedures described in the literature are based on clinical experience. The result is a great diversity in treatment policies and preventive approaches in daily dental practices. Most publications involving the head- and neck-irradiated patient are concerned with one sequelae. Usually each institution usually has its own protocol and treatment standards, which are extremely concise. The primary issues of patient care before radiation exposure include screening, consequential treatment, patient motivation, and initiation of preventive measures. Management of the patient during radiation therapy is characterized by prevention and treatment of acute complications and sequelae by radiation exposure of which are of short duration. Attention also must be addressed at the postradiation situation, as prevention and treatment of chronic dental disease must be addressed with close follow-up and continued care of the head- and neck-irradiated patient.

To maximize the effect of screening patients preradiation therapy, adequate time must be considered for dental treatment, fabrication of fluoride carriers, radiation-protective mouthguards, and wound healing (120). It is suggested that this initial appointment for dental and oral evaluation be made immediately after the diagnosis of oral cancer, within 2 weeks before the onset of radiation therapy and before simulation. At the initial appointment, the patient dentition should be examined and checked for carious lesions; defective restorations, which are sources of potential irritation of the oral mucosa, should be replaced, and the periodontium and the vitality of the pulp must be evaluated. Periodontal status is the major dental consideration and should be thoroughly screened by measuring pocket depth, as well as assessing furcation involvement. Oral hygiene must be evaluated and assessed. Plaque and gingival hemorrhage on dental pocket probing are very helpful in deciding the treatment plan regarding dental intervention (e.g., preradiation extractions). The patient's dental awareness is of utmost importance at this evaluation. The patient must possess motivation to maintain dentition properly and must comply completely with the prescribed oral hygiene preventive regimen. The oral mucosa and alveolar

process should be evaluated and considered for possible future prosthetic intervention. Areas evaluated for ulcerations, fibromas, irritation, hyperplasia, bony spicules, and tori should be included in this evaluation. The fit of dentures should be checked because ill-fitting dentures are a potential source of irritation after mucosal surfaces are exposed to radiation, with the possibility of ulceration to underlying bone (120a). The maximum mouth opening should be recorded before radiation therapy as a baseline to compare the interarch distance at different times post-radiation therapy to evaluate the degree of trismus. Trismus can be anticipated if the temporal mandibular joints and other muscles of mastication are included in the field of radiation. Decayed, missing, and filled rates of teeth should be recorded, as well as a generalized periodontal evaluation including gingival and plaque indices. A panoramic radiograph supplemented by intraoral radiographs, when necessary, is most suitable for detection of periodontal disease, periapical infections, cyst, third molar pathology, unerupted or partially erupted teeth, and residual root tips.

As a general rule, any teeth with acute and symptomatic periodontal problems should be extracted before head and neck radiation therapy. The decision of extractions of asymptomatic teeth prior to the commencement of radiation therapy can be based on several factors of importance. These include tumor prognosis and the patient's motivation to comply with the preventive regimen. A lack of motivation on the part of the patient should lead to a decision to extract questionable teeth before radiation therapy. Radiation exposure, type, portal field, fractionization, and total dosage are also part of the decision formula (120b), in addition to tumor prognosis and expediency of control of the cancer (Table 19-6).

Advanced carious lesions with questionable pupal status or pupal involvement
Extensive periodontal lesions
Moderate to advanced periodontal disease (pocket depth in excess of 5 mm, especially with advanced bone loss, mobility, or root furcation involvement)
Residual root tips not fully covered by alveolar bone or showing radiolucencies
Incompletely erupted teeth that are not fully covered by alveolar bone, or that are in contact with the oral involvement

From Berger AM, Kilroy TJ. Oral complications. In: DeVita, Jr VT, Hellman S, Rosenberg SA, eds. *Cancer: principles & practice of oncology.* 6th ed. Philadelphia: Lippincott Williams & Wilkins, 2001, with permission.

TABLE 19-6. INDICATIONS FOR EXTRACTIONS (PRERADIATION THERAPY)

Deeply impacted teeth that are completely covered by bone and mucosa are usually left without risk of late problems. Teeth that are class II or III mobility and would not be beneficial as abutment teeth for retention of a prosthesis should also be considered for extraction preradiation therapy. Extractions of residual root tips, impacted teeth, and other focus which can be of potential infection should be performed atraumatically with regarded tissue handling. Alveolectomy and primary wound closure are considered for eliminating sharp ridges and bone spicules, which could project to the overlying soft tissues. This is particularly important for prosthetic consideration because negligible bone remodeling can be expected after radiation therapy. Generally, dental extraction can be performed in the general dental office.

Nonvital teeth located in the portal fields that are without periapical radiolucency and are not causing symptoms should be treated endodontically. In mandibular molars, endodontics with possible retrograde filings are preferred because of an increased ORN risk in this region. Teeth with small amount periapical granulomas, without periodontal involvement, and which are important for oral function or rehabilitation should be treated with apicoectomies.

Adequate time for healing of extraction sites before radiation therapy is essential. Healing times of 14–21 days generally are considered safe and should be the rule. Antibiotics are not routinely recommended because there is no evidence that they influence healing in the absence of infection. Careful examination of extraction sites must be performed before radiation therapy commences. Communication between the dentist, patient, and radiation therapist is the cornerstone for successful maintenance of the oral cavity. Patients are very susceptible to dental caries (decay) at the cervical areas of all teeth after radiation therapy to the head and neck region. Patients are instructed about effective daily plaque removal. Instructions regarding use of soft toothbrushes and a fluorinated toothpaste is essential. The patients are told to brush and floss at least three to four times a day, beginning immediately. A neutral 1% sodium fluoride gel, self-applied every night for 5 minutes (120c), a brush-on gel, or a fluoride mouth rinse is prescribed in conjunction with strict oral hygiene measures. Acidulated gels are usually not prescribed because they might lead to significant decalcification without sufficient remineralization potential in the presence of xerostomia. In addition, sodium fluoride preparations are preferred to stannous fluoride because the latter has unpleasant side effects (e.g., bad taste, sensitivity of teeth and gingiva, and staining arrested lesions). Daily compliancy of fluoride for the rest of the patient's life is more of an issue than the modality of fluoride application.

Radiation-induced dental effects primarily depend on salivary changes and occur when the glands are included in the field of treatment, rather than on direct irradiation of the teeth themselves. Direct irradiation of teeth may alter the organic or inorganic components in some manner, making them more susceptible to decalcification or hypocalcification. There have been no clinical studies to support the possibility that radiation therapy directly effects the pupal chamber; however, many teeth in the direct irradiated field could be desensitized thus, if early caries involve the nerve, might be asymptomatic. Thus it is essential for meticulous home care including daily fluoride application.

Oral candidiasis is a common acute and chronic oral sequela of head and neck radiation therapy. These lesions can be removable (whitish) chronic or hyperplastic (nonremovable), chronic erythematous (diffused as patchy erythema), and frequently appear as angular cheilitis (first signs or symptoms). Treatment of oral candidiases includes mycostatin (troches), nystatin (liquid or ointment), or clotrimazole. Pseudo membranous candidiasis is successfully treated topically. Chronic candidiases usually require much longer treatment and may require oral ketoconazole, fluconazole, or intravenous amphotericin B.

XEROSTOMIA

Xerostomia in head- and neck-irradiated patients is a major sequela. Its magnitude is dependent on the radiation dosage, location, and volume of exposed salivary glands. However, significant xerostomia has not been shown as a sequela in patients treated with chemotherapy alone. The degree of xerostomia is usually reported subjectively by both patients and clinicians, and can affect oral comfort, fit of prostheses, speech, and swallowing. Many of the enzymes (mucin) found in xerostomia patients contribute to the growth of caries-producing organisms. This sequela of a decrease in quantity and quality of saliva can be devastating to the dentition with the formation of caries. It has been previously mentioned that oral hygiene regimens, with the use of water/saline and daily fluoride application along with brushing teeth at least three times daily, can reduce colonization and proliferation of oral pathogens.

Sialogogues such as pilocarpine have recently been investigated and suggested to stimulate residual salivary parenchyma pilocarpine. Improvement has been reported in some patients (121,122 and 123). Extreme caution in the use of pilocarpine is important due to reported side effects of glaucoma, cardiac problems, and sweating.

A randomized, controlled trial of standard fractionated radiation with or without amifostine, administered at 200 mg/m^2 as a 3-minute i.v. infusion 15–30 minutes before each fraction of radiation, was conducted in 315 patients with head and neck cancer. Patients were required to have at least 75% of both parotid glands in the radiation field. The incidence of grade 2 or higher acute xerostomia (90 days from the start of radiotherapy) and late xerostomia (9–12 months after radiotherapy), as assessed by the Radiation Therapy Oncology Group Acute and Late Morbidity Score and Criteria, was significantly reduced in patients receiving amifostine. At 1 year after radiotherapy, whole saliva collection after irradiation showed that more patients given amifostine produced 0.1 g of saliva (72% versus 49%). In addition, the median saliva production at 1 year was higher in those patients who received amifostine (0.26 g versus 0.10 g). Stimulated saliva collections did not show a difference between treatment arms. These improvements in saliva production were supported by the patients' subjective responses to a questionnaire regarding oral dryness (124).

Artificial saliva, usually with carboxymethcellulose as a base, has not been demonstrated to increase oral cavity comfort. Sugarless gum and hard candies are frequently used by patients for comfort, with reported subjective improvement. The dental team should also encourage the patient to quit or reduce the use of tobacco and alcohol.

LONG-TERM EFFECTS OF RADIATION

The long-term effects of head and neck radiation therapy can include soft tissue fibrosis and obliterative endoarteritis. These changes become more substantial over time, including trismus and non- or slow-healing mucosal ulcerations. Surgical wounds (i.e., extraction sites) in the irradiated area usually heal slowly. The muscles of mastication or the temporal mandibular joint (if in the field of radiation therapy) can become fibrotic with clinical entities. Early exercises, with trismus appliances postradiation, can prevent this sequela. Use of tongue depressors taped together, along with 10-minute sets of exercise 10–15 times a day, can be effective in reducing trismus. Fibrosis of the muscles of mastication (temporalis, masseter, external and internal pterygoids), can occur even 1 year postradiation; thus, jawopening

exercises should be commenced after mucositis has subsided, and should be continued for over a year after completion of radiation therapy.

ORN is a relatively uncommon clinical entity and is now described as related to hypocellularity, hypovascularity, and ischemia of tissues rather than of a bacterial origin (125). This process can be spontaneous, but is usually initiated after trauma, such as dental extraction. This process can progress to pathological fracture, infection of surrounding soft tissues, and severe pain. Most studies have reported ORN after tooth extractions, postradiation or preradiation, in cases in which there hadn't been 10–14 days of healing before commencement of radiation therapy. The risk of ORN does not diminish over time, and some authors believe it can even increase many years post-radiation therapy.

Some authors maintain that traditional treatment of ORN with antibiotics and surgical débridement and curettage have been unsuccessful. Recent literature supports hyperbaric oxygen to boost tissue oxygenation in damaged irradiated wounds for anticipated difficult extractions, as well as for patients with radiographical interpretation of trabicular bony pattern avascularity and thin and telegentasia covering mucous membranes or gingiva (126). Further controlled and randomized clinical studies are needed to support hyperbaric oxygen as adjunctive treatment. Dental extractions after radiation therapy require consultation between dentist and radiation oncologist to minimize the risk of ORN. Most reported studies demonstrate a low incidence of ORN if preradiation dental consult and appropriate treatment (e.g., extractions) are rendered (127,128 and 129). Follow-up and recall of the head and neck patient for dental preventive maintenance and treatment are essential to prevent sequelae in the oral cavity.

PRURITUS

ALAN B. FLEISCHER, JR.
DEBRA C. DALGLEISH

Like the sensation of pain, pruritus (itching) can diminish the quality of life in cancer patients. Because of the distress pruritus may cause, the cancer clinician should be aware of its importance and its management. Pruritus in cancer patients may be attributable to a primary skin disease, a coexisting medical condition, a medication, or the cancer itself. Indeed, to quote Krajnik and Zylicz, “There is no one cure for all pruritic symptoms. Better understanding of mechanisms of pruritus may help develop better treatments” (1). Beyond this, there have been articles, chapters, and texts by noted authorities (1,2,3,4,5,6,7,8,9,10,11,12 and 13). This chapter focuses on pruritus in cancer patients and reviews its etiology, diagnosis, and management. Readers should bear in mind that patients with cancer are eligible to be affected by the same pruritic conditions that noncancer patients may acquire, in addition to cancer- and cancer treatment-associated pruritic conditions.

PRURITIS SENSATIONS

In simplest terms, *pruritus* is the sensation that provokes scratching behavior. Like the sensation of pain, objective analysis cannot easily confirm the presence or severity of pruritus. Nevertheless, patients are generally thought to be reliable in their assessment of pruritus severity. Scratch marks *(excoriations*), skin thickening (*lichenification*), and visible cutaneous disease support patients' subjective complaints.

To complicate the issue, some patients with typically itchy diseases, such as scabies, deny that they itch. These patients may complain of burning, stinging, tingling, tickling, or a crawling sensation. These symptoms are closely related to pruritus, have similar pathogenic mechanisms, and are treated identically. Bernhard (14) summarized this notion by stating, “one man's itch is another man's tickle . . .and one man's stinging itch is another man's pain.” For most people, itch is readily distinguished from pain, and many patients with severe pruritus would be happy to have pain instead (15).

Pruritus is a distinct, complex sensation that may be considered a primary sensory modality (10). The itch receptor is a dermal, free, nerve arborization that has recently been differentiated from other sensory fibers (15). Although itch fibers are difficult to distinguish from the pain receptor histologically, they may be distinguished electrophysiologically. Unmyelinated C fibers carry pruritus sensations to the thalamus and subthalamus via the spinal cord. Experimental injection of histamine into the skin induces itch or pain. This histamine-induced pruritus may be suppressed by systemic antihistamine administration (16). Because many patients with pruritus show no signs of histamine release (e.g., cutaneous wheal and flare), it is likely that other compounds (e.g., cytokines and neuropeptides) cause most pruritus. Furthermore, the failure of many pruritic conditions to improve with nonsedating antihistamines suggests that histamine is a minor pruritus mediator (17,18). Studies have revealed that pruritus may be caused by opiates, serotonin and other neuropeptides, prostaglandins, kinins, proteases, and physical stimuli (10). Each of these agents may induce pruritus primarily or act via secondary mediators.

The sensation of pruritus also may arise within the central nervous system. Systemic opioids are known to induce pruritus, and the opioid-antagonists, including naloxone hydrochloride, naltrexone hydrochloride, and nalmefine hydrochloride, decrease the pruritus of cholestatic and other liver disease (19,20,21 and 22). Exogenous opioids administered in small quantities to spinal levels in spinal anesthesia relieve pain and can stimulate itch (23). Plasma from patients with cholestatic itching cause facial scratching when introduced into the medullary dorsal horn of monkeys; this scratching is abolished by administering the opioid receptor antagonist naloxone hydrochloride (24). Although opioids may promote histamine release by mast cells (e.g., exacerbating urticarial itch), opioid peptides generally do not cause any release of histamine when injected alone.

Other central nervous system pruritic phenomena include cerebrovascular accident pruritus (25) and phantom limb or phantom breast pruritus (i.e., pruritus in an amputated extremity or removed breast) (26,27). Thus, it is clear that pruritus is often not histamine induced and may not arise in the skin.

DERMATOLOGICAL DISEASES AND PRURITUS

Many skin diseases may contribute to the sensation of pruritus. Dry skin, or *xerosis*, is commonly seen in cancer patients who have generalized wasting or who have undergone chemotherapy or radiation therapy. Xerosis makes the skin more susceptible to irritation from environmental assault (28).

Many other diseases may present with pruritus, including scabies, atopic dermatitis, dermatitis herpetiformis, bullous pemphigoid, miliaria, pediculosis, and urticaria (29). These cutaneous diseases often are readily diagnosed by careful clinical examination. Signs of dermatological diseases may be remarkably subtle or nonspecific in any given patient, particularly in the immunocompromised host. There is no substitute for an excellent physical examination of the skin surface (30,31,32,33,34,35 and 36).

PRURITUS AND MALIGNANCY

Pruritus may be associated with virtually any malignancy (Table 20-1) (37,38,39,40,41,42,43,44,45,46,47,48,49,50,51,52 and 53). Some neoplasms are more frequently associated with pruritus. Primary polycythemia, for example, has a pruritus prevalence of 30–50%, and Hodgkin's disease has a prevalence of 15%. Cutaneous T-cell lymphoma, peripheral T-cell lymphoma, and other cutaneous lymphomas are notoriously pruritic. Generally, the etiology of the pruritus in these patients is a poorly understood paraneoplastic phenomenon. The presence of severe pruritus may be more troublesome than from a symptomcontrol perspective alone. Gobbi and colleagues (48) reported that severe pruritus in Hodgkin's disease predicts a poor prognosis. Pruritus may also be a sign of malignant physical obstruction of the biliary system (51).

TABLE 20-1. SYSTEMIC CONDITIONS REPORTED ASSOCIATED WITH GENERALIZED PRURITUS

PRURITUS AND NONMALIGNANT INTERNAL DISEASES

Cancer patients are not exempt from having concurrent medical conditions. There is no question that other internal diseases may be associated with pruritus. Pruritus has been reported to herald the onset of thyroid disease (54), renal insufficiency (55), liver disease (56), iron deficiency (57), diabetes mellitus (58), paraproteinemia (59), Sjögren syndrome (60), and other conditions. Cancer patients can independently develop other medical conditions, or the cancer itself may cause a systemic condition, such as biliary obstruction, that may cause pruritus. Mechanisms of pruritus induction in most of these diseases are poorly understood. It has been postulated that renal disease may induce a metastatic calcification, hyperphosphatemia, xerosis, mast cell proliferation, and other changes that might be associated with pruritus.

CANCER THERAPY

Pruritus may be the result of a chemotherapy reaction, radiation therapy, or medications used for symptom management. Pruritus has been reported as an adverse reaction to chemotherapeutic agents, including those listed in Table 20-2 (61,62,63,64,65 and 66). New combinations of chemotherapeutic agents in ever increasing dosage regimens undoubtedly will be associated with increased cutaneous toxicity.

Bacille Calmette-Guérin
Bleomycin sulfate
Carboplatin
Carmustine
Chlorambucil
Cisplatin
Cyclophosphamide
Cytosine arabinoside and daunomycin
Daunomycin
Docetaxel
Doxorubicin
Gemcitabine hydrochloride
Hydroxyurea
Interleukin-2 with levamisole hydrochloride or alpha interferon
L-Asparaginase
Mechlorethamine hydrochloride
Megestrol acetate
Methotrexate
Mitomycin
Paclitaxel
Procarbazine hydrochloride

TABLE 20-2. ANTITUMOR AGENTS ASSOCIATED WITH PRURITUS

Acute radiodermatitis may cause erythema and pruritus. Additionally, chronic radiodermatitis can be associated with severe xerosis, skin thinning, and ease of irritation. Total body electron beam radiation may make the entire skin surface dry and pruritic.

All clinicians managing cancer patients are familiar with the typical morbilliform drug rash from antibiotics and other supportive agents. Similar to this eruption is the engraftment phenomenon in bone marrow transplant recipients; however, many pruritogenic drugs do not induce any rash. As stated, opiates may induce pruritus via central nervous mechanisms. Others, such as estrogens or ketoconazole, may precipitate cholestatis and thus induce pruritus. It is noteworthy that placebo agents may induce pruritus in as many as 5% of the people treated. More than 100 medications are reported to cause pruritus without a rash (62). Careful review of the medication history and simplification of the drug regimen is essential.

NEUROPSYCHIATRIC DISEASE AND PRURITIS

Calnan and O'Neill (67) found that in most patients with a chief complaint of generalized pruritus, the itch began at a time of emotional stress. Edwards and colleagues (68) later reported that a high level of psychological stress enhances a person's ability to perceive intense itch stimuli. In cancer patients, psychological stress, depression, anxiety, and organic brain diseases undoubtedly contribute to cutaneous diseases (69,70 and 71). Recognition of neuropsychiatric disease may lead to better control.

EVALUATION OF THE PRURITIC PATIENT

Obtaining a focused history, a directed review of symptoms, and a focused clinical examination may lead to a clinical diagnosis. The physician first should probe for likely pharmaceutical agents that could exacerbate pruritus. A temporal history of therapeutic agent initiation within 2 weeks of the onset of pruritus may be helpful. Other historic points of value include an abnormal or excessive bathing history, others in the family or household with similar problems, and symptoms of neuropsychiatric disease. Complete dermatological clinical examination quickly excludes urticaria, scabies, and a host of other dermatological diagnoses.

Some patients with long-standing, generalized pruritus may require further evaluation. For practicing dermatological clinicians, further investigation may be warranted. This evaluation should include a careful history, physical examination, and appropriate, limited, screening laboratory tests. Extensive, undirected evaluation of these patients rarely leads to a specific attributable cause (72).

There is no single list, nor are there specific guidelines for tests that must be performed in any individual patient. Scabies preparations, fungal examinations, and skin biopsies may be needed to diagnose specific dermatological diseases.

TOPICAL TREATMENT

Ideally, the physician would choose the single topical medication that corrects the underlying condition. Although this scenario occasionally occurs (e.g., permethrin for scabies infestation), symptomatic treatment is less specific. Therefore, the clinician must use all diagnostic skills to provide the patient with reasonable relief. Table 20-3 presents the advantages and disadvantages of different topical agents.

Topical agent	Examples	Advantages	Disadvantages
Emollients and moisturizers	Petrolatum moisturizing lotions	Inexpensive, reduces irritant dermatitis	May be too greasy, insufficient in inflammatory diseases
Corticosteroids	Hydrocortisone	Effective for inflammatory dermatoses, mainstay of topical therapy	May cause atrophy, sensitivity, adrenal suppression
	Desoxide	—	—
	Triamcinolone	—	—
	Fluocinonide	—	—
	Halobetasol	—	—
Topical immunomodulators	Tacrolimus	Effective for inflammatory dermatoses, no atrophy	May cause burning on application
Anesthetics	Camphor	Excellent pruritus relief, no atrophy or adrenal suppression	Potentially sensitizing
	Pramoxine	—	—
	Benzocaine	—	—
	Prilocaine (EMLA)	—	—
	Menthol	—	—
Antihistamines	Diphenhydramine hydrochloride	Modest relief, no atrophy or adrenal suppression	Potentially sedating and sensitizing
	Doxepin hydrochloride	—	—
Cooling agents	Calamine	May be soothing and cooling	Calamine leaves visible film
	Alcohol	—	Alcohol dries the skin
Miscellaneous	Coal tar	Coal tar is anti-inflammatory	Tar is not elegant and stains
	Capsaicin	Capsaicin works differently than other agents	Capsaicin often burns

TABLE 20-3. ADVANTAGES AND DISADVANTAGES OF TOPICAL AGENTS

One of the most important aspects of skin therapy that must be addressed is hydration and lubrication of the skin surface (28,73). A simple but sometimes effective therapeutic approach is to apply emollients (lotions, creams, and ointments) on the dry skin twice daily. Emollients with camphor and menthol (e.g., Sarna lotion), phenol, pramoxine (PrameGel, Pramosone, or Aveeno anti-itch lotion) or benzocaine (Lanacane) may provide relief. Camphor, phenol, menthol, pramoxine, and benzocaine have local anesthetic effects (12).

Age-old remedies such as cool compresses (application of a wet washcloth for 20 minutes) and shake lotions (calamine) may prove highly efficacious. Cooling the skin

may provide remarkable pruritus relief. Oatmeal baths (Aveeno) or baths in therapeutic salts may also provide short-term symptomatic relief.

Topical corticosteroids may be useful adjunctive agents for pruritus control. When used properly, they should be prescribed in amounts necessary to cover the affected skin. Table 20-4 provides prescribing quantity information. Although any topical corticosteroid may be useful in a given patient, for widespread pruritus, hydrocortisone (1% or 2.5%) or triamcinolone (0.1%) preparations are generally effective. Because of the relatively thin skin of some cancer patients, long-term use of halogenated corticosteroids should be approached with great caution. Overuse of corticosteroids in unsupervised or overzealous patients is a common cause of dermatological iatrogenic disease (74). Even when topical corticosteroids are required, the use of emollients remains indicated (75,76).

Location	One application (g)	Twice daily for 1 wk[a]	Twice daily for 1 mo[a]
Hands, scalp, genitalia, or face	2	30 g (1 oz)	120 g (4 oz)
Upper extremity or one side of trunk	3	45 g (1.5 oz)	180 g (6 oz)
One lower extremity	4	60 g (2 oz)	240 g (8 oz)
Entire body	30–60	540 g (1 lb)	2700 g (5 lb)

[a]Although the twice-daily dosing of corticosteroid agents is appropriate for many patients, clinicians employ these agents from daily to four times daily.

TABLE 20-4. AMOUNTS OF TOPICAL CORTICOSTEROID AGENT PRESCRIBING INFORMATION

Topical tacrolimus (Protopic) 0.1% ointment is also an effective anti-inflammatory product for itching. It may cause some burning and stinging on topical application, but can be used for long periods of time on any skin site without risk of atrophy (77,78). Although success has been demonstrated only with atopic dermatitis, it is likely to be effective for a broad range of diseases that involve cutaneous inflammation.

Capsaicin cream (Zostrix) is of limited help in selected patients with a wide range of inflammatory and noninflammatory dermatoses (79,80 and 81). Topical capsaicin should be applied three times daily and may be used indefinitely. Its application requires careful patient instruction, as it often initially produces burning or stinging sensations or superficial burns. In many cases, after 1 or more weeks, the burning sensation diminishes and relief from pruritus follows. Capsaicin is not appropriate for generalized pruritus because of its significant expense and irritation potential.

Other agents have modest topical efficacy in relieving pruritus. The eutectic mixture of local anesthetics lidocaine and prilocaine (EMLA) has been demonstrated to be helpful in experimentally induced pruritus (82) and may prove useful in recalcitrant pruritic conditions. However, it is likely to offer no additional advantages over other anesthetics mentioned. Topical doxepin hydrochloride (Zonalon), an antidepressant and antihistamine, is a useful noncorticosteroid pruritus medication with modest demonstrated efficacy (83). Topical doxepin hydrochloride may cause sedation and is particularly likely to cause allergic contact dermatitis. Clinicians should be aware that all topical agents, including emollients, corticosteroids, antihistamines, and anesthetics, have sensitizing potential and may induce allergic contact dermatitis.

ORAL TREATMENT

In patients with pruritus that interferes with sleep or pruritus that may have a significant neuropsychiatric component, oral antipruritic agents may prove important in symptomatic relief. Antihistamines, such as hydroxyzine (Atarax) and diphenhydramine hydrochloride (Benadryl), not only are occasionally antipruritic but also have important central nervous system effects. In a review of the pharmacological control of pruritus from nearly two decades ago, Winkelmann (84) stated that the most effective antihistamines have central nervous system effects. Moreover, ensuring adequate sedation can be important now that there is good evidence that pruritus disturbs normal sleep (85). However, some patients, especially the elderly, may have increased sensitivity to antihistamines, and memory impairment or impaired psychomotor function may result from their administration (3,4). Cetirizine hydrochloride (Zyrtek) is an antihistamine that is less sedating than hydroxyzine, but more sedating than the typically nonsedating antihistamines (e.g., loratidine and fexofenadine hydrochloride).

In conditions other than urticaria, the nonsedating antihistamines may have only marginal therapeutic effect. There are conflicting data on the antipruritic efficacy of terfenadine and acrivastine in atopic dermatitis (18,86). Although they may be useful agents in the treatment of urticaria, nonsedating antihistamines have limited application in nonurticarial conditions. Moreover, the role of histamine in itch mediation in cancer patients is even more questionable. Burtin and colleagues (87) found a decreased skin response to histamine injection in cancer patients. They postulated that the presence of a tumor mimics the effects of general administration of histamine H_1 antagonists on the skin response to histamine.

Doxepin hydrochloride, a tricyclic antidepressant with antihistamine activity (88), may be an effective agent for the treatment of refractory pruritus, but *in vivo* has similar efficacy in suppressing histamine to hydroxyzine.

Systemic corticosteroids for pruritus are often highly effective, but their use can present certain difficulties. All oncologic practitioners are aware that chronic pathological states, including hypertension, diabetes, fluid retention, and osteoporosis, all may be exacerbated by intramuscular or oral corticosteroids. Systemic corticosteroids are particularly effective for brief periods for morbilliform drug eruptions and allergic or irritant contact dermatitis. More prolonged use may induce adverse sequelae.

A variety of other systemic agents have been used with some effect in specific disease states (Table 20-5). Activated charcoal (89), naloxone hydrochloride (19,20), naltrexone hydrochloride (22), and cholestyramine (90), for instance, have been demonstrated to be effective in the pruritus of biliary cirrhosis. Rifampin may be effective for the pruritus of primary biliary cirrhosis (90,91). Aspirin occasionally exacerbates pruritus but has been reported to be helpful in the treatment of pruritus associated with polycythemia rubra vera (50). Interferon-a has been used with some success in intractable pruritic conditions, especially polycythemia vera (52,53), but its cost and side effects demand careful consideration. Although purely anecdotal, our experience with thalidomide, a teratogenic anti-inflammatory agent, suggests that this agent is also extremely useful for intractable pruritus if skin inflammation is present (92).

Disease	Drug or modality	Reference
Renal insufficiency or failure	Ultraviolet B phototherapy	97–99
Hepatic cholestasis	Activated charcoal	89
	Rifampin	90,91
	Ondansetron	91,94
	Cholestyramine	90
	Nalmefine hydrochloride	21,22
Inflammatory skin diseases	Systemic corticosteroids	7–10,12,13
	Topical corticosteroids	7–10,12,13
	Topical tacrolimus	77,78
	Phototherapy	96–99
Urticaria	Antihistamines	13
	Systemic corticosteroids	13

TABLE 20-5. SYSTEMIC OR PHYSICAL MODALITY PRURITUS TREATMENTS FOR SPECIFIC CONDITIONS

The serotonin agents paroxetine hydrochloride (93) and ondansetron (94) have shown some effect with intractable pruritus, but their mechanism of action is unclear. Although these findings are preliminary, the reported efficacy with this class of pharmacological agents represents one of the most important recent advances in pruritus. These agents may have a role to play in the pruritus of liver disease and a wide variety of other conditions.

The reader always should bear in mind that if a patient obtains relief with any given medication, the medication cannot always take credit. In a classic study, Epstein

and Pinski (95) found that placebo therapy provides pruritus relief with a surprisingly high success rate.

PHYSICAL TREATMENT MODALITIES

Ultraviolet A (UVA), ultraviolet B (UVB), and psoralen photochemotherapy have been successfully employed in a wide range of pruritic disorders, from atopic dermatitis to renal disease (96,97 and 98). Because of its high degree of efficacy, UVB has become the treatment of choice for uremic pruritus in some centers, including our own. We administer UVB, combination UVA-UVB, and psoralen photochemotherapy treatments for pruritus. UV doses are usually administered three times weekly in doses (99). UV doses are progressively increased until erythema is attained, then the therapy is individually adjusted to accommodate the patients' photosensitivity. To attain symptomatic relief, 20–30 treatments may be necessary; occasionally, weekly maintenance therapy is continued.

CONCLUSIONS

Pruritus in cancer patients is common and provides a diagnostic and therapeutic challenge for the physician. Evaluation may be limited to obtaining an excellent history and physical examination. Alternatively, an exhaustive search for systemic disease occasionally may be indicated. The physician should address the therapeutic intervention to correct the underlying cutaneous disease. Systemic antipruritics are often beneficial and well tolerated but have wellknown side effects. Above all, diagnosis and therapy should be individualized for the patient.

TREATMENT OF TUMOR-RELATED SKIN DISORDERS

JOHN A. CARUCCI
DAVID J. LEFFELL

As the number of patients diagnosed with cancer continues to rise, a concomitant increase in tumor-related skin disor-ders can be expected. Management of these conditions, which can be challenging, is essential to the patient's overall sense of comfort and well-being. In some cases, diagnosis of tumor-related skin disorders may permit early detection of occult malignancy. In this chapter, tumor-associated skin conditions are divided into three groups: (a) generalized eruptions associated with internal malignancy, (b) cancer-related genodermatoses, and (c) incurable nonmelanoma skin cancer. These disorders are reviewed with respect to commonly associated malignancies (Table 21-1). Emphasis is placed on the more common examples of these uncom-mon conditions, and potential management strategies are discussed.

Tumor-associated disorder	Commonly associated cancer
Pruritus	Hodgkin's lymphoma
Leser-Trelat	Gastric adenocarcinoma
Erythema gyratum repens	Lung cancer
Hypertrichosis lanuginosa acquisita	Lung cancer
Necrolytic migratory erythema	Glucagonoma
Paraneoplastic pemphigus	Non-Hodgkin's lymphoma Chronic lymphocytic leukemia
Bazex's syndrome	Aerodigestive tract carcinoma
Acanthosis nigricans	Gastric adenocarcinoma
Dermatomyositis	Ovarian carcinoma
Sweet's syndrome	Leukemia Colorectal carcinoma
Muir-Torre syndrome	Colorectal carcinoma
Cowden's syndrome	Breast carcinoma Thyroid carcinoma
Multiple endocrine neoplasia	Pheochromocytoma Thyroid carcinoma
Peutz-Jeghers syndrome	Colonic adenoma
Nevoid basal cell carcinoma syndrome	Basal cell carcinoma
Xeroderma pigmentosum	Squamous cell carcinoma Melanoma

TABLE 21-1. TUMOR-ASSOCIATED SKIN DISORDERS

GENERALIZED ERUPTIONS ASSOCIATED WITH INTERNAL MALIGNANCY

Pruritus

Pruritus, or itch, is often nonspecific. It is one of the most common complaints in the elderly patient and is usually secondary to xerosis (dry skin, Fig. 21-1B) (1). However, intractable pruritus accompanied by severe excoriations may be an indicator of internal malignancy (1). This type of pruritus is most commonly encountered in Hodgkin's lymphoma but can be observed with any internal malignancy (2). There are often no true primary lesions on examination, but secondary changes, including excoriations and subsequent lichenification and pigmentary alterations, can be significant (Fig. 21-1A). Pruritus has been reported in up to 25% of patients with Hodgkin's disease and may be an indicator of less favorable prognosis when associated with fever or weight loss (2). Pruritus of Hodgkin's disease is described as intense and burning and usually begins on a localized area.

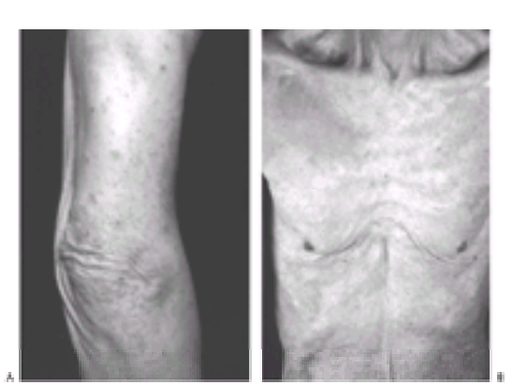

FIGURE 21-1. A: Pruritus in Hodgkin's disease. **B:** Pruritus associated with xerosis. (From NYU Skin & Cancer slide collection, with permission.)

Pruritus also may be a sign of cholestatic liver disease, renal disease, human immunodeficiency virus, thyrotoxicosis, or diabetes (1). Infestation with scabies must also be considered in the differential diagnosis.

In contrast to the nonmalignant associations of localized pruritus, adenocarcinoma and squamous cell carcinoma (SCC) of the brain (3,4), breast (5,6), colon (7,8), pancreas (9), and stomach (10) have been associated with generalized pruritus. Unilateral paroxysmal facial pruritus was reported as a presenting sign in two children with brainstem glioma (3). In both cases, pruritus resolved after radiation therapy for the glioma.

Intractable pruritus is best evaluated by a dermatologist who can distinguish primary pruritus from pruritus secondary to some other cutaneous condition. Work up should include a thorough history and physical examination, including baseline evaluation of complete blood count, liver function tests, and chest x-ray. Skin biopsy of primary lesions (if present) may determine the cause of the pruritus. In addition, age-appropriate and symptom-directed cancer screening should be updated. Treatment options include oral antihistamines (especially sedating antihistamines), topical corticosteroids, and ultraviolet light therapy.

Sign of Leser-Trelat

The sign of Leser-Trelat is defined as the sudden appearance of numerous seborrheic keratoses in association with internal malignancy. It has been most commonly associated with gastric carcinoma (11,12). The sign has been attributed separately to Edmund Leser and Ulysse Trelat (12,13). Interestingly this represents a misnomer because both individuals were actually observing cherry hemangiomas. In fact, it was Hollander who first emphasized the association between internal cancer and seborrheic keratoses in 1900 (14). Little is known about the pathogenesis of Leser-Trelat; however, some investigators point toward increases in tumor-derived growth factors (15).

Seborrheic keratoses are benign lesions and are best described as waxy, hyperpigmented papules or plaques (Fig. 21-2). They appear to be “stuck on” and look as though they might be easily peeled away from the surface of the skin. They are extremely common in older individuals and represent no danger to patients. The differential diagnosis may include benign, premalignant, and malignant lesions including lentigines, nevi, actinic keratoses, atypical nevi, pigmented Bowen's disease, and melanoma. Diagnosis can be confirmed by simple skin biopsy performed by a dermatologist. Leser-Trelat is characterized by the sudden eruption of multiple seborrheic keratoses and most commonly affects the back and chest, although the extremities, groin, and even the face may be affected (12). It must be emphasized that although seborrheic keratoses are common, the sudden appearance of numerous lesions or their appearance before the third decade is not common and should prompt further investigation. Vielhauer et al. report the diagnosis of occult renal cell carcinoma in a patient with Leser-Trelat (11). Curative nephrectomy was performed as a result of early diagnosis.

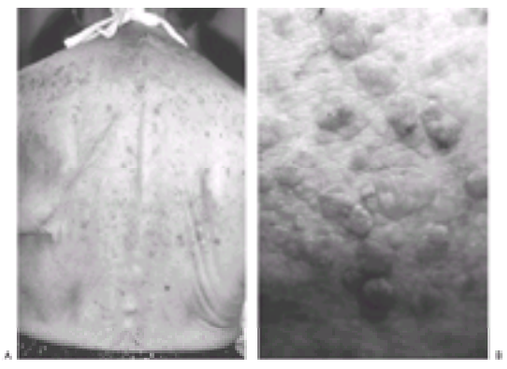

FIGURE 21-2. A: Leser-Trelat associated with lung cancer—note pneumonectomy scar. **B:** Close-up view of seborrheic keratoses in Leser-Trelat. (From Yale Dermatology Residents' slide collection, with permission.)

Further investigation in patients with Leser-Trelat should include a complete history and physical examination, accompanied by routine blood studies including complete blood count, LFTs, chest x-ray, mammogram, and Pap smear for women or prostate-specific antigen test for men. Endoscopic evaluation of the colon should also be considered, as should any symptom-directed diagnostic studies.

The presence of the seborrheic keratoses themselves is not dangerous to the patient, and reassurance of this is necessary. If desired, the keratoses may be removed by curettage under local anesthesia with little risk of scarring. Other treatment methods include cryosurgery with liquid nitrogen and chemical cauterization with topical application of trichloroacetic acid.

Erythema Gyratum Repens

Erythema gyratum repens is part of the group of gyrate erythemas (16). These are reactive, inflammatory dermatoses that share morphologic characteristics and have been described as “figurate,” “ploycyclic,” and “serpiginous” in appearance (16,17). None of the gyrate erythemas has the characteristic appearance of erythema gyratum repens.

Erythema gyratum repens was first described in 1952 by Gamel, who reported it in association with breast carcinoma (18). Since that time, the overwhelming majority of cases have been associated with internal malignancy (16).

On clinical examination, there are serpiginous, erythematous bands that take on a “wood grain” or “zebra-like” appearance (Fig. 21-3). There is usually scaling associated with the lesions and there are often multiple bands. Lesions may be indurated and are likely to migrate over the course of hours. There may be associated pruritus. Unlike the characteristic clinical picture, histopathologic findings are nonspecific and may include hyperkeratosis, acanthosis, spongiosis, and a superficial perivascular lymphohistiocytic infiltrate (16).

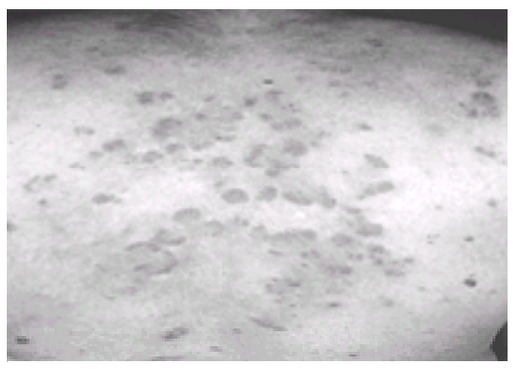

FIGURE 21-3. Erythema gyratum repens in a patient with lung cancer. (From NYU Skin & Cancer slide collection, with permission.)

Suspicion for erythema gyratum repens should result in a dermatological consultation for confirmation. Due to the likelihood of association with internal malignancy, screening for internal malignancy should be performed. Standard screening laboratory and imaging studies should be performed, with special attention toward ruling out cancer of the lung (19). Although most commonly associated with lung cancer (20), erythema gyratum has been reported with breast and renal cancer (18,21) and, in rare cases, in the absence of malignancy (22,23 and 24). It is especially important to repeat screening tests periodically because the eruption may precede the onset of malignancy (16,19).

The most effective treatment is removal of the underlying tumor (16,19). Skin manifestations have resolved after removal of localized tumors and may persist until death in the face of widespread disease. Associated pruritus and inflammation may be relieved with oral antihistamines in combination with midpotency topical corticosteroids.

Hypertrichosis Lanuginosa Acquisita

Hypertrichosis lanuginosa acquisita, also referred to as *malignant dow*n, is characterized by the growth of fine, nonpigmented hair that occurs primarily on the face (25,26). It is most commonly associated with small cell and non–small cell carcinoma of the lung (27) and colorectal cancer (28,29) and has been reported with

carcinomas of the kidney (30), pancreas (31), and in metastatic melanoma (32). It has also been associated with other conditions, among them shock, thyrotoxicosis, porphyria, and ingestion of drugs, including cyclosporine, streptomycin sulfate, phenytoin, spironolactone, diazoxide, minoxidil, interferon, and corticosteroids (25,26).

The most effective treatment for malignant down is that which successfully treats the underlying tumor. Management of cosmesis may be attempted through electrolysis, depilatories, or shaving. Because the hairs are not pigmented, treatment with hair removal laser would likely be unsuccessful, as lasers target melanin in the hair follicle. Treatment with eflornithine hydrochloride cream (13.9%) applied to the affected area twice daily may be successful. This agent inhibits ornithine decarboxylase, a key hair cycle enzyme, and may result in noticeably diminished hair growth (33). The presence of hypertrichosis lanuginosa implies poor prognosis and a survival time of less than 2 years in most patients (25,26,32).

Necrolytic Migratory Erythema

Necrolytic migratory erythema refers to cutaneous manifestations of the glucogonoma syndrome caused by a tumor of the pancreatic islet a-cells (25,34,35). The eruption begins as an erythematous patch involving the groin that spreads to the buttocks, perineum, thighs, and extremities (Fig. 21-4).

FIGURE 21-4. Necrolytic migratory erythema in the glucagonoma syndrome. **A:** Perianal blistering. **B:** Stomatitis. **C:** Characteristic periungal involvement. **D:** Histologic findings include superficial epidermal necrosis and dyskeratotic cells. (From NYU Skin & Cancer slide collection, with permission.)

The erythematous areas eventually undergo scaling and blister formation. Erosions occur subsequent to rupture of blisters, and healing with induration and pigmentary change follows over the course of several weeks. This may follow a relapsing and remitting course and may be associated with stomatitis. The differential diagnosis includes intertrigo, superficial candidiasis, bullous drug eruption, and pemphigus (25,34,35). Histologic findings include dyskeratotic epidermal cells with superficial epidermal necrosis (Fig. 21-4D) (25,34,35). Elevated plasma glucagon levels are considered diagnostic. Dermatological consultation should be sought to confirm the diagnosis as well as to rule out other skin disorders that may mimic necrolytic migratory erythema. As with other paraneoplastic syndromes, effective tumor therapy results in improvement of cutaneous symptoms (36). Unfortunately, patients with necrolytic migratory erythema may have metastatic disease at presentation. There have been reports of successful treatment using the somatostatin analog octreotide acetate. Jockenhovel et al. reported temporary resolution of cutaneous symptoms with octreotide acetate but noted that the drug had no effect on tumor growth (37). Resolution may be noted as early as 1 week after beginning therapy, but resistance can develop. Shepherd et al. reported successful treatment of cutaneous symptoms with intravenous amino acids (38). While waiting for response, denuded areas should be gently cleansed twice daily, covered with a bland emollient, and dressed with a nonstick bandage. Appropriate monitoring for secondary infection is indicated and is especially important in the hospitalized patient. Interestingly, one of the originally described patients was recently reported as a long-term survivor 24 years after diagnosis (39).

Paraneoplastic Pemphigus

Pemphigus is an immunologically mediated blistering disorder of the skin (40). The three main subtypes, based on target antigens, include pemphigus vulgaris, pemphigus foliaceus (including fogo salvagum, an endemic form), and paraneoplastic pemphigus (PNP). PNP is characterized by severe stomatitis, oral ulcers, and skin lesions with variable morphology (41,42 and 43). It is characteristically associated with hematological malignancies, especially non-Hodgkin's lymphoma and chronic lymphocytic leukemia (42). It has also been associated with spindle cell sarcoma, Waldenstrom's macroglobulinemia, thymoma (malignant and benign), Castleman's tumor, and pancreatic carcinoma (42,44,45,46,47 and 48). The pathogenesis centers on production of autoantibodies that attack components of the hemidesmosome and desmosome that function to link the epidermal cells to their basement membrane and to one another (42). Weakening of this scaffolding system renders the epidermal cells more susceptible to shearing forces, resulting in formation of blisters. The blisters rupture and result in erosive stomatitis, oral ulcers, and cutaneous erosions. In PNP there may be autoantibodies that recognize desmoglein 3, desmoglein 1, plakin proteins, and the hemidesmosomal BP230 (BPAg1) antigen (49).

On physical examination, there is erosive stomatitis and ulceration of the oral mucosa (42,43). There may be associated polymorphous skin lesions (Fig. 21-5). The oral lesions are typically painful and interfere with eating. Skin biopsy reveals varied findings (42). Perilesional biopsy reveals suprabasilar acantholysis of oral epithelium or skin epidermis. Necrotic keratinocytes, along with a scant lymphocytic infiltrate, may be observed. Direct immunofluorescence studies may demonstrate deposition of IgG and C3 on epidermal surfaces and variably along the basement membrane (50). Indirect immunofluorescence studies show the presence of antibodies that recognize antigens on monkey esophagus as well as transitional epithelium from rat bladder (50). Immunoprecipitation studies demonstrate the presence of autoantibodies to desmogleins 1 and 3, desmoplakins, or BPAg1 (42). Due to the complex nature of the disease and its diagnosis, the consideration of PNP demands consultation with a dermatologist.

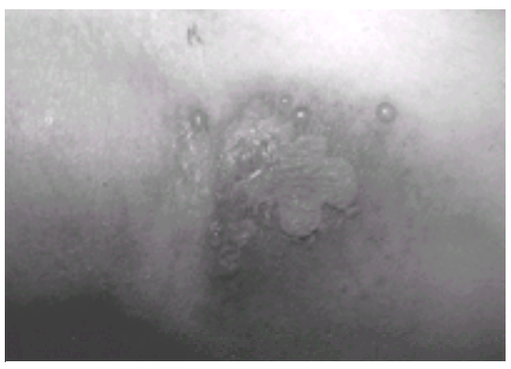

FIGURE 21-5. Paraneoplastic pemphigus. Although paraneoplastic pemphigus commonly affects the oral mucosa, other areas may present with superficial blisters as seen in this patient. (From NYU Skin & Cancer slide collection, with permission.)

Treatment can be difficult. Topical therapy, for the most part, is unrewarding; however, some patients may experience relief with application of high-potency steroid gels to affected oral mucosa on a twice daily basis. Viscous lidocaine generally is of little value, with most patients complaining of burning rather than experiencing relief. Resolution of ulcers has been obtained with administration of cyclosporine (5 mg/kg) in two to three divided daily doses (42). Cyclosporine, a potent immunosuppressive drug, is not without risk of significant side effects, including hypertension and renal compromise, and should only be administered by physicians who are familiar with its use and its side effect profile. Williams et al. report successful treatment of skin and oral lesions in a patient with PNP using mycophenolate mofetil (51). Mycophenolate mofetil is also a potent immunosuppressive agent with side potential effects that include bone marrow suppression.

Bazex's syndrome

Bazex's syndrome, or *acrokeratosis paraneoplastica*, refers to a cutaneous syndrome of psoriasoform lesions on the ears, fingers, and toes, with associated nail changes, that occurs in the context of an internal malignancy (Fig. 21-6) (52). Bazex et al. initially described this in association with carcinoma of the piriform sinus (53). Subsequent reports have described associations primarily with cancers of the aerodigestive tract and carcinomas metastatic to lymph nodes and mediastinum

(52,54,55). In addition, Bazex has been reported with colon (56), bladder (55), and neuroendocrine cancer (57), as well as primary cutaneous SCC (58).

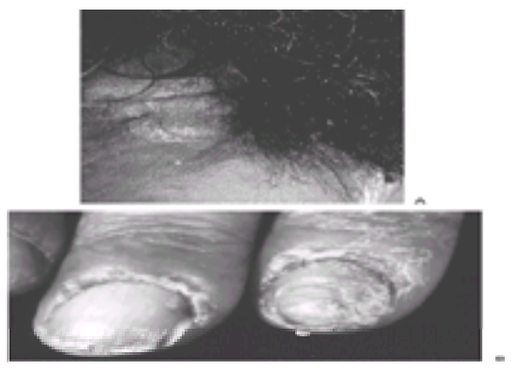

FIGURE 21-6. Bazex's syndrome. **A:** Psoriasoform dermatitis. **B:** Characteristic periungal involvement. (From Yale Dermatology Residents' slide collection, with permission.)

The syndrome may evolve through three stages (52,54,55). In the initial stage, there is vesicle formation with thickening of the periungal skin, subungal hyperkeratosis, and nail dystrophy. Erythematous, scaled plaques develop on the ears, fingers, and toes. The lesions characteristically affect the dorsal aspects of the digits and the helices of the ears. This stage can last anywhere between 2 and 12 months. The second stage ensues if the tumor remains undiagnosed and untreated, and is characterized by progression of skin lesions that are usually refractory to local therapy. With progression comes violaceous color change noted on the palms and soles. If the tumor remains unrecognized, the third stage of Bazex's syndrome is characterized by spread of skin lesions to the trunk, extremities, and scalp.

Histopathologic analysis may reveal foci epidermal cytoplasmic eosinophilia and vacuolization of keratinocytes with pyknosis of their nuclei. A perivascular mixed cell infiltrate may be present in the superficial dermis (52). In one report of Bazex's syndrome associated with SCC of the tonsil, direct immunofluorescence studies showed deposition of IgA, IgM, IgG, and C3 on the basement membrane (59). The authors stated that this supported and immunologically mediated pathogenic mechanism.

Treatment of the tumor can result in resolution of cutaneous symptoms (52,60). This was illustrated in a recent report of Bazex that occurred in association with a primary cutaneous SCC of the lower extremity (58) In that case cutaneous manifestations of Bazex's syndrome resolved after excision of the skin cancer.

Acanthosis Nigricans

Acanthosis nigricans can be associated with internal cancers, particularly gastric adenocarcinoma, as well as endocrinopathies resulting in hyperinsulinemia and insulin resistance (26,61,62). The pathogenesis may lie in the similarity of insulin and insulin-like growth factor (26). Binding of insulin-like growth factor receptors by insulin or by tumorderived growth factors may result in cellular growth and subsequent development of characteristic clinical findings.

On physical examination, velvet-like, hyperpigmented plaques are present on the neck, axilla, inframammary folds, and groin (Fig. 21-7) (62). There may be mucosal thickening as well (63). Microscopic examination shows hyperkeratosis and papillomatosis without epidermal hyperplasia or excess melanin deposition.

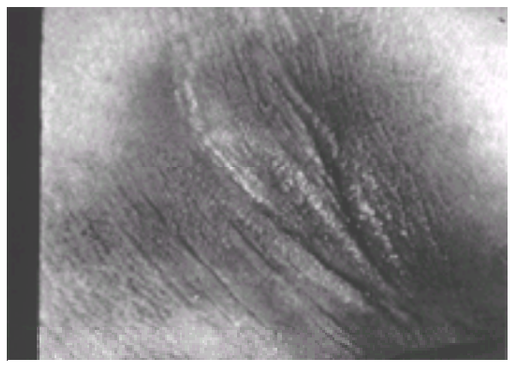

FIGURE 21-7. Acanthosis nigricans. Acanthosis nigricans is characterized by velvety, hyperpigmented plaques involving intertriginous areas. (From Yale Dermatology Residents' slide collection, with permission.)

Acanthosis nigricans is most frequently associated with adenocarcinoma of the stomach (64) but may be associated with almost any internal cancer. Recently, the coexistence of acanthosis nigricans and Leser-Trelat was reported in a patient with advanced gastric adenocarcinoma (15). In that case, appearance of both conditions preceded other manifestations of the malignancy by 6 months. Treatment is difficult even with successful treatment of the underlying cancer.

Dermatomyositis

Dermatomyositis is characterized by proximal muscle weakness in conjunction with characteristic cutaneous findings and may occur in adults in association with any internal cancer (65). The proximal muscle weakness manifests with inability to perform daily activities such as combing hair, putting on or removing a shirt or coat, and rising from a seated position. Cutaneous findings usually involve the periorbital area, chest, back, and fingers.

Cutaneous examination frequently reveals a heliotrope rash, Gottron's papules, and poikiloderma in the shawl distribution (Fig. 21-8) (65). The heliotrope rash is characterized by an erythematous dermatitis involving the periorbital areas of the face. Guttron's papules are characteristic raised lesions present on the extensor aspects of the fingers. The shawl sign refers to poikiloderma (blotchy erythema with telangiectasias, atrophy, and hypopigmentation) involving the upper chest, shoulders, and upper back.

FIGURE 21-8. Dermatomyositis. **A:** Gottron's papule. **B:** Characteristic erythematous dermatitis. (From Yale Dermatology Residents' slide collection, with permission.)

Skin biopsy is remarkable for superficial and deep perivascular infiltrate, and there may be basement membrane thickening as in lupus (65). CPK and aldolase are

elevated in dermatomyositis. Anti-jo-1 antibody and antinuclear antibodies may be present (65). The combination of the characteristic cutaneous findings, proximal muscle weakness, and elevated CPK and aldolase values are diagnostic.

Dermatomyositis may be associated with any malignancy, particularly ovarian cancer (65,66). This is supported by the findings of Cherin et al. (67), who reported ovarian cancer in 21% of their female patients older than 40 years of age with dermatomyositis. This represents a significant increase over the percentage of ovarian carcinoma in the general population (approximately 1%). Dermatomyositis has been reported with B cell lymphoma (68), thymoma (69), colon cancer (70,71), and metastatic melanoma (72). It should be clear that patients with dermatomyositis must be evaluated for the presence of an internal malignancy, with special attention to gynecological cancers.

Sweet's Syndrome

Acute febrile neutrophilic dermatosis was first described by Robert Sweet (73,74). It is characterized by the combination of acute onset of fever, anemia, neutrophilia, and characteristic skin lesions (26,75,76). Skin lesions can be described as erythematous plaques and blisters that involve the face, neck, chest, and extremities (Fig. 21-9). Involvement of the eyes, joints, and oral mucosa, as well as involvement of lung, liver, kidney, and central nervous system, has been described (76).

FIGURE 21-9. Sweet's syndrome. An indurated plaque in a patient with Sweet's syndrome in acute myelogenous leukemia. (From NYU Skin & Cancer slide collection, with permission.)

Sweet's syndrome occurs in the context of hematopoietic tumors, especially leukemia, and has been reported with solid malignant tumors (76). It has also been reported with chronic inflammatory disorders (77) and, in rare cases, with pregnancy (78). In one review of 249 cases, it was reported that Sweet's syndrome was associated with hematological malignancies in 40% of cases and with solid tumors in 7% of cases (76). In a study of cases of Sweet's syndrome associated with solid tumors (79), the most commonly associated malignancies were genitourinary carcinomas (37%), breast carcinomas (23%), and cancers of the gastrointestinal tract (17%). Sweet's syndrome responds rapidly to oral corticosteroid therapy (77). Other treatments, including potassium iodide, colchicine, dapsone, clofazimine, and cyclosporine, have been reported (76,77,80).

CANCER-RELATED GENODERMATOSES

Muir-Torre Syndrome

Muir-Torre syndrome (MTS) was first described by Muir et al. in 1967 (81) and by Torre in 1968 (82). It was Torre who noted the association of sebaceous adenomas of the skin and internal cancers. The internal cancers were most commonly low-grade colorectal carcinomas. MTS is transmitted in autosomal dominant fashion (83). The skin lesions most often associated with MTS are sebaceous adenomas, sebaceous epitheliomas, sebaceous carcinomas, and keratoacanthoma (83).

On physical examination, sebaceous adenomas appear as flesh colored to yellow papules, usually measuring less than 5 mm. They are commonly located on the face but can occur anywhere. Sebaceous epitheliomas can take on a cystic appearance, whereas sebaceous carcinomas typically appear as a papule on the eyelid and can be overlooked in the early stages. Sebaceous carcinomas are common on the eyelid but may appear as cystic lesions on the extremities (Fig. 21-10). Keratoacanthomas are a subtype of SCC and usually occur as a rapidly growing nodule with a keratinaceous central core.

FIGURE 21-10. Muir-Torre Syndrome. A sebaceous carcinoma in a patient with Muir-Torre Syndrome. (Photo by John Carucci, MD, PhD, Weil Medical College of Cornell University.)

The treatment of choice for sebaceous carcinoma and keratoacanthomas like SCC on the face is Mohs' micrographic surgery (MMS) (84). MMS offers the highest rate of cure and the advantage of tissue conservation due to superior margin control. Sebaceous epitheliomas can be excised with clear margins whereas sebaceous adenomas can be removed by tangential (shave) excision. Incomplete removal is likely to result in local recurrence. Management must proceed beyond treatment of the primary skin lesions. MTS is associated with colorectal, genitourinary, and hematological malignancies and appropriate cancer screening must be performed on patients and their family members due to the autosomal dominant mode of inheritance (83).

Cowden's Syndrome

Cowden's syndrome is also known as multiple hamartoma syndrome and facial and oral lesions in association with cancers of the breast and thyroid (85). Multiple hamartoma syndrome is inherited in autosomal dominant fashion, and although only approximately 100 cases have been reported thus far, it may be more common than originally thought (85,86). The usual age of presentation is between 20 and 40 years and the primary mucocutaneous manifestations include facial trichilemmomas and oral papillomas (85,86). Cowden's syndrome is believed to be due to mutations in the PTEN gene (87).

Trichilemmomas appear as tan to yellow verrucous papules on the central face (Fig. 21-11). Oral papillomas give a cobblestone appearance to the tongue and oral mucosa (85). There may be associated acral keratotic papules on the hands and wrists and translucent punctate keratoses on the palms and soles.

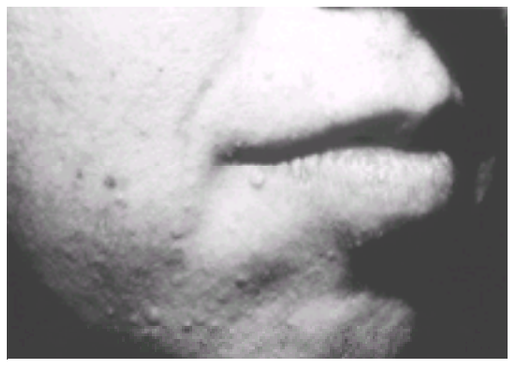

FIGURE 21-11. Cowden's syndrome. Perioral trichilemmomas are characteristic in Cowden's syndrome. (From Yale Dermatology Residents' slide collection, with permission.)

Suspicion for Cowden's syndrome should result in dermatological consultation for confirmation. Appropriate cancer screening should be performed with attention to breast and thyroid carcinomas (88,89 and 90). Trichilemmomas are benign lesions; however, trichilemmomal carcinoma has been reported in Cowden's syndrome (91). Treatment may be attempted by laser ablation, dermabrasion, or shave excision.

Multiple Endocrine Neoplasia

Multiple endocrine neoplasia (MEN IIb) is also known as the *multiple mucosal neuroma syndrome* (92). It is inherited in autosomal dominant fashion due to a mutation on chromosome 10q11.2 but can occur sporadically in up to 50% of cases (92). Patients usually present early and it is key that the appearance of mucosal lesions may precede development of internal cancers by 10 years. It is thought to be due to a mutation in the RET proto-oncogene, which may affect neural crest development (93).

Mucocutaneous signs include neuromas on the tongue, lips, and oral mucosa. These appear as papules or nodules and may involve the palatal, nasal, and laryngeal mucosa (92). Patients with MEN IIb exhibit a marfanoid habitus. Associated internal cancers include pheochromocytoma and medullary carcinoma of the thyroid. Gastrointestinal neuromas may lead to diarrhea, constipation, and megacolon.

If MEN IIb is suspected, consultation with a dermatologist and geneticist is indicated. Patients and family members need to be evaluated for internal malignancies and work up should include urine catecholamine level, thyroid scan, thyroid function tests, and computed tomography scan of the abdomen. Treatment of neuromas by excision often results in recurrence.

Peutz-Jeghers Syndrome

Peutz-Jeghers syndrome (PJS) or *periorificial lentiginosis* is characterized by perioral skin lesions in association with colonic polyps that have malignant potential (94,95 and 96). It can be inherited in autosomal dominant fashion or may occur sporadically (94,95 and 96). The pigmented lesions appear around the mouth during the first few years of life and precede the development of colonic polyps by at least 10 years in most cases (94,95 and 96).

The cutaneous lesions are pigmented macules usually measuring between 2 and 5 mm (Fig. 21-12) (94,95 and 96). They are uniformly brown to black in color, symmetrical, and occur in the perioral area, buccal mucosa, palms, soles, and digits.

FIGURE 21-12. Peutz-Jeghers syndrome. Labial lentigines in a patient with Peutz-Jeghers syndrome. (From Yale Dermatology Residents' slide collection, with permission.)

Suspicion for PJS should result in consultation with a dermatologist and gastroenterologist. PJS is associated with hamartomas of the colon, which have the potential to develop into adenocarcinoma. There is also increased risk of ovarian, breast, and pancreatic carcinoma. Therefore, adequate periodic screening is essential for patients with PJS.

Lentigines can be treated successfully with the Q-switched ruby laser (693 nm) (97,98 and 99).

INCURABLE NONMELANOMA SKIN CANCER

The incidence of nonmelanoma skin cancer (NMSC) continues to rise, with over 1.2 million cases reported in the United States last year (100). The majority of these (75%) were basal cell carcinomas (BCCs), the most common human cancer. The majority of the remaining 25% (>200,000) were primary cutaneous SCC. In most instances, these cancers are curable through office-based dermatological surgical procedures (101). The highest cure rates (99% for primary cutaneous carcinomas) and greatest conservation of normal tissue are offered by MMS (102). Other procedures, including standard excision, curettage and desiccation (C&D), and ablation by other methods have also proven successful (101). However, there exists a small subset of patients for whom the overall prognosis is not as favorable, and in whom NMSC may in fact be incurable. These include patients with inherited syndromes such as nevoid basal cell carcinoma syndrome (NBCCS) and xeroderma pigmentosum (XP).

Nevoid Basal Cell Carcinoma Syndrome

NBCCS is an inherited (autosomal dominant) condition characterized by predisposition for development of hundreds of BCCs in conjunction with findings that may include borderline intelligence, broad nasal root, palmar pits, and odontogenic cysts (103,104). The syndrome occurs because of defects in the PTCH regulatory gene (105). Mutations in PTCH are found in sporadic BCC as well as in NBCCS.

On physical examination, patients may present with hundreds of BCCs, mostly appearing as superficial erosions (106). Although usually small, lesions may become large over time if neglected (Fig. 21-13). It is likely that palmar pits represent small BCCs as well. The presence and severity of other physical findings may vary. Treatment of vast numbers of BCCs in a single patient presents a therapeutic challenge and requires the use of numerous methods including MMS, excisional surgery, destructive therapy such as C&D and cryotherapy, and treatment with topically applied agents including 5-fluorouracil (5-FU) and imiquimod.

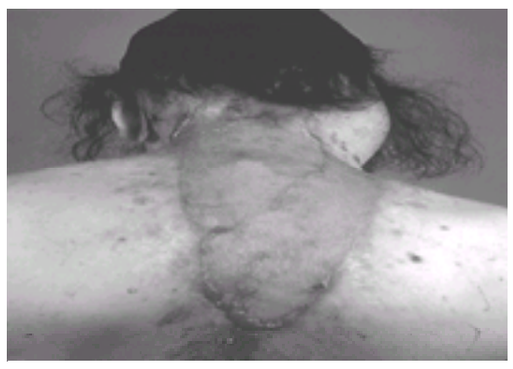

FIGURE 21-13. Nevoid basal cell carcinoma syndrome. Long-neglected, superficial basal cell carcinoma in a patient with nevoid basal cell carcinoma syndrome. (From NYU Skin & Cancer slide collection, with permission.)

Mohs' Micrographic Surgery

MMS offers the highest cure rates, along with the highest rate of tissue conservation (107). The principles of MMS have been reviewed extensively (84,107). In brief, MMS is performed by specially trained dermatological surgeons in an outpatient setting under local anesthesia. The clinical extent of skin cancer is assessed by curettage followed by removal of the lesion and a 1-mm margin of clinically normal skin. The specimen is mapped precisely and processed immediately under direction of the Mohs' surgeon. Slides are then interpreted by the Mohs' surgeon and any remaining areas of tumor positivity are removed in directed fashion in subsequent stages. After complete removal of the cancer, wound repair options are considered; repairs can be performed with confidence because MMS offers the highest sensitivity in achieving tumor-free margins. In NBCCS, we tend to reserve the use of MMS for high-risk cancers (i.e., skin cancers with aggressive histology or those that occur at high-risk anatomical sites such as the eyelid, nasal tip, or ear).

Excision

Excision of skin cancers offers excellent cure rates when tumor-free margins are achieved. Surgical margins of 4 mm can clear the tumor in 95% of cases (108). However, difficulties arise when performing excisions in NBCCS because there are so many skin cancers that it is difficult to determine where one cancer “ends” and another “begins.” Compounding this is the fact that superficial BCCs are multifocal in nature and tumor-free margins may be more difficult to obtain by conventional excision. We have found that tangential excision followed by gentle cautery is useful in the management of the majority of superficial BCCs encountered in NBCCS.

Destruction of Tumors

Superficial BCCs can be managed by destructive techniques, including C&D and cryosurgery. C&D is performed in three cycles of curettage followed by electrodesiccation (109). Although effective in the management of superficial skin cancers on the trunk and extremities (109), the potential drawbacks include a risk of hypertrophic scarring, along with a lack of histologic confirmation of negative margins.

Cryosurgery is performed by direct application of liquid nitrogen to lesions resulting in a temperature of –50°C (110). Although potentially effective in the management of superficial skin cancers, there are risks of hypopigmentation, hypertrophic scarring, and recurrence due to lack of margin control.

Medical Management

Topical therapies that have been used in superficial skin cancers include 5-FU and imiquimod. Topical 5-FU has been used extensively in the management of actinic keratoses (111) and has been used successfully in combination with cryosurgery for patients with NBCCS (112). Application of 5-FU usually results in a profound inflammatory response that may be disconcerting to the patient if he or she is not adequately prepared.

Imiquimod is a topically applied agent that induces local production of IFN-a (113,114). This, in turn, results in an immunologically mediated inflammatory response that in some cases results in regression of skin cancers (113,114). In pilot studies, it was found that imiquimod was effective in the treatment of superficial BCCs (113,114).

Xeroderma Pigmentosum

XP is an inherited condition characterized by photosensitivity, progressive neurological symptoms, and development of numerous ultraviolet-induced skin cancers that may result in metastasis and death (115,116 and 117). XP is transmitted in autosomal recessive fashion and occurs due to defective DNA excision repair after exposure to ultraviolet radiation (115,116 and 117). Defective postreplication repair occurs in the “XP variant” group (115,116 and 117).

Clinical manifestations appear during infancy and are characterized by severe photosensitivity and sunburn reactions (115,116 and 117). Signs of severe sun damage follow during childhood and include development of lentigines, telangiectasias, and actinic keratoses and skin cancers (Fig. 21-14) (118,119 and 120). The increased risk in development of BCC, SCC, and melanoma is approximately 1000-fold. Management should include aggressive measures to protect patients from the sun. These include limiting outdoor activity to nighttime and using sun protective clothing and sunscreens when traveling during the day.

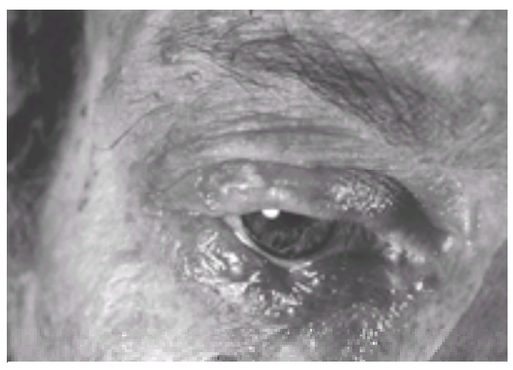

FIGURE 21-14. Xeroderma pigmentosum. Invasive carcinoma involving the lower eyelid in a patient with xeroderma pigmentosum. (From NYU Skin & Cancer slide collection, with permission.)

NMSCs must be managed appropriately by a combination of methods including MMS, excision, or C&D (121). Superficial NMSC and precancerous lesions can be managed topically with 5-FU or imiquimod (113,114,122). Treatment with isotretinoin may be effective in reducing development of SCCs; however, any benefits are lost on discontinuation of therapy (123). Turner et al. report on a patient with XP who was successfully treated for melanoma *in situ* with intralesional interferon (124).

Periodic screening for melanoma is especially important due to the increased risk of XP. Melanoma, if detected, must be managed in standard fashion by excision with appropriate margins based on tumor depth (125).

CONCLUSION

Tumor-associated skin disorders may appear in many forms with varying degrees of severity. In selected cases, prompt diagnosis and effective management can allow for early detection of cancer and alter prognosis. It is therefore essential that any suspected case be evaluated by a dermatologist.

MANAGEMENT OF PRESSURE ULCERS AND FUNGATING WOUNDS

MARGARET T. GOLDBERG
NANCY L. TOMASELLI

This chapter presents two skin manifestations—pressure ulcers and fungating wounds—that are commonly seen in the palliative care patient.

PRESSURE ULCERS AND THE ONCOLOGY PATIENT

Pressure ulcers are complex wounds that are defined as lesions caused by unrelieved pressure resulting in damage of underlying tissue (1). Pressure ulcers pose a threat to the patient when immobility, nutritional deficits, advanced age, incontinence, radiation effects, metabolic abnormalities, pain, and persistent or recurrent disease coexist (2). In advanced cancer, clinical conditions such as anorexia-cachexia, malnutrition, anemia, and some metabolic alterations can further affect the skin (3). In the terminally ill, advancing weakness, fatigue, and immobility result in an increased risk of pressure ulcer development (4). Pressure sores can complicate care, increase costs, and more importantly, threaten the quality of life (5). The incidence of pressure ulcers in terminally ill individuals has been reported as ranging from 15–24% (6,7), with an average prevalence of 21% in a hospice setting (8). Given the condition of many advanced cancer patients, these high rates of pressure ulcers are understandable. Although there is extensive literature on pressure ulcers, there are few welldesigned, empirical studies investigating risk, causation, and prevention (9), and fewer still in the palliative care population. This leaves many questions unanswered, and the prevention and management of pressure ulcers remains anecdotal (10). Caregivers and patients must be educated in the current modalities of pressure ulcer prevention and management so that they can decide on the goals of care, and whether the prevention or treatment carries a greater burden than benefits. It should be noted, however, that in certain groups of patients pressure ulcers may develop or worsen despite aggressive preventative or curative treatment. It has been suggested that for patients in the terminal stages of an illness, limited treatment or comfort care and symptom limitation should be the primary goals (11).

ETIOLOGY OF PRESSURE ULCERS

Pressure ulcers develop as a consequence of the occlusion of capillaries from unrelieved external pressure. When pressure is applied from an external surface to a bony prominence (as in the ischial tuberosities when sitting or the coccyx when lying down), the soft tissue is compressed, causing localized ischemia. If the pressure is unrelieved, the capillaries collapse, further disrupting the flow of blood and nutrients. Eventually, hypoxia and edema lead to cellular necrosis (12).

FACTORS THAT INCREASE THE RISK OF PRESSURE ULCER FORMATION

Risk factors may be classified as intrinsic and extrinsic.

Intrinsic Risk Factors

Intrinsic risk factors for pressure ulcer formation include reduced mobility or immobility, sensory impairment, decreased level of consciousness, extremes of age, vascular disease, severe chronic or terminal illness, previous history of pressure damage, malnutrition, and dehydration (13).

Extrinsic Risk Factors

Pressure is the major causative factor in pressure ulcer formation. The pathological effect of excessive pressure on soft tissue can be attributed to the intensity and duration of the pressure and the tolerance of the tissue (the ability to endure pressure without adverse sequelae) (13).

Shearing

Shearing is causative in the creation of pressure ulcers. Shearing occurs when the skin remains stationary and the underlying tissue shifts (e.g., when the head of the bed is raised and the patient slides down toward the foot of the bed). The loosely attached superficial layer of tissue slides over the well-anchored, deeper tissue through which the blood vessels pass to reach the skin. Vessels may rupture, compress, or become distorted, resulting in deep tissue destruction (14).

Friction

Friction injuries occur when the skin moves across a coarse surface, such as bed linens (12), causing an abrasion of the epidermis and the dermis. This makes these tissues generally less tolerant of pressure and shear and provides a potential entry route for infective agents (9).

Urinary Incontinence

Urinary incontinence, which allows moisture to remain on the skin, can lead to maceration and excoriation, disrupting the integrity of the skin. Fecal incontinence and

diarrhea positively correlate with the development of pressure ulcers (15).

PRESSURE ULCER PREVENTION

Prevention of pressure ulcers is consistent with the goals of palliative care, which are to provide relief from suffering and improve the quality of life of both patients and their families (16). Chaplin (4), however, suggests that the comfort of the patient, along with the need to ensure quality of life for the patient and family, must be maintained at all times and may take precedence over the prevention of pressure ulcers. Therefore, pressure ulcers are not always preventable in those who are dying, and comfort may be more important to the patient and family.

If prevention is the choice of the patient and family, efforts begin with control or management of pressure ulcer etiology along with contributing factors. Pressure reduction (especially over bony prominences), keeping the skin clean and as free as possible from contamination by urine or feces, frequent turning, promotion of adequate hydration, and correction of nutritional deficiencies, along with providing active and passive motion, are all helpful strategies. Educating the patient and family regarding the need for a prevention program has been suggested as a preventive strategy for pressure sores in hospice patients (14). The Agency for Health Care Policy and Research (AHCPR) (1) developed guidelines for both the prevention and treatment of pressure ulcers. These guidelines were developed by independent, multidisciplinary panels of private-sector clinicians and other experts convened by the AHCPR to review the research and grade the evidence. In the absence of research, most of the guideline recommendations were made by expert opinion and panel consensus. The prevention guidelines have four components: risk assessment, skin care and early treatment, mechanical loading and support surfaces, and education (13). A comprehensive plan for pressure ulcer prevention is included in Table 22-1 (1). The risk for acquiring a pressure ulcer must be calculated on an ongoing basis and whenever the condition of the patient changes.

Activity or mobility deficit: bedbound patients
Reposition at least every 2 h.
Use pillows or foam wedges to keep bony prominences from direct contact.
Use devices that totally relieve pressure on the heels.
Decrease skin injury caused by friction and shear forces with proper positioning, transferring, and turning techniques.
Use devices that totally relieve pressure on the heels.
Avoid positioning directly on the trochanter.
Elevate the head of the bed as little and for as short a time as possible.
Use lifting devices to move rather than drag patients during transfers and position changes.
Place at-risk patients on a pressure-reducing mattress.
Do not use a donut-type device.
Activity or mobility deficit: chairbound patients
Reposition at least every h.
Have the patient shift weight every 15 min if able.
Use pressure-reducing devices for seating surfaces. Do not use donut-type devices.
Consider postural alignment, distribution of weight, balance, and stability, and pressure relief when positioning patients in chairs or wheelchairs.

TABLE 22-1. EARLY INTERVENTIONS

Risk Assessment/Identification of Patients at Risk

Clinicians are encouraged to select and use a method of risk assessment that ensures systematic evaluation of individual risk factors. Many risk assessment tools exist, but only the Braden Scale (17) and the Norton Scale (18) have been tested extensively. Risk should be reassessed periodically. Care should be modified according to the level of risk (25). Frequency of reassessment usually depends on patient status and institutional policy.

Pressure/Support Surfaces

The reduction or elimination of interface pressures involves the use of support surfaces. There are a variety of support surfaces available, but few clinical trials exist that evaluate these surfaces in terms of outcomes (19). Several factors are involved in the selection of a support surface for the individual patient. The AHCPR guidelines state that a static support surface can be used if a patient can assume a variety of positions without bearing weight on a pressure ulcer.

Moisture/Incontinence

1. Cleanse skin at time of soiling.
2. Minimize skin exposure to moisture. Assess and treat urinary incontinence. When moisture cannot be controlled use products that shield the skin from effluent, and use underpads or briefs that are absorbent and present a quick-drying surface to the skin.

Nutritional Deficits

1. Investigate factors that compromise patient's dietary intake (especially protein or calories) and offer support with eating.
2. 2. Plan and implement a nutritional support or supplementation program for nutritionally compromised persons, if it is consistent with the plan of care as agreed by the patient and caregivers.

Cachexia describes a combination of anorexia (loss of appetite), progressive weight loss, weakness, fatigue, malaise, and loss of skeletal muscle and adipose tissue. Patients with cachexia have a disturbed metabolic activity. Anorexia is common with most advanced cancers. Patients with anorexia may also have dysphagia (difficulty swallowing), abnormal taste sensation, depression, shortness of breath, dry mouth, or chronic nausea as contributing factors to anorexia (20). Treatment of depression, shortness of breath, dry mouth, and nausea may improve caloric intake (16). Supplements usually do not alter survival or the nutritional status of patients, and it is unclear whether they provide any symptomatic benefits. Dietary advice and counseling on the need to tailor nutrition to the patient's wishes and the futility of intensive or invasive nutrition are necessary (16).

Documentation

Interventions should be monitored and documented. Specific details are needed on who should provide the care, how often, and the supplies and equipment needed. How the care is to be undertaken should be individualized, written, and readily available. Furthermore, results of the interventions and the care being rendered and adjustment in the interventions as indicated by the outcomes should be documented. To ensure continuity, documentation of the plan of care must be clear, concise, and accessible to every caregiver (12).

MANAGEMENT OF EXISTING PRESSURE ULCERS

The aim of proposed treatment must be considered in the patient with existing pressure ulcers. Healing may not always be a realistic goal, and the priority then becomes patient comfort and the prevention of further complications (5). Care decisions taken must be discussed by the team providing care and documented with a clear rationale for the decisions reached (4). For example, if pain precludes turning and repositioning or even placement on a support surface, documentation of this agreement and knowledge of its consequences must be carried out. Early treatments of pressure ulcers are listed in Table 22-2.

Skin care and early treatment guidelines
Inspect skin at least once a day. Individualize bathing schedule, avoid hot water, and use a mild cleansing agent.
Minimize environmental factors, such as low humidity and cold air. Use moisturizers for dry skin.
Avoid massage over bony prominences.
Use proper positioning, transferring, and turning techniques.
Use lubricants to reduce friction injuries.
Institute a rehabilitation program.
Monitor and document interventions and outcomes.

TABLE 22-2. EARLY TREATMENTS

PRINCIPLES OF WOUND MANAGEMENT

Elimination or Reduction of Causative Factors

The main cause of a pressure ulcer is pressure; however, malnutrition, incontinence, friction, and shearing, if present, must be managed to facilitate wound healing (21). Assessment for these conditions (Table 22-3) is necessary; if present, interventions such as the following may be needed:

Eliminate/ reduce cause and contributing factors	Provide systemic support	Topical therapy: remove impediments to healing
Pressure Moisture Friction Shear	Assess and monitor patient's overall condition	Necrosis Infection Excess exudate Retain moisture and heat

TABLE 22-3. PRINCIPLES OF WOUND MANAGEMENT: PRESSURE ULCERS

1. Implementation of a turning/repositioning schedule if pressure appears to be the main cause.
2. Use of appropriate measures to reduce friction and shearing (e.g., trapeze, turning sheet, socks, use of knee gatch when head of bed is elevated).
3. Selection of a support surface that can deal with pressure, moisture, friction, or shearing.
4. Management of incontinence with external collection devices, bowel training, prompted voiding.

Doughty (21) maintains that failure to address cause will result in a nonhealing wound despite appropriate systemic and topical therapy.

Systemic Support

Optimizing the overall condition of the patient is necessary to facilitate wound healing. Inadequate oxygen and nutrients retard or prolong the wound healing process. Interventions are predicated on findings and may include actions that support tissue oxygenation, control of diabetes, measures to control insufficient dietary intake, the reduction of edema, and restoration of blood flow (21).

Topical Therapy

The purpose of topical therapy is to provide an optimal environment for facilitating wound healing; this begins with the removal of impediments to healing. Necrosis in a pressure ulcer provides a medium for bacteria and also prolongs the inflammatory phase of wound healing. Débridement usually is indicated for the necrotic pressure ulcer. Another impediment to wound healing that prolongs the inflammatory phase is infection. Pressure ulcers should be assessed for any signs of infection and cultured where appropriate. If the infection invades the surrounding tissue, systemic antibiotics should be considered so that blood and tissue antibiotic levels adequate for infection control can be achieved. Excess exudate can macerate surrounding skin and dilute wound healing factors and nutrients at the wound surface. Protection of the wound includes maintaining a moist wound surface, thereby preventing desiccation and enhancing epidermal migration. This also promotes angiogenesis and connective tissue synthesis. Thermal insulation of the wound maintains normal tissue temperature, which improves blood flow to the wound bed and enhances epidermal migration (22). Appropriate topical treatment is directed by these principles (21).

Education

The AHCPR treatment guidelines strongly propose pressure ulcer education not only for health care professionals but also for patients, family, and caregivers. The guidelines themselves can be used to educate colleagues about evidence-based pressure ulcer treatment. These guidelines are being used by many regulatory agencies to survey health care facilities, and Medicare benefits are reimbursed according to these guidelines. In addition, the guidelines have been used as the standard of practice in the courtroom (23).

Patient's Overall Physical and Mental Status

Comorbid illnesses (e.g., peripheral vascular disease or diabetes, immune deficiencies, collagen vascular disease, malignancies, and psychosis) may limit an individual patient's capacity to heal.

Nutritional Status

It must be verified that the patient is eating. The health history should be reviewed for recent weight loss and to determine whether the serum albumin level is below 3.5 g/dl. If intake continues to be inadequate, impractical, or impossible, dietary counseling should be initiated.

Pressure Reduction Needs

All patients with existing pressure ulcers should be assessed to determine their risk for developing additional pressure ulcers. A static support surface can be used if a patient can assume a variety of positions without bearing weight on a pressure ulcer and without “bottoming out.” An overlay mattress can be checked at various anatomical sites while the patient assumes various positions and outstretched hand (palm up) under the overlay below the body part. If there is less than an inch of support material, the support surface has bottomed out. A dynamic support surface is used when the patient cannot assume a variety of positions without bearing weight on a pressure ulcer, if the patient fully compresses the static support surface, or if the ulcer does not show evidence of healing. If the patient has large stage III or IV pressure ulcers on multiple turning surfaces, a low-air-loss bed or an air-fluidized bed may be indicated (23).

Assessment of Existing Ulcers

Assessment of the ulcer is the basis for planning treatment as well as evaluating the effects of interventions (Table 22-2). Establishing a baseline by in-depth assessment also improves communication among caregivers.

Pressure sores exist on a continuum from reddened yet intact skin to open wounds with extensions to underlying muscle and bone (10). Classification systems provide a means of assessing the extent of ulceration directly attributed to pressure, shear, friction, or a combination of these factors, and use of a recognized pressure ulcer classification system is advisable (24).

Stage

Staging or grading is a method for classifying wounds according to the tissue damage observed. Staging of a necrotic-covered wound cannot be confirmed until the wound base is visible. The Wound Ostomy and Continence Nurses Society (WOCN), in conjunction with the National Pressure Ulcer Advisory Panel (NPUAP), has

incorporated a four-stage classification system. It should be noted that although progression through the stages may occur, down-staging or reversal of the staging process cannot occur.

Stage I

Nonblanchable erythema of intact skin is the heralding lesion of skin ulceration. In those patients with darker skin, discoloration of the skin, warmth, edema, induration, or hardness also may be indicators.

Stage II

Partial-thickness skin loss involving the epidermis, dermis, or both, which may also present as a blister, is seen in stage II.

Stage III

Stage III involves full-thickness skin loss involving damage to, or necrosis of, subcutaneous tissue that may extend down to, but not through, underlying fascia. The ulcer presents clinically as a deep crater with or without undermining adjacent tissue.

Stage IV

Full-thickness skin loss with extensive destruction, tissue necrosis, or damage to muscle, bone, or supporting structures (e.g., tendon or joint capsule) occurs in stage IV.

Location

The location of the pressure ulcer identifies the position in which the patient remained for too long. Pressure ulcers occur over bony prominences, and the most common sites for pressure ulcers are coccyx/sacral, trochanter, and ischial areas, as well as the heels. However, elbows, ears, and occipital areas are also common pressure ulcer sites.

Size

The length, width, and depth of an ulcer must be measured, and checks should be done for sinus tracks, undermining, and tunneling. Measurements of these areas can be accomplished by using a sterile Q-tip or tongue blade.

Characteristics

It is important to note the presence of any granulation tissue, epithelialization, necrosis, and slough; measure the percentage present; and document these findings. If drainage is present, the amount, color, and consistency should be documented.

Periwound

The tissue surrounding the ulcer should be inspected, and any maceration, excoriation, or signs of infection, such as warmth or induration, should be noted.

Goals of Treatment

The goal of patient comfort may take precedence. A patient who experiences pain or agitation on turning or during administration of tube feedings may simply wish to forgo the sort of intensive management that may be required to heal advanced pressure ulcers (23).

Local Care

Goals are established for the care of the wound based on a thorough assessment of the ulcer and the patient. Setting goals for local ulcer care and consistently assessing for progress toward these goals allows new objectives to be set when goals have been met (22). If débridement is the goal, dressings that encourage débridement are no longer necessary once the necrotic tissue has been removed. Topical treatment of wounds involves the goals of cleansing, débridement, reduction of bacteria, and protection. Table 22-4 describes product selection based on the interventions derived from wound assessment.

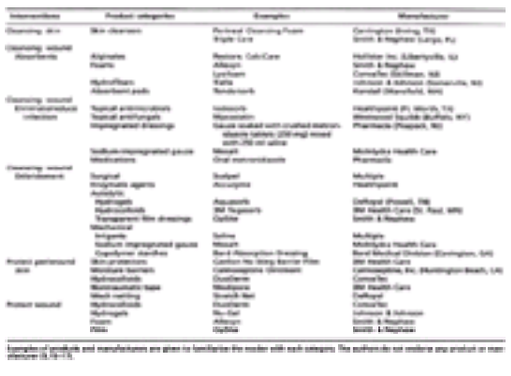

TABLE 22-4. WOUND CARE PRODUCT SELECTION FOR PRESSURE ULCERS

Cleansing

Skin. Cleaning the skin involves the removal of wastes and drainage from the skin around the wound. This goal can be accomplished easily by using skin cleansers that emulsify waste materials for ease of removal. Many of these also neutralize odors, which makes them excellent for use on the incontinent patient. Use of these skin cleansers facilitates the removal of surface debris without irritation to the epidermal layers. Some do not require rinsing, and others contain moisturizers that may interfere with adhesion of tapes or dressings. The manufacturer's directions should be followed for each specific product.

Wound. There are a few appropriate methods of cleansing a wound. Absorption of drainage and debris along with preservation of a moist environment or flushing with fluid to remove debris are appropriate methods of wound cleansing.

Absorbents. Absorbents absorb the exudate and debris from the wound and surrounding tissue. In this way, they reduce drainage and even edema from surrounding tissue while cleansing the wound and preserving a moist environment. They vary in the manner in which absorption occurs and the amount of drainage they can absorb. Many absorbents are used to fill in dead space and maintain a moist interface with each wound surface.

Irrigants. These fluids are used as mechanical cleansers to clean surface debris. It is the force of the fluid that accomplishes the results rather than the composition of the fluid itself; therefore, irrigants should be chosen with care. Sometimes, irrigation fluids are used to wet dressings for packing into wounds to eliminate dead space. Some of these fluids have been found to have some cytotoxic activity and thus may interfere with or delay wound healing (21). Irrigants that have been shown to be nontoxic are preferable, especially for the clean, noninfected wound.

Débridement. There are three main methods of débridement: autolytic, whereby the body's own fluid breaks down necrotic tissue; chemical, whereby chemicals

containing enzymes erode the necrotic tissue; and mechanical, which involves a mechanical force to disrupt the necrotic tissue.

Autolytic Débridement. Autolytic débridement is also known as *self-débridement* and includes the following:

1. Occlusive (moisture retentive) dressings: trap exudate, enabling white blood cells to liquefy and phagocytize necrotic tissue. This is selective (specific) débridement in that only necrotic tissue is affected.
2. Film or moisture vapor-permeable dressings: semiocclusive dressings in that they allow the exchange of gases and vapors but trap exudate under the dressing.
3. Hydrogels/gels: aid in rehydration of necrotic tissue, enabling autolysis to occur. These must be kept moist and not allowed to dry out.

Chemical Débridement. Enzymes chemically digest debris and necrotic tissue. Eschar must be cross hatched to facilitate penetration of enzymes. Surrounding skin must be protected from moisture. Iodine renders some chemical débriders ineffective, as does a change in the pH of the wound. Some require a moist environment and multiple dressing changes. As with all dressings, the specific manufacturer's directions must be followed.

Mechanical Débridement

1. Impregnated gauze: creates a hypertonic environment, which causes wound fluid to soften necrotic tissue. It must be used on wet wounds because it is ineffective on dry wounds.
2. Surgical débridement: most effective in selective dissection of necrotic tissue.
3. Wet to dry dressings: plain gauze, as it dries, traps debris that is removed when dressing is removed. It is nonselective in that all tissue, both necrotic and viable, is removed with the dressing. Gauze with large interstices to trap debris should be used.
4. Whirlpool/irrigation: the removal of necrosis and debris with fluid as the mechanical force.

Protection

Skin

1. Creams and lotions: lubricate and soften skin to promote rehydration.
2. Ointments: form an occlusive barrier over skin to protect from chemical irritation as in the presence of wound drainage or incontinence.
3. Skin sealants: form a layer of plastic polymer over the skin to protect it from friction of tape removal and irritating drainage. Some contain alcohol and sting if applied to denuded skin. One new product contains no alcohol and can be applied to excoriated skin.
4. Gelatin/pectin or hydrocolloid wafers: form seals over the skin. These are excellent dressings to use under tapes.

Wound

1. Moisture vapor-permeable dressings: semiocclusive dressings that allow the exchange of gases and vapors; they are helpful for the protection of superficial wounds.
2. Gelatin/pectin wafers, hydrocolloid wafers (occlusive-moisture retentive dressings): seal off a wound to protect it from the outside world. No fluid or bacteria can penetrate the hydrocolloid dressings. In addition, they provide the wound with an optimal healing environment. Because fluid is formed over the wound bed, trauma from dressing removal is eliminated. These are quite useful with incontinent patients.
3. Ointments and gels: provide a protective, moist environment for wounds and prevent desiccation.

Many of these treatments must be reapplied often to maintain a moist environment. Always refer to the package inserts and follow the manufacturer's directions to achieve optimal outcomes.

SUMMARY

People who are receiving palliative care are at great risk for acquiring pressure ulcers and at further risk of poor wound healing once ulcers do occur. However, a few small studies (4,5) have shown that those principles of care applied in acute care may also be useful within palliative care. Indications that pressure sores may be prevented in some instances and that healing can take place in the weeks leading up to death are beginning to be observed. Although these are not clinical research studies, they do reflect a willingness to identify interventions to deal with pressure ulcers and thereby improve quality of life in this patient population (Table 22-4).

MANAGEMENT OF MALIGNANT CUTANEOUS WOUNDS

The research-based evidence in the literature to guide caregivers in the management of malignant cutaneous wounds is sparse (26,27). Since 1966, approximately 90 articles have been published in recognized journals. Although the prevalence *is* low, these wounds present significant challenges for the patient and their health care providers (28,29) because they progress from skin erythema to a fungating mass with infection, bleeding, and odor. The information currently available in the literature concurs that management and assessment should be based on a holistic and interdisciplinary approach (30).

Definition

Malignant cutaneous wounds infiltrate and proliferate into and through the epidermis of the skin and are also referred to as *fungating* or *ulcerated wounds*. The patient may present with a cutaneous wound from a rapidly growing tumor, end stage disease, or from a tumor that was untreated or ignored (29,30,31 and 32). They occur in 5–10% of persons with metastatic disease and skin involvement, most often during the last 6 months of life (29). The wound originates from a local tumor, such as a basal cell or squamous cell carcinoma or a malignant melanoma. These wounds can also metastasize along a suture line after surgery for a primary lesion, from recurrence of a cancer, or via the lymphatics or bloodstream from a distal primary lesion. They grow rapidly, with either a fungus- or cauliflower-like appearance, or may ulcerate and form shallow craters. Some of these wounds are malodorous, exudative, and hemorrhagic, with sinus tracts or fistulas, and may cause pain and infection.

Pathophysiology

As the tumor infiltrates the skin, malignant cells spread through pathways of least resistance such as tissue planes, blood and lymph, capillaries, and perineural spaces. The tumor extends throughout the skin presenting as a fungating, foul-smelling mass. The smell is caused by the organisms *Proteus, Klebsiella, and Pseudomonas*. In addition, the blood, lymph interstitial tissue, and intracellular and extracellular compartments can be affected, resulting in disturbances in hemostasis. The tumor develops its own blood supply, which it may subsequently outgrow, resulting in necrosis in the center of the tumor. Abnormalities in the vascularization of the lesion and surrounding tissue result in hypoxic areas that provide a medium for anaerobic organisms to proliferate in the necrotic tissue. This results in the characteristic smell and exudate associated with these wounds. The hyperpermeability of the tumor to fibrinogen and plasma colloid, and the secretion of vascular permeability factor by many tumors, contributes to the large amount of exudate. Bleeding is caused by the neovasculature and pressure on adjacent tissues (28,30).

Malignant cutaneous wounds may occur as a solitary lesion or in a group. The color ranges from pink to red, violet, brown, or skin color. Many present as a sore that will not heal, progressing to a hard mass fixed to underlying tissue and then to a friable ulcerating lesion with purulent exudate, odor, bleeding, pain, and pruritus (27).

Etiology

Malignant cutaneous wounds are most often associated with cancer of the breast, lung, head, neck, oral cavity, stomach, kidney, bladder, uterus, cervix, vagina, vulva, ovary, colon, lymphoma, and skin. Collier (28) identifies the location of these wounds as follows: breast, 62%; head/face, 24%; groin/genitals, 3%; back, 3%; and others, 8%. The most prevalent types are breast cancer for females and lung cancer for males (27,30).

Goals of Management

Patient comfort is the primary aim of management, with a focus on control of symptoms such as pain, infection, bleeding, odor, exudates, and cosmesis. Toward that end, goals for the patient are to improve quality of life, maintain dignity, maintain independence, and foster self-esteem (29,30). The goals for management are to control tumor growth and bleeding and to preserve and restore tissue viability (28).

Assessment

The health care provider must perform a holistic assessment in consultation with the patient and caregivers. Assessment techniques must be appropriate and practical, based on the problems as perceived by the patient and family. There are several parameters to address for wound assessment.

Psychosocial Issues

The effects of the cutaneous malignant wound are devastating. The patient's previous coping skills, feelings, and reactions to the wound, as well as to the primary disease, should be assessed (33). There are several quality of life issues related to a malignant cutaneous tumor that may cause reactions such as fear, anxiety, depression, denial, anger, guilt, blame, loss of control, and lowered self-esteem. The patient may have difficulty with symptom management and feel embarrassed and isolated. The disease may be advanced and uncontrollable with accompanying pain management issues. The odor can cause a social stigma and inhibit intimacy. Self-image and sexuality can also be affected, with feelings of lowered self-worth regarding cosmetic appearance. The health care provider must be sensitive to the physical, psychological, spiritual, and emotional consequences of the disease (30).

Wound Characteristics

Wound appearance is described in terms of the percentage of viable or nonviable tissue. Terms used to describe the wound are *necrosis, slough, bleeding, ulceration, or granulation*.

Measurements of the size of the wound are vital to determine if the wound is improving or deteriorating. A paper ruler or camera with a scale within the frame can be used to obtain objective measurements for length, width, depth, and any undermining. Due to the friability of these wounds, it is not recommended to trace them on a clear paper covering, as bleeding may be induced (28).

Odor is assessed by the subjective report of the patient and family. Odor may indicate necrosis or infection. It can be foul or sweet.

The condition of the periwound skin should be assessed. Signs of local infection include inflammation, erythema, heat, or pain. The patient may also be febrile and have an elevated white blood count if the infection is systemic. The local area may be edematous or tender, and a fungal rash may be present.

Pain assessment involves noting the type of pain, severity, duration, precipitating factors, and impact on activities of daily living.

Exudate is assessed for color, consistency, and amount. Increased drainage may be indicative of infection; areas of maceration should be noted.

Wound characteristics should be assessed and documented on initial assessment and weekly thereafter. Accuracy and consistency of wound assessments can be facilitated through the use of charts (36), which can be used by the multidisciplinary team to evaluate the current status of the wound. Based on the wound assessment, planning can then begin to determine the treatment objectives. The treatment objective then drives decisions for treatment regimens.

Management/Interventions

Antineoplastic Treatments

Antineoplastic treatments include radiotherapy, surgery, cryosurgery, laser therapy, and cytotoxic or hormone replacement therapy (28,33). Palliative radiation can provide symptom control by decreasing pain, bleeding, and exudate. It may also preserve structure, function, and cosmesis. Chemotherapy or hormonal therapy can relieve tumor symptoms by reducing tumor size, pain, and bleeding. Surgical intervention can be used to excise or debulk the tumor or minimize the risk of fungation. Laser therapy reduces pain and necrotic tissue in preparation for possible excision of the tumor and skin grafting (29,34). All symptomatology exhibited by the patient must be addressed to achieve optimal patient outcomes.

Local Wound Care

Wound Care Product Selection

Caution must be used when selecting a dressing to ensure it will not interact with any course of treatment at the time, such as use of occlusive dressings during radiation treatments (28). Other considerations for wound care products include cost, number of dressing changes, availability, ease of application, and education (35). Dressing selection is predicated on the assessment process. Table 22-5 describes product selection according to interventions that are derived from wound assessment.

TABLE 22-5. WOUND CARE PRODUCT SELECTION—MALIGNANT WOUNDS

Wound Cleansing

Wound cleansers remove exudate and necrotic tissue from the wound bed, providing odor management, débridement, reduction of bacterial load, and cosmesis. Cleansing should be gentle to prevent pain, further trauma, or bleeding. Products that achieve this goal include irrigants (such as commercial cleansers and saline) that mechanically cleanse the wound, and absorbent dressings.

Pain

The amount of pain is dependent on the position of the wound site, degree of disease, nerve involvement, soft tissue damage, and the individual's pain tolerance.

To minimize the level of pain and trauma, maintain a moist wound environment and reduce the number of dressing changes. Examples of dressing categories that accomplish these goals include contact layer dressings, nonadherent gauzes, coated gauzes or impregnated gauzes, and semipermeable foam dressings. Anesthetic gels or systemic analgesics may be needed to reduce pain and can be administered before the dressing change (34).

Odor

Wound cleansing, containment of drainage, dressings with an airtight seal, and proper disposal of soiled dressings are the first steps for odor control. Wound cleansing helps to remove necrotic tissue and reduce bacterial growth. Débridement can also be instituted to remove necrotic tissue. There are several products that can be used for odor control. Topical metronidazole gel can be applied to the wound or given by a suppository (29). Charcoal dressings are available that are odor absorbent with antimicrobial activity. Sodium-impregnated gauze can also be used to control odor. External deodorizers and air fresheners that mask odors are rarely used, as they

can be nauseating when mixed with wound odor.

Exudate

Copious amounts of exudate can be absorbed with alginates, foams, and hydrofibers in conjunction with absorbent pads. Dressings should be changed once strikethrough (the drainage can be observed through the back of the dressing) is present. Large amounts of drainage can be contained with a drainage pouch if dressings require changing more than every 4 hours (40). Some of these pouches provide access to the wound without removal for dressing changes, and also have adaptors to connect to over the bedside drainage (such as a urinary collection bag) for highly exudative wounds.

Bleeding

Care must be taken when removing dressings to prevent bleeding. Warmed normal saline irrigation can be used to further moisten the dressing to prevent adherence to the wound. Capillary bleeding can be reduced with silver sulfadiazine (34). Alginates, collagens, and nonadherent gauzes provide hemostasis for light bleeding and absorption without adhering to the wound bed. Bleeding can also be stopped with local pressure for 10–15 minutes. For bleeding that continues, hemostatic dressings, such as gelfoam, can be used to promote clotting (29). In addition, cautery can be achieved with silver nitrate sticks. For profuse bleeding, ligation or cauterization may be necessary.

Infection

As the necrotic tissue becomes colonized with aerobic and anaerobic bacteria, infection can result. If the wound shows signs of clinical infection such as induration, inflammation, erythema, heat, or pain, a biopsy of viable tissue is necessary to determine systemic antibiotic therapy. Topical antimicrobial creams, gauze dressings soaked with crushed metronidazole tablets (250 mg) mixed with 250 ml normal saline, and sodium-impregnated gauze can reduce bacterial loads. For systemic infection evidenced by fever, leukocytosis, or cellulitis, oral antimicrobials or oral metronidiazole may be indicated. Fungal infections can be treated with topical antifungals.

Periwound Skin

Exudate can cause maceration of the periwound skin. This area can be protected with skin protectors or moisture barriers. A more absorbent dressing or more frequent dressing changes may be indicated. Prevention of periwound maceration also reduces pain. This is achieved through the use of protective barrier films, cream or ointment barriers, hydrocolloid barriers, nontraumatic tape, and mesh netting to anchor dressings.

Débridement

Débridement is achieved by surgical, enzymatic, autolytic, or mechanical methods.

Autolysis can be achieved with hydrocolloids, hydrogels, or transparent film dressings. Enzymatic agents chemically débride necrotic tissue. Mechanical methods include irrigants, sodium impregnated gauze, and absorbent products.

Cosmesis

Patient participation is important so as to choose a dressing that is aesthetically acceptable. The goal is to restore symmetry. Dressings that are low profile or fill a defect may be used to maintain symmetry. Other team members that can assist with cosmesis include social services, psychiatry, image consultants, or cosmetologists (34).

SUMMARY

The primary goal of management for malignant cutaneous wounds is the control of the symptoms. Realistically, the goals are to provide an optimal environment for wound healing; reduce odor, drainage, and pain; and provide psychosocial support.

A holistic assessment in consultation with the patient enables the health care provider to implement the optimal wound dressing and provide psychological, emotional, social, and spiritual comfort for the patient. Caregivers should be included in this process to assist the multidisciplinary team in meeting all the needs required for the patient with a malignant cutaneous wound.

LYMPHEDEMA

MARGARET L. FARNCOMBE
E. DRUMMOND ROBERTSON

Lymphedema is an abnormal accumulation of tissue proteins, edema, and chronic inflammation caused by damaged or blocked lymphatic vessels. Significant discomfort, impaired function, and unsatisfactory body image resulting from this complication to cancer and its treatment can cause individuals profound morbidity and adversely affect their quality of life.

Although lymphedema can be congenital *(primary*) or acquired *(secondary*), only lymphedema secondary to malignant disease is discussed in this text. Acquired lymphedema secondary to cancer is often considered benign and not life-threatening. Accordingly, lymphedema remains poorly researched and understood, and its true occurrence is probably underdiagnosed. No clearly defined, universally accepted diagnostic guidelines have been developed or used, and as a consequence, treatment is often ignored. All too often, comments such as “You will have to live with it” or “There is nothing we can do to help” are the conclusions presented to patients. In other cases, well-intentioned but inappropriate treatment may be initiated.

Based on the studies available to date, it is clear that the incidence and prevalence of lymphedema secondary to all types of malignancies make it a common condition, one that instills significant morbidity in patients as well as having far-reaching implications in our health care systems.

PATHOPHYSIOLOGY

The lymph vascular system's function is to clear the interstitial spaces of macromolecules (proteins too large to reenter the blood vessels directly) and the water that acts as their carrier from the tissues and transport them back to the intravascular circulation (1) (Fig. 23-1). Normally, this process relies almost entirely on local tissue movement to induce the lymph flow. The flow is therefore a passive process that is dependent on changes in local hydrostatic and osmotic pressures.

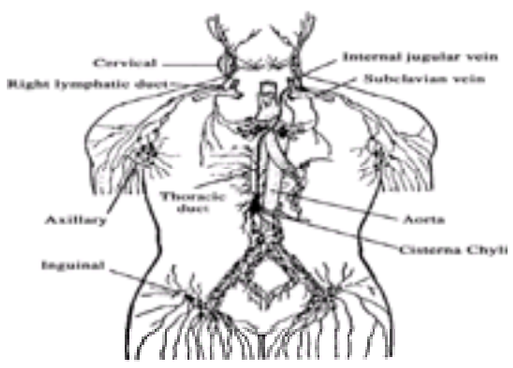

FIGURE 23-1. The lymphatic system.

Although pure lymphedema remains poorly understood and clinically difficult to induce, it is generally accepted that it occurs when lymphatic production exceeds the lymphatic transport capacity. In most patients with lymphedema secondary to malignant disease or due to treatment of the disease, an obstruction of lymph drainage occurs, resulting in a gradual buildup of the macromolecule proteins within the tissues. The resultant failure of the lymph vascular system to maintain an adequate drainage capability, in combination with an inadequate scavenging of stagnating plasma proteins by macrophages, results in progressive chronic lymphedema.

Chronic edema rarely, however, arises from the failure of one system alone (2). Damage to the vascular system as a result of surgery, radiotherapy, or progression of the disease also frequently causes damage to other vessels. Edema is therefore often secondary to blocked lymphatics plus venous stasis. Recent studies suggested that the pathophysiology of edema in postmastectomy patients may involve several additional mechanisms, including a possible rise in capillary blood pressure, which in turn may cause an increase in net capillary filtration, placing an increased load on already damaged lymphatics (3).

PATIENTS AT RISK

Factors that contribute to the development of lymphedema include radical surgeries and extent of lymph node dissection, radiation of lymph nodes, postoperative wound complications, and subsequent cellulitis of the limb.

Patients most at risk of developing secondary lymphedema are as follows (4):

1. Breast cancer patients who have had surgery involving nodal dissection. There is an added risk if such patients have undergone postoperative radiotherapy.
2. Patients with malignant melanoma of the arms or legs with nodal dissection or radiotherapy.
3. Prostate cancer patients who have had surgery or whole pelvic radiation.
4. Patients with gynecological cancers with advanced disease, surgical procedures, or radiotherapy.
5. Patients with advanced testicular cancer.
6. Patients suffering advanced neoplastic disease in which the metastatic spread is found in the lower quadrants of the abdomen, thus impeding venous and lymphatic drainage.

Other factors, such as advanced age, poor nutritional status, and obesity, should be monitored as they may lead to delayed wound healing, which in turn is an important risk factor for the development of lymphedema. Other concomitant diseases, such as diabetes, renal failure, and cardiac disease, also aggravate edema of a limb (5).

INCIDENCE

The overall incidence of lymphedema is difficult to determine. Research published on its incidence and prevalence tends to be variable, and can also be misleading because the diagnostic criteria has not yet been standardized, the type and extent of surgery are variable, and the length of the studies undertaken is frequently too short to include patients with lateonset lymphedema.

For most patients, no investigations are currently routinely performed to determine whether the edema is entirely secondary to lymphatic obstruction or also involves damage to other vascular structures. In addition, statistics reported in specific studies tend to refer to lymphedema from one particular malignancy alone, the most widely studied and reported being breast cancer.

Breast cancer is currently the most prevalent malignancy in women in the United States. It is projected that it will affect one in nine women during their lifetime. Surgical and medical therapies based on mastectomy and radiotherapy are increasingly extending patient life spans, but these procedures also may place patients at high risk of developing lymphedema (6). Primarily because of the nonstandard reporting criteria outlined earlier, the available literature suggests that the overall incidence of lymphedema in patients with breast cancer who have had surgical intervention, with or without radiotherapy, is between 6.7% and 62.5% (7,8 and 9). The research, however, does agree that axillary node clearance and postoperative radiotherapy do increase the risk for developing lymphedema, with radiotherapy cited as the most important risk factor (10,11).

Although the reasons for performing either axillary or groin nodal dissections during surgery may have changed from being solely therapeutic to also being important for staging and diagnostic potential, it still causes profound disability by increasing the risk of lymphedema (12). Early detection and longer survival also have increased the incidence and length of time patients experience this complication.

TYPES, STAGES, AND GRADES OF LYMPHEDEMA

Edema is generally not detectable clinically until interstitial volume reaches 30% above normal. Symptoms have been reported to occur immediately after surgery and to persist. In most cases, however, lymphedema first occurs 18–24 months after treatment. It has been reported to occur as a new finding even 30 years after diagnosis and treatment of malignant disease.

There are four specific types of lymphedema (13):

1. Acute transient and mild occurring within a few days after surgery as a result of cutting lymphatic channels. It usually responds to elevation and exercise such as muscle pumping (i.e., making a fist and releasing it).
2. Acute and painful edema occurring 4–6 weeks postoperatively as a result of acute lymphangitis or phlebitis. This can be successfully treated with elevation and antiinflammatories.
3. The third type is an acute erysipeloid form, which often occurs after an insect bite or other minor injury or burn and can be superimposed on a chronic edematous limb.
4. The most common form of lymphedema is insidious and painless and is not associated with erythema. It develops much later and is most apparent 1–2 years after treatment. It is the most difficult edema to reverse because of its pathophysiology. This chronic lymphedema occurs secondary to a deficient lymphatic system that is incapable of compensating for the increased demand for fluid drainage. Consideration should always be given in this patient population to rule out recurrence of disease.

This last and most prevalent form of lymphedema is staged according to appearance of the limb and response to management. During the early stage edema is pitting and decreases with elevation of the limb. As the condition progresses untreated, the edema becomes firm and nonpitting, this change being secondary to chronic inflammation, fibrosis, and sclerosis caused by stagnation of the plasma proteins. The late stage results from the overproduction of connective tissue, resulting in hardening of the skin, and the condition is commonly referred to as *lymphostatic elephantiasi*s.

Lymphedema is often graded using the following scale (14):

1. Edema that is barely detectable.
2. A slight indentation is visible when the skin is depressed.
3. A deeper fingerprint returns to normal in 5–30 seconds.
4. Edema is the maximal grade; the affected extremity may be 1.5–2.0 times its normal size.

This scale has limitations, however, and can be used only during the early stages or when edema is pitting.

INVESTIGATIONS

Lymphography and lymphangiography previously were considered the “gold standards” for demonstrating lymphatic abnormalities. These techniques are, however, invasive and difficult to perform in the presence of edema. They also are limited in providing information on anatomical detail and frequently visualize only the large subcutaneous collecting lymphatics (15).

Quantitative lymphoscintigraphy (isotope lymphography) (16,17) has been more useful in detecting lymphatic insufficiency because the dynamics of flow and rate of transit via lymphatic vessels are studied using a gamma camera. It is also a more comfortable procedure for the patient because it is administered by an interstitial injection instead of direct cannulation of peripheral lymphatics.

Magnetic resonance imaging is also sometimes used to view soft tissues and lymphatics and is even less invasive. Color Doppler (18) has been used to define or rule out venous abnormalities and can be useful in patients for whom more invasive tests are contraindicated or inappropriate.

In general, for determining the management of lymphedema symptoms, invasive investigations are frequently not necessary in patients with acquired lymphedema secondary to cancer. They may, however, be helpful in determining the management required for patients who do not respond to conservative treatment or in whom a mixed etiology of limb edema is suspected.

CLINICAL ASSESSMENT

A full clinical assessment for lymphedema (Table 23-1) should address the history of the primary disease, including previous surgery, any nodal dissection, and radiotherapy. It also should include a full history of the duration of the edema, symptoms, complications, and past treatments. The physical examination must include measurements of the affected limb and the contralateral normal limb for comparison. An assessment of motor and sensory function is imperative, and pulses should be checked. It is also helpful to be aware of the cardiac and renal function of each patient, as treatment to mobilize fluid could put added strain on these organs.

History
Primary disease (including surgery, nodal dissection, and radiotherapy)
Lymphedema (duration, symptoms, complications, treatment)
Functional and social history
Changes in activities of daily living, depression, self-esteem
Physical examination
Inspection
Pulses
Motor function
Sensory function
Measurement of affected and normal limbs

TABLE 23-1. CLINICAL ASSESSMENT

Although pain and other discomforts are common complaints, patients are often even more concerned about the “heaviness” and loss of function in the limb. Many describe the limb as “ugly” and find it impossible to wear their own clothing because of the physical size of the affected limb.

A functional history with specific questions concerning activities of daily living, difficulty with clothing, and other possible limitations secondary to the edema are essential. The patient's sense of self or selfesteem and any possible signs and symptoms of depression need to be assessed. Patients frequently feel they have lost their independence and freedom because of both the difficulty experienced in managing the activities of daily living with the often “useless, heavy arm or leg” and the embarrassment of going out and meeting people with “this deformity.” For all these reasons, the patient's quality of life is often severely compromised and should be considered to constitute an integral part of the treatment process.

MONITORING

The size of the limb should be measured before treatment is begun and then at regular intervals during management to permit detailed monitoring of the patient's progress. Several methods of measurement have been used in the past (19). In some centers, the arms are measured at only one location and compared with previous measurements, with a difference of 2.5 cm indicating moderate lymphedema. Other centers use the same basic method but take measurements at two or three levels and compare the results. These methods tend to be unreliable because of the variability of the shape of the limb from point to point and because of differences in shape before and after treatment. Other practitioners advocate submersion of the limb in water and measuring the volume of the displaced liquid. This method, although considered the most accurate, is a complicated and often messy procedure that makes it impractical for home use.

An accurate and more practical method of assessing volume of the limb is shown in Figure 23-2, which demonstrates measurements for the upper limb. The circumference of the arm is taken at 2-cm intervals using a tape measure with weights at either end, which are allowed to hang freely. Assessment bias can occur if the examiner adjusts the tension on the tape. An adapted formula for the volume of a cylinder is used to determine the volume of the arm from wrist to axilla. This methodology is more precise than using only a few comparative points and allows more accurate and detailed comparisons with the other arm and with the same arm over time. It is also much easier and less cumbersome than submersion in water and can be undertaken readily in the patient's home. It does not, however, provide for the volume of the hand, which must be determined and compared separately.

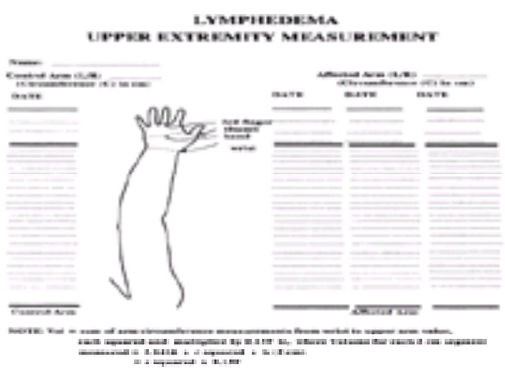

FIGURE 23-2. Technique for measurement of upper extremity lymphedema.

Perhaps more important than the particular method used is the need for consistency in the technique used (Table 23-2) (20). A decrease in limb size indicates that treatment is beneficial and should be maintained. More importantly, such a result also tends to encourage patient compliance because a measurable improvement can be seen readily; this is particularly important at times when visual changes are not obvious. Volumetric measurements provide a quantitative result and are extremely valuable for determining and following the treatment progress.

At each measuring occasion:
Position the limb at the same height
Remark the limb
Record the starting point accurately
Ensure that tension is not applied to the tape measure
Ensure that the tape measure is straight
Use the same number of measurement

TABLE 23-2. GUIDELINES FOR LIMB VOLUME MEASUREMENTS

Several other methods of assessing and monitoring lymphedema are currently being investigated. Studies to assess the elasticity and the viscosity of skin by using a technique involving vertical extensibility by suction may prove useful in assessing functional difficulties in relation to skin infiltration and may be useful in followup (21). Subcutaneous interstitial fluid pressure and arm volume also can be measured by the wick-in-needle method (22). Multifrequency bioelectrical impedance analysis may offer a means to an earlier diagnosis and more accurate monitoring of extracellular fluid changes during and after treatment (23). It is unclear at this time whether any of these techniques offer any information beyond that provided by a good clinical assessment.

PREVENTION

The ultimate prevention would be a change in the method of diagnosing and treating the previously mentioned malignancies. A change from aggressive, disfiguring surgeries such as radical mastectomies to more conservative lumpectomies for breast cancer has been helpful in decreasing many postoperative complications, including lymphedema. As removal of lymph nodes during initial surgery has also increased the incidence of lymphedema, any reliable method to eliminate this procedure while obtaining the same results would also be very important in preventing this unpleasant complication. The lymph nodes are small structures (approximately the size of a small pea) located throughout the body that serve as an immunological filter. In patients with a breast malignancy, cancer cells migrate to the lymph nodes in the axilla. During axillary node dissection, a sample of five to ten of the existing (over 50) small nodes are removed to be studied microscopically. A sentinel node biopsy is a new procedure presently being investigated in an attempt to reduce the extent of axillary node dissection by removing the one node most likely to have cancer cells (24). This technique uses a combination of a radioactive tracer and a color dye. The dye is injected around the tumor or into the biopsy cavity. The dye migrates through the lymphatic channels to the regional lymph nodes drained by the cancer. The specific node most likely to be involved with cancer is then identified and only this node is removed for analysis. This method can be nearly as effective as an axillary dissection. Although the research is not completely refined, the goal is to find a noninvasive test that is even more predictive than axillary dissection.

Ideally patients should be assessed preoperatively and taught the appropriate exercises to squeeze soft tissue and encourage proximal lymph flow. These exercises then would be continued postoperatively (25). The main problem with this prophylactic treatment plan is compliance. Not surprisingly, patients who have never experienced the symptom of lymphedema personally have a tendency to feel complacent and believe that this will never happen to them; therefore they stop treatment.

Patients also should learn to recognize early warning signs, such as tightness, aching, pain, or other sensory changes in the limb. Any signs of infection or cellulitis should be reported and managed appropriately, and delayed wound healing should be regarded as a risk factor for the development of lymphedema.

TREATMENT

Although the full pathophysiology of lymphedema is poorly understood, the edema experienced in a limb, whether secondary to the primary diagnosis or resulting from treatment for the disease (e.g., surgery and radiotherapy), is probably multifactorial, with damage not only to lymphatics but also to the venous circulation system and other tissues as well. For this reason, treatment also must be variable. However, lymphedema is a chronic condition, and therefore treatment must also be chronic. To be effective and to encourage patient compliance, treatment must be consistent, clearly understood, and convenient.

Management of lymphedema is extremely variable in the medical profession, ranging from aggressive diagnostic procedures to precipitous operations. Scattered between these two extremes are quite a number of various conservative methods (5). Although treatment for lymphedema is usually the same for patients with or without active malignant disease, it is generally perceived that this treatment is more effective if there is no active disease present.

As early as 1855, in the German literature, surgeons Esmarch and Kulenkampff (26) described a treatment modality consisting of hygienic measures, elevation, and compression. Later, in 1892, Winiwarter (27), also a surgeon, advocated a similar conservative approach as the first choice of treatment. Excellent results were reported at that time; with minor alterations, this same treatment plan can still be very effective today. However, it must be remembered at all times that the single most important factor in management of lymphedema is patient compliance (28).

Treatment is most effective when a multidisciplinary approach involving physicians, nurses, massage therapists, physiotherapists, and occupational therapists is followed. As patient cooperation and compliance is of such great importance in the success or failure of what is often a lengthy course of treatment, an assessment by and continued consultation with a psychiatrist or psychologist is often also valuable in identifying problems and providing appropriate intervention related to the patient's overall psychological adjustment (29). Treatment consists of several basic but important elements (Table 23-3), which should be used in combination for maximum results (30,31).

Education
Manual lymphatic drainage
Massage
Compression garments
Bandaging
Compression sleeves or stockings
Exercise
Skin care
Consistent follow-up and compliance

TABLE 23-3. BASIC TREATMENT FOR LYMPHEDEMA

Education

Patients must be aware from the beginning that treatment probably will be required for the rest of their lives. It is important for patients to begin management as early as possible and to be consistent and dedicated. To enlist their active cooperation and compliance, they also need to be told about the predicted good results anticipated with treatment. Education includes a thorough discussion about the “do's” and “do not's” of caring for the lymphedematous limb (6). There are a number of things that can be done to manage lymphedema and avoid complications:

- Observe skin carefully each day and report any skin breakdown, weeping, or reddened areas to their doctor immediately.
- Avoid heavy lifting with the affected limb.
- Avoid use of hot tubs and saunas.
- Avoid cuts or burns to the affected limb by wearing gloves when gardening or doing housework.
- Refuse to allow blood pressure measurements or venipunctures from the affected limb.
- Maintain a healthy body weight.
- Exercise the limb regularly.
- Wear a compression sleeve when doing strenuous exercise or work or when traveling by air.
- Carry out self-massage daily, concentrating on using light pressure (if the skin turns red, the pressure is too firm). Ensure that strokes go up the arm to move the fluid out of the limb. Do not push fluid into the axilla. Spend more time on firm areas.

Manual Lymphatic Drainage

Recommended treatment for lymphedema is massage therapy plus the application of compression garments. This specialized treatment has several different names: *combined decongestive therapy, complex physical therapy, combined decongestive physiotherapy, and manual lymphatic drainage* (MLD). Regardless of the terminology, the treatment involves light massage, compression garments, exercise, and skin care. It is imperative that patients with lymphedema see their physicians before beginning treatment and that recurrence of disease, deep venous thrombosis, and cellulitis are ruled out (32).

A thorough knowledge of the mechanism and process of clearing the body of lymphatic waste must be understood before the treatment of MLD can be fully comprehended. The lymphatic system functions as a drainage and transport vehicle moving waste material from the interstitium. It removes proteins, fat, water, chemicals, organic and inorganic cellular products, and foreign organisms such as bacteria and viruses, clearing them from the interstitial spaces. This system relies almost exclusively on local tissue movement for lymph flow. The lymphatic vessels bring the fluid from the periphery to the lymph nodes, where it is filtered and the waste excreted and the useful material dumped back into the blood stream. The body has areas that have a high concentration of these nodes, known as *watersheds*. They are located in the neck, axilla, groin, and throughout the abdomen. These watersheds collect lymph from the body in quadrants. Although the nodes on one side of the body collect fluid from the same side quadrant (e.g., fluid from the lymphatic vessels from the right arm and right side of the trunk anteriorly and posteriorly superior to the umbilicus drain into the right axilla), there is some crossover between the right and left sides of the body. This communication is known as *lympholymphatic anastomoses* (33). Massage often takes advantage of this crossover to divert fluid to the contralateral fully functional lymph nodes. The lymphatic system can be further divided into superficial vessels situated just below the skin and superficial to muscle and deep vessels located near major veins and muscles. The fluid thereby is moved along superficial vessels by contraction of small muscles (and in the case of lymphedema, by the assistance of MLD or massage) and to deeper vessels and nodes by larger muscle contraction and venous flow.

MLD is a gentle massage technique that was developed in Europe in the 1930s. This very light massage directly affects the superficial lymphatics and helps to move the fluid along the pathways. The massage begins at the trunk and moves out to the periphery and back again. The massage starts at the neck, which is known as the *terminus*. This is where the lymph fluid returns to the bloodstream. The treatment begins here to clear the pathway so that it can accept more fluid. Then massage is continued on the unaffected side, with work on the chest and axilla for patients with upper extremity edema and on the abdomen and axillary nodes for those with lower extremity lymphedema. Again, this is to make room for the fluid from the contralateral side. Next we work on the affected side, directing all strokes to the unaffected side's axilla or to the abdomen. This is done to develop collateral lymphatics so they can handle the lymph-obligatory load (34). The limb is massaged gradually, moving distally until the hand or foot is reached. The therapist always follows the direction of the lymph flow towards the trunk. Once the hand or foot is completed the limb is massaged again, moving proximally to the trunk and collateral lymphatics. Treatment should last approximately 45 minutes per limb but can be considerably longer. For best results, treatment should be given twice each day for 2–4 weeks. These guidelines depend on the severity of the condition and patient availability. All during this process, more time is spent massaging any areas that are congested or firm due to buildup of fluid. Measurements should be taken every fifth treatment to monitor effects and encourage patient compliance. Once there has been a significant reduction in limb size, the compression bandaging can be replaced by a compression garment and the frequency of the treatment can be reduced (33).

Compression Garments

After massage treatment is completed, it is important to put some compression on the limb. This is done to preserve the positive results of the massage treatment. When the affected limb is under compression it increases the tissue pressure, resulting in a reduction of abnormal increased ultrafiltration and improved reabsorption. Compression also reduces fibrosis and sclerosis and increases the effectiveness of the joint-muscle pump (35). Ideally, the limb would be wrapped in a layer of foam

and short stretch bandages (Fig. 23-3, Fig. 23-4). A compression sleeve is often used instead for convenience, comfort, and ease of application. This is also something the patient can manage independently. The advantage of the bandages is that they create a higher pressure and usually obtain better results. For patients with very severe lymphedema, a prebandage combined with exercise can be done before treatment to get the fluid moving more quickly (33).

FIGURE 23-3. Patient with bandaging of upper extremity.

FIGURE 23-4. Patient with bandaging of lower extremity.

There are four standardized grades of compression. Grade I and II have little place in this treatment and are used more for superficial effects only in treating venous insufficiency. Grade III is used for superficial and deep tissue effects for grade I lymphedema. Grade IV is needed to produce a deep tissue effect for grade II and III lymphedema. Compression bandages are usually used for the initial treatment stage to quickly reduce limb size and compression garments to maintain this result long term (35).

Exercise

The third component to treatment is exercise; this is where patient compliance is especially critical. The joint-muscle pump assists in the movement of lymph and is, therefore, the key element in treatment. The exercises are not strenuous but rather simple range-of-motion-type exercises to keep muscles alternately contracting and relaxing to encourage lymph flow. There is no special equipment required. Exercises should be prescribed that fit within the person's pain-free range of motion and should only be done wearing a compression garment. The exercises should start distally and work proximally. It is important not to exercise too long or too strenuously, which could cause an unwanted increase in blood flow into the limb, possibly leading to more edema. It is recommended that each individual develop an exercise program that is comfortable for his or her general health, and increase the amount of exercise gradually as tolerated. The limb should also be elevated whenever possible to allow gravity to work on excess fluid (33).

Skin Care

The final but vital component to this treatment modality is good skin care. This is done to avoid any abrasions or irritations to the skin that could lead to infection. It is recommended that a water-soluble, fragrance-free lotion be used to moisturize the skin to avoid irritation (36). Abrasive products should not come in contact with the skin on the lymphedematous limb. The patient should also visually inspect the limb daily for trauma as sensory changes may have occurred, resulting in decreased perception to painful stimuli. If any abrasion or tear in the skin is found it should be treated immediately with an antibiotic cream (32).

It is imperative that MLD, which is the complete treatment of massage, compression, exercise, and skin care, be taught and performed by a qualified massage therapist or other health care professional with expertise and experience in this treatment modality. In time, patients (and families) can be taught to continue this treatment at home (37).

Intermittent Sequential Pneumatic Compression Pumps

Intermittent sequential pneumatic compression pumps have been used extensively in recent years to treat lymphedema, and some reported results have been encouraging, especially over the short term (38). However, for prolonged effects, patients in the studies still wore compression sleeves between sessions with the pump, and it is unclear whether the combination of pump and sleeve or stocking is any better over the long term than the compression garment alone. A study to evaluate the effects of pneumatic massage with uniform pressure, pneumatic massage with differentiated pressure, and manual lymphatic massage showed no difference between uniform-pressure pneumatic massage and manual massage, and both were better than differentiated pneumatic massage. Again, all patients wore compression garments between treatments (39).

Pneumatic pumps necessitate prolonged periods in clinic for treatment. Treatment becomes less accessible, more time consuming, and less convenient, all of which affects longterm patient compliance. Pumps may have a more beneficial effect in the early treatment of severe edema to soften the limb. A note of caution regarding in-home use of pumps is necessary. The use of sequential gradient compression pumps at home without the simultaneous MLD to prepare the healthy and impaired quadrants to receive the stagnant lymph being milked out of the edematous limb is a potentially dangerous medical practice. It often only relocates the site of the edema. In addition, excessive pressure can collapse the superficial lymphatics in a compromised system. Prolonged use of the pumps can also cause additional fibrosis and further exacerbate the lymphedema. Finally, these pumps are very expensive. For all these reasons, use of compression pumps has declined dramatically over the past few years.

If the pump is used, a compression garment must be applied afterward to prevent recurrence of edema, and care must be taken to ensure that the garment is not too tight if edema recurs. Pumps should never be used in patients with edema involving the trunk.

Other Treatment Modalities

A variety of other treatments deserve mention, as outlined in the following sections.

Antibiotics

Antibiotics should be used early, at any sign of cellulitis. Usually, oral penicillin or erythromycin is sufficient. When weeping edema is present, or for patients experiencing recurrent attacks of cellulitis, antibiotics may be required for a prolonged period (2).

Steroids

Steroids are often useful when edema is assessed to be secondary to obstruction by tumor or enlarged lymph nodes (2). If there are no contraindications to the use of steroids, a trial of dexamethasone is recommended in these cases only. This is best combined with MLD.

Diuretics

Diuretics act primarily by limiting capillary filtration and reducing circulating blood volume. They may be of benefit therefore in treating limb edema if the swelling is of a mixed origin; however, the function of the lymphatics is to remove protein and other macromolecules from the tissues. With the use of diuretics, fluid can be absorbed back into the vascular compartment, but proteins can return only via lymphatics, or can be broken down by phagocytosis. Diuretics therefore offer little improvement in true lymphedema and, in fact, may cause complications by mobilizing fluid from everywhere except the lymphedematous limb, resulting in hypotension and electrolyte disturbances (2). It is occasionally beneficial to combine steroids, diuretics, and MLD in patients with obstruction of the lymphatic system in the areas of the major lymph nodes due to active disease. The steroids are used to decrease inflammation at the site and open up the flow, the MLD to mobilize fluid, and the diuretics to promote renal excretion of excess fluid.

Benzopyrones

Coumarin, a 5,6-benzo(alpha) pyrone, has been used in Australia to treat lymphedema (40). It is available only in a few centers in North America. It reportedly has provided a therapeutic effect by stimulating macrophages to scavenge plasma proteins. The reduction in lymphedema is reportedly much slower than with decongestive therapy. It would seem reasonable that if coumarin is used, it should be in conjunction with physiotherapy to ensure treatment of both aspects of lymphedema: the decreased lymph flow and the abundance of proteins in the fluid.

Benzopyrones also may cause increased protein catabolism as a result of the continuous degradation of protein molecules. It is unclear at this time whether this could result in troublesome side effects in patients with an inadequate protein intake in their diets.

Diet

Diet, as a factor in the treatment of lymphedema, has not been widely studied. Two patients with idiopathic unilateral limb lymphedema responded to a diet with restriction of long-chain triglycerides (41). More research is needed to assess any possible benefit of this treatment on patients with lymphedema secondary to malignant disease. Obesity is, however, a factor that increases the risk of developing lymphedema.

Surgery

Surgical treatment of chronic limb lymphedema is either *physiologic* (an attempt to improve lymphatic drainage) or *excisional* (removal of edematous subcutaneous tissue with or without overlying skin) (42,43). This intervention is seldom appropriate in patients with malignant disease. Surprisingly, amputation is still occasionally advised for some patients with severe chronic lymphedema.

Intraarterial Infusion of Autologous Lymphocytes

This still experimental treatment was used in a few patients with refractory primary or acquired lymphedema with promising results, including a reduction in size, a decrease in pain, and softening of the limb (44,45).

COMPLICATIONS

Once treatment for lymphedema is initiated, compliance is of major importance. Factors that can negatively affect compliance include the amount of delay before starting treatment, the size of the limb when treatment is started, the availability of social and financial supports, and the presence of complicating health problems (46).

Untreated lymphedema leads to worsening of the symptoms of fullness, numbness, paresthesia, weakness, and pain. All too often the weight of the heavy arm in patients with upper-extremity edema can cause shoulder dislocation and further pain and loss of function. Lymphedema also plays an active role in the development of brachial plexus entrapment and carpal tunnel syndrome in patients who have previously had a mastectomy and radiotherapy (47). Recurrent cellulitis or erysipelas also occur more frequently in a lymphedematous limb and can, in turn, lead to further worsening of the edema (48). A more serious but rarer complication is lymphangiosarcoma, which is associated with lymphedema in patients with a previous diagnosis of breast cancer and subsequent radiotherapy treatment. The prognosis for these patients is poor, with metastases to lung, pleura, and chest wall occurring early in the course of the disease.

CONCLUSIONS

Lymphedema is not only a prevalent symptom in patients with cancer, but one that causes considerable morbidity and greatly affects patients' quality of life. It can occur secondary to the disease and subsequent treatment, especially surgery that includes nodal dissection and radiotherapy. Unfortunately, it can appear initially even years after the primary disease diagnosis and also can affect those in whom a cure or remission is achieved.

The treatment of acquired *(secondary*) lymphedema must be chronic and consist of several modalities. It must also, however, be relatively easy, convenient, inexpensive, and visibly effective to encourage patient compliance over the long term.

PRINCIPLES OF FISTULA AND STOMA MANAGEMENT

DOROTHY B. DOUGHTY

A significant number of patients with solid tumors involving the abdominal organs have surgically created stomas or spontaneously occurring fistulas. Palliative care for these patients must provide effective containment of the effluent and odor, protection of the adjacent skin, and maintenance of fecal and urinary elimination. This chapter addresses the specific needs of patients with stomas or fistulas involving the intestinal or urinary tract.

FISTULA MANAGEMENT

Fistulas are abnormal openings between two internal organs or between an internal organ and the skin. The majority of fistulas arise from the gastrointestinal (GI) tract and are caused by delayed healing and anastomotic breakdown after a surgical procedure; fistulas may also occur as a result of direct tumor invasion or as a complication of radiation therapy (1,2,3 and 4). Fistula development is always a devastating development, and despite significant progress in management of complications such as sepsis and malnutrition, fistulas continue to be associated with significant morbidity and mortality. For the cancer patient, fistula development may be even more devastating; the addition of a fistula may overwhelm the patient's defenses, both physically and psychologically. Statistics indicate higher mortality rates among this patient population— for example, a retrospective review of patients treated at the National Institutes of Health Clinical Center from 1980 through 1994 revealed a 42% fistularelated mortality rate among cancer patients with enterocutaneous fistulas (2). In addition to the issues related to the fistula itself, the development of a fistula may delay or prevent treatment for the underlying malignancy, and malignant involvement of the fistulous tract may prevent closure, even with surgical intervention (2,4). Effective fistula management is thus a critical component of effective palliative care.

Classification Systems

Fistulas are commonly classified according to the organs involved, point of drainage, or volume of output (1,4). Fistulas are named according to the organs involved and the pathway followed by the effluent (Table 24-1). Fistulas also may be classified as internal or external. Internal fistulas involve an abnormal communication between two internal organs (e.g., enteroenteric or enterocolic fistulas). These fistulas may be silent in that they produce no obvious pathology, but they can greatly affect the patient's nutritional status by bypassing absorptive segments of small bowel (4). External fistulas are those communicating with the skin or with organs that drain onto the skin, such as the vagina. These fistulas produce obvious symptoms and present major challenges in management (4). The third mechanism for classifying fistulas is by volume of output. Fistulas producing more than 500 ml of output per day have been labeled *high-output fistulas*, and those producing 200–500 ml/day are generally classified as *low-* or *moderate-output fistulas* (1,4). As might be expected, high-output fistulas have a higher incidence of sepsis, malnutrition, and death than fistulas with low or moderate output (2).

Origin	Termination	Name
Small bowel	Skin	Enterocutaneous
Colon	Skin	Colocutaneous
Bladder	Skin	Vesicocutaneous
Small bowel	Vagina	Enterovaginal
Colon	Vagina	Colovaginal
Bladder	Vagina	Vesicovaginal
Rectum	Vagina	Rectovaginal

TABLE 24-1. TERMINOLOGY FOR COMMON FISTULAS

Phases of Fistula Management

Effective fistula management can be divided into several distinct phases: stabilization, investigation, conservative therapy, and definitive management (1,4).

Stabilization

Initial goals in fistula management include normalization of fluid and electrolyte balance, establishment of nutritional support, and elimination of sepsis (1,4). Specific fluid and electrolyte needs depend on the type and volume of fistula output; for example, small bowel fistulas usually produce high volumes of effluent containing potassium, sodium, magnesium, phosphate, and zinc (1,4). The patient with a high-output fistula requires close monitoring of fluid electrolyte balance, with replacement titrated in response to type and volume of output and based on laboratory indices. Fluid and electrolyte anomalies remain a significant problem in the management of these patients, and effective management can significantly reduce morbidity (1,4,5).

Malnutrition is another major problem associated with GI fistulas, especially high-output fistulas. Most of these patients require parenteral nutritional support, although continued low-volume enteral intake is frequently advocated to prevent atrophy of the villi (4). Aggressive nutritional repletion may sometimes be contraindicated for the patient with an underlying malignancy, especially if there is a delay in initiation of antineoplastic therapy. However, failure to provide nutritional support may result in a catabolic state that further compromises the patient's overall condition. Thus decisions regarding nutritional support for the cancer patient with a high-output fistula must be made within the context of the overall treatment plan and management goals (1,4). Fistula development is often associated with intraabdominal abscess formation, and sepsis is the most common complication of enterocutaneous fistulas. Therefore, initial management includes prompt management of any intraabdominal infectious process (i.e., drainage of all abscesses and initiation of appropriate antibiotic therapy) (1,4).

Investigation

The second goal in fistula management is to identify the origin of the fistulous tract and to elucidate any anatomical conditions that would prevent spontaneous closure of the fistula, such as distal obstruction, development of an epithelial-lined tract between the skin and the fistula opening (i.e., pseudostoma formation), complete disruption of bowel continuity, persistent abscess, or tumor involvement of the fistulous tract (1,4). Studies commonly involved in the investigative phase of fistula management include fistulograms (to identify the origin of the fistula) and computed tomography scans (to determine the presence of tumor involvement or persistent

abscess) (4).

Conservative Management

If there are no anatomical factors that would prevent spontaneous closure of the fistula tract, initial management is likely to be conservative in nature. This approach is based on studies indicating that a significant proportion of fistulas close spontaneously (if there is no inhibiting pathology), and on the fact that surgical closure is frequently ineffective until the underlying factors contributing to fistula development have been corrected (1,4). Even among cancer patients, spontaneous closure of fistula tracts is possible: Chamberlain reported a spontaneous closure rate of 33% for enterocutaneous fistulas (2).

Conservative management includes continued attention to fluid and electrolyte balance, nutritional repletion, and control of infection. In addition, measures are instituted to reduce the volume of effluent. The goal is to ensure sufficient intake of nutrients to support the healing process while minimizing the volume of drainage through the fistulous tract. Specific measures to reduce fistula output include limitation (or elimination) of oral intake and administration of octreotide acetate (1,4). Octreotide acetate is a synthetic somatostatin analog that is given subcutaneously to reduce the volume of intestinal secretions and to prolong GI transit time. The data on octreotide acetate's impact on fistula volume and fistula closure are inconclusive; however, in general, octreotide acetate has been shown to reduce the volume of fistula output, and in some studies has appeared to significantly reduce the time frame for spontaneous closure. To date, there is no evidence that octreotide acetate actually increases the number or percentage of fistulas closing spontaneously, so the clinician must weigh the potential benefit against the expense and discomfort of repeated injections (3,4,6,7). The decision to restrict oral intake must also be made within the context of the overall treatment plan, as such restrictions can significantly affect quality of life (5). If oral intake *is* significantly restricted, it may be beneficial to administer H_2 receptor antagonists to prevent stress ulceration and to reduce gastric secretions (4).

Definitive Therapy

When it is recognized that spontaneous closure is unlikely or impossible, a determination must be made regarding further management. The two options are palliative management (with no expectation of closure) or surgical intervention. The optimal surgical approach involves resection of the fistulous tract with end-to-end anastomosis (4). If the involved segment of bowel cannot be isolated because of dense adhesions, it may be necessary to perform a bypass procedure, or, occasionally, to divert the fecal stream proximal to the fistula (1,4). If the fistulous tract is embedded in tumor and a radical resection is not feasible, the fistula tract may be defunctionalized by dividing the involved bowel segment proximal and distal to the fistula with a stapling device and performing an end-to-end anastomosis between the proximal and distal limbs of the normal bowel. Fistula drainage is thus reduced to the small volume of mucous and intestinal secretions produced by the isolated segment of bowel containing the fistula (8). There are also reports of a successful “extraabdominal” approach to fistula closure in a small series of patients with dense adhesions or irradiated tissue (9). Finally, the infusion of fibrin glue into lowoutput fistula tracts has been reported to significantly reduce the time to closure; however, this approach is not appropriate for high-output fistulas (10).

Palliative Fistula Management

In the patient with advanced malignancy, neither spontaneous closure nor surgical correction of the fistula may be achievable or practical. In this case, therapy is directed toward maintenance of patient comfort via containment of drainage and odor, protection of the perifistular skin, and continued attention to fluid-electrolyte balance, nutritional support, and control of sepsis (1,5).

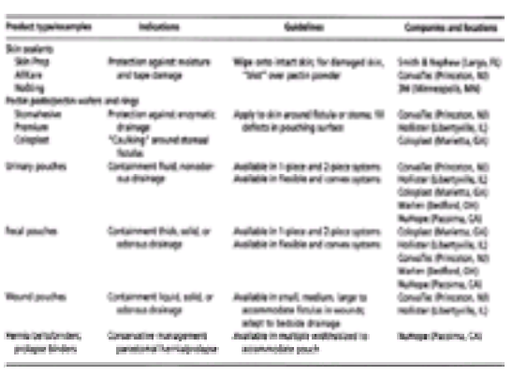
A major component of effective fistula management is containment of the effluent and odor and protection of the surrounding skin; these aspects of care have a profound impact on the patient's quality of life (5). Today, fistulas are treated as spontaneously occurring stomas, and ostomy pouches and products are used to protect the skin while containing the drainage and odor. In addition to promoting the patient's psychological and physical comfort, an effective pouching system permits quantification of output, which is critical to accurate replacement of fluid losses (1,4).

Guidelines for Pouching

Many products and techniques are now available for use in containing the drainage and odor and protecting the perifistular skin. Selection is determined by the type and volume of drainage, the contours of the surrounding tissue, and the integrity of the perifistular skin (1). Additional factors to be considered include the cost and availability of products, the technical difficulty of the procedures compared to the caregiver's cognitive abilities and technical skills, and the availability of professional assistance [e.g., Wound Ostomy Continence (ET) nurses and home care nurses].

Products for Skin Protection

The volume and characteristics of the effluent dictate the level of skin protection required. Drainage that contains proteolytic enzymes or that is highly alkaline or acidic can produce rapid and severe skin breakdown (especially if the fistula is also high-output). Thus gastric, pancreatic, and small bowel fistulas require aggressive protection of all perifistular skin and effective containment of the drainage, if at all possible (1). In contrast, drainage from the colon is usually low volume and nonenzymatic; severe skin breakdown is unlikely, and containment is needed more for odor control than for skin protection. Products available for skin protection include plasticizing skin sealants, pectin-based pastes and wafers, and moisture barrier ointments. The indications and guidelines for use of each of these products are outlined in Table 24-2.



Product type/examples	Indications	Guidelines	Companies and locations
Skin sealants			
Skin Prep All Kare Nu-Stay	Protection against moisture and tape damage	Wipe onto intact skin; for damaged skin, "blot" over pectin powder	Smith & Nephew (Largo, FL) ConvaTec (Princeton, NJ) 3M (Minneapolis, MN)
Pectin pastes/pectin wafers and rings			
Stomahesive Premium Coloplast	Protection against enzymatic drainage "Caulking" around stomal fistulae.	Apply to skin around fistula or stoma; fill defects in pouching surface	ConvaTec (Princeton, NJ) Hollister (Libertyville, IL) Coloplast (Marietta, GA)
Urinary pouches	Containment fluid, nonodorous drainage	Available in 1-piece and 2-piece systems Available in flexible and convex systems	ConvaTec (Princeton, NJ) Hollister (Libertyville, IL) Coloplast (Marietta, GA) Marlen (Bedford, OH) Nu-Hope (Pacoima, CA)
Fecal pouches	Containment thick, solid, or odorous drainage	Available in 1-piece and 2-piece systems Available in flexible and convex systems	Coloplast (Marietta, GA) Hollister (Libertyville, IL) ConvaTec (Princeton, NJ) Marlen (Bedford, OH) Nu-Hope (Pacoima, CA)
Wound pouches	Containment liquid, solid, or odorous drainage	Available in small, medium, large to accommodate fistulae in wounds; adapt to bedside drainage	ConvaTec (Princeton, NJ) Hollister (Libertyville, IL)
Hernia belts/binders, prolapse binders	Conservative management parastomal hernia/prolapse	Available in multiple widths/sizes to accommodate pouch	Nu-Hope (Pacoima, CA)

TABLE 24-2. PRODUCTS COMMONLY USED FOR POUCHING/SKIN PROTECTION

Pouching Principles

As stated earlier, effective containment of drainage and odor is best accomplished via successful application of an adherent pouching system, similar to the systems used to contain ostomy output. Successful pouch application requires adher ence to the following principles: The pouching system selected should be compatible with the type of drainage; the pouching system must be applied to a dry skin surface; and the surface of the pouching system must “match” the perifistular skin contours (1).

In selecting a system that is compatible with the type of drainage, the clinician should assess the effluent for fluidity and odor. Output that is very fluid and relatively nonodorous can be effectively managed with pouches designed for urinary stomas. These systems are odor-resistant (but not completely odor-proof) and equipped with narrow drainage spouts that cannot accommodate thick effluent. Output that is thick or malodorous should be managed with either fecal pouches or wound drainage systems. These systems are odor-proof and are equipped with tapered openings that permit drainage of thick or solid drainage.

As noted, it is essential to assure a dry pouching surface to obtain a good seal between the pouch and the skin. Denuded and weeping perifistular skin interferes with adhesion; unfortunately, perifistular skin damage is common due to the corrosive nature of the drainage. Weeping skin can be treated by a procedure commonly known as *crusting*. A pectin-based powder [Stomahesive Powder by ConvaTec (Princeton, NJ) or Premium Powder by Hollister (Libetyville, IL)] is sprinkled onto the wet skin to absorb the drainage and create a “gummy” surface; the powder is then “sealed” to the skin by blotting over the powder with a moist gloved finger or an alcohol-free skin sealant [e.g., Skin Prep No Sting by Smith and Nephew (Largo, FL), or No Sting by 3-M (Minneapolis, MN)] (1).

Matching the contours of the pouching system to the patient's skin surface is accomplished by carefully evaluating the perifistular skin with the patient in both the supine and sitting positions, and then selecting a pouch that is compatible with those contours. If the perifistular contours are fairly smooth, almost any system can be

used. However, the patient with deep creases in the perifistular skin usually requires an all-flexible pouching system that will “bend and mold.” If the fistula is in a “valley” and the perifistular contours are concave, a convex pouching system is advantageous. It is frequently necessary to use “filler” products such as pectin paste or pectin barrier strips to fill small defects and create a smoother pouching surface (1).

Pouching Procedures

Most fistulas can be managed with a standard pouching procedure using either a standard ostomy pouch or a wound drainage pouch. The standard pouching procedure is outlined in Table 24-3.

Select an appropriate pouch based on type of drainage and abdominal contours.
Size the pouch opening appropriately:
  For fistulas or skin-level stomas, size the opening to clear the fistula/stoma margins by 1/8–1/2 in.; this helps to prevent tunneling of the drainage under the barrier and pouch.
  For protruding stomas, size the opening 1/8 in. larger than the stoma.
Treat any skin damage with skin barrier powder (“seal” with damp finger or skin sealant).
Use pectin paste to fill any surface defects and to “caulk” around the stoma or fistula opening (a wet finger facilitates paste application).
Press pouch into place and use gentle pressure to assure adherence.
Change pouch every 5–7 d and as needed (for leakage).

TABLE 24-3. STANDARD POUCHING PROCEDURE

In patients with very irregular abdominal contours or a large associated wound, the standard pouching procedure is frequently ineffective. One pouching procedure that is frequently effective when standard pouching fails is the trough procedure; however, it is important to note that this technique is appropriate only for fistulas located in open wounds. The basic concept is to protect the perifistular skin with overlapping strips of a skin barrier such as Stomahesive and a pectin-based paste, and then to place transparent adhesive dressings [such as OpSite by Smith and Nephew (Largo, Florida)] over the wound to seal the wound edges. At the most inferior aspect of the wound, a large opening is created in the transparent adhesive dressing, and a pouch is placed over this opening (1). The wound thus becomes a trough, with drainage funneled to the bottom of the wound, where it is collected. Suction can be added to this system for very high-output fistulas. The trough procedure is outlined in Table 24-4 and illustrated in Figure 24-1.

Treat any damaged skin with skin barrier powder (“seal” with damp finger or skin sealant).
Cut skin barrier strips and apply overlapping strips along periphery of wound. Use pectin paste to caulk the junctions between strips and to protect any exposed skin. Note: The strip placed along the inferior aspect of the wound should be a solid U-shaped strip with no overlapping junctions to prevent leakage.
Select transparent adhesive dressing strips that are approximately 4 in. longer than the widest point of the wound; this assures a 2-in. overlap onto intact skin on each side of the wound bed.
Modify one strip of transparent adhesive dressing as follows:
  With paper backing still in place, cut an opening in the dressing wide enough to encompass the inferior aspect of the wound (if wound diameter is 1 1/2 in. at the inferior aspect, the opening should be cut at least 1 1/2 in. in diameter).
  Select a one-piece ostomy pouch or wound pouch and cut an opening in the pouch that matches the opening in the adhesive dressing.
  Peel paper backing off the pouch and stick the pouch to the nonadhesive surface of the transparent adhesive dressing strip
Peel paper backing off transparent adhesive dressing strip with pouch attached and apply to the inferior aspect of the wound
Apply remaining strips of transparent adhesive dressing in overlapping fashion to cover the remaining area of the wound.

TABLE 24-4. TROUGH PROCEDURE FOR FISTULA MANAGEMENT

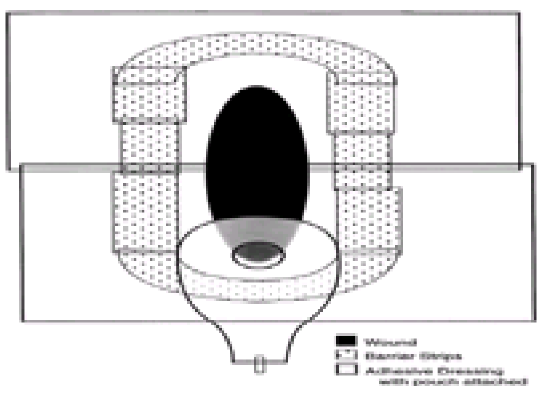


FIGURE 24-1. Illustration of trough procedure for fistula management.

An alternative to the trough procedure for bedbound patients is the closed suction method of management. With this approach, the perifistular skin is again protected with overlapping strips of a skin barrier and skin barrier paste; the wound bed is then lined with a layer of damp gauze and suction catheters are placed over the gauze inferior to the fistulous opening(s). Transparent adhesive dressings are then used to seal the wound on all sides, and the suction catheters are connected to wall suction.

If all pouching procedures fail, or if the caregiver is unable to manage a pouching system, the focus becomes skin protection and odor control. Skin protection can be provided in one of two ways: either by placing overlapping strips of skin barrier along the wound edge, or by applying a thick layer of a zinc-oxide-based moisture barrier along the wound edges. Absorptive dressings are then used to absorb the effluent; these dressings are best secured with a nonadherent system (e.g., burn netting), which facilitates frequent dressing changes. Odor control can be provided by charcoal cover dressings or by oral deodorants (e.g., chlorophyllin copper complex 100 mg once or twice daily). See Table 24-5 for odor control options.

Product type/examples	Mechanism of action	Indications/guidelines for use	Companies and locations/contact information
Odor absorbing dressings: Odor Absorbing Dressing (Hollister); CarboFlex Odor Control Dressing (ConvaTec)	Dressing is impregnated with charcoal; when used as cover dressing, odor molecule forced through charcoal for odor elimination	Indicated for odor control with fistulas being managed with dressings as opposed to pouch; Use as cover dressing, secure on all 4 sides with tape	Hollister (Libertyville, IL) (800-323-4060); ConvaTec (Princeton, NJ) (800-325-8005)
Pouch deodorants: M9 Deodorizing Drops (Hollister); OAD (Coloplast); Marlen Deodorizer; Ostopure (Nu-Hope); Commercial mouthwash	Reduce or neutralize odors in pouches to minimize odor when pouch opened for drainage or replacement	Fecal stomas; Malodorous wounds or fistulas being managed with pouching	Add recommended amount to pouch each time pouch is emptied OR saturate cotton ball with deodorizer and add to pouch each time pouch is emptied
Room deodorants: REFRESH (Cymed); Hex-On (Coloplast)	Reduce or neutralize odors in air; for use when pouch emptied or changed	Spray into air just before opening pouch	Cymed (Berkeley, CA) (800-582-0707); Coloplast (Marietta, GA) (800-533-0464)
Internal deodorizers: Devrom (Bismuth Subgallate), Parthenon Co.; Derifil (Chlorophyllin Copper Complex), Rystan	Significantly reduce or eliminate fecal odor when taken orally on routine basis	Fecal stomas and fistulas; Follow guidelines for dosage and administration; available over the counter	Parthenon Co. (Salt Lake City, UT) (800-453-8898); Rystan (Little Falls, NJ) (973-256-3737)

TABLE 24-5. OPTIONS FOR ODOR CONTROL

Vaginal Fistulas

One type of fistula that cannot be managed by pouching is the vaginal fistula. Patients with rectovaginal fistulas may be managed most effectively by keeping the stool formed to minimize fecal contamination of the vagina. Patients with vesicovaginal fistulas frequently can be managed effectively by placement of an indwelling urethral catheter to decompress the bladder. Patients with enterovaginal fistulas and patients with combined vesicovaginal fistulas, however, require containment to prevent significant perineal skin breakdown. An effective approach for these patients is outlined in Table 24-6.

Perform a vaginal examination to determine the size of the vaginal vault [use a topical anesthetic such as viscous lidocaine (Xylocaine) if patient has significant tenderness].
Obtain a soft rubber *nipple* shield or baby nipple (depending on size of vault) and a mushroom catheter.
Cut a small hole in the tip of the nipple or nipple shield; thread the catheter through so that the mushroom tip is resting within the nipple or shield. Secure the catheter to the nipple or shield with waterproof tape.
Fold the nipple shield down around the catheter, lubricate the nipple shield generously with a water-soluble lubricant, and gently push it into the vagina until the entire shield is in the vault; gently pull back on the catheter until the nipple shield is seated at the vaginal orifice.
Connect open end to bedside drainage unit.

TABLE 24-6. VAGINAL FISTULA MANAGEMENT

Resources

Any patient with a significant fistula can benefit from referral to a Wound Ostomy Continence/ET nurse specialist. These nurses specialize in the management of patients with complex wounds and stomas. Information regarding availability of these specialists can be obtained from the national office of the Wound Ostomy Continence Nursing Society (888-224-9626) or from their Web site (www.wocn.org).

STOMA MANAGEMENT

Urinary or fecal stomas may be created in conjunction with surgical removal of the bladder or rectum due to a malignant tumor, or they may be performed for palliative management of advanced disease producing colorectal or ureteral obstruction. Thus palliative care for patients with GI or genitourinary malignancies frequently requires attention to stoma management and maintenance of GI/genitourinary function.

Management of Fecal Diversions

Descending/Sigmoid Colostomy

A descending or sigmoid colostomy is constructed when the rectum or sigmoid colon is removed or bypassed (11,12). The output from a descending/sigmoid colostomy is typically formed stool, and elimination patterns are similar to preoperative bowel patterns for the individual patient. These patients usually have two options for management (13). One option is to wear an odor-proof pouch and to allow evacuation to occur spontaneously. The other option is to regulate bowel elimination via routine colostomy irrigations. The patient is taught to instill 500–1500 ml of lukewarm tap water into the stoma via a cone tip irrigator that prevents bowel perforation as well as backflow of water (11,14,15 and 16). The distention of the bowel stimulates peristalsis, which usually causes evacuation of the left colon within approximately 30 minutes. Evacuation of this bowel segment typically produces approximately 24–48 stool-free hours. Repeated administration of the same stimulus over time tends to "regulate" bowel emptying so that the potential for fecal spillage between irrigations is reduced. The patient who manages his colostomy with routine irrigation usually can wear a simple stoma cover or a stoma cap between irrigations; the stoma cap provides for absorption of mucus and also deodorizes and vents flatus (11,12 and 13).

Management issues for the patient with a descending or sigmoid colostomy include measures to control odor, reduce gas, and prevent or manage diarrhea and constipation (13,14). Routine measures to control odor include maintenance of an intact pouch seal and a clean drainage "spout"; the pouch material is odor-proof, so odor occurs only if there is a break in the seal or if fecal material is left on the drainage spout. Additional odor-control measures include the use of pouch deodorants (or the addition of 1 teaspoon of mouthwash into the pouch each time it is emptied) or administration of oral deodorants (as outlined in Table 24-5) (14,15). Measures to reduce gas include limitation of gas-producing foods, such as broccoli, cabbage, onions, and beans (13,14 and 15). Diarrhea can occur as a result of a viral illness or in response to some chemotherapeutic agents, and is managed similarly to management of diarrhea in the patient with an intact rectum and anus. The patient is counseled to remain on a low-fat, low-roughage diet; to increase fluid intake; and to take over-the-counter antidiarrheal medications if desired (13,14 and 15). The patient who manages with routine irrigation is instructed to omit irrigations until bowel function and stool consistency return to normal. Constipation is much more common than diarrhea in the patient with advanced malignancy and a descending/sigmoid colostomy; this is due to the antiperistaltic effects of reduced fiber intake, reduced activity, and increased use of analgesics, a triad common in the setting of advanced disease. Acute constipation can be alleviated by the administration of laxative agents (e.g., bisacodyl, milk of magnesia, or polyethylene glycol preparations) or cleansing irrigations. Constipation should also trigger adjustments in the patient's management program: Key elements in an effective program include assurance of adequate fiber and adequate fluid intake (i.e., 28–30 g fiber/day and 30 cc fluid/kg body weight/day). If the patient is unable or unwilling to ingest adequate amounts of dietary fiber, he or she should be counseled to begin a bulk laxative (e.g., Metamucil, Citrucel, Konsyl, PerDiem Fiber) or a bran mixture (1 cup miller's bran plus 1 cup applesauce plus onefourth cup prune juice) at an initial dose of 2 tablespoons/day. The patient is instructed to increase the daily dose by 1 tablespoon each week until normal bowel patterns are reestablished. The patient must be cautioned regarding the critical importance of sufficient fluid intake and the risk of bowel obstruction if bulking agents are consumed without adequate fluids (17,18). If the patient is unable to maintain adequate fluid intake, bulking agents should be discontinued and the patient should be placed on a softener/stimulant combination, such as docusate and casanthranol (17).

Transverse Colostomy

A transverse colostomy may be performed to provide fecal diversion in the patient with distal obstruction. Fecal output from the transverse colon is generally mushy in consistency, and the patient typically experiences output after meals and at other unpredictable times (14). Unlike the descending/sigmoid colostomy, a transverse colostomy cannot be regulated by routine irrigation because of continuous peristalsis in the ascending colon. Therefore, these patients must wear an odor-proof pouch to collect the stool. Management issues for these patients include odor and gas control and management of diarrhea (as discussed in the section Descending/Sigmoid Colostomy) (14). Constipation usually does not occur because the stool in the transverse colon is quite soft and peristalsis in the ascending colon is fairly continuous.

Ileostomy (or Ascending Colostomy)

An ileostomy is most frequently done when the entire colon and rectum are removed for disease processes such as familial polyposis, multiple colonic tumors, or inflammatory bowel disease (11,12). Cecostomies and ascending colostomies are not usually performed but occasionally are required to relieve acute obstruction of the distal ascending or proximal transverse colon (12). Output from these stomas is a thick liquid that contains proteolytic enzymes, which are extremely damaging to the skin (11,14). Management must therefore include continuous pouching with a well-fitting pouch and meticulous skin care to prevent fecal contact with the peristomal skin.

Ascending Colostomy

Management issues for the patient with an ascending colostomy include skin protection, maintenance of fluidelectrolyte balance, and medication modifications (14). The patient is taught to size the pouch carefully to fit closely around the stoma and to protect any exposed skin with pectin-based paste. Patients are also taught to maintain a daily fluid intake of approximately 2 l and to aggressively replace fluids and electrolytes during periods of increased loss (e.g., diarrhea or heavy perspiration); a practical recommendation is to drink a glass of replacement fluid (such as vegetable juice, broth, or a sports drink) each time the pouch is emptied. The patient is taught to recognize signs and symptoms of fluid-electrolyte imbalance and to report such symptoms promptly to the physician (11,14). Medication modifications include avoidance of time-released and enteric-coated medications because these forms are likely to be incompletely and unpredictably absorbed as a

result of reduced bowel length and transit time (14).

Ileostomy

The issues of skin protection, fluid-electrolyte balance, and medication modification are equally critical to the patient with an ileostomy. In addition, the ileostomy patient must be taught how to modify his or her diet to prevent food blockage (11,12,14,19). Food blockage is a complication unique to the ileostomy patient: It occurs when a bolus of fibrous undigested food obstructs the lumen of the bowel at the point where the bowel is brought through the fascia-muscle layer (a point of potential narrowing). Patients with ileostomies are taught to add high-fiber foods (e.g., raw fruits and vegetables, coconut, popcorn, nuts, etc.) to their diets one at a time and in small amounts, to chew thoroughly, and to maintain adequate fluid intake. They are also taught to recognize and report signs of partial or complete blockage (i.e., high-volume malodorous liquid output or no output, coupled with abdominal cramping, distention, and possibly nausea and vomiting) (11,14,15). Food blockage is managed by ileostomy lavage performed by the physician or ostomy nurse specialist. A catheter is inserted into the stoma until the blockage is reached and 30–50 ml of warm saline is instilled. The catheter is then removed to allow for returns, and the procedure is repeated until the blockage is removed (11,14,15).

Continent Fecal Diversions

Most continent fecal diversions are performed for nonmalignant conditions affecting the colon, such as familial polyposis and ulcerative colitis (11,20). These patients, however, are not immune to other malignancies that may progress to an advanced state, and their care must include management of the continent diversion.

Continent Ileostomy

A continent ileostomy (also known as *Koch Pouch* or *Barnett Continent Ileal Reservoir*) differs from a standard ileostomy in that an internal reservoir is constructed between the proximal bowel and the abdominal stoma. The diversion is made continent by intussuscepting the segment of bowel between the reservoir and the abdominal stoma, thus creating a one-way valve (11,12,15,20,21). The patient drains the reservoir by intubating the stoma with a largebore catheter approximately three to four times daily. If the stool is too thick to drain readily, the patient is taught to instill tepid water through the catheter into the reservoir to fluidize the stool (19,20). Management issues include avoidance of foods with peels (because the peels tend to obstruct the drainage catheter) and medication modifications. In addition to avoiding enteric-coated and timereleased medications, these patients must avoid wax-matrix medications because the wax shells do not dissolve and cannot be drained through the catheter. Patients are also instructed to flush the reservoir until clear one or two times daily to prevent pouchitis, an inflammation of the reservoir thought to be caused by bacterial overgrowth (15,20).

Ileal-Anal Reservoir

An ileal-anal reservoir is performed in conjunction with a colectomy and proctectomy. The sphincter mechanism is preserved. A reservoir is then created from the distal small bowel, and anastomosed to the anal canal (20,22). The patient's own sphincter therefore serves as the continence mechanism. The patient with an ileal-anal reservoir has mushy stools with residual enzymes; therefore, meticulous skin care is essential at all times and is even more critical during episodes of diarrhea (20,21,23). The ileal-anal patient is also at risk for pouchitis; symptoms include burning, itching, bleeding, and fecal urgency, and treatment typically involves clear liquids and antibiotics (e.g., ciprofloxacin and metronidazole) (20,22,23).

Management of Retained Nonfunctional Distal Bowel Segment

Patients with a loop or double-barrel colostomy and patients with a Hartmann's pouch have a variable length of distal bowel that is nonfunctional. This segment continues to produce mucus, and some patients require periodic lowvolume rectal enemas to eliminate inspissated mucus (24). It is also relevant to note that medications can be administered rectally even when the rectum is no longer in continuity with the proximal bowel.

Management of Urinary Diversions

Urinary diversions are required for patients with pelvic malignancies necessitating removal of the bladder and for patients with ureteral obstruction that cannot be managed with internally placed ureteral stents. The standard diversion previously was the intestinal conduit, but the current trend is toward construction of continent diversions or orthotopic neobladders anastomosed to the urethra (25).

Intestinal Conduits

Ileal conduits and other intestinal conduits normally produce clear urine with strands of mucus (because a bowel segment is used as the conduit for urinary drainage). Because there is no reservoir for urine collection, urine drainage is almost continuous, and patients must wear a pouch to contain the output (14,26). The most important management issues are prevention and recognition of urinary tract infections. Patients are taught to maintain adequate fluid intake and to recognize and promptly report signs of infection. Confirmation of urinary tract infection and organism identification are usually accomplished by obtaining a catheterized specimen for culture and sensitivity; these data provide the basis for organism-specific treatment (14).

Ureterostomy

Ureterostomies are rarely constructed because of the numerous associated complications (e.g., ineffective drainage, stenosis, and pouching problems). However, these diversions are occasionally required when it is not feasible to construct an ileal conduit. Output from a ureterostomy is clear urine without mucus, and management is the same as for patients with intestinal conduits. In addition, these patients need to be monitored for evidence of stenosis (i.e., reduced output, flank pain, chronic urinary tract infections). Stomal dilatation or stoma revision may be required for management (14,27).

Continent Urinary Diversions

The trend in urinary diversions is construction of continent reservoirs. A variety of surgical procedures exist, but all involve construction of a low-pressure reservoir; an antireflux mechanism between the reservoir and the ureters; and a continent, catheterizable channel between the reservoir and the abdominal surface (20,25,26). The two most commonly performed are the Koch Urostomy and variations of the ileocecal reservoir (e.g., Indiana Reservoir, Florida Pouch, and Miami Pouch) (20,28). Normal output is clear urine with strands of mucus; long-term management involves intermittent intubation and irrigation of the reservoir (with water or saline) to remove the mucus and prevent pouchitis (20). Adequate fluid intake and close adherence to the catheterization schedule help to prevent urinary tract infections (20). These patients typically need only an absorptive pad over the stoma, and significant leakage is uncommon. Patients who develop significant leakage usually are managed by using two-piece pouching systems. This provides for containment of the urinary leakage while maintaining ready access to the stoma for routine catheterizations. (Routine catheterization must be continued to prevent urinary retention and resultant infection.)

Orthotopic Neobladder to Urethra

The newest approach to urinary tract reconstruction after cystectomy is construction of a neobladder with anastomosis to the retained urethral sphincter mechanism. This procedure is limited to patients whose malignancy can be resected adequately without compromising the sphincter (20,29). Because the neobladder is usually a noncontractile reservoir constructed from detubularized bowel, effective emptying depends on effective relaxation of the voluntary sphincter in combination with abdominal muscle contraction to increase the pressure in the reservoir (20,29). Patients must be monitored for urinary retention, and patients who are unable to empty the reservoir completely are taught to augment voluntary voids with clean, intermittent catheterization to prevent urinary stasis and resulting infection (20,29). Another common problem is some degree of urinary leakage, particularly at night (when the voluntary pelvic floor muscles are partially relaxed). Depending on the severity of the leakage, absorbent products may be required for containment.

Pouching: Products and Principles

As outlined in the section Fistula Management, the key principles in stoma management include containment of the drainage and odor and protection of the peristomal skin. The degree of skin protection required is dictated by the characteristics of the output. Drainage that is proteolytic or highly acidic or alkaline requires meticulous protection of all peristomal skin, whereas nonenzymatic drainage with a pH that is essentially neutral primarily requires protection against pooling of drainage and subsequent maceration (14). Thus, ileostomies and ascending colostomies require aggressive skin protection, whereas descending/sigmoid colostomies and urinary diversions primarily require protection against prolonged contact between the drainage and the skin.

Products available for protection of peristomal skin include skin sealants, skin barriers, and pectin-based paste. The use of these products is outlined in Table 24-2. As mentioned earlier, pouching systems are available for both urinary and fecal drainage. Pouching systems are also available as both one-piece and two-piece systems.

One-piece systems typically are constructed with a barrier ring and tape border to which the pouch is welded, and are available in both precut and cut-to-fit varieties. Two-piece pouches typically consist of a barrier wafer to which a raised flange is attached and a pouch with a matching gasket that is snapped onto the flange (14,15). Application guidelines are the same as those for fistula pouch application (Table 24-3).

Management of Peristomal Complications

Common peristomal complications include epithelial denudation, monilial rash, and allergic reactions to ostomy products. Prompt recognition and appropriate intervention usually result in complete resolution of the problem.

Denudation

Superficial skin loss in the peristomal area is usually caused by a poorly fitting or incorrectly sized pouch that allows the effluent to contact the peristomal skin. The area of damage typically extends from the stoma along the path taken by the effluent; the area is usually red, raw, and painful (27,30). The most important intervention is correction of the underlying problem (i.e., modification of the pouching system). Actual treatment of the denuded areas involves application of a pectin-based powder [e.g., Stomahesive by ConvaTec (Princeton, NJ) or Premium by Hollister (Libertyville, IL)] to the denuded areas; the powder can then be "sealed" by blotting with a moist finger or an alcohol-free skin sealant [e.g., No Sting by 3M (Minneapolis, MN) or Skin Prep No Sting by Smith and Nephew (Largo, FL)]. Severely denuded areas may require several layers of powder and sealant to provide a thick protective layer. The correctly sized pouching system can then be applied over the treated surface (27).

Monilial Rash

Peristomal yeast rashes can occur as a result of antibiotic administration with resulting overgrowth of yeast organisms in the bowel, or as a result of constant moisture resulting from a leaking pouch or heavy perspiration under the plastic pouch material. The rash has a maculopapular appearance with distinct border (satellite) lesions and is commonly pruritic. It usually responds promptly to nystatin powder dusted onto the peristomal surface and then blotted with a skin sealant or moist finger to create a dry or sticky pouching surface (14,15,27).

Allergy

Any product used to protect the peristomal skin or to contain the output can be an allergen. Allergic contact dermatitis is typically characterized by an area of erythema that corresponds to the skin surface exposed to the allergen. The patient typically describes the area as pruritic and tender, and vesicles may be noted with severe reactions (15,27). The first step in management is to identify and eliminate the allergen, which can be a challenge when the patient is using a variety of products on the involved skin. Usually the distribution of the reaction helps to identify the offender, although patch testing may be required when the identity of the allergen is unclear (14,27). Until the specific allergen is identified and the peristomal skin has normalized, product use should be minimized; for example, use of paste, powder, and sealants should be eliminated if possible, and the patient should be managed with a solid barrier and pouch (such as a two-piece pouching system with a barrier wafer to which the pouch is attached). Patients with severe blistering or pruritus may require topical or systemic antihistamines or corticosteroids in addition to the measures already identified. If topical products are used, sprays or vanishing gels should be selected because creams and ointments interfere with pouch adhesion (14,15).

Management of Stomal Complications

Although stomal complications are uncommon, they can interfere with normal ostomy function or with effective containment of the output. Therefore, the clinician needs to be knowledgeable regarding their management.

Peristomal Hernia

Peristomal hernia involves herniation of the bowel through the muscle defect created by the stoma and into the subcutaneous tissue (11,15,27). The hernia usually reduces spontaneously when the patient is in a reclining position and intraabdominal pressure is reduced. Problems created by peristomal hernias include the potential for strangulation and bowel obstruction, which is uncommon, and difficulty with maintenance of an effective pouch seal, which is more common (27,30,31). In the patient with advanced cancer, surgical intervention is usually reserved for emergency situations involving strangulation and obstruction (31). Conservative management commonly includes use of a hernia belt, which is an abdominal binder with a cutout that accommodates the stoma and pouch (27,30). The belt is applied while the patient is recumbent and the hernia is reduced, and the resistance provided by the belt helps maintain reduction of the herniated loop of bowel. Colostomy patients who manage their stomas with routine irrigation must be cautioned to irrigate only with a conetip irrigator (because a catheter could cause perforation of the herniated loop) and to instill the irrigation fluid in the recumbent or semirecumbent position (so that the hernia is reduced) (27).

Stenosis

Stomal narrowing to a point that interferes with normal function can occur at either the skin level or the fascia level (30). Stenosis at the skin level may be evidenced by visible narrowing of the stomal lumen, but stenosis at fascia level can be detected only by digital examination. Signs of stenosis include reduced output, cramping pain, abdominal distention (with fecal diversions), and flank pain or infection (with urinary diversions). Stenosis that interferes with normal function requires surgical revision, either local excision of the stenotic area or open laparotomy (15,27).

Retraction

Early retraction of the stoma to a plane below skin level can occur postoperatively as a result of tension on the bowel or mesentery or due to breakdown of the mucocutaneous suture line. Late retraction can be caused by ascites or intraperitoneal tumor growth causing abdominal distention or tension on the mesentery. Retraction can also be caused by excessive postoperative weight gain (30). Management involves modification of the pouching system to accommodate the change in peristomal contours; typically, a convex pouching system is required (27).

Prolapse

Factors contributing to stomal prolapse include increased intraabdominal pressure, loop stoma construction, location of the stoma outside the rectus muscle, and formation of an excessively large aperture in the abdominal wall (32). Prolapse is usually quite upsetting to patients; however, prolapse does not represent a surgical emergency unless there is evidence of incarceration and stomal ischemia (30,32). Sometimes a prolapsed stoma can be reduced—the patient is placed in a recumbent position to reduce intraabdominal pressure, and manual reduction is attempted (33). (If the stoma is very edematous, a hypertonic substance, such as sugar or salt, may be applied topically to reduce the edema before reduction is attempted.) Once the prolapse is reduced, a hernia belt with prolapse overbelt (or a simple abdominal binder) can be used to prevent recurrence. If this approach fails, surgical intervention may be required (15,27,30).

Bleeding

Slight stomal bleeding during pouch changes is common due to the vascularity of the stoma. However, significant or spontaneous bleeding is not normal and requires investigation and intervention. Bleeding from the stoma itself usually can be managed by direct pressure, application of ice, or silver nitrate cauterization (27). Bleeding originating from the bowel requires further work up, with intervention determined by the causative factors and the patient's overall status (27).

Specific Issues for Oncology Patients

Some specific ostomy-related issues are relevant only to cancer patients. These issues include management of a stoma in the radiation field, management of stomatitis, and the impact of advancing disease on selfcare and management.

Stoma in Radiation Field

The goal in management of a stoma in the radiation field is to prevent peristomal skin damage. If the radiation oncologist wishes to have the pouch removed for each treatment, the patient should be switched to a nonadhesive pouching system [e.g., Hollister one-piece Karaya (Libertyville, IL) ring pouches with belt attachment or Cook (Wound Ostomy Continence, Spencer, IN) nonadhesive pouches] (34). If the radiation oncologist elects to leave the pouch in place during treatments, the pouching system should be modified to eliminate any metallic agents that could cause scatter of the radiation beam at skin level (e.g., tapes containing zinc oxide) (34). Pectin-based barriers, plastic pouches, and porous paper tape are all safe for peristomal use. Any peristomal damage that does occur can usually be managed by

applying a hydrocolloid wafer dressing [e.g., DuoDerm by ConvaTec (Princeton, NJ)] to the peristomal skin under the pouch.

Management of Stomatitis

Stomatitis, a common side effect of both radiation therapy and chemotherapy, is manifested by stomal edema, vasocongestion, and possibly ulceration. The goals of treatment are to prevent secondary infection and to prevent trauma and bleeding. Colostomy patients who manage their stomas with routine irrigation are instructed to omit irrigation during courses of pelvic radiation and during any episodes of stomatitis caused by chemotherapy (34). Patients also are counseled to avoid vigorous cleansing of the stoma and, if the stoma is friable, may be advised to add small amounts of mineral oil to lubricate the inside of the pouch (once radiation is complete). Patients with continent diversions may need to use smaller catheters, additional lubricant, and extreme caution in intubating the reservoir. Patients who develop stomatitis secondary to chemotherapy usually require treatment with antifungal agents (35) because the entire length of the alimentary canal is likely to be affected.

Impact of Advancing Disease on Self-Care and Management

One of the most significant issues facing the ostomy patient with advanced disease is selfcare and management. It is frequently necessary to modify the patient's management regimen or to teach a family member to change the pouch or intubate the stoma as the patient becomes less able to manage his or her own care. The colostomy patient who has managed with irrigation and who is no longer able to perform this procedure needs to be placed on a drainable pouching system. As noted earlier in this chapter, constipation is a common problem for the colostomy patient with advanced cancer, but usually can be managed with bulk and stimulant laxatives, stool softeners, and irrigations as needed (36). Removal of impacted stool usually can be accomplished by administration of a 1:1 solution of milk and molasses given as an irrigation.

The patient with a continent urinary diversion (or orthotopic neobladder) may be managed by insertion of an indwelling catheter into the reservoir if to do so is more feasible for the caregiver than intermittent intubation. The caregiver should be instructed in once or twice daily irrigations to eliminate retained mucous.

The home health or hospice nurse can be extremely valuable in assisting the patient and family to modify their care routines in the most effective and manageable way.

SUMMARY

Effective management of fistulas and stomas requires containment of drainage and odor plus protection of the surrounding skin. These aspects of care have a significant impact on the quality of life for patients with advanced disease.

MANAGEMENT OF DYSPNEA

EDUARDO BRUERA
CATHERINE SWEENEY
CARLA RIPAMONTI

Dyspnea has been defined as an uncomfortable awareness of breathing (1). Although everybody has experienced the sensation and has an intuitive understanding of this symptom, there is no universal agreement as to its definition. Dyspnea is a subjective sensation and cannot be defined by the physical abnormalities that accompany such unpleasant subjective experience. For the purpose of this chapter, dyspnea is defined as an unpleasant sensation of difficult, labored breathing.

Dyspnea is a frequent and devastating symptom in patients with advanced cancer (2,3). It has been reported to occur in 21–79% of advanced cancer patients (4). There is evidence that good symptom control, even by experienced palliative care teams, is achieved less frequently for dyspnea than for other symptoms such as pain or nausea (5). In addition, limited research and education are available on the adequate assessment and management of dyspnea in cancer patients.

The aim of this chapter is to review the pathophysiology, prevalence, assessment, and treatment of dyspnea in cancer patients. Discussion of areas where future research should focus is also included.

PATHOPHYSIOLOGY

Dyspnea is frequently associated with abnormalities in the mechanisms that regulate normal breathing. However, the actual expression of dyspnea by a patient results from a complex interaction between the abnormalities in breathing and the perception of those abnormalities in the central nervous system. The origins of dyspnea in different clinical settings can be traced to specific abnormalities. These are discussed in the following paragraphs.

Regulation of Breathing

Figure 25-1 summarizes the regulation of normal breathing. Respiration is integrated as a system with three main components, as discussed in the following sections.

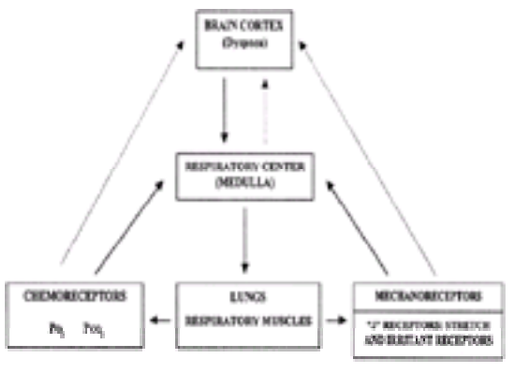

FIGURE 25-1. Regulation of normal breathing.

Respiratory Center

The respiratory center is located in the medulla. Its neurons receive information from both central and peripheral chemoreceptors and peripheral mechanoreceptors. It also receives information from the cerebral cortex, which regulates voluntary breathing such as occurs during speaking and singing. Efferent neurons stimulate the diaphragm, the intercostal muscles, and the accessory muscles (6,7).

Receptors

The levels of oxygen and carbon dioxide in the blood stimulate chemoreceptors located both centrally and peripherally. These chemoreceptors are capable of stimulating the respiratory center and increasing respiratory rate (8,9). Although strong debate continues on this subject, recent evidence suggests that chemoreceptors are probably also able to stimulate the brain cortex directly and cause dyspnea (9). An alternative explanation for the dyspnea caused by increases in PCO_2 and decreases in PO_2 is that chemoreceptors stimulate the respiratory center; increasing the respiratory effort, which stimulates mechanoreceptors capable of stimulating the brain cortex, resulting in the sensation of dyspnea. The mechanoreceptors are located primarily in the respiratory muscles and the lung. These receptors respond to either irritants or, more commonly, pulmonary stretch, including vascular congestion (7).

Respiratory Muscles

The respiratory muscles promote gas exchange. Changes in the PO_2 and PCO_2 are detected by the chemoreceptors. Changes in the tension within the abdominal wall and the lung are detected by the mechanoreceptors. This information is fed back to the respiratory center. Sensory receptors are found inside the respiratory muscles, including the intercostal, sternomastoid, and diaphragm. The balance between the contractual activity and stimulation of the sensory receptors is of great importance in the type of input provided to the respiratory center and the cortex.

Although the three aforementioned factors are the main elements in the regulation of breathing, the actual sensation of dyspnea is a result of cortical stimulation. The sensation of dyspnea has been related to the activation of mechanoreceptors in the respiratory muscles and lung (10). Elegant research has shown that both in normal volunteers and patients, different stimuli capable of stimulating mechanoreceptors are able to produce dyspnea even in absence of increased respiratory activity (7,8). In addition, two other possible mechanisms of dyspnea have been proposed. On one hand, the previously discussed role of chemoreceptor stimulation, on the other hand, some authors have proposed a role for the respiratory center as a potential cause of dyspnea by direct ascending cortical stimulation (8,9,11).

Production of Dyspnea

Dyspnea is produced by physical and biochemical abnormalities (Fig. 25-2). The perception is then modulated by anxiety, depression, or administration of opioids. Somatization and cultural factors further influence a patient's expression of dyspnea.

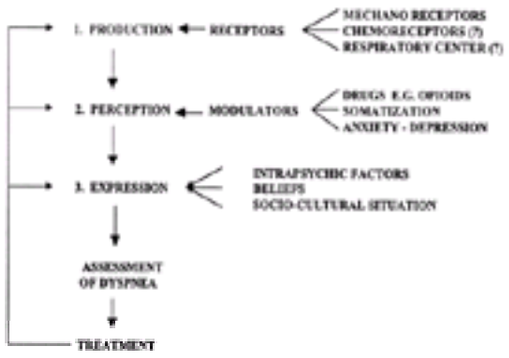

FIGURE 25-2. Stages in the production of dyspnea.

A number of researchers have found great variability in the expression of dyspnea among patients with similar levels of functional abnormalities. Among patients with asthma, approximately 15% did not report dyspnea despite severe airflow obstruction (forced expiratory volume in 1 second of less than 15% of the predicted) (12). Similarly, among patients with chronic obstructive pulmonary disease (COPD), the complaint of dyspnea was not well correlated with abnormalities in the pulmonary function tests (13). Among these patients who were defined as having disproportionate dyspnea (complaint of dyspnea in the presence of a mean forced expiratory volume in 1 second of 1.8 liter), almost all patients were considered to have a psychiatric diagnosis (mostly anxiety and depression) (13). Anxiety has been shown to be an independent correlate of the intensity of dyspnea in cancer patients (14). This association is not entirely clear as anxiety may contribute to dyspnea but may also arise from its presence.

These studies suggest that some patients have modulators that either amplify or decrease the intensity of the symptom that is perceived at the cortical level. Patients receiving drugs such as opioids for pain can perceive significantly less dyspnea (2).

Finally, the expression of a certain symptom may be influenced by cultural factors, the belief about the mechanism for the symptom, and other factors such as somatization (15). Because neither the production nor the perception of dyspnea can be measured at present, the entire assessment is based on the patient's expression. This issue is discussed in the following section.

Clinical Situations Associated with Dyspnea

Dyspnea can result from three main pathophysiological abnormalities (7):

1. An increase in respiratory effort to overcome a certain load (e.g., obstructive or restrictive lung disease, pleural effusion)
2. An increase in the proportion of respiratory muscle required to maintain a normal workload (e.g., neuromuscular weakness, cancer cachexia)
3. An increase in ventilatory requirements (hypoxemia, hypercapnia, metabolic acidosis, anemia, etc.)

In many cancer patients, different proportions of the three abnormalities may coexist, thereby making the pathophysiological interpretation of the intensity of dyspnea more complex.

Role of Respiratory Muscles

During recent years a number of authors have found that respiratory muscle weakness has an important role in the dyspnea associated with a number of chronic conditions. Palange et al. (16) found that malnutrition significantly affected the muscle aerobic capacity and exercise tolerance in patients with COPD. They suggested that high wasted ventilation might be responsible for the weight loss. Diaphragmatic fatigue has been associated with dyspnea in patients with COPD (17). In chronically malnourished patients without pulmonary disease, malnutrition reduces respiratory muscle strength and maximal voluntary ventilation. Therefore, malnutrition might impair the respiratory muscle capacity to handle increased ventilatory loads in cardiopulmonary disease (18). In normal volunteers, the sensation of dyspnea has been correlated with respiratory muscle fatigue (19).

A study in cancer patients determined that the maximal inspiratory pressure, a reliable functional test of the strength of the diaphragm and other respiratory muscles, is severely impaired in cancer patients with dyspnea (20). Maximal inspiratory pressure has subsequently been found to be an independent correlate of intensity of dyspnea in a subgroup of advanced cancer patients with moderate to severe dyspnea (14).

PREVALENCE OF DYSPNEA

The large variation in reported prevalence of dyspnea (21–79%) is a result of the different natures of patient populations reported by different authors and the lack of a general consensus on the assessment methods for identifying and quantifying the presence and intensity of dyspnea.

Higginson and McCarthy (5) conducted a prospective study in 86 consecutive patients with advanced cancer referred to a Community Palliative Care Service. Eighteen patients (21%) reported dyspnea as their main symptom before death. The symptom assessment scores for patients with dyspnea showed no change over time, as compared with a significant decrease in the intensity of pain reported by this same patient population.

Reuben et al. (21) reported on the prevalence of dyspnea in patients admitted to the National Hospice Study. Dyspnea occurred in 70% of 1754 patients sometime during the last 6 weeks of life. The frequency of dyspnea increased during the last weeks of life and more than 28% of patients rated the severity of their symptoms as moderate or worse during the self-report assessment. During the last 6 weeks of life, 27.5% of patients reported dyspnea all the time. Although 33% of patients had the diagnosis of primary or metastatic lung cancer, 24% of patients with dyspnea did not have any known lung or heart disease or evidence of pleural effusion. Grond et al. (22) reported a prevalence of dyspnea of 24% among 1635 cancer patients referred to a pain clinic. Donnelly et al. (23) found dyspnea in 28% of 1000 patients referred for consultation to a palliative care service. Of those patients who reported dyspnea, 63% rated this symptom as moderate or severe.

Twycross and Lack (24) found a prevalence of 51% of dyspnea in 6677 patients admitted to a palliative care program. Muers (25) found breathlessness to be a presenting complaint for 60% of 289 patients with no-small cell lung cancer, half of whom described their shortness of breath as moderate or severe.

A number of authors have reported dyspnea in a significant percentage of advanced cancer patients without intrathoracic malignancy. The National Hospice Study (15) found a frequency of 24% in patients with no known lung or heart disease. Cachexia occurs in more than 80% of patients with advanced cancer (26). In addition, asthenia and electrophysiological abnormalities in muscle function are detected in a large proportion of patients with advanced cancer. A recent study of 222 patients with chronic congestive heart failure found that dyspnea was the exerciselimiting symptom in 160 and generalized fatigue in 62 patients. No significant differences were found between any of the cardiovascular parameters of these two groups. The authors concluded that both symptoms are “two sides of the same coin,” and they express the same underlying pathophysiological process (27). It is possible that in some patients with advanced cancer, dyspnea may be one clinical expression of the syndrome of overwhelming cachexia and asthenia that is highly prevalent in the comprehensive assessment of these patients, including frequent pulmonary function tests.

In summary, dyspnea appears to be a common symptom in patients with advanced cancer. It is reported more commonly in patients during the last weeks of life. Although it is more common among patients with lung cancer or pulmonary metastases, it is also frequent in patients with no demonstrable tumor involvement in the lung. Most patients who develop dyspnea tend to rate this symptom as one of their main problems.

Figure 25-3 summarizes the common causes of dyspnea in cancer patients. Less common causes include dyspnea in cancer patients: atelectasis, phrenic nerve palsy, tracheal obstruction, carcinomatous infiltration of the chest wall, abdominal distention, pneumothorax, and metabolic acidosis. The pathophysiology of dyspnea in most

cancer patients is complex. For example, a given patient may have an increase in respiratory effort necessary to overcome the presence of a large pleural effusion, in addition to an increase in the proportion of respiratory muscle required for breathing because of cachexia and increased ventilatory requirement resulting from severe anemia.

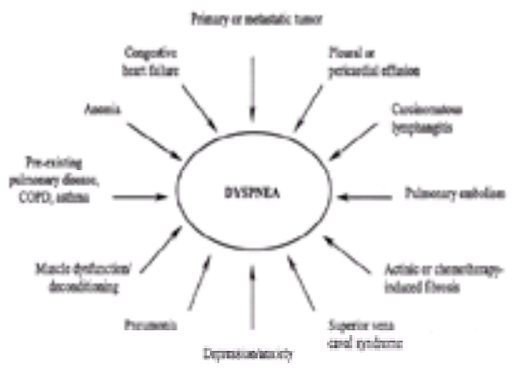

FIGURE 25-3. Common causes of dyspnea in patients with advanced cancer. COPD, chronic obstructive pulmonary disease.

ASSESSMENT

Although most cancer patients develop dyspnea as a progressive complication over days or weeks, some patients present with sudden onset of dyspnea as an acute medical emergency. The management of the latter group always should be considered a medical emergency.

History

The cause of dyspnea can be determined easily in most patients by taking an adequate history and performing a physical examination. The intensity of dyspnea should be assessed using a validated system. An additional approach that could potentially lead to the collection of useful information regarding the pathophysiological basis of dyspnea in individual patients is to look at descriptors of dyspnea.

Intensity of Dyspnea

The expression of the intensity of dyspnea can be assessed using visual analogue, numerical, and verbal scales (28,29,30,31 and 32). The intensity of dyspnea is included in some of the available supportive care tools, such as the Support Team Assessment Schedule (4) and the Edmonton Symptom Assessment System (32). Quality-of-life questionnaires, including the European Organisation for Research and Treatment in Can cer Quality of Life Core Questionnaire, have provided for a more detailed assessment of the intensity of dyspnea in certain modules (e.g., lung cancer) (33).

In addition to these more general questionnaires, some specific dyspnea questionnaires have been developed. The chronic respiratory questionnaire was tested against a number of physical parameters in patients with COPD (34,35 and 36). The Medical Research Council Scale has been tested in patients with dyspnea from a variety of respiratory and cardiovascular origins (37,38). Mahler et al. (39) compared the Medical Research Council Scale with a recently developed baseline dyspnea index and the oxygen cause diagram in 153 patients with various respiratory illnesses who sought medical care because of dyspnea. The authors found correlation between the different dyspnea scores. Agreement between two observers or with repeated use was satisfactory with all three clinical rating methods.

The Borg Category Scale (30,40) was originally developed for rating perceived dyspnea during exercise. It consists of 15 grades, with numbers ranging from 6–20. A more recent modification revised the numbers from 0–10, and the verbal descriptors are placed so that doubling the numerical rating corresponds to a twofold increase in sensation intensity. In addition to these scales, other dyspnea scales have been developed during recent years (41,42). In summary, a large number of scales are available for assessment of the intensity of dyspnea. They range from simple analogue and numerical scales to more complex scales, including multiple items. Many of these scales have been adequately validated and are highly reproducible.

One of the main problems associated with assessment of dyspnea is the variable intensity of this symptom according to the level of activity and during different times of the day. The variation in intensity of dyspnea over time makes pharmacological and nonpharmacological symptomatic interventions difficult to assess. In patients with respiratory and cardiovascular diseases, one approach to this problem has been the performance of dyspnea-causing activities to be able to compare therapeutic interventions (43,44). Most of these interventions consist of progressive exercising on a treadmill or bicycle so that patients or volunteers are subjected to a predictable workload. Dyspnea then is measured at fixed intervals and expressed in relationship to the workload. However, most cancer patients are too ill to participate in these stress tests. One potentially less invasive approach to the production of dyspnea is breath-holding (45,46), which has been used successfully to assess different mechanisms of dyspnea. Immediately after breath-holding, there is a period when no particular respiratory sensation is experienced (20–30 seconds in healthy subjects). This is followed by a second period in which there is progressive discomfort until breaking point. It has been found that training plays an important role in prolongation of total breath-holding time, but has little effect on the period of no respiratory sensation. In addition, the period of no respiratory sensation in patients with COPD is apparently shortened and measurement of this period can be useful in the study of the genesis of dyspnea (47). Breath-holding has not been prospectively validated for use as an assessment tool in cancer dyspnea.

Another potential approach to dyspnea assessment is to use reading to measure the limiting effects of breathlessness. A recent study (48) looked at a simple test involving reading of numbers in 30 cancer patients and 30 controls. Five 60-second readings off a number grid were undertaken on three occasions, two on the same day and one a week later. Patients read fewer numbers, and fewer numbers per breath than controls. Twelve of 30 patients were unable to complete all five readings in all three tests due to tiredness. The test was found to have good repeatability, both within and between days, and was sensitive to improvement seen following drainage of pleural effusions in 13 patients.

Descriptors of Dyspnea

In the case of pain, specific descriptors are associated with specific pathophysiological syndromes (49). For example, a burning or numb sensation traditionally has been associated with neuropathic pain. In many cases, the descriptor alone is enough to make a diagnosis and suggests the need for specific drug therapy. Simon et al. (50) attempted to associate specific descriptors with specific pathophysiology in 53 patients with dyspnea caused by a number of known causes. Patients were asked to choose descriptions of their sensation of breathlessness from a dyspnea questionnaire listing 19 descriptors. Cluster analysis then was used to identify natural groupings among those descriptors.

Although descriptors, such as “rapid” or “heavy,” were associated with exercise, “tight” frequently was associated with asthma, and “suffocating” frequently was associated with congestive heart failure. Mahler et al. (51) used a questionnaire with 15 items that described qualities of breathlessness in 218 patients who sought medical care for breathlessness. The authors concluded that patients with different cardiorespiratory conditions experience distinct qualities of breathlessness and that using a questionnaire containing descriptors of dyspnea might help to establish a specific diagnosis. However, a recent study has suggested that different ethnic groups use different words to describe breathlessness in the presence of airflow obstruction (52). This requires further clarification. In addition, more research is needed to better characterize the quality of dyspnea associated with specific clinical conditions.

Physical Examination and Investigations

A general physical examination with focused attention on the cardiac and respiratory systems is essential. A chest radiograph, digital oximetry, and simple blood tests can help in determining its cause. Pulmonary function tests can be particularly useful in the assessment of obstructive and restrictive pulmonary disorders as well as neuromuscular weakness. These tests can be performed repeatedly at the bedside and are useful in assessing the response to different therapies, in particular bronchodilators. The measurement of maximal inspiratory pressure may also be useful in cancer patients (14).

Multidimensional Assessment

Although some researchers have described a good correlation between the abnormality of pulmonary function tests and the intensity of subjective dyspnea (39), others found this correlation to be extremely poor (42). In some cases, the authors suggested that the lack of correlation between objective and subjective findings might be

due to underlying psychiatric disorders (13).

Figure 25-2 shows the different stages in the production of dyspnea. These are common to other symptoms, such as pain. Neither the production nor perception of dyspnea can be measured. Expression of the intensity of dyspnea can be influenced by a number of factors described in the figure and should not be interpreted as a direct representation of the intensity of production of dyspnea at the level of mechanoreceptors or chemoreceptors.

The complex nature of dyspnea in many cancer patients means that assessment of dyspnea in isolation is inappropriate and may result in over treatment or inappropriate treatment of a patient's expression of dyspnea. Multidimensional assessment of dyspnea using tools that look at dyspnea in the context of other physical and psychological symptoms allows for determination of the part played by other factors such as pain, anxiety, depression, and somatization in the expression of dyspnea. The Edmonton Symptom Assessment System is an example of a validated multidimensional assessment tool (32,53). Identification of the various factors influencing the expression of dyspnea in a given patient allows for the implementation of a multidimensional therapeutic approach for that patient.

TREATMENT

Treatment of dyspnea should focus on a patient's expression of dyspnea rather than his or her apparent level of dyspnea as judged by tachypnea and use of accessory muscles of respiration, or the level of oxygen in the blood. It is not unusual for patients to have marked tachypnea and not report difficulty in breathing or conversely to report severe dyspnea in the absence of tachypnea.

Treatment approaches include therapies aimed at modifying a specific pathophysiologic cause and therapies aimed to provide general symptom control.

Treatments of Specific Pathophysiological Causes

In patients in which a specific cause of dyspnea is suspected, appropriate treatment of the potential underlying cause should be initiated. Treatment modalities include radiation therapy, often accompanied by high-dose corticosteroids for superior vena cava syndrome, and chemotherapy for some patients with pleural effusions or carcinomatous lymphangitis. High-dose corticosteroids may also be useful for patients with the latter. Drainage of pleural or pericardial infusions can give rapid relief. Other procedures, such as pleurodesis or creation of a pericardial window, may be necessary when effusions are recurrent.

Reversible airway obstruction is a common cause of dyspnea in cancer patients who have a history of heavy smoking (56). Optimum treatment of airway obstruction using bronchodilators, corticosteroids, and, if necessary, antibiotics for infective exacerbation of symptoms should be addressed in these patients. In addition, infections including pneumonia are responsible for the deaths of almost half the patients who die with advanced cancer (55). Dyspnea associated with pneumonia can be effectively treated with appropriate antibiotics.

In addition to the aforementioned causes, patients may present with severe anemia, massive ascites, an acute exacerbation of chronic asthma, or acute panic attacks as part of a chronic panic disorder. The latter is characterized by hyperventilation. Occasionally, metabolic acidosis associated with acute renal failure or lactic acidosis can result in hyperventilation. All these diagnoses should be considered during assessment of a patient with dyspnea and advanced cancer because specific therapy may result in rapid symptom relief.

Symptomatic Treatment

Symptomatic management of dyspnea is based on three main elements: oxygen therapy, drug therapy, and general measures of support and counseling. Evidence for the role of these three therapeutic approaches are discussed in subsequent paragraphs. For the purpose of this review, a Medline search of the literature on dyspnea published between 1966–2000 was conducted. All studies relating to the symptomatic therapy of dyspnea were reviewed. Studies were classified according to their methodology in three levels of evidence (56).

Oxygen

Long-term oxygen therapy has beneficial effects on the outcome of patients with COPD (57,58). However, the symptomatic effects of this therapy are less clear. Some studies suggest that oxygen has no symptomatic effects in cancer dyspnea (59,60). In addition, the evidence for a beneficial effect of oxygen in patients with congestive heart failure is also controversial.

Table 25-1 summarizes studies that have addressed the use of oxygen for symptom relief in a number of conditions. Only studies with level 1 evidence (randomized controlled trials) are discussed in this chapter. In the case of COPD, most studies suggest that there is a significant symptomatic improvement at rest and during exercise as a result of the administration of supplemental oxygen (61,62,63 and 64). However, Liss and Grant (65) found that the administration of 0, 2, or 4 liters per minute of oxygen to patients with COPD was not superior to air on resting dyspnea. These authors also found a significant increase in breathlessness after nasal anesthesia with lidocaine. The authors suggested that the reduction in breathlessness caused by nasal oxygen is a placebo effect caused by wearing the nasal canula and is unrelated to gas flow or the increase of arterial oxygen tension. In the case of congestive heart failure, one study found that supplemental oxygen could improve subjective scores for fatigue and breathlessness during steady-state exercise (66). Another study, however, found no significant benefit from supplemental oxygen on the symptomatic scores of patients subjected to regular walking (67).

TABLE 25-1. SYMPTOMATIC EFFECT OF OXYGEN THERAPY[a]

Although the balance of evidence suggests that oxygen does have symptomatic effects in COPD and also probably in congestive heart failure, patients with dyspnea due to cancer most frequently have restrictive respiratory failure that might not respond to oxygen in the same way. There are three randomized controlled trials in which cancer patients with dyspnea were randomized in a crossover design to 5 liters (68,69) or 4 liters per minute of oxygen (70). In the first two studies, all patients were hypoxemic on room air. In these patients, oxygen had a significant beneficial effect. In the third study, only 6 of 38 evaluable patients were hypoxemic; both oxygen and air were significantly superior to baseline (70). Swinburn et al. (61) studied the role of oxygen in a group of 10 patients with interstitial lung disease in addition to their main sample of 12 patients with COPD. Results in interstitial lung disease patients were as beneficial as those observed in the COPD group.

Oxygen has been found to improve functional capacity in patients with COPD (71,72). It is possible that oxygen supplementation could improve function in patients with cancer dyspnea but such studies have not been conducted. The main objective of oxygen therapy in advanced cancer patients is symptomatic relief rather than the prevention of long-term complications; therefore, intermittent use can be acceptable and less psychologically burdensome in patients who present with intermittent exacerbations of dyspnea.

In summary, although more research is needed, there is some compelling evidence for the use of oxygen as a symptomatic treatment for patients with cancer-related dyspnea. In particular, patients who are hypoxemic on room air are quite likely to benefit from this approach. It is possible that oxygen would be effective in relieving dyspnea at concentrations higher than those required to maintain optimal saturation of hemoglobin. Anecdotal experience in cancer patients and patients with congestive heart failure suggest that oxygen might give significant symptom relief to patients who are not hypoxemic. This hypothesis should be tested in prospective clinical trials.

When there are doubts about the effectiveness of oxygen for symptom relief in a given patient, an “N of 1” study can be conducted (69). The method used by the investigators in this study is summarized in Table 25-2. By performing multiple, double-blind crossovers between oxygen and air, it is possible to determine with great accuracy, in less than 1 hour, whether a specific patient does or does not benefit from the supplemental oxygen.

Measurements
O_2 saturation—pulse oximetry
Visual analogue scale scores of dyspnea: baseline and during blinded treatment with oxygen and air
Patient and investigator selected treatment of choice
Patient rated differences between the two treatments
Procedure
1. Baseline 5 min—no treatment
2. Patient and investigator blinded to treatments, either 5 l/min of 100% oxygen or air via face mask for 5 min
3. Followed directly by 5 min of alternate treatment
4. Repeat steps 1–3 six times

TABLE 25-2. N OF 1 STUDY FOR ASSESSMENT OF EFFECT OF SUPPLEMENTAL OXYGEN ON DYSPNEA

Pharmacological Interventions

A number of drugs have been suggested to affect the intensity of dyspnea in patients with cancer and other chronic conditions.

Opioids

Table 25-3 summarizes studies on the use of opioids in the treatment of dyspnea associated with a number of nonmalignant conditions (74,75,76,77,78,79,80 and 81). Table 25-4 summarizes studies of systemic opioids in the treatment of cancer-related dyspnea. In the case of cancer-related dyspnea, all the published studies have agreed on the beneficial effect of systemic opioids for cancer dyspnea (82,83,84,85,86 and 87). However, the optimal type, dose, and modality of administration of opioids has not yet been determined. Cohen et al. (84) treated eight patients with cancer dyspnea with continuous intravenous morphine. Significant symptomatic relief was observed, but the authors found that in this population of patients with no previous exposure to morphine, the continuous intravenous infusion resulted in a significant increase in the levels of PCO_2 . Bruera et al. (82,83) conducted two trials using intermittent subcutaneous morphine for the relief of cancer dyspnea. In the second study (83), intermittent doses of up to 2.5 times the regular opioid dose resulted in no significant change in the end-tidal CO_2 level. Most of these patients had already been chronically exposed to opioids and therefore had developed tolerance to their respiratory depressant effects. Mazzocato et al. (86), in a double-blind, crossover trial, looked at the effect of morphine 5 mg in seven opioid-naïve elderly cancer patients and 3.5 mg in addition to their regular dose in two patients already on 7.5 mg oral morphine every 4 hours. They found a significant improvement in dyspnea following treatment with morphine as compared with placebo with no significant changes in oxygen saturation.

TABLE 25-4. SYSTEMIC OPIOIDS IN THE TREATMENT OF CANCER-RELATED DYSPNEA[a]

Allard et al. (87) looked at the effect of two different doses of opioids on dyspnea in patients receiving regular opioid therapy. Fifteen patient pairs were given supplemental doses of 25% or 50% of the equivalent 4-hourly dose. The findings suggested that 25% of the patient's usual 4-hourly dose was sufficient to reduce dyspnea intensity and tachypnea for 4 hours.

One of the main methodological problems in the design of clinical trials of opioids in cancer dyspnea is the changing intensity of dyspnea both spontaneously and as a result of definite maneuvers. For these reasons, some groups advocate the use of intermittent opioids, as needed, when dyspnea occurs or for the anticipation of dyspnea associated with specific maneuvers.

Nebulized Opioids

During recent years a number of authors reported symptomatic relief when patients with dyspnea are administered different types and doses of nebulized opioids (summarized in Table 25-5) (88,89,90,91 and 92). The possibility that opioids might affect receptors in the lung is exciting because of recent evidence suggesting that morphine does have an analgesic effect peripherally (93) and also because a small dose of nebulized morphine might be devoid of systemic opioid side effects.

Author (reference)	No. of patients	Drug	Disease	Level of evidence[a]	Findings	Assessment
Clark et al. (88)	78	Morphine (5–60 mg) or placebo	Cancer	I	-	VAS and modified Borg scale

TABLE 25-5. USE OF NEBULIZED OPIOIDS IN DYSPNEA[a]

Pharmacokinetic studies suggest that the systemic bioavailability of nebulized morphine is extremely poor (94). Therefore, the effects reported in most studies would have to be of a local nature. This is further supported by the lack of reports of side effects usually observed when morphine is administered systemically, such as edation and nausea.

The evidence for a symptomatic effect in patients with COPD is controversial. Two controlled studies suggested a positive effect, in one case for morphine (90) and another case for morphine-6-glucuronide (89). Morphine was found to be ineffective in two studies (89,91). The largest uncontrolled study in cancer patients reported beneficial results (92). A more recent controlled trial in patients with cancer dyspnea showed no symptomatic benefit for nebulized morphine compared with placebo (88).

Benzodiazepines

Benzodiazepines are commonly used in the management of cancer-related dyspnea. Table 25-6 summarizes studies in which benzodiazepines were used for the management of dyspnea associated with both exercise and COPD (95,96,97,98 and 99). Four of the five studies found no significant difference between benzodiazepines and placebo. Mitchell-Heggs et al. (99) studied four patients with COPD in a controlled, single arm, blinded study comparing diazepam and placebo. The authors reported a sustained benefit for three of four patients after diazepam.

TABLE 25-6. EFFECT OF BENZODIAZEPINES ON DYSPNEA[a]

In some patients, benzodiazepines may be used when dyspnea is considered to be a somatic manifestation of a panic disorder or when patients have severe anxiety. There is no evidence to support the routine use of benzodiazepines in the management of dyspnea.

Corticosteroids

A number of authors have suggested that corticosteroids are highly effective in the management of dyspnea associated with carcinomatous lymphangitis. However, we are not aware of randomized controlled trials testing their role in this condition. In addition, corticosteroids are used frequently in the management of superior vena cava syndrome. They are highly effective in treating bronchospasm associated with both asthma and COPD (100,101). On the other hand, evidence exists that corticosteroids induce negative functional and pathological alterations in several muscle groups (102). It has been suggested that the effects are more pronounced on the diaphragm than on other muscles. These findings might be important because of the frequent presence of cachexia and muscle weakness in patients with advanced cancer.

Bronchodilators

Both nebulized and orally administered bronchodilators are useful in the management of bronchospasm associated with both asthma and COPD (100). A large proportion of the patients with cancer-related dyspnea have a history of smoking or COPD. Congleton and Muers (54) demonstrated that almost half of 57 consecutive patients with lung cancer treated by their group had evidence of airflow obstruction. A strong association was found between airflow obstruction and dyspnea. Of the 17 patients who accepted the offer of a trial of bronchodilator therapy (a combination of nebulized adrenergic and anticholinergic agents four times a day), most experienced significant symptomatic improvement.

Nebulized furosemide has been found to be protective against the bronchospasm induced by exercise in asthmatic patients (103). It has also been shown to have bronchodilator effect in acute asthma (104,105). There are reports of its use for the treatment of dyspnea in a palliative care setting (106).

Previous studies suggested that dyspnea in some patients with nonreversible obstructive airway disease could improve following the administration of theophylline (107). Aminophylline, theophylline, and caffeine all improve diaphragmatic contractility both in normal volunteers (107,108 and 109) and in patients with COPD (110). Because of the frequent presence of asthenia and generalized muscle weakness with or without cachexia (27), some cancer patients might benefit from the effect of xanthines on respiratory muscle contractility.

Other Drugs

Several studies suggested that alcohol might be able to decrease the intensity of dyspnea in patients with COPD (75,111). Although there is some consistent evidence for a symptomatic benefit for alcohol, the side effects associated with both acute and chronic administration, in addition to the potentially dangerous interaction with other drugs, suggests that alcohol may be an impractical option. A number of drugs, such as indomethacin (111) and medroxyprogesterone acetate (112), are being studied as a potential treatment for dyspnea, but the evidence for a role of these and other agents is very limited, and they could not be recommended for clinical use.

General Support Measures

A number of measures can be implemented for the support of the patient and the family. Most of these measures can be implemented in the acute-care hospital setting, continuingcare hospitals, and at home.

Activity Level

Dyspnea is a variable symptom. Most of the aggravating factors are related to muscle effort associated with different physical activities. It is important to educate patients and families so that they can recognize the type of maneuvers associated with episodes of increased dyspnea. Once these maneuvers are recognized, the two most effective approaches are anticipatory symptom relief and avoidance of effort. Anticipatory relief can include the administration of doses of drugs for symptomatic

relief before the dyspnea-causing maneuver, and psychological support techniques such as relaxation or imagery. Avoidance of effort involves assisting the patient to the maximum with the maneuver to minimize the muscle effort and the consequent development of dyspnea. This includes the use of different devices to assist the patient with transportation to and from the bathroom and for mobilization. It is important for patients and families to understand that they can remain quite active while not necessarily making muscle efforts. With the use of wheelchairs and portable oxygen it is possible for patients to return to the community.

On the other hand, there is substantial recent evidence that exercise programs and pulmonary rehabilitation in patients with COPD improve dyspnea and exercise tolerance (113,114,115,116,117 and 118). It is postulated that skeletal muscle dysfunction is an important contributor to exercise intolerance and dyspnea in COPD patients (117). The dysfunction is probably related to several factors, many of which also exist in advanced cancer patients, such as deconditioning secondary to immobility, malnutrition, and the use of corticosteroids. In addition inflammatory factors, such as interleukins and tumor necrosis factor, contribute to muscle wasting associated with cachexia in cancer patients.

Ventilatory Support

In patients with severe neuromuscular disorders, positive pressure ventilation provides significant relief for respiratory muscle fatigue. Techniques include continuous positive airway pressure ventilation or intermittent positive pressure ventilation via face or nasal masks. Continuous positive airway pressure ventilation has been shown to reduce inspiratory muscle effort and improve sleep in patients with both COPD and congestive heart failure, and to reduce dyspnea and fatigue in the latter group (119,120). By providing respiratory muscle relief, these techniques can decrease the sensation of breathlessness at rest and during exercise. The recognition of progressive muscle weakness in cancer patients and the correlation between maximal inspiratory pressure and dyspnea (14) indicate that some patients in whom respiratory muscle weakness can be demonstrated could possibly benefit from positive pressure ventilation. Specialized personnel, such as a chest physician or a trained chest therapist in an inpatient setting, should initiate these techniques.

Support of the Patient and Family

Explanation of dyspnea and addressing the fears of the patient and family is of great importance. Dyspnea can elicit major psychological reactions in the patient and the family, both of whom may fear that the patient may “choke to death.” It is important to anticipate the possibility of a crisis of respiratory failure. Symptomatic drugs should be made available together with instructions for administration. Telephone numbers of persons to be contacted should also be made available. Even if patients are not requiring oxygen at a given time, it is important that oxygen be available immediately if a respiratory crisis occurs.

Because dyspnea is frequently associated with tachypnea and the use of accessory respiratory muscles, patients may appear to be significantly dyspneic even when they are in good symptom control. As mentioned previously it is important for the relatives and members of the staff to remember to assess dyspnea only by asking patients how short of breath they feel rather than by estimating their dyspnea from the degree of tachypnea and use of accessory muscles. The goal should be symptomatic therapeutic intervention of the patient's expression of dyspnea rather than relief of the objective variables that accompany this symptom.

Future Research

Many aspects of dyspnea in cancer patients have not been adequately researched. These include areas of assessment and management. The use of simple noninvasive assessment methods, including reading and breath-holding, should be researched in greater detail. The potential role of descriptors of dyspnea to indicate underlying clinical conditions causing dyspnea should receive closer attention. Areas of treatment, including the roles of nebulized loop diuretics and various opioids, in addition to the effects of xanthines on respiratory muscle contractility, should be addressed by investigators. The effects of exercise training on dyspnea in patients with advanced cancer and the role of positive pressure ventilation in those with demonstrated respiratory muscle weakness should also be investigated.

HEMOPTYSIS

RANDOLPH J. LIPCHIK

Hemoptysis, the coughing or expectoration of blood that originates in the lung, can be an alarming symptom for both patient and physician. It can range from bloodtinged or streaked sputum to *massive hemoptysis*, the latter defined as blood loss of 400–600 ml per day. Massive hemoptysis occurs in fewer than 5% of cases but carries a mortality rate of up to 85% if surgical intervention is not feasible (1,2). The management of hemoptysis, therefore, requires careful consideration of the cause, severity of the process, and functional status of the patient. Management may be more aggressive and invasive early in the course of a malignancy, whereas this could be inappropriate or dangerous for a patient in the terminal stages of an illness.

PATHOGENESIS

The lung is perfused by two distinct circulations that must be considered when determining the source and planned treatment of hemoptysis. The pulmonary circulation delivers blood under low pressure from the right ventricle to the alveolar capillaries for exchange of oxygen and carbon dioxide. The bronchial circulation, which is approximately 1–2% of the cardiac output, arises from the systemic circulation and provides nutrient flow to the lung parenchyma. A detailed review of the anatomy and physiology of the bronchial circulation has been published (3) and is beyond the scope of this chapter. In brief, two or more arteries arise from the aorta or upper intercostal arteries, enter the lung, and eventually form a plexus, which accompanies the branching airways with small, penetrating arteries, forming another plexus that supplies the bronchial mucosa down to the terminal bronchioles. Farther on, they anastomose with both precapillary pulmonary arterioles and pulmonary veins. Bronchial venous return is more complex: Veins from the proximal airways return blood to the right atrium via the azygos, hemiazygos, or intercostal veins, whereas the intrapulmonary bronchial venous blood returns via the pulmonary veins to the left ventricle. The latter occurs as a result of anastomoses between bronchial and pulmonary veins and carries the bulk of bronchial venous return. Although the bronchial circulation is nonessential in the normal adult lung, in the setting of chronic inflammation, neoplasm, or repair after lung injury, bronchial blood flow increases as the result of increases in both the size and number of vessels. Elevations of pulmonary vascular pressure can affect the bronchial circulation because of the many anastomoses between the dual circulations. In general, hemoptysis occurs because of disruption of the highpressure bronchial vessels, which become abnormally enlarged and exposed within diseased airways.

ETIOLOGY

This discussion concentrates on the malignant causes of hemoptysis, but awareness of other causes is important because many patients have underlying conditions that may become active problems during treatment of a malignant disease. The differential diagnosis for a patient presenting with hemoptysis is extensive (Table 26-1). Some conditions that are more likely to be associated with massive hemoptysis are shown in Table 26-2. In past years, tuberculosis, bronchiectasis, and lung abscess were the most common causes of massive hemoptysis. The incidence of the latter two has declined in industrialized nations, but tuberculosis remains a significant problem worldwide. Experience with tuberculosis has helped us to understand the pathophysiology of massive hemoptysis. Up to 7% of deaths from tuberculosis have been attributed to massive hemoptysis; autopsy examinations have revealed ruptured pulmonary artery aneurysms. Rasmussen (4) described localized ruptures of aneurysmal portions of pulmonary arteries passing through thick-walled cavities of chronic tuberculosis, so-called “Rasmussen's aneurysms.” Rupture occurs secondary to the infection or the associated inflammatory response (4). Healed calcified mediastinal lymph nodes from prior tuberculosis can erode into the bronchial mucosa, also causing significant bleeding. Tuberculosis distorts lung architecture, causing bronchiectasis with resulting hypertrophy and proliferation of bronchial vessels. Infection or inflammation in these diseased portions of airway can cause rupture of vessels; the result is massive bleeding caused by the high systemic arterial pressure.

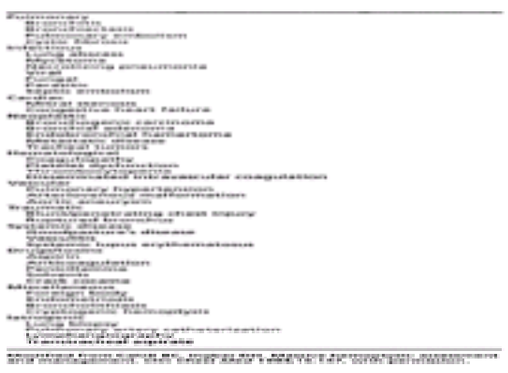

TABLE 26-1. CAUSES OF HEMOPTYSIS

Pulmonary tuberculosis
Bronchiectasis
Lung abscess
Mycetoma
Bronchogenic carcinoma
Pulmonary carcinoid
Pulmonary arteriovenous fistula
Pulmonary vasculitis
Broncholithiasis

TABLE 26-2. CAUSES OF MASSIVE HEMOPTYSIS

Nonmalignant Conditions

Patients with preexisting cavitary lung disease resulting from mycobacterial infections, sarcoidosis, bullous emphysema, lung abscess, lung infarction, and fibrocavitary disease secondary to rheumatoid disease are at risk for mycetoma formation, most often due to *Aspergillus*. This noninvasive infection results in a thick-walled cavity with vascular granulation tissue and inflammatory cells, the former the result of proliferation of the bronchial circulation. Bleeding is a result of vascular injury from

fungal endotoxin, proteolytic activity, or a type III hypersensitivity reaction (5). Bacterial superinfection also can promote hemoptysis in the setting.

Deep venous thrombosis and subsequent thromboembolic disease are common in hospitalized patients, especially those with underlying risk factors. The presence of a malignancy is a major risk factor, and the onset of hemoptysis warrants consideration of the possibility of pulmonary embolism and subsequent infarction. With current standard anticoagulation therapy, pulmonary embolism is a treatable condition with a 2.5% mortality rate. In a prospective study of the clinical course of pulmonary embolism, almost 24% of patients died within 1 year of diagnosis. Many cases, approximately 35%, had some form of cancer (6). A less well-appreciated and studied source of pulmonary embolism is upper extremity thrombosis resulting from indwelling venous catheters. In some series, the incidence of central line thromboembolism has been as high as 12% (7). Although most commonly seen in the pediatric population, there have been reports of inhaled foreign bodies in adults that, if unrecognized, have caused hemoptysis (8).

Malignant Conditions

In a retrospective review of 877 cases of lung cancer, Miller and McGregor (9) reported a 19.3% overall incidence of hemoptysis, with non–life-threatening hemoptysis occurring equally among histologic types (9). Twentynine cases (3.3%) were massive and terminal events, due almost exclusively to proximal, cavitary squamous cell carcinomas. In only 6 of these 29 cases was there no antecedent nonlethal bleeding. The cause of this sudden catastrophic bleeding was tumor hemorrhage or invasion of a pulmonary artery or vein. In another series, Panos et al. (10) also found an association between cavitary squamous cell tumors and fatal hemoptysis. Metastatic endobronchial disease (carcinoma of breast, colon, kidney, and melanoma) is more likely to cause nonfatal hemoptysis rather than a terminal bleeding event. The incidence of hemoptysis in patients with bronchial carcinoid tumors approaches 50%, resulting from mucosal ulceration or airway inflammation disrupting the bronchial arteries supplying these tumors. The high incidence of symptomatic bleeding is not surprising, as 85% of carcinoids arise in the proximal airway and are often very vascular (11). Malignant tracheal tumors are uncommon; when present, they usually result in obstructive symptoms. Hemoptysis does occur from these tumors, but less frequently than with bronchogenic carcinoma (12). A Danish series of pulmonary hamartoma cases found that only 39% of patients were symptomatic but that nearly onefourth of those patients noted hemoptysis (13).

Patients with a hematological malignancy may develop hemoptysis for many reasons, including thrombocytopenia, coagulation abnormalities, and infections. In one series, fatal hemoptysis was associated strongly with the autopsy findings of vascular invasion, thrombosis, and hemorrhagic infarction secondary to invasive fungal disease (14). Idiopathic alveolar hemorrhage is a rare cause of fatal hemoptysis, accounting for only 2–3% of leukemia deaths, but it also is associated with nonfatal hemoptysis. This is hypothesized to be attributable to the combination of thrombocytopenia and diffuse alveolar damage, the latter a result of chemotherapy, radiotherapy, sepsis, viral infection, or a combination of any of these (14).

Thromboembolic disease already has been discussed in this chapter, but pulmonary embolic disease also may be caused by intravascular tumor metastases, resulting in a clinical presentation indistinguishable from the more common venous thromboembolism. Hemoptysis is unusual, and symptoms of dyspnea and right heart failure predominate. Rarely, massive tumor embolism results in pulmonary infarction with hemoptysis. Pulmonary infarction due to malignant compression of pulmonary veins also has been reported (15).

DIAGNOSIS

The key element of diagnosis in cases of hemoptysis is the localization of bleeding to the lower respiratory tract. Although blood from the stomach usually has a low pH and blood from the respiratory tract a high pH, bleeding from the nasopharynx, larynx, or gastrointestinal tract may be difficult to distinguish clinically from hemoptysis. Furthermore, bleeding from these sources may result in cough and the appearance of blood, which can be misinterpreted as hemoptysis. When there is doubt, a thorough examination of the nasopharynx, larynx, and upper gastrointestinal tract should be performed.

Once the lung has been identified as the source of bleeding, the next step is to localize the site of bleeding. Physical examination alone is not sensitive enough; a chest radiograph should be performed, and often is helpful in revealing a tumor or abscess. However, it can be misleading, as blood may be coughed into uninvolved portions of the lungs. Bronchoscopy is the surest way to visualize the source (or at least the segment) from which there is active bleeding. Flexible fiberoptic bronchoscopy usually is attempted first because it can be done relatively quickly at the bedside without putting the patient under general anesthesia and can access more distal airways than the rigid bronchoscope. The latter has the advantages of greater suction capability, removal of clots or foreign bodies, and airway control that allows for patient ventilation, often necessary in cases of massive hemoptysis. Computed tomography (CT) scan has been compared with bronchoscopy in studies in which hemoptysis is the presenting problem. Patients with preexisting cancer constituted a small proportion of those studied. A CT scan is superior in identifying bronchiectasis, lung abscess, aspergilloma, and distal parenchymal abnormalities; however, the bronchoscope can obtain material that allows a cytological, histological, and microbiological diagnosis (16,17). In patients with established malignancies, a CT scan may offer important information, as it can delineate peribronchial or mediastinal involvement of tumors that cannot be seen with a bronchoscope. Routine use of CT is not of proven benefit but should be considered in cases in which the chest radiographic findings are inconclusive or to provide a more detailed anatomical localization of an abnormality for the bronchoscopist.

MANAGEMENT

The severity of hemoptysis determines the pace at which a work up should proceed. In a review of 10 years' experience at Duke University Medical Center, the mortality rate was 9% and 58% if blood loss was less than or more than 1000 ml per 24-hour period, respectively (1). A malignant cause for hemoptysis of greater than 1000 ml per 24 hours increased the mortality rate to 80%. Massive hemoptysis requires rapid intervention to guarantee that the patient has an adequate airway while attempting to control bleeding. If blood loss is minimal and sporadic, a more detailed evaluation can occur without immediate attention to resuscitative efforts. Early consultation with a pulmonary physician and thoracic surgeon is recommended.

Initial diagnostic studies should include chest radiograph, hematocrit, platelet count, blood urea nitrogen and creatinine levels, and coagulation panel, which might include a bleeding time if aspirin or nonsteroidal antiinflammatory agents have recently been used. Oxygenation should be monitored by arterial blood gas determination or pulse oximetry and adequate intravenous access established. Typed and crossmatched blood should be available in cases. of significant bleeding. Mild sedation and judicious use of a cough suppressant can be employed, but excessive use compromises a patient's ability to clear their airway.

If oxygenation is compromised or the patient continues to bleed vigorously, elective intubation should be considered. The endotracheal tube should be large enough to allow passage of a bronchoscope (7.5 or 8.0 mm). If it is known from which side the patient is bleeding, the patient should be placed in a lateral decubitus position with the bleeding side down to help minimize aspiration of blood into the good lung. Placement of a doublelumen endotracheal tube is sometimes necessary to allow separate ventilation of each lung while preventing aspiration of blood throughout the bronchial tree. The two small lumina preclude bronchoscopy with anything but a pediatric bronchoscope, and suctioning is limited because only small-caliber catheters can be passed distally. Newer-generation tubes with larger internal diameters may be less troublesome (18). The decision to intubate a patient with a terminal illness may be difficult. If bleeding can be localized and controlled quickly, a short period of intubation may not be unreasonable if it allows for improved quality of life. This would be unlikely for a patient in the later stages of a terminal illness, especially in the setting of massive hemoptysis.

Bronchoscopy

If bronchoscopy identifies the site of bleeding, several maneuvers can be done to stop or slow the bleeding. Bronchial lavage with iced saline (19), application of topical epinephrine (1:20,000), and topical thrombin and fibrinogen-thrombin solutions (20) all have been reported in small series to have varied success; however, they have not been evaluated in large numbers of patients in controlled studies. A pulmonary tamponade balloon can be inflated in the segmental bronchus leading to the site of bleeding, allowing time for stabilization of the patient and consideration of more definitive therapy 21). Bleeding from visible lesions in the trachea and proximal bronchi can be coagulated with a laser. This is particularly useful when the hemoptysis arises from an obstructing tumor, as both problems can be addressed simultaneously. In a series of 43 patients with advanced bronchogenic carcinoma (16 with concomitant hemoptysis), 38 were treated successfully (22). One patient died of continued tumor bleeding and aspiration of blood and two required tracheostomy to facilitate management of secretions. There was one pneumothorax, and one transient bronchial obstruction by a tumor fragment mobilized by laser therapy.

Radiotherapy

External beam radiation for 6–7 weeks usually is employed to attempt cure for inoperable nonsmall cell carcinoma. In the palliative setting, therapy is delivered in the shortest time possible, with lower doses to achieve symptom relief while minimizing side effects: 8 Gy in 1 fraction, 20 Gy in 5 fractions, and 30 Gy in 10 fractions have all been used with success. Hemoptysis can be stopped in more than 80% of cases by using palliative radiotherapy (23). Although significant symptoms from radiation fibrosis are uncommon, there are reports of massive hemoptysis occurring long after, and attributed to, external beam radiotherapy (24). Such cases are rare, however, probably because most patients succumb to their underlying cancer before significant vascular abnormalities develop.

Endobronchial brachytherapy with iridium 192 is another alternative. A useful summary of this modality is available (25). Dose rates can be low (up to 1 Gy per hour), intermediate (2–10 Gy per hour), or high (greater than 10 Gy per hour). The higher dose rates decrease the time of treatment and permit outpatient rather than

inpatient therapy. Gollins et al. (26) reported results of high-dose-rate brachytherapy in 406 patients. Of 255 patients with hemoptysis, brachytherapy arrested the bleeding in 89% at 1.5 months, 84% at 4 months, and 77% at 12 months after the first treatment. The results were not as favorable for patients who received brachytherapy after failure of external beam radiation; 84%, 56%, and 25% of patients had resolution of hemoptysis 1.5, 4, and 12 months after brachytherapy, respectively. Although most patients died of their cancer during the study (mean survival was 173 days), control of hemoptysis was quite good. Massive hemoptysis as a terminal event occurred in 32 patients (8%). Retrospective results of different brachytherapy dose rates are summarized in Table 26-3. Brachytherapy has been combined with bronchoscopic laser therapy in some centers (27,28). The Mayo Clinic reported results from 65 patients, 40 of whom had received prior laser therapy. In 24 patients with hemoptysis, bleeding resolved in 19. Response was poorer in patients who had received laser therapy, most likely because of more advanced disease (28). Potential complications of brachytherapy include mucositis, fistula formation, and fatal hemoptysis (29). The latter event has a reported incidence of 6–30%. Recent studies have addressed the issue of hemoptysis in more detail. Hennequin et al. (30) documented a 7.4% rate of hemoptysis after intermediate dose rates given to149 patients. Multivariate analysis indicated that tumor length and upper lobe location were risk factors for hemoptysis. In this series, 10 of 11 cases of hemoptysis were fatal; and all but one case occurred in patients with progressive disease. Other studies have implicated highdose-rate brachytherapy (³15 Gy) as a risk factor for fatal hemoptysis, particularly in patients who have already received external beam radiation (31,32).

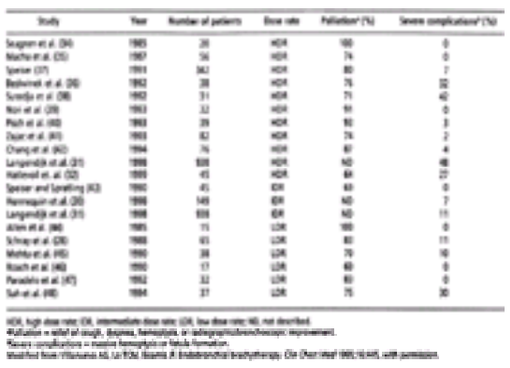

TABLE 26-3. ENDOBRONCHIAL BRACHYTHERAPY

Bronchial Artery Embolization

Bronchial artery anatomy is quite variable but generally arises from the ventral surface of the descending aorta or as branches from the intercostal arteries at the level of T5 and T6. Intimate knowledge of this vascular anatomy is essential because the anterior spinal artery often arises from the bronchial arteries and inadvertent embolization could result in spinal cord infarction. Bronchiectasis, tuberculosis, and aspergilloma frequently result in hypertrophy of bronchial vessels, but there are often transpleural collaterals from other systemic vessels, such as the subclavian, internal mammary, or intercostal arteries, which must be identified. After angiographic identification of the vessels in question, a variety of agents (e.g., Gelfoam, polyvinyl alcohol particles, and metallic coils) can be injected selectively to stop blood flow. Initial success rates reported in the literature vary between 75% and 90%, with a rebleeding rate of 15–30%. Hayakawa and colleagues (33) reported immediate (within 1 month) and long-term results for 63 patients. Of the 12 patients with hemoptysis due to neoplasm, bleeding was controlled in seven (58%). Long-term control was documented for four of these seven patients, with a median hemoptysis control period of 6 months (range, 0–9 months). All but one of the patients died within the 9-month followup period. Patients with bronchiectasis, inflammation, or idiopathic causes had immediate control in 94% of cases, with the median period of control lasting 15 months (range, 1–132 months) and a mortality rate of 11%. Recurrent bleeding can be treated with repeat embolization.

Surgery

The definitive therapy for massive hemoptysis is resection of the diseased portion of the lung; however, this is often precluded by the severity of the underlying lung disease. Similarly, massive hemoptysis from a bronchogenic carcinoma usually results from proximal endobronchial tumor, which is typically not amenable to surgical resection. Therefore, surgery is not an option for the vast majority of palliative care patients.

AIRWAY OBSTRUCTION, BRONCHOSPASM, AND COUGH

JULIE A. BILLER

Disorders of the airways may produce debilitating or life-threatening symptoms in a diverse patient population. Therefore, health care providers, including generalists and those of many subspecialties, may be called on to diagnose and treat these disorders. Often, a multidisciplinary approach is needed. Airway obstruction, bronchospasm, stridor, and cough not only may produce symptoms that reduce the quality of life of the patients affected, but they can produce profound distress to those patients' families. In some situations, even our current best therapies do little to palliate symptoms. It is my hope that we shall see continued improvement in these areas. In this chapter, the diagnostic and current therapeutic approach to airway disorders are reviewed.

TRACHEOBRONCHIAL OBSTRUCTION

The tracheobronchial tree quite literally can be “between a rock and a hard place,” resulting in airway obstruction. Obstruction may occur on the basis of large exophytic endobronchial tumor causing intrinsic obstruction of the airway. On the other hand, mediastinal pathology can cause obstruction by extrinsic compression of the airways. Etiologies differ somewhat between the two modes of obstruction. *Intrinsic* obstruction usually is caused by primary malignancies arising from the airway epithelium. Two histologic types of tumors, squamous cell carcinoma and adenoid cystic carcinoma, constitute twothirds of the primary tracheal malignancies (1). The remaining third comprises a diverse group of tumors, both benign and malignant, detailed in Table 27-1. More commonly, the trachea can be a site of locally extensive disease, usually from organs in close proximity, such as the lung, larynx, thyroid, and esophagus. Intrinsic obstruction of the bronchial tree most frequently is seen in primary cancers of all histologic types. Approximately 5% of metastatic disease to the lungs is predominately endobronchial. Renal cell, colon, rectum, cervical, breast carcinomas, and malignant melanomas are the most common primary malignancies to give rise to endobronchial metastasis (2).

Intrinsic obstruction	Chondromas
Malignant	Hamartoma
Primary tumors	Lipoma
Tracheal	Leiomyoma
Squamous carcinoma	Granular cell myoblastoma
Adenoid cystic carci-noma	Granuloma 2 retained for-eign body
Bronchogenic	Hemangiomas
Squamous	Postintubation strictures
Adenocarcinoma	Low-grade malignancy
Small cell	Carcinoid
Mixed morphology	Extrinsic obstruction
Metastatic	Malignancy
Breast cancer	Lung
Melanoma	Lymphoma
Larynx	Esophageal
Esophagus	Thyroid
Renal cell	Benign
Colon	Fungal infection
Rectal	Reactive lymphadenopathy
Cervical	Bronchomalacia
Kaposi sarcoma (rarely obstructing)	Mediastinal fibrosis
Benign	Vascular compression
Papillomas	Goiter

TABLE 27-1. ETIOLOGIES OF AIRWAY OBSTRUCTION

Extrinsic obstruction occurs when the airways are surrounded by firm tumor or encased by pathologically enlarged lymph nodes, usually caused by locally advanced disease arising from the lung, esophagus, and thyroid. Lymphoma, which can involve significant lymphadenopathy, is another cause of extrinsic compression. A variety of benign lesions that may imperil airway patency are listed in Table 27-1.

Evaluation

Patients with tracheobronchial obstruction usually present with complaints of dyspnea, hemoptysis, wheezing, or stridor, and sometimes with pneumonia or atelectasis. The onset of these obstructive symptoms can be insidious, and patients often are treated for other diseases, such as asthma or chronic obstructive pulmonary disease (COPD). Patients occasionally come to medical attention when pulmonary function tests obtained for other reasons suggest upper airway obstruction.

The evaluation of airway obstruction is primarily through radiographical studies and bronchoscopy. Posteroanterior and lateral chest radiographs should be the first diagnostic study ordered. Grossly abnormal radiographs with a large central parenchymal mass or mediastinal mass/adenopathy causing tracheal narrowing or deviation rapidly raise concern for the patency of the airway. Unfortunately, there can be significant compromise to the airway but only subtle radiographical changes. Therefore, close attention must be paid to the tracheal air column. Often, abnormalities are more obvious on the lateral view.

Computed tomography (CT) of the neck and chest are extremely useful for better definition of airway anatomy, allowing accurate measurement of the diameter of the central airways to determine the extent of obstruction. It is important in treatment planning to determine whether the obstruction is primarily intrinsic or extrinsic. This differentiation often can be made by CT scan. In medically stable patients, pulmonary function testing, including spirometry and, most important, flowvolume loop, may identify upper airway obstruction quickly, inexpensively, and noninvasively. Frequently, such testing can localize whether the obstruction is extrathoracic or intrathoracic. Figure 27-1A shows the typical flow-volume loop in a fixed airway obstruction. The most common causes of this type of lesion are tracheal stenosis, tumor (malignant or benign), goiter, fixation of vocal cords, and a large foreign body. Variable, extrathoracic, upper airway obstruction (Fig. 27-1B) affects primarily the inspiratory loop of the flow-volume curve. Common causes of this are bilateral vocal cord paralysis, epiglottis, vocal cord adhesions, and foreign body. Variable intrathoracic obstruction (Fig. 27-1C) affects primarily the expiratory loop of the flow-volume curve after the effortdependent peak expiratory flow, which can be caused by intraluminal polypoid tumors or tracheomalacia.

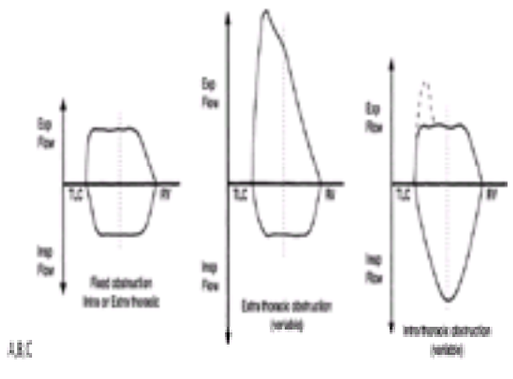

FIGURE 27-1. A: Maximal inspiratory and expiratory flow-volume curves in fixed obstruction. **B:** Extrathoracic variable obstruction. **C:** Intrathoracic variable obstruction. Dashed line represents a flow transient that occasionally is observed just before the plateau in intrathoracic obstruction. RV, residual volume;TLC, total lung capacity. (From Kryger et al. Diagnosis of obstruction of the upper and central airways.Am J Med 1976;61:85–93, with permission.)

To complete the evaluation of the patient with upper airway obstruction, more invasive procedures may be necessary, which typically involve fiberoptic evaluation, including laryngoscopy or bronchoscopy. It may be necessary to have multiple subspecialists involved in complicated cases, including otolaryngologists, thoracic surgeons, pulmonologists, and anesthesiologists. Bronchoscopy may be performed for several reasons, principally to obtain pathological material for diagnosis or as a therapeutic maneuver (see the section Therapy below). This is especially important if small cell lung carcinoma is considered in the differential diagnosis. If there is any question about the adequacy of the airway, bronchoscopy is best performed by a thoracic surgeon in the operating room with an experienced anesthesiologist present. At biopsy, the patient may have complications of airway obstruction or hemorrhage, which may endanger a marginal airway. Frequently, in this patient population, rigid bronchoscopy, with its better suctioning capabilities and ability to ventilate through the bronchoscope, is the procedure of choice.

Therapy

Patients who have airway obstruction on the basis of primary malignancies of the trachea or larynx, benign strictures (such as postintubation tracheal stenosis or extrinsic compression secondary to goiter or lymphoma) should be referred to the appropriate specialist (surgeon, oncologist, or radiation oncologist) for evaluation of definitive therapy Palliative therapeutic options for airway management in patients who are not candidates for definitive therapeutic procedures include airway stents, laser therapy, brachytherapy, and tracheostomy. Some patients may be helped by using several of these modalities in combination.

For any palliative therapy to be attempted, the airway must be wide enough to allow passage of a rigid or flexible bronchoscope and still maintain oxygenation and ventilation. In the case of large exophytic tumors that compromise the patency of the central airways, the bronchoscopist still can usually pass a bronchoscope instrument past the tumor. If this is not possible, a rigid bronchoscope may be used to “core out” the obstructing tumor, with its tip inserted in corkscrew fashion (1). If significant bleeding occurs, the rigid bronchoscope may be used to exert pressure and tamponade the bleeding. Ventilation can be maintained through the rigid bronchoscope, and it has a large suction channel to clear blood and tissue from the airways. Sometimes it is necessary to pass a fiberoptic bronchoscope through the rigid bronchoscope to clear blood, secretions, or tissue fragments from the more distal airways. Some authors are strong proponents of this technique. Although it requires expertise to reduce the risk of complications, such as tracheal perforation, hemorrhage, or rupture of the pulmonary artery, it does not need special equipment and usually requires only one endoscopic procedure. In a series from Mathisen and Grillo (3), 51 of 56 patients had significant improvement in airway obstruction after bronchoscopic “core out,” and only two patients required a second procedure. The patients who did not improve had distal obstructing disease. Because a rigid bronchoscope is used to perform a “core out,” it is best suited for large, central airway disease. Distal lesions or those obstructing the upper lobe orifices are less likely to be accessible with a rigid bronchoscope.

The other option for palliative resection of intrinsically obstructing lesions of the large airways is laser endobronchial resection (Fig. 27-2, Fig. 27-3) (3). Lasers transform light energy to heat, which causes tissue coagulation and vaporization. With advances in laser technology, this has become an increasingly popular modality over the past 15 years. Currently, the neodymium:yttrium, aluminum, garnet (Nd:YAG) laser is best suited for endobronchial resection. These lasers can be delivered through both rigid and flexible bronchoscopes. The wavelength of the laser is such that it is poorly absorbed by hemoglobin and water, resulting in deep tissue penetration. Because of high-power output, it can thermally coagulate blood vessels up to 2–3 mm in diameter and vaporize tissue (4). There seems to be a preference toward rigid bronchoscopy because of its ability to ventilate the patient better and its improved suctioning abilities. However, there are many reports of the use of flexible fiberoptic bronchoscopic resections in patients unable to tolerate general anesthesia and rigid bronchoscopy (5,6). In some situations, both types of procedures may be performed in combination. The bronchoscope is passed into the airway and the base of the tumor is identified. The Nd:YAG laser is aimed at the base of the tumor parallel to the wall of the trachea. Using varying energy levels, pulsations of laser energy are used first to coagulate the tumor mass and then to vaporize the tissue. The tracheal wall is avoided to reduce the risk of perforation or hemorrhage. In addition to these complications, there is also risk of tracheoesophageal fistula formation, combustion and fire within the bronchoscope, and ocular damage to operating personnel if appropriate protective gear is not used. Other drawbacks to laser resection include the need for special equipment and its time-consuming nature. Most patients improve after the first endoscopic resection but may require multiple sessions to complete the excision.

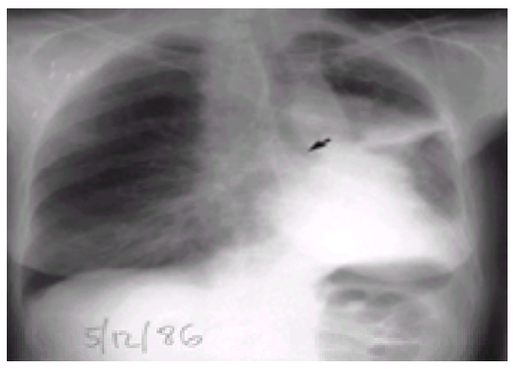

FIGURE 27-2. Chest radiograph showing cutoff airway (arrow) from obstructing tumor, significant volume loss of the left hemithorax, and postobstructive pneumonia.

FIGURE 27-3. Chest radiograph of the same patient after laser resection of the tumor. Notice the resolution of volume loss and resolving pneumonitis.

Success rates are quite substantial with most patients having relief of symptoms or reexpansion of obstructed lung. In a series of 100 Nd:YAG-laser ablations performed on 40 patients, 22 patients were considered to have an excellent response to therapy and another ten a fair response (7). Besides improving quality of life, some patients have prolonged survival from what would otherwise have been a fatal complication of their underlying disease.

Bronchoscopic brachytherapy is the placement of a radiation source in close proximity to an endobronchial tumor. *Brachytherapy*, or short-distance therapy, is in contrast to conventional, external-beam radiation therapy delivered at a distance from the lesion. Brachytherapy is another modality to palliate locally extensive disease in the airways. Patients first undergo bronchoscopy to evaluate the extent of intraluminal tumor. A catheter then is advanced through a channel in the bronchoscope to the desired level, and the bronchoscope is removed. Correct placement is verified by reinsertion of the bronchoscope. The catheter is secured to the nasal orifice, and a radioactive source, usually iridium-192 or iodine-125, is placed in the catheter. Conventional-dose brachytherapy (50–120 cGy/hr) requires the catheter to remain inserted for 48–96 hours with the patient in a shielded hospital room. High-dose brachytherapy (675 cGy/min at 1 cm), delivered by a Gamnaed II remote afterloading unit, has a treatment duration of only a few minutes. No special radiation measures are needed for the patient after the afterloading unit is removed. Patients must have sufficient pulmonary reserve to undergo bronchoscopy and catheter placement. Brachytherapy also can be delivered by the insertion of radiation seeds or pellets into endobrachial lesions. Brachytherapy can improve symptoms of dyspnea and hemoptysis in approximately 90% of patients with stable airway disease (8). Because of

the need for a stable airway, several studies combined laser endobronchial resection with brachytherapy (4,9). High-dose brachytherapy was tolerated better with slightly improved survival compared with conventional-dose brachytherapy. Early complications to brachytherapy include airway obstruction secondary to mucous plugs requiring therapeutic bronchoscopy, radiation esophagitis, and laryngospasm. Long-term complications are more ominous, including fatal hemorrhage from fistula formation between airways and major blood vessels as well as airway esophageal fistula formation (9). Long-term survivors are at risk of airway stenosis at the site of laser or radiation therapy (9).

Extrinsic compression of the airway is not amenable to the above-mentioned therapies. Pressure from extraluminal tumor, vasculature, or luminal weakness can cause the airways to narrow or collapse. Intraluminal pressure is needed to counteract these external forces. Over the past two decades, insertion of airway stents to maintain airway patency has gained popularity as an effective palliative treatment for extrinsic compression. Stents can be inserted through rigid or flexible bronchoscopes. Their most impressive benefit is the immediate palliation of airway obstruction on placement of the stent (Fig. 27-4, Fig. 27-5). Several different types of airway stents are available, including silicone stents (Dumon, Montgomery T-tube, Hood) or expandable metallic stents (Gianturco, Wall, William Cook, etc.). Both types of stents are placed in a similar manner. The stents are compressed to an extremely small diameter within an introducer and are inserted into the airway bronchoscopically after the airway has been dilated with either a balloon or successively larger rigid bronchoscopes. When correct placement is verified, the stent is deployed, expanding to enlarge the airway. Stents come in varying diameters and lengths for use in the trachea and mainstem bronchi.

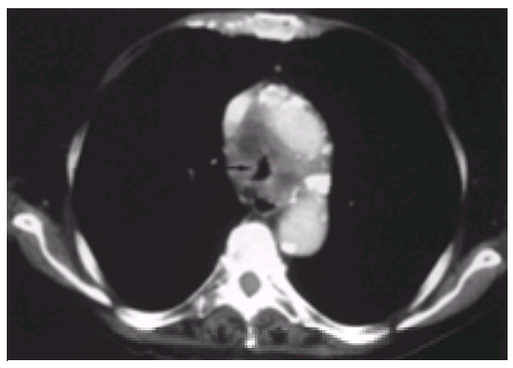

FIGURE 27-4. Tracheal compression (arrow) causing dyspnea in a 63-year-old woman. Biopsy of the tumor revealed squamous cell carcinoma.

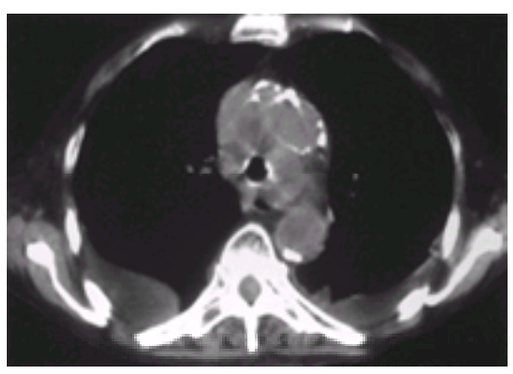

FIGURE 27-5. The same patient after placement of a stent into the trachea, which has increased the diameter of the airway and relieved her symptoms.

However, none of the stents is without drawbacks. Silicone stents may migrate or even may be coughed completely out of the airway. Therefore, it is extremely important to place the appropriately sized stent, as migration usually is seen with stents that are too small (10). Silicone stents placed in the right mainstem bronchus may obstruct the orifice to the right upper lobe, putting the patient at risk for atelectasis and infectious complications. Silicone stents also are believed to interfere with mucociliary clearance and pulmonary toilet (11). T-tube stents are placed in the trachea and usually require tracheostomy. A rare complication of stent placement is fatal erosion into a central vascular structure. Despite these potential drawbacks, silicone stents are well tolerated and quite successful in the treatment of extrinsic airway obstruction (12,13).

Expandable metallic stents are the newest type of stents to be used in the treatment of airway obstruction, but they have many drawbacks. Because these stents are made of loops of wire, they do not obstruct orifices of smaller airways, such as the opening of the right upper lobe, when placed in the right mainstem bronchus. Unfortunately, because of the loops, endobronchial tumor may grow through the stent and compromise the airway. The metallic stents have an irritant effect on the airways. Cough and granuloma formation are the most common complications (14). Some patients improve with inhaled corticosteroids and laser resection. Because of the tissue reaction, removal of the stents is difficult, often causing damage to the airways. There have been reports of fatal hemorrhage, broken suction catheters, stent migration, and stent breakage (15,16 and 17).

Last, some patients with upper airway obstruction may have relief of symptoms following tracheostomy, which is useful only in patients with laryngeal or very proximal tracheal obstruction. In patients with distal tracheal or small airway obstruction, the tracheostomy tube is not able to bypass the obstructing lesion. Recent improvements in tracheostomy tube technology can improve patient communication and decrease the risk of complications such as granulation tissue formation and bleeding.

Tracheobronchial obstruction is a devastating complication from both malignant and nonmalignant disease. There are many possible therapies for palliation. These therapies are not mutually exclusive, and their use in combination should be encouraged. A multidisciplinary approach with appropriately trained personnel is needed.

STRIDOR

Stridor is loud, harsh breathing, particularly on inspiration. It occurs from obstructed airflow in the upper airway and large intrathoracic central airways. Stridor may indicate a pathological narrowing of the airway, which is unable to maintain adequate oxygenation and ventilation of the patient. Therefore, evaluation and management of these patients should be done expediently. Treatment for stridor depends on the location of the obstruction and its etiology. When evaluating a patient presenting with stridor, it is useful to consider the airway as three areas or zones (18,19). The first is the *supraglottic zone*, which includes the nose, oral cavity, pharynx, and supraglottic larynx. This area is composed of soft tissues that are only loosely supported and hence more easily obstructed. Lesions in this area tend to cause stridor only on inspiration. The second is the *extrathoracic tracheal zone*, which is composed primarily of the glottis and subglottis. Because this area has more support, obstruction generally occurs more gradually. Lesions in this area may cause stridor both on inspiration and expiration known as *biphasic stridor*. Last is the *intrathoracic tracheal area*, which also includes the proximal portions of the mainstem bronchi. Stridor from this region may be primarily expiratory and may be confused with wheezing from distal intrathoracic airway obstruction. Of note, patients frequently deviate from these patterns of clinical presentations. The causes of stridor are numerous, some of which are listed in Table 27-2.

TABLE 27-2. CAUSES OF STRIDOR

Evaluation

The tempo of evaluation of the patient presenting with stridor is determined by the acuity of the illness. Patients who present in severe respiratory distress with inadequate oxygenation or ventilation need the immediate establishment of an airway. Because they may have lesions that make intubation difficult or impossible, it is necessary to have available experienced personnel, including an anesthesiologist and otolaryngologist. Fiberopticassisted intubation may be necessary and also may be helpful in establishing the etiology of stridor.

In patients who appear stable, a brief history may help in differentiating the causes of stridor. Gradual onset of symptoms over weeks or months, especially if accompanied by constitutional symptoms, would suggest neoplasm. Stridor that occurs in hours or days, especially if the patient is febrile, is suspicious for an infectious etiology, such as epiglottis croup or abscess. A history of previous intubation is quite important because subglottic stenosis may not appear for months after a traumatic or prolonged intubation. Close questioning regarding episodes of choking or coughing while eating may raise the possibility of aspiration. Foreign body in either the airway or esophagus may cause stridor, especially in younger patients. Pressure exerted from an esophageal foreign body may partially obstruct the airway (20).

Physical examination of a patient with stridor typically begins with the examiner's unaided ear. Loud, noisy breathing is heard. The patient's respiratory rate, depth of respiration, use of accessory muscles of respiration, level of alertness, and evidence of cyanosis should be observed. Inability to handle oral secretions should be noted because it may suggest peritonsillar abscess, retropharyngeal hematoma or abscess, epiglottis, or foreign body.

Palpation of the airway should be performed to assess for crepitation, suggesting subcutaneous emphysema. A displaced trachea or firm mass could indicate tumor or goiter. Lymphadenopathy could suggest neoplasm. Auscultation of the entire airway may help localize the anatomical location of the lesion; so one should listen especially carefully over the larynx, extrathoracic trachea, and central chest.

Radiological studies of the chest, as discussed earlier in this chapter, should be obtained to evaluate stridor in stable patients. In addition, anterior-posterior and lateral radiographs of the neck should be obtained. If more detailed imaging of the airway is needed, CT scans should be obtained. Spirometry with flow-volume loops, as discussed in evaluation of tracheobronchial obstruction, may be an important aid in evaluation of stridor.

Therapy

Stridor secondary to infectious etiologies requires treatment with appropriate antimicrobial therapy. Hemophilus influenza is the most common bacterial cause of epiglottitis, although its incidence has been declining steadily. Respiratory syncytial virus infection may cause airway edema resulting in stridor. This infection is typically seen in children, although the virus has been recovered in immunocompromised adults. Treatment with the antiviral drug ribavirin may be considered in the acutely ill patient. Anaerobes, streptococcal species, and a wide assortment of less common agents may cause abscess formation, leading to airway obstruction. While waiting for the culture results, it is appropriate to treat the patient with broad-spectrum antibiotics.

Several therapies are available to stabilize the stridorous patient who is clinically decompensating. Heliox, a mixture of helium and oxygen, has been useful in improving oxygenation, ventilation, and decreasing work of breathing in patients with stridor from a wide variety of causes (21,22,23 and 24). These causes included postextubation edema, extrinsic compression from tumor, and status asthmaticus. Because heliox has a lower density than ambient nitrogen-oxygen gas mixture, there is decreased airway turbulence and airway resistance. The typical heliox mixture varies from helium 60%-oxygen 40% to maximal concentration helium 80%-oxygen 20%. It can be delivered via a tightfitting face mask, and relief of respiratory distress is often immediate. Treatment with high-dose intravenous (i.v.) corticosteroids should be started using methyl prednisolone 1 mg/kg every 6–8 hours. Racemic epinephrine 2.25%, 0.5 ml in 2.5 ml saline delivered via hand-held nebulizer as often as hourly, but usually every 3–4 hours, may be used especially for postextubation stridor (25).

Noninvasive mask ventilation with continuous positive airway pressure or bilevel positive airway pressure may decrease the work of breathing and overcome large airway obstruction, although currently no studies have evaluated the efficacy of this therapy. Close coordination with a respiratory therapist is needed if this therapy is initiated. Either a tight-fitting mask over the nose or nasal pillars applied to the nares may be used. Positive pressure of 5 cm H_2O is started and titrated up to a maximum of 20 cm H_2O. Most patients are unable to tolerate higher pressures. If needed, supplemental oxygen and humidification can be “bled” into the positive pressure system. Finally, endotracheal intubation or tracheostomy should be considered in appropriate clinical situations for patients severely affected.

BRONCHOSPASM

Bronchospasm is the state of abnormal narrowing of the airways and is usually episodic. Airflow is obstructed and becomes turbulent, resulting in severe dyspnea. Patients complain of dyspnea, chest tightness, or pressure, although occasionally cough is the only symptom. Exacerbation of symptoms frequently occurs in the early hours of the morning, when bronchial tone is normally increased. Wheezing is heard on auscultation of the chest, occasionally needing to be provoked by forced expiration or deep breathing. Expiration time is usually prolonged. Patients may use accessory muscles of respiration and pursed lip breathing.

Bronchospasm is the end result of airway narrowing, which is believed to be a consequence of a state of hyperresponsiveness of the airways to a wide variety of stimuli (26). More recently, airway inflammation has been considered of prime importance in the development of airway hyperactivity. The airway epithelium is thickened and friable, and microscopically there is infiltration with inflammatory cells, especially eosinophils and mast cells. Mucous glands are hyperplastic, and goblet cells are more numerous compared with normal persons (27). Bronchial lavage fluid of the lung reveals high concentrations of cytokines, prostaglandins, histamine, triptase, and immunoglobulin E (26). In severely affected persons, the airways may be plugged with excessive inflammatory secretions and desquamated epithelium (28). Airway muscle is both hyperplastic and hypertrophied, but it has been found to contract normally when stimulated (29). Smooth-muscle mass is increased, probably in response to growth factors, such as histamine, or as a result from increased work (30,31).

Evaluation

The differential diagnosis for bronchospasm includes asthma, COPD, upper/large airway obstruction (see the section Tracheobronchial Obstruction) congestive heart failure, bronchiolitis (infectious or inflammatory, medication induced), lymphangitic tumor spread, or rarely, pulmonary embolism. Multiple etiologies for bronchospasm are common in an individual patient. The extent of evaluation depends on the complexity of an individual patient's medical condition. In a patient with a significant smoking history, chronic sputum production, and diffuse bronchospasm on examination, it is likely that an exacerbation of COPD explains the clinical situation. Obviously, in a patient who has a similar history but is immunocompromised, the diagnostic possibilities must be widened.

Chest radiographs should be obtained in patients presenting with bronchospasm. Bronchial wall thickening, flattened diaphragm, and increased retrosternal air space are consistent with hyperexpansion and air trapping and would support the diagnosis of asthma or COPD. In addition, the chest radiograph may reveal complications of obstructive lung disease, such as pneumonia, pneumothorax, or atelectasis.

A chest radiograph with no change from the patient's baseline film or with atelectasis or small pleural effusion should alert the clinician to possible pulmonary embolism, and a ventilation/perfusion scan ( ) should be obtained to access for pulmonary embolism. The scan needs to be compared with the chest radiograph for accurate interpretation. A completely normal perfusion scan effectively excludes pulmonary embolism. Segmental perfusion defects in areas of normal ventilation define a high probability scan, which indicates an 85–90% probability of pulmonary embolism, which must be interpreted with care, as one of the few causes of false-positive scans is bronchospasm. Helical CT scanning of the chest may be more cost effective and more accurate than scanning in identifying clinically significant pulmonary emboli (32). Again, if the clinical situation warrants further evaluation, noninvasive testing to detect lower extremity deep venous thrombosis or pulmonary angiography may need to be pursued.

Spirometry not only confirms airway obstruction but can suggest its anatomical location (upper versus intrathoracic) and quantify the extent of airway obstruction. In addition, it also may be helpful in monitoring treatment response. Forced vital capacity (FVC) and forced expiratory volume at 1 second (FEV_1) are reduced in an obstructive lung defect with the reduction in FEV_1 greater than that of FVC. In airway obstruction, the ratio of FEV_1 to FVC will be less than 70%. The severity of the obstructive defect is graded by the patient's percentage of predicted FEV_1 (70% or greater, mild; between 60–70%, moderate; between 50–60%, moderately severe;

between 35–50%, severe; and less than 34%, very severe) (33).

The contour of the expiratory portion of a flow-volume loop shows concavity, which worsens with the extent of the obstructive lung defect. Patients with chronic obstructive lung disease have fixed airway obstruction but can have some degree of variability in FVC and FEV_1 during exacerbations. On the other hand, most patients with asthma should have normal or near normal spirometry between episodes of illness. Spirometry often is obtained before or after use of inhaled bronchodilators. Patients who have at least a 15% improvement in FVC or FEV_1 and 200 ml absolute increase in FVC or FEV_1 are considered to have a significant immediate response. This group is considered to benefit most from inhaled bronchodilators and corticosteroids, although many studies have reported conflicting results regarding this issue (34). Patients who do not improve immediately after inhaled bronchodilators may have spirometric or clinical improvement with regular use; therefore, these medications should not be withheld.

Therapy

The goals of therapy in bronchospasm are to dilate the distal airways and reduce inflammation, hence relieving airway obstruction. There are many pharmacological agents available to treat bronchospasm (Table 27-3). The severity of the patient's symptoms guides which of these medications are used and in what order. Beta adrenergic agonists continue to be important pharmacological agents to relieve bronchospasm. They can be administered in many forms: inhaled through metered-dose inhalers, inhaled through hand-held nebulizers, taken orally, or injected subcutaneously or intravenously. Over the past decade, there has been a strong movement against using oral beta agonists as their efficacy is similar to the inhaled forms but they have a higher incidence of side effects. Subcutaneous forms are used sparingly for emergency treatments. Intravenous administration of isoproterenol is no longer recommended (35).

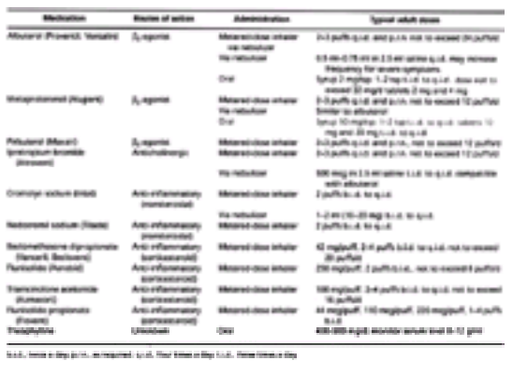

TABLE 27-3. MEDICATIONS COMMONLY USED TO TREAT BRONCHOSPASM

Beta adrenergic agents promote airway smooth-muscle relaxation by a mechanism that is not completely understood. In addition, they increase mucociliary clearance and increase the secretion of electrolytes by the airways. Side effects include tremor, tachycardia, palpitations, hypokalemia, and hyperglycemia. Usually these side effects are most pronounced when the medications are first initiated and lessen over time. Sustained-release, oral, beta-adrenergic agonists have a useful role in patients with significant nocturnal symptoms. Patients with mild bronchospasm may be started on beta-adrenergic agonists alone to control symptoms. For patients with more severe presentations, other therapies are needed. The recent trend has been to have patients use these medications on an as-needed basis for mild symptom control. Recent studies have found equal efficacy between metered-dose inhalers and nebulized beta adrenergic agents if proper technique is used and the dose is increased to five or six inhalations. Some patients benefit by using a spacer device to improve delivery with metereddose inhalers. The total dose of beta-adrenergic agonist should be 24 or fewer inhalations in a 24-hour period to prevent tachyphylaxis. Patients who do not find relief with use of beta-adrenergic agonists or who must increase their usual dose should be evaluated for additional therapies. The recent spate of literature on the safety of beta-adrenergic agonists found that mortality increased when patients were undertreated for asthma (36,37,38 and 39).

Anticholinergic agents act by decreasing parasympathetic bronchoconstriction of the airways. They are most useful in COPD, in which parasympathetic activity is believed to be greater than normal. Ipratropium bromide is the only anticholinergic agent available for inhalational use in the United States. Because of recent reports suggesting ipratropium bromide may be more effective than betaadrenergic agonists in promoting bronchodilation in patients with COPD, some authors believe it should be the first agent used in maintenance therapy in COPD (40,41 and 42). Corticosteroids are widely used in the treatment of bronchospasm. Patients with mild to moderate symptoms may benefit from inhaled corticosteroids. They are especially attractive because they act locally, with minimal absorption and limited toxicity. However, reports of hypothalamic-pituitary-adrenal axis suppression and cataract formation were recently reported with the use of high dose inhaled corticosteroids (43). In addition, patients should be cautioned that these medications must be used regularly and may take weeks for therapeutic effect. Therefore, corticosteroids should not be used as monotherapy for acutely symptomatic patients. Inhaled corticosteroids also may allow patients on systemic corticosteroid therapy to have their doses reduced or discontinued altogether. Patients with more serious symptoms or those in respiratory distress require systemic corticosteroids. These medications may take up to 12 hours to have clinical effects. Prednisone, 0.5–1.0 mg/kg per 24 hours, may be used for 1–2 weeks and then gradually tapered. Seriously ill patients should receive methyl prednisolone, 1–2 mg/kg every 6–8 hours i.v., until improvement is noted. At that time, the i.v. dose may be tapered over several days and the patient switched to oral corticosteroids. Peak flow meters along with physical examination and arterial blood gases help determine a patient's response to therapy.

Besides corticosteroids, cromolyn sulfate and nedocromil sodium are other antiinflammatory agents. Their exact mode of action is unclear, but likely they act as mast cell stabilizers. These medications are particularly useful in children for symptoms related to exercise or cold air and for patients with a strong allergic component to their bronchospasm. Cromolyn sulfate is available as a metered-dose inhaler, two puffs four times a day, or inhalational solution, 1–2 cc four times a day via nebulizer. Nedocromil sodium is used two puffs four times daily via metered-dose inhaler. Again, patients must be educated to use these medications regularly because its maximal effects are not noted for 4–6 weeks.

Theophylline, once a mainstay of therapy, has lost its place as a first-line therapy in the treatment of bronchospasm because of excessive toxicity and potential for serious drug interactions. It is still used in patients with COPD in an effort to augment respiratory muscle function and for its weak bronchodilator effects. In addition, it is used in corticosteroid-dependent asthmatics in hopes of decreasing their daily steroid dose (44). Typically, patients are started on long-acting preparations at a dose of 400–900 mg/day to achieve serum levels of 8–12 µ/ml. The dose must be individualized depending on concurrent medications, smoking history, and medical history, such as congestive heart failure, as all of these change drug clearance. Critically ill patients in respiratory failure secondary to bronchospasm who do not respond to maximal therapy, including intubation and mechanical ventilation, should be considered for bronchial muscle relaxation with inhalational anesthetics.

COUGH

Etiology

Cough is a protective, complex reflex that helps clear the airways of foreign material or excessive secretions. It is a common problem that translates into 30 million physician visits per year and millions of dollars spent on over-the-counter medications (45).

The cough reflex is complicated and not fully understood. Suffice it to say that cough results from stimulation of cough receptors, which may be found in the larynx, respiratory epithelium, tympanic membranes, esophagus, pericardium, and sinus mucosa. Afferent impulses travel via the vagus, trigeminal, glossopharyngeal, and phrenic nerves to cough centers in the medulla. Efferent impulses travel via the vagus, phrenic, and spinal nerves to the glottis and respiratory muscles, which produce the high-velocity flow of air that defines a cough (46,47).

Evaluation

Cough is a common complaint in patients with advanced cancer. In the cancer patient, cough may be secondary to endobronchial tumor, pericardial disease, vocal cord paralysis, or aspiration. Cough also may be due to complications of treatment, such as radiation pneumonitis or chemotherapyinduced interstitial disease (48). In addition, patients with underlying cancer may have all the same causes of cough found in the general population. The most common etiologies of chronic cough include postnasal drip syndrome, asthma, and gastroesophageal reflux (49,50).

A detailed history and physical examination are most helpful in determining the cause of chronic cough (47). Chest radiographs should be obtained early in the evaluation of cough (51). In patients who chronically produce sputum or in whom there is a suspicion of interstitial lung disease, a high-resolution chest CT scan may be helpful. Of patients with interstitial lung disease, 10–15% have a normal chest radiograph. Computed tomography scan is very helpful in the evaluation of

bronchiectasis.

Sinus imaging, including radiographs and CT scanning, are needed to evaluate for chronic sinus disease. Some authors recommend a trial of antihistamine-decongestants before pursuing sinus radiographical studies (45). Spirometry, before and after inhaled bronchodilators and methacholine challenge, help to evaluate for asthma or chronic obstructive lung disease. Evaluation for gastroesophageal reflux disease can be undertaken with barium esophagography or 24-hour esophageal pH monitoring. Finally, if no cause has been found for chronic cough, bronchoscopy should be considered to evaluate for occult foreign body aspiration or small endobronchial lesions, such as carcinoid tumors or bronchogenic cancer, although studies have found this to be of low yield (49).

Therapy

Treatment of cough is most successful if it is tailored to a specific etiology. Postnasal drip syndrome may be well controlled with the use of antihistamine-decongestant therapy. Asthma therapy was discussed earlier in this chapter (see section on Therapy under Stridor) Gastroesophageal reflux disease is treated with H_2 receptor blockers or proton pump inhibitors along with lifestyle changes. In patients for whom no cause is found for their cough or it is due to airway involvement with tumor, empiric medical therapy is reasonable. Some patients obtain relief with the use of b_2-adrenergic agonists such as Albuterol, two or three inhalations every 4–6 hours or 0.5 ml Albuterol solution in 2 ml saline via nebulizer every 4–6 hours.

For generations, opiates have been used and are variably effective antitussives (46,52). There is no evidence of superior antitussive effect with one preparation over another. Codeine, 15–30 mg every 4–6 hours, is a reasonable starting dose, with titration upward to control symptoms if the side effects are tolerable. Nonnarcotic cough preparations, such as guaifenesin and dextromethorphan, may be tried, although they have been only weakly effective. Two recent articles review the many conflicting studies evaluating overthe-counter and prescription cough medications (52,53).

Inhaled lidocaine is used to suppress cough during bronchoscopy. Animal studies and a few human studies suggest that lidocaine has an antitussive effect when inhaled via nebulizer, probably acting on afferent C-fibers in the larynx and trachea. The dose is empiric; a starting dose is 5 ml of 2% lidocaine solution every 4 hours via hand-held nebulizer (46,48). Patients should be cautioned regarding anesthesia of the oropharynx and larynx, which puts them at risk for buccal injury or aspiration. The dose may be increased if needed, but there are no studies giving explicit guidelines for this therapy. Generally, during bronchoscopy, doses higher than 300 mg of lidocaine (15 ml of 2% solution) are avoided to decrease the risk of seizures, as there is significant systemic airway absorption of lidocaine.

In patients who have underlying chronic bronchitis, a trial of inhaled ipratropium bromide, two puffs four times a day, may diminish the cough (54). Finally, some patients respond to corticosteroids. Some of these patients have underlying asthma, whereas others may have other reasons for airway inflammation, such as chronic bronchitis, bronchiectasis, or radiation pneumonitis. Inhaled steroids such as flunisolide two puffs twice daily and triamcinolone two to four puffs four times a day may be tried as initial therapy or maintenance therapy after oral agents. Patients not responding to inhaled therapy should be tried on prednisone, 0.5–1.0 mg/kg per day for 2–4 weeks. If the cough subsides, the prednisone should be tapered to the lowest dose to control symptoms, or patients should be switched to inhaled steroids.

MANAGEMENT OF PLEURAL AND PERICARDIAL EFFUSIONS

JOHN C. RUCKDESCHEL
LARY A. ROBINSON

One of the most common and troubling problems for the cancer patient is the development of a malignant effusion of any body cavity. When it occurs in the pleural cavity or the pericardium, this abnormal accumulation of fluid may cause severe symptoms or may even be life threatening. Any type of cancer can metastasize to these serous cavities, and this problem is most common in disseminated malignancies. Although the development of a malignant pleural or pericardial effusion almost always indicates that the patient has an incurable cancer, prompt recognition and diagnosis followed by appropriate treatment can result in excellent palliation and a marked improvement in the patient's quality of life. In addition, it is critical that an accurate diagnosis is made to establish the malignant cause of the effusion, because cancer patients can often develop an effusion from a benign cause such as radiation therapy, infection, chemotherapy, or heart failure. All cancer patients with pleural or pericardial effusions, especially when associated with symptoms, deserve a thorough evaluation and an opportunity for prompt therapy.

PLEURAL EFFUSIONS

Incidence

In a general hospital patient population, 28–61% of all pleural effusions are malignant; the highest incidence is in the over-50 age group (1,2,3 and 4). A malignant pleural effusion is the initial manifestation of cancer in 10–50% of patients (4,5). In patients with known breast cancer, almost half will develop a malignant effusion during the course of their illness (3), although this figure may be somewhat lower now with more recent treatment regimens. For lung cancer, 7–15% of all patients develop this complication (5). Eventually, about half of all disseminated cancer patients develop a malignant pleural effusion (4). Overall, this is a highly significant clinical problem, because approximately 100,000 malignant pleural effusions occur annually in the United States (6). Table 28-1 lists the frequency of the various tumor types that are associated with malignant pleural effusions. The tumor origin is not found in 15% of effusions. In such cases the cell type is usually metastatic adenocarcinoma with the primary site unknown.

Tumor type	Incidence (%)
Lung	35
Breast	23
Lymphoma/leukemia	10
Adenocarcinoma, unknown primary	12
Reproductive tract	6
Gastrointestinal tract	5
Genitourinary tract	3
Primary unknown	3
Other cancers	5

TABLE 28-1. TUMOR CAUSES OF MALIGNANT PLEURAL EFFUSIONS FROM COLLECTED SERIES

The appearance of a symptomatic, malignant, pleural effusion in a patient with known cancer significantly alters his or her quality of life. Although it is reported that up to 25% of patients with an effusion are asymptomatic, this may prove to be an overestimate if a careful history is elicited (7). In general, a prompt diagnosis accompanied by timely treatment of the effusion can markedly enhance the patient's functional status and should be considered early after the development of this common complication of advanced cancer.

Etiology and Pathophysiology

The pleura is a serous membrane that invests each lung to form a closed sac called the *pleural cavity*. There is a continuous passage of an almost protein-free fluid (protein content, 1.5 g/dl) through the pleural membrane thought to be based primarily on hydrostatic and colloid osmotic pressures. The net pressure in the parietal pleura is 9 cm H_2O, favoring movement of fluid into the pleural cavity, which is balanced with a net 10 cm H_2O pressure in the visceral pleura, favoring absorption of pleural fluid by the visceral capillaries. Therefore, the overall direction of movement of fluid is from the systemic circulation in the parietal pleura across the pleural cavity back into the pulmonary circulation in the visceral pleura. At any one time, either pleural cavity has only 2–5 ml of fluid present, although as much as 5–10 liters flow through this space in any 24-hour period (8,9). Any imbalance in these pressures that disturbs the normal equilibrium may lead to a net accumulation of fluid in the pleural cavity.

Traditionally it has been held that the normal equilibrium may be interrupted, leading to the accumulation of an effusion. Some of these changes that may occur include the following:

- Increased capillary permeability due to inflammation from infection or tumor cell implantation
- Increased oncotic pressure of fluid in the pleural space from the inflammatory reaction from tumor cells or infection
- Decreased systemic oncotic pressure due to hypoalbuminemia from malnutrition
- Increased negative intrapleural pressure due to atelectasis, possibly from tumor obstructing a bronchus
- Increased hydrostatic pressure in the pulmonary circulation, as in congestive heart failure from cardiac or pericardial metastases

In addition, a malignant effusion may result from obstruction of the visceral or parietal lymphatic channels by tumor, resulting in impaired absorption. Most malignant effusions are probably the result of a combination of the factors, with an overall increase in fluid production and a decrease in absorption (3,10,11).

More recently, the role of vascular hyperpermeability as mediated by vascular endothelial growth factor (VEGF) has received increasing attention. Fidler's group at M. D. Anderson has demonstrated that pleural invasion by malignant cells expressing VEGF mRNA is required for production of malignant effusions and that the effusions (but not tumor growth) could be abrogated by transfection of the cells with an antisense VEGF (12). PTK 787, a compound that blocks VEGF receptor tyrosine kinase phosphorylation (among other receptor tyrosine kinases) leads to reduced pleural fluid formation but not to reduced proliferation of the tumor cells (13). Several investigators have described increased levels of VEGF in the fluid of patients with malignant effusions (14,15,16,17,18 and 19) and the presence of increased FLT-1 VEGF receptors (fms-like tyrosine kinase receptor of VEGF) on mesothelial cells (15). A Dutch group has demonstrated that antibodies against VEGF or SU5416, a small molecule tyrosine kinase inhibitor, can also block production of both pleural and peritoneal fluid accumulation *in vitro* (20). Although still in an early phase of understanding, the role of vascular hyperpermeability may explain why some agents that do not induce brisk fibrosis in the pleural space may still be useful in the treatment of malignant effusions (21).

Pleural effusions caused by a malignancy usually result in an exudate with a high protein content, although rare exceptions have been reported (1,5). However, transudative effusions (low protein) may occur as the indirect result of an advanced cancer, as in the patient with malnutrition and hypoalbuminemia, congestive heart failure due to cardiac failure, or liver disease secondary to metastases (3).

Clinical Presentation

The most critical initial step in evaluating the patient with a suspected malignant pleural effusion is to take a complete history and perform a careful physical examination. This simple step will usually exclude other causes of an effusion, such as heart failure or infection.

The clinical presentation of a malignant pleural effusion is almost always related to collapse of lung from the increased pleural fluid and the resulting initial symptom of exertional dyspnea. Later, resting dyspnea and orthopnea develop as the effusion increases in volume. A dry, nonproductive cough, a sense of heaviness in the chest, and occasionally pleuritic chest pain are also experienced. Nevertheless, an occasional patient (<25%) will appear completely asymptomatic in the face of a large effusion (11).

The physical findings of a malignant pleural effusion often include dullness to percussion of the affected hemithorax, decreased vocal fremitus, decreased breath sounds, egophony, and no demonstrable diaphragmatic excursion. Rarely, a very large effusion will result in a mediastinal shift with contralateral tracheal deviation and possibly even plethora or cyanosis from partial caval obstruction (3,7). Other signs and symptoms may be present initially but are usually related to the underlying primary tumor and not the effusion.

Diagnosis

The approach to the diagnosis and subsequent treatment of a patient with a suspected malignant pleural effusion is shown in Figure 28-1.

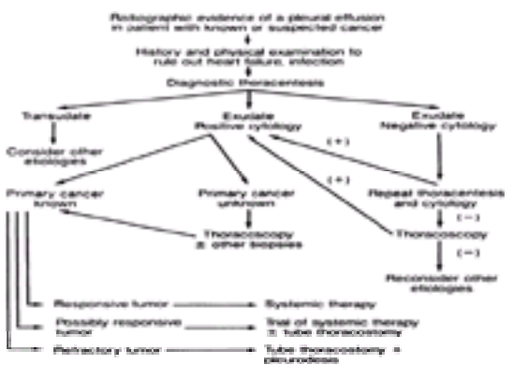

FIGURE 28-1. Approach to the diagnosis and treatment of malignant pleural effusions. +, study result is positive; –, study result is negative. (From Ruckdeschel JC. Management of malignant pleural effusion: an overview. *Semin Oncol* 1988;15:24–28, with permission.).

The initial screening examination is the posterior-anterior chest radiograph, including decubitus views, which will confirm the presence of free pleural fluid and will also suggest the presence of any loculated fluid. An upright posterioranterior chest radiograph that demonstrates blunting of the costophrenic angle will detect 175–500 ml of fluid, while a decubitus view will show as little as 100 ml (22).

Computed tomography (CT) may play a role in the evaluation of malignant pleural effusion patients. This is especially necessary if the hemithorax is opaque on chest radiograph, when a mesothelioma is suspected, or when the underlying primary tumor is unknown. However, a large effusion often obscures an underlying tumor in the lung, and CT may prove more useful after drainage of the effusion and lung reexpansion. Occasionally, chest ultrasonography may prove useful in differentiating between pleural fluid and pleural thickening (23), but its more common application is to localize small effusions as a guide in thoracentesis (24).

After confirmation of a pleural effusion radiographically and after exclusion of any obviously nonmalignant causes, the next step is a diagnostic thoracentesis. In general, when a malignant effusion is suspected, only a small amount of fluid is withdrawn for diagnosis (at least 250ml is needed for cytology). This leaves a moderate amount behind so that insertion of a chest drainage tube later is easier.

The use of a disposable thoracentesis kit with a specially designed multihole catheter is preferred, because it tends to lessen the chance of complications such as a pneumothorax. Rapid removal of a large amount of fluid, especially over 1,500 ml, is not advised, because this may result in life-threatening reexpansion pulmonary edema, a real and not infrequent complication of large-volume thoracenteses (25).

The fluid removed should be heparinized and sent to the lab for protein and lactic acid dehydrogenase (LDH) determinations and cytology. Other tests, including pH determination (for which the fluid must be collected in an anaerobic container), glucose level, cell count, and cultures with smears, are often obtained, although they are not necessary. With a malignant pleural effusion, the pH and glucose level are often low, but these are nonspecific findings (3). A malignant effusion is frequently hemorrhagic (erythrocyte count >100,000/mm^3), but this is also nonspecific and occurs in only one third of cases (5). The Health and Public Policy Committee of the American College of Physicians has demonstrated that elevated levels of LDH or protein in the fluid, and ratios of fluid to concurrent serum levels of LDH and protein, are all that are required for the distinction of a transudate from an exudate (Table 28-2) (26). If the fluid is found to be a transudate, then a malignancy is essentially excluded. An exudate with a negative cytology result demands a second diagnostic thoracentesis with cytology, which will add approximately 6–11% more malignant diagnoses (3).

Test	Positive predictive value (%)
(1) Fluid LDH >200 international units	100
(2) Fluid/blood LDH ratio >0.6	99
(3) Fluid protein >3 g/dl	95
(4) Fluid/blood protein ratio >0.5	99
(1), (2), or (4) above	99

LDH, lactic acid dehydrogenase.

TABLE 28-2. DIAGNOSTIC TESTS CONFIRMING THE PRESENCE OF AN EXUDATE

Cytology is the best method of diagnosing a malignant pleural effusion, although it is somewhat dependent upon tumor type, the experience of the cytopathologist, and the amount of fluid that is sent for cytologic analysis; at least 250 ml is preferred for the best yield (27). In patients with an effusion eventually proved to be malignant, the first cytology result will be positive in 53–59% of cases, rising to 65% when a second thoracentesis is performed (3). In some tumors, such as Hodgkin's disease, the rate of positive cytology results is relatively low at 23%, while with others, such as breast or lung cancer, the diagnosis rate is as high as 73% (3). A variety of immunocytochemical staining techniques and, recently, cytogenetic markers have been added to complement the standard cytologic techniques. These methods have resulted in some increased diagnostic yield, although they often lack sensitivity and specificity, and also the laboratory expense is increased (3,10). We do not recommend using these tests outside of a clinical trial.

If the result of cytologic examination is negative, traditionally a blind pleural biopsy has been attempted, with some expectation of increased diagnostic yield. Although a blind biopsy may be a sensitive test in pleural tuberculosis because of its diffuse involvement, malignancies involving the pleura are commonly patchy in distribution, and a blind pleural biopsy usually adds little to the diagnosis. Although earlier series suggest that the pleural biopsy may be valuable in diagnosing malignancy in a patient with negative cytology results (3), a more recent direct comparison of pleural fluid cytology versus blind pleural biopsy casts doubt on its benefit. In this important series (28), cytology results were diagnostic of cancer in 71% of cases and suggestive in another 8%. Blind biopsy of the pleura gave positive results for malignancy in 45% of cases but provided a diagnosis in only 3% of cases where the cytology result was nondiagnostic.

Therefore, if two exudative pleural fluid cytology results are negative for malignancy, most clinicians now bypass the blind pleural biopsy and move promptly to video-assisted thoracoscopy (VATS), wherein visually directed pleural biopsies are readily obtained and the diagnostic yield is quite high. In large series, the diagnostic sensitivity of VATS with malignant pleural effusion is 97% (29). Although VATS is a surgical procedure usually requiring general anesthesia, the mortality and morbidity is quite low at 0.5% and 4.7%, respectively (30).

In addition to providing a high diagnostic yield of malignancy by directed biopsies during VATS, this procedure, when the ipsilateral lung is collapsed and the patient is under general anesthesia, permits direct definitive therapeutic intervention with lysis of adhesions, mechanical pleurodesis, pleurectomy, or talc poudrage, with a very low recurrence rate (31). Finally, when the fluid cytology result is positive but the primary site is unknown, VATS may be employed occasionally to obtain a larger amount of tissue for more definitive studies or to rule out the presence of a mesothelioma, especially when “adenocarcinoma, unknown primary” is the working diagnosis according to cytology. The advent of VATS has virtually eliminated the need for diagnostic open thoracotomy when a malignant effusion is suspected.

Prognosis

Once the diagnosis of a malignant pleural effusion has been made, the choice of therapy must be put in perspective with the extent of the tumor, the condition of the host, and the prognosis. Virtually all of these patients have an incurable disease, so the treatment must be aimed at the most effective palliation for maximal, comfortable time outside of the hospital. For all patients, the overall mean survival time is 3–6 months. The mortality is as high as 54% at 1 month and rises to 84% at 6 months (11,33). Some malignant effusion patients with responsive tumors, such as breast cancer, may have a longer survival averaging 7–15 months (11); 20% have a 3-year survival (32). Ovarian cancer patients with a malignant effusion also have a longer expected mean survival of 9 months (23). Conversely, lung cancer patients have a worse prognosis, with a mean survival of 2 months, and 66% will die by 3 months (11).

Treatment

Systemic Therapy

When the effusion is small and asymptomatic and the tumor is likely to be sensitive to systemic therapy, as with lymphoma, leukemia, breast cancer, ovarian cancer, small cell lung cancer, or germ cell tumors, the first line of therapy should be systemic chemotherapy or hormonal therapy, preceded by thoracentesis if the patient is symptomatic (7,10). When the tumor is relatively chemoresistant or has been shown to be so in the past, as with non-small cell lung cancer or pancreatic cancer, the choice then is for prompt tube thoracostomy followed by intrapleural therapy. Table 28-3 lists methods of controlling malignant pleural effusions.

Systemic chemotherapy
Repeated thoracentesis
External radiotherapy
Tube thoracostomy alone
Tube thoracostomy with drug instillation
Pleurectomy
Pleuroperitoneal shunt
Videothoracoscopy with pleurodesis

TABLE 28-3. METHODS OF CONTROLLING MALIGNANT PLEURAL EFFUSIONS

Thoracentesis

Thoracentesis alone may relieve symptoms briefly, but the fluid usually reaccumulates rapidly. In a study of 94 patients, the mean time to reaccumulation of the pleural effusion after thoracentesis was 4.2 days, and 97% had a recurrence of the fluid by 1 month (34). In addition, repeated thoracenteses carry the risk of empyema, pneumothorax, a trapped lung from inadequate drainage and loculation of fluid, and the real possibility of progressive malnutrition from repeated removal of a large amount of the high-protein effusion fluid.

Radiation Therapy

Radiation therapy may occasionally be useful as primary therapy, but only when directed at paramalignant effusions caused by mediastinal lymphadenopathy and lymphatic obstruction (35). Improvement is rarely seen before 3 weeks, and therefore radiation has little application in the more acutely symptomatic effusion.

Tube Thoracostomy

Tube thoracostomy alone has been proposed as effective therapy for malignant effusions (3). But careful review of the results demonstrate that none of these older studies reliably supports the conclusion that chest tube drainage alone is efficacious in long-term control (3). However, tube thoracostomy appears quite useful in draining the pleural cavity and maintaining opposition of the pleural surfaces when a therapeutic agent is subsequently instilled into the chest for sclerotherapy. Anderson and associates found that chest tube drainage greatly improved the response to intrapleural nitrogen mustard, compared with instillation of the agent after thoracentesis alone (34). The relative direct antitumor effect of any of the sclerosing agents is probably little, or at best some agents are cytostatic (36) and their primary action is mostly local inflammation.

Recently, some enthusiasm has been voiced for the use of small-bore (8 French or 12 French) catheters for gravity drainage or even suction drainage of the pleural cavity followed by intracavitary sclerotherapy. The long-term results of this technique are still undetermined (37), although the selection of patients with free-flowing effusions can enhance the outcome significantly (38). These small-bore catheters rapidly become occluded from debris and fibrin clots, and generally effective suction can be maintained in the pleural cavity for only a few hours. If, as it is thought, the visceral and parietal pleurae should be kept in direct opposition for a day or two after instillation of the sclerosing agent to obtain a pleurodesis, then it is unlikely that these small catheters will be as successful as larger chest tubes.

To achieve the best palliation, the pleural cavity should be drained completely and the lung fully expanded. This is best accomplished by closed tube thoracostomy. A no. 24 French or 28 French chest tube is usually inserted in the sixth or seventh interspace in the midaxillary line with the tube directed posterior to the lung to maximize drainage. Generally the patient is given 3–6 mg morphine sulfate intravenously just before the procedure for sedation and to allay anxiety. The patient is positioned supine but turned up with the appropriate side of the chest elevated at 45–60 degrees and with the physician standing behind the patient. After sterile prepping and draping of the skin, 20–40 ml 1% lidocaine is infiltrated into the skin, the subcutaneous tissue, and most important into the intercostal musculature and pleura of the interspace where the tube will enter. A brief thoracentesis is always performed first at the planned pleural entrance interspace to make sure that there is

free aspiration of fluid. If no fluid is obtained, the chest tube entrance site must be altered to a place where fluid is readily obtained by thoracentesis. A small 2- to 3-cm skin incision is made 1.0–1.5 interspaces below the target interspace, and a subcutaneous tunnel is created bluntly with a clamp. Likewise, the pleural cavity is initially entered with a blunt clamp, which is spread wide to create a generous opening for the chest tube. A clamp is placed on the introductory end of the chest tube to pass the tube through the subcutaneous tunnel into the pleural space and to direct the tube posterior and cephalad. The opposite end of the tube is also clamped off during the insertion to avoid an open pneumothorax and a gush of fluid from the chest. The physician should slowly twirl the tube as he passes it into the chest so he can avoid kinking the tube, because the tube will not twirl easily if it bends over inside the chest cavity. As long as the tube remains straight, it will twirl easily. Once the tube is inserted to a predetermined depth based on numerical markings on the tube itself, it is firmly sutured into place to the skin with heavy silk suture (0-silk or larger). The tube is then attached to an underwater seal drainage device at approximately 20 cm H_2O suction. If there is a very large effusion, it should not be all drained immediately. Instead, 1,000–1,500 ml should be drained initially, and then the tube should be clamped for 30–60 minutes, draining approximately 1,000 ml every 60 minutes until the chest is completely empty. More rapid drainage of a large pleural effusion encourages the development of the life-threatening problem of reexpansion pulmonary edema, a real and preventable phenomenon (25). Although some physicians use a trocar chest tube, the risks of laceration of the lung or even the heart or diaphragm are significant.

Chest radiographs are obtained initially and then daily as long as the tube is in place. The chest tube is left on suction for total drainage of the effusion and to encourage reexpansion of all possible lung. When a properly positioned chest tube is completely open and is on suction, essentially all of the fluid that is drainable will have drained within a few hours of insertion and certainly after overnight drainage. Likewise, all lung that is expandable and is not trapped will have expanded after overnight suction. Although some authors suggest waiting an indefinite period of time until the chest tube drainage has decreased to an arbitrary 100 ml per 24 hours (10), waiting this extra time is probably not necessary and may even lessen the chance of success. The prolonged presence of the tube irritating the pleural cavity may encourage loculations and lessen the eventual distribution and effectiveness of the sclerosing agent. Therefore, the decision when to instill the intracavitary agent should rest on the appearance of the chest radiograph and not the daily drainage. Usually, the best time to instill the sclerosing agent is the day after chest tube insertion.

Fibrinolytic Agents

If the chest radiograph the day after chest tube insertion shows apparent residual fluid, and especially if the fluid is thick or gelatinous, it may be worthwhile to try intrapleural instillation of urokinase 100,000 units in 100 ml 0.9% saline, clamping of the tube for 6 hours, and then resumption of suction for another 24 hours (39). This technique has been reported to improve drainage and lung expansion in loculated empyemas as well as with loculated malignant effusions with no side effects or systemic effects on coagulation or fibrinolysis. (39,40).

Pleural Sclerotherapy

By far the most common palliative treatment of malignant pleural effusions is drainage of the pleural space with reexpansion of the lung, followed by instillation of a chemical agent into the pleural cavity. It is thought that the treatment works by causing a pleuritis designed to create a symphysis between the visceral and parietal pleurae (also called *pleurodesis by sclerotherap*) to prevent reaccumulation of fluid in this space. The most commonly used method to drain the effusion is with a chest tube, as previously described (see the section Tube Thoracostomy), and at least some nonrandomized studies suggest that this method gives superior results with sclerotherapy compared with drainage and sclerotherapy by needle thoracentesis alone (34).

Another apparent determinant of the success in pleural sclerosis is the glucose level and the pH of the pleural effusion. Several authors have found that a low glucose level (<60 mg/dl) and pH (<7.20) in the malignant effusion result in a higher recurrence rate after attempted chemical pleurodesis as well as an overall shortened patient survival (41,42). Although interesting, the exact significance of these isolated reports is uncertain and probably should not influence the choice of agent or techniques employed.

Controversy abounds as to which is the most effective chemical sclerosing agent for malignant pleural effusions. Comparison of the many published reports about various agents is often difficult because of the difference in reporting response rates, patient criteria, side effects, methods of evaluating results, and followup. The most widely followed set of guidelines to analyze results in the literature is that published by Hausheer and Yarbro (3), which is summarized in Table 28-4. However, we believe that a simpler and more accurate means of assessing therapeutic efficacy is to follow the time to recurrence compared with the chest radiograph taken after pleurodesis and removal of the chest tube. In many instances, the pleural effusion recurs or progresses, but retreatment is not indicated because the patient has progressive disease elsewhere. For assessment of therapeutic efficacy, these cases still need to be counted as “failures.” On the other hand, whether the progression is clinically meaningful—that is, needs retreatment—is a significant issue in cost-effectiveness studies.

Patient must survive 1 mo after the procedure[b]
Objective response:
No major fluid reaccumulation 1 mo after pleural sclerosis, as determined by chest radiographs
No clinical requirement for thoracentesis within that mo
Failure:
Reaccumulation of more than 50% of the original effusion volume in comparison with the immediate postpleurodesis chest radiograph
Clinical requirement for thoracentesis within 1 mo of the pleurodesis

TABLE 28-4. COMMONLY USED GUIDELINES FOR EVALUATING THE THERAPEUTIC EFFICACY OF PLEURAL SCLEROSIS[a]

Mechanism of Sclerosis

The mechanism of action of sclerosing agents appears to vary somewhat depending on the type of agent and the laboratory model tested. One of the earliest studies (43) employed the rabbit as the test animal and found that the pH of the solution instilled into the pleural cavity appeared to be an important determinant of success. The most acidic solutions tested, including unbuffered tetracycline (the most acid being pH 2.5), were quite effective in creating a small polymorphonuclear-predominant effusion and resulted in complete pleural symphysis on postmortem examination of the animals. Other agents with higher, more neutral pHs, such as nitrogen mustard and quinacrine, had no significant effect on the rabbit pleurae in this study. However, a later study by the same group (44) using the same model but adding bleomycin and sodium hydroxide to the series test agents found that the pleural sclerosing effect was actually Patient must survive 1 mo after the procedure independent of pH and was more related to the increasing dosage of tetracycline, the only agent causing a pleural sclerosis in this model.

Another rabbit study explored the effects of various dosages of intracavitary bleomycin versus tetracycline and found similar results of vigorous pleural fibrosis and symphysis with tetracycline, but no effect was seen with bleomycin (45). Minocycline was compared with tetracycline in another study using the rabbit model, and it proved to be as effective as tetracycline in creating a pleurodesis (46). When the mechanical agent talc was instilled by open thoracotomy in a study comparing various methods of pleurodesis using the canine model, this substance was found to cause a very intense pleuritis and a dense pleural symphysis that was even more pronounced than that caused by mechanical abrasion of the pleura or by tetracycline (47).

Clinical studies in humans have shown a significant discrepancy and lack of correlation with animal studies in the efficacy of sclerosing agents such as bleomycin. Bleomycin and even nitrogen mustard have been demonstrated to be highly effective agents in humans (3) despite the complete lack of effect in the rabbit model. Traditionally, it has been held that the rabbit model is of little relevance because of these discrepancies. It is possible that we are examining the wrong outcome measure. The presence or absence of pleural fibrosis [and all of its molecular findings such as a marked rise in basic fibroblast growth factor after talc pleurodesis (21)] may in fact be an epi-phenomenon. If the full role of VEGF and related compounds is better elucidated, it may well be that the balance of permeability enhancing and suppressing factors caused by variations in tumor, inflammatory response, and “sclerosing” agent is, in fact, the key determinant in measuring the outcome of various clinical interventions. The various “sclerosing” agents and laboratory measures (e.g., pH, white blood cell count) will then need to be reassessed.

Technique of Pleural Sclerotherapy

The most common technique used to instill the sclerosing agent into the pleural cavity has developed primarily from convention and common usage (3,48,49 and 50) and not on the basis of rigorous studies. After complete drainage of the pleural cavity with a chest tube and reexpansion of the lung on suction, the tube is clamped and the patient is placed into the lateral decubitus position with the affected hemithorax upward to assure that all of the sclerosing agent initially drains into the chest. Most

clinicians will administer a parenteral narcotic, such as morphine 3–6 mg, intravenously 10 minutes before the procedure to minimize the potential and unpredictable pain of the chosen sclerosing agent. Approximately 150 mg lidocaine (15 ml of a 1% solution without epinephrine) are instilled initially into the pleural cavity through the chest tube using a Luer-lock syringe and 22-gauge needle. It is allowed to dwell several minutes for local analgesia. The sclerosing agent dissolved in 50–100 ml 0.9% saline is then injected into the chest tube, and the tube is left clamped for 2 hours. The use of talc slurry requires a slightly different technique using a bulb syringe and a saline flush (51).

Usually the patient is then turned and repositioned every 15 minutes for the 2 hours to assure even distribution of the agent throughout the pleural cavity. However, when this patient repositioning maneuver was investigated carefully in a comparative clinical study, rotation of the patient during the time the chest tube was clamped offered no significant benefit to the success of the attempted pleurodesis (50). After 2 hours, the chest tube is unclamped and the tube is placed back on suction. The patient is followed with daily chest radiographs to verify continued complete drainage of the pleural cavity. The chest tube is removed when the daily drainage drops to 100 ml or less (49) (or <50 ml/8hr), and the patient is discharged the same day, once a confirmatory radiograph has been taken after removal of the chest tube. Most physicians create a moderately long subcutaneous tunnel (1.0–1.5 interspaces) through which the chest tube is initially inserted, so that with tube removal the wound seals well without the necessity (and discomfort) of placing sutures to close the skin wound.

Sclerosing Agents

Historically, a wide variety of agents have been instilled into the pleural space to create a pleurodesis (3,39,47). Table 28-5 lists most of the agents that have been described in the literature. These agents have differed greatly as to their effectiveness, side effects, availability, and even cost. Many are of only historical interest, while others, such as talc, bleomycin, and doxycycline, are in common use. Table 28-6 summarizes the efficacy of the most widely used sclerosing agents reported in the literature, comparing them with other methods of therapy designed to prevent the recurrence of malignant pleural effusions. Whenever possible, response rates are compared according to the criteria listed in Table 28-4.

Tetracycline
Doxycycline
Minocycline
Bleomycin
Talc
Quinacrine
Nitrogen mustard
Doxorubicin
Radioisotopes (I-131, Y-90, P-32, AU-198)

TABLE 28-6. MALIGNANT PLEURAL EFFUSIONS: RESPONSE RATES OF CURRENTLY AVAILABLE THERAPY

Tetracycline. Since the first description of tetracycline as an agent for intrapleural sclerotherapy in 1972 by Rubinson and Bolooki (52), this agent has gained widespread acceptance and was preferred in the United States (53) and Europe (54). The intrapleural dosage of 500 mg was initially used, but soon, as clinical studies began to appear, the standard dose became 1 g (20). This agent has demonstrated consistent efficacy, with a mean objective response (using the increased 1-g dose) of 69–85%, averaging 72% (3,48). It has been proved to be safe, effective, quite inexpensive, and easily administered, with adverse reactions limited to fever (7–33%) and pain (17–62%) (3,30). The effect of tetracycline was generally believed to be related to its low pH of 2.0–3.5, which caused an extensive pleuritis in the rabbit model. However, a hydrochloric acid solution of the same pH failed to achieve the same sclerosing effect, which suggests that tetracycline had other actions (43). Unfortunately, parenteral tetracycline is no longer commercially available.

Over the years, a variety of comparative clinical series, mostly nonrandomized, have been published with disparate methodology, patient selection, and response criteria, as well as retrospective analyses and variable results (3,48). Despite these limitations, most older studies comparing tetracycline with other agents such as nitrogen mustard, quinacrine, mustine, doxorubicin, bleomycin, and *Corynebacterium parvum* consistently demonstrated that tetracycline gave superior or at least equivalent results with much less toxicity (55). Of the few recent randomized larger trials, the series of Ruckdeschel and associates (56) and Johnson and Curzon (57) comparing intrapleural bleomycin and tetracycline showed a significantly better response to pleurodesis with bleomycin, with similar toxicity profiles. Nevertheless, tetracycline's ready availability and lower cost kept it as a preferred agent for pleurodesis of malignant effusions (53,54).

Doxycycline. Clinical studies with doxycycline have begun to accumulate now, after the demise of parenteral tetracycline (58), but all thus far have been nonrandomized, noncomparative trials (39,59,60 and 61). Despite these limitations, doxycycline has consistently demonstrated effective results: response rates range from 73–95%, which is similar to those of bleomycin (Table 28-6); yet, its toxicity is also similar, and its pain on administration may actually be less than tetracycline. The 500-mg dosage of doxycycline empirically chosen for these preliminary studies was probably too low, since over one-third of patients required repeat dosing to be effective (39). The major problem in using doxycycline, as noted in prior studies, is that it frequently requires several dosings to obtain equal efficacy (62), and this seriously reduces its cost effectiveness because of the need for longer hospitalizations (63).

Minocycline. Minocycline has had much less use for pleural sclerotherapy. Rabbit studies (46,62) demonstrate inflammatory changes in the pleura similar to those seen with tetracycline. The only clinical series reported using minocycline (300 mg) was small, with seven patients, but the complete response rate was 86%, similar to that of doxycycline, and the reported toxicity was likewise low (64). However, little information is currently available on this agent, and its eventual role in pleural sclerotherapy awaits further study.

Bleomycin. The most extensively studied cytotoxic chemotherapeutic agent used for intrapleural sclerotherapy is bleomycin. Not only does it play a significant role in the treatment of various solid tumors by parenteral administration, but also it has been shown to be highly effective in the palliative treatment of malignant pleural effusions, with response rates averaging 84% (3). Numerous nonrandomized studies have compared this agent to its primary competitor tetracycline, and most have suggested that there is no significant difference in efficacy or toxicity (55).

A few randomized trials of bleomycin versus tetracycline have been performed, with varying results. Kessinger and Wigton (65), in their study of 41 patients, found no significant difference in the response rates using 89 units of bleomycin (67%) versus 500 mg tetracycline (61%), and both agents had similar toxicities. However, Ruckdeschel and associates (56), in their multiinstitutional randomized study of 74 patients receiving either 60 units bleomycin or 1 g tetracycline intrapleurally, found the complete response rate at 1 month to be 64% (18/28) in the bleomycin arm and 33% (9/27) in the tetracycline arm. Unfortunately, not all patients in this trial were restudied at 30 days, although the complete response rates were also significantly different at 90 days with 70% (26/37) and 47% (17/36), respectively. Johnson and Curzon, in their randomized trial of 60 patients, found an 87% complete response rate at 90 days with bleomycin, compared with 56% with tetracycline (57). The acute toxicities of both drugs were similar, although there tended to be a higher incidence of pain in the tetracycline arm in both of the latter studies (56,57) (Table 28-7).

TABLE 28-7. MULTI-INSTITUTIONAL PROSPECTIVE, RANDOMIZED TRIAL (ECOG 8592) COMPARING INTRAPLEURAL BLEOMYCIN VERSUS DOXYCYCLINE VERSUS TALC: ENDPOINTS TO MEASURE

Although 45% of the intrapleural dose of bleomycin is absorbed (66), myelosuppression is not seen. However, since the plasma half-life of bleomycin increases with renal failure, systemic toxicity with alopecia and mucositis is possible and has rarely been reported in renal failure patients (67). Therefore, caution is advised in using intrapleural bleomycin in patients with renal failure. Some have also recommended using the lower dose of 40 units/m^2 body surface area in the elderly because of their potential reduced plasma clearance of the drug (68).

The major disadvantage of bleomycin is its elevated cost in comparison with other agents such as doxycycline and talc. This has been the major impediment to its widespread use. However, if it proves to be a more effective agent resulting in reduced hospital stays, and if consistently only a single dose is required for sclerotherapy, the cost factor may be overcome and bleomycin may actually be less expensive overall. And it is important to remember that one additional hospital day would pay for any extra cost of this agent, if it is actually more efficient than less expensive agents.

D. K. Fuller (69) and Belani and associates (63) argue that bleomycin is more cost effective overall than talc, tetracycline, and doxycycline on the basis of their questionable post hoc comparative analyses of a variety of disparate clinical studies (often published many years apart) that commonly used inadequate doses of the test agent in the trials (i.e., 500 mg doxycycline instead of the current 1 g).

Talc

Talc Insufflation. Talc is a generic term referring to a natural product containing the mineral talc (a trilayered magnesium sheet silicate) found in talcose or soapstone, which is usually contaminated with chlorite and trace minerals (quartz, calcite, and dolomite) (70,71) The most important contaminant of talc is asbestos (fibers of actinolyte, amosite, anthophyllite, chrysolite, crocidolite, and tremolite), which has been linked to carcinogenesis. However, for clinical use, USP talc has been purified with particle sizes generally less than 50 µm. Most important, USP talc has been asbestos-free for many years, although it still requires sterilization prior to use.

Talc is the oldest, cheapest to purchase, and perhaps the most effective agent in causing a pleurodesis. The first description of talc as a pleural sclerosant was in 1935 by a Canadian surgeon, Norman Bethune, who insufflated talc into the pleural cavity of dogs and cats after creating a pneumothorax (72). Two patients were also described receiving an intrapleural dusting of talc just prior to lobectomy to create adhesions. Multiple studies with various animal models have followed, with the most recent by Mathlouthi and associates (73) demonstrating that talc insufflated into dogs causes a nondose-dependent parietal and visceral inflammation followed by a granulomatous pleural reaction. After talc administration, the resultant intense adhesive pleuritis, possibly accompanied by an adhesion-stimulating factor (70) obliterating the pleural space, is believed to be its primary clinical benefit in preventing the recurrence of malignant pleural effusions (71).

Insufflation of talc into the pleural cavity, or talc poudrage (“powdering”), is highly effective. Many studies demonstrate a response rate with malignant pleural effusions ranging from 87–95%, averaging 92% (41,70,71,74). The successful use of talc insufflation has also been described with benign effusions, chylothorax, pneumothorax, and even empyema (70). The primary disadvantage of talc poudrage is the requirement for thoracoscopy to be performed, usually with the patient under general anesthesia, to allow complete collapse of the lung to assure uniform distribution of the talc. An atomizer or bulb syringe is filled with dry talc, usually 2.5–5.0 g, and the talc is blown into the the pleural cavity after ensuring that all loculations are removed. In selected patients, the risks of this procedure are small, with low perioperative morbidity and mortality (70). However, many patients with malignant pleural effusions are debilitated and are poor candidates for an operative approach, or they are reluctant to have such a procedure because of their short life expectancy. In addition, thoracoscopic talc poudrage usually increases hospitalization time, adds surgical and anesthesia costs, and increases the potential for complications. Fortunately, several studies have suggested that similar results are possible with bedside talc slurry administration through a chest tube, obviating the need for the more invasive operative approach (3,51).

Currently, there is an ongoing national cooperative randomized trial of sclerosis of pleural effusions with intrapleural talc comparing delivery by videothoracoscopic insufflation with delivery by chest tube instillation as talc slurry (Cancer and Leukemia Group B 9334). The results of this study should answer the question which is the preferable technique in terms of efficacy and cost effectiveness.

Talc Slurry. Twenty-three years after the first described use of talc with an open thoracotomy, J. S. Chambers in 1958 reported the successful use of talc instilled through a tube thoracostomy to control a malignant pleural effusion (75). In subsequent studies (48,51,70,55,76), the administration of talc in a suspension or slurry has proved to be as efficacious as by poudrage (62,71), with response rates ranging from 72–100% and averaging 96% (3). The administration of talc slurry is generally performed at the bedside with 2–5g of sterile USP talc suspended in 30–50 ml 0.9% saline solution in a bulb syringe instilled into a larger-bore chest tube after complete drainage of the pleural space. Usually, intrapleural lidocaine premedication is used (51,70).

Although the efficacy of talc is generally well recognized, concerns about its adverse effects and safety have slowed its use. The usual side effects reported are pain on administration in most patients (51), but this is readily manageable, as with other sclerosing agents. Fever also accompanies talc slurry administration 16–69% of the time, but it is usually short-lived (71). Talc empyema is reported in 0–11% of cases (71) and can be exceedingly difficult to treat effectively, because talc is a foreign body and cannot be removed from the site of infection: the pleural cavity. Nevertheless, in at least one series talc has actually been instilled to obliterate the pleural space after empyema (70).

However, the more worrisome potential adverse effects are rare but definitely can occur, including talc microemboli to the brain (71); pulmonary complications of acute pneumonitis, pulmonary edema, and adult respiratory distress syndrome (78); and death (62,71). The definite mechanism of respiratory complications is unknown. But it is probably related to the suspected uptake of talc by the parietal pleural lymphatic system, with subsequent transport to the mediastinal lymph nodes and thoracic duct and hence to the systemic circulation (78,79). Talc administration has been reported (71) to be associated with a variety of acute cardiovascular complications—arrhythmias, cardiac arrest, chest pain, myocardial infarction, and hypotension—but it is often difficult to attribute these effects to the talc itself versus the other coexisting procedures, such as thoracoscopy in some cases. Preliminary results of Cancer and Leukemia Group B 9334 were reported at the 2000 American Society of Clinical Oncology meeting. There was little difference in clinical outcome between talc poudrage or talc slurry but both treatments caused a nontrivial incidence of significant respiratory distress (15–16%) and death (6.5%) (80).

The last hurdle to the use of talc is the need for sterilization at the point of use, because it has yet to be readily available as a sterile preparation in the United States. Ethylene oxide gas, gamma irradiation, and dry heat sterilization, along with surveillance cultures of each batch of sterilized talc, are methods that have been described, although no one method is considered standard (81). Of these techniques, dry heat sterilization is the least expensive and the most commonly used. A commercially produced disposable spray canister of 4 g of asbestos-free talc for use during talc poudrage has recently been described (82), although its availability in the United States has been sporadic and is currently unreliable. Whether talc should be employed in this clearly palliative setting has engendered a significant amount of controversy (85).

Other Antineoplastic Agents

One of the first agents used intrapleurally to treat malignant effusions was the cytotoxic agent nitrogen mustard. This alkylating agent is highly reactive and loses its activity within minutes after contact with tissue. The response rates with nitrogen mustard varied greatly in various small series, from 27–95%, but averaged only 44% (3). When it was compared with other agents, the response rates were generally lower but the adverse reactions were much higher (3). The toxicity of nitrogen mustard was severe nausea and vomiting, commonly for 24 hours, in addition to local pain and fever (48). The lack of efficacy and its significant toxicity have made this an

undesirable agent, of historical interest only (30).

Many other chemotherapeutic agents have been described in various small series, including thio-TEPA, 5-fluorouracil, doxorubicin, combination cisplatin and cytarabine, etoposide, mitoxantrone, and mitomycin-C (3,30,62). Generally, the results have been unimpressive and clearly are no better than those obtained with more common agents such as tetracycline and its derivatives or bleomycin (3). However, their systemic absorption by intrapleural administration is considerable and often leads to prolonged plasma levels and significant systemic toxicity, including myelosuppression. At present, the use of these agents in this context is investigational and is not generally recommended (10,30,62).

Biological Agents

Corynebacterium parvum

Corynebacterium parvum is an anaerobic gram-positive bacterium first described for intrapleural use to cause a pleurodesis in a trial in six patients in 1978 (82). Its effect was not found to be from its postulated role as stimulator of cell-mediated immunity. Rather, C. *parvum* recruits neutrophils to the pleura, causing a subsequent fibrogenic response with fibrotic pleural thickening (83). C. *parvum* averaged response rates of 76% in single-agent studies but consistently demonstrated the same or worse response compared with bleomycin or tetracycline (49,62). C. *parvum* also has moderate toxicity, including fever (5%), pain (43%), cough (6%), and nausea (39%), and furthermore requires multiple instillations over a 2-day period. C. *parvum* offers no advantages as a pleural sclerosant and is also not available in the United States, resulting in its lack of current clinical use.

Interferons and Interleukins

The most recent attempt to use biological therapy for malignant pleural effusions involves the use of interferon-a, b, or g with the intent to stimulate natural killer cells, in addition to their cytotoxic effects (62). The response rates have not been impressive, with only a 41% complete response in a series of 29 patients (84). Intrapleural administration of interferon still remains investigational.

Several recent studies have investigated the use of recombinant interleukin-2 alone or in combination with lymphokine-activated killer cells in malignant pleural effusions from lung cancer (86,87). These preliminary studies have commonly shown the disappearance of the pleural effusion and occasionally the cancer cells themselves (87), but no serious side effects occurred. These studies are intriguing but require more study in larger patient groups.

Radioactive Isotopes

Finally, the use of intrapleural radioisotopes, especially radioactive gold and phosphorus, for control of malignant pleural effusions had a period of popularity beginning in 1951 when they were first described (88) until the late 1960s. The overall effectiveness of these agents was less than that of other available agents, with a mean response rate of 59% (3). The isotopes were also expensive and potentially hazardous to hospital personnel, patients needed to be isolated until the radioactive emissions were acceptably low, and special personnel and equipment were needed. Because of their relative ineffectiveness and their many disadvantages, radioisotopes are not currently recommended for pleural sclerotherapy and are of historical interest only (3).

Surgical Interventions

Pleurectomy

A thoracotomy with mechanical pleurodesis, or a pleurectomy to remove most of the parietal pleura, has occasionally been done in the past as a primary procedure for malignant effusions. Martini and associates (89) in 1975 reported the use of pleurectomy in 106 patients with malignant effusion and saw no recurrence in 100%, but there was a 9% mortality and a 23% rate of major complications: bleeding, air leaks, pneumonia, empyema, pulmonary embolus, respiratory insufficiency, and cardiac failure. Currently, this procedure should be considered for application only at the time of thoracotomy when a lung cancer is found to be unresectable with pleural metastases. Occasionally, a well-selected patient of good performance status and a long life expectancy, in whom all other attempts at control of the effusion have failed, might be considered a candidate for open pleurectomy. However, the advent of videothoracoscopy now allows these procedures to be done, if necessary, in a minimally invasive manner, essentially making an open thoracotomy for this purpose rarely necessary.

Pleuroperitoneal Shunt

Internal drainage of the malignant effusion into the abdomen using an implanted, valved, manually operated pump (Denver shunt, Denver Biomaterials; Denver, CO) was initially described in 1984, with the most recent series reported in 1993 (90). Implantation of this device usually requires general anesthesia (local anesthesia occasionally may be used in selected patients) and the performance of a small thoracotomy and small celiotomy that are needed to implant the two limbs; the pump is implanted subcutaneously. Since the shunt must carry fluid from a negativepressure area (the pleural cavity) to a positive-pressure area (the abdomen), major patient or family participation is necessary. For the shunt to function properly, it requires manual pumping 100 times on five occasions per day. The shunt is occasionally an option in compliant, wellmotivated patients with good performance status who have a trapped lung and an intractable effusion (5,10,49). Malfunction of the shunt over time, requiring its replacement, may further limit the usefulness of this device.

Videothoracoscopy

As experience with VATS grows, some investigators are now reporting series of successful VATS pleurectomy for malignant effusions. Waller and associates (91) performed a VATS parietal pleurectomy on 19 patients (13 mesothelioma and 6 metastatic adenocarcinoma) with no operative deaths or major complications, and the median hospital discharge was on the fifth day. Another approach to VATS pleurectomy was described by Harvey and colleagues (92) in 11 selected patients with malignant pleural effusion in which they performed a parietal pleurectomy assisted by dissection of the pleura with a stream of water (hydrodissection). The effusion did not recur in any patient.

Another Invasive Technique

An innovative technique for approaching the lung cancer patient with pleural metastasis was described recently by Matsuzaki and associates (93). This approach took advantage of the antineoplastic effect of hyperthermia. The pleural cavity was irrigated using an extracorporeal circuit with a 43°C saline and cis-platinum solution for 2 hours in 12 patients with pleural metastases, who also underwent resection of their primary tumors. The pleural effusion was controlled in all 12 patients, and their median survival was 20 months, compared with 6 months in a cohort of seven matched control patients with pleural metastases. This report is preliminary but provocative, and the technique bears watching as further work is reported.

Recurrent Effusions

The most perplexing and frustrating problem to deal with is the refractory pleural effusion in which the first attempt at pleural sclerotherapy failed. Generally, a second attempt at tube thoracostomy followed by intrapleural sclerotherapy is recommended, usually employing a different agent. If this second attempt fails, and if the patient has a good performance status and a reasonable estimated life span, then proceeding with VATS talc poudrage or VATS pleurectomy may be an option. Alternatively, such a patient may rarely be a candidate for a pleuroperitoneal shunt.

Recommendations

It is important to remember that the primary goal of therapy of a malignant pleural effusion is entirely palliative. The patient generally has a terminal disease with a very limited life span, usually counted in terms of a few months at best. The choice to treat and the actual treatment chosen must reflect the clinician's realistic understanding of the patient's overall prognosis and a desire to provide these terminally ill patients with the maximum possible comfortable time at home with the best quality of life. The timing of treatment is also critical. Waiting for “significant” symptoms to develop before draining a malignant effusion rarely improves the palliative benefits for the patient.

Our recommendations are as follows:

1. In a patient with a chemosensitive tumor such as lymphoma, breast cancer, or small cell lung cancer, systemic therapy is the treatment of choice. If a thoracentesis is not needed for staging purposes, the patient can proceed directly to treatment if the effusion is asymptomatic, otherwise a therapeutic thoracentesis followed by

systemic treatment is preferred.

2. In the patient with a less responsive or refractory solid tumor, all significant effusions should be drained and treated. We prefer standard chest tube drainage at present but await comparative data on small bore catheters (94). Our choice of sclerosing agent is not clearly resolved, with bleomycin, doxycycline, and talc all having their proponents. Our first choice is for a clinical trial. Talc is used whenever a second pleurodesis needs to be done for recurrent disease. We almost never use shunts.

3. Our policy is increasingly moving to earlier use of thoracoscopy, in lieu of a second diagnostic thoracentesis. This reflects our situation as a cancer hospital and the benefits of being able to reduce adhesions, draw the fluid, and initiate drainage all at the same setting.

PERICARDIAL EFFUSIONS

Incidence

The appearance of a malignant pericardial effusion in patients with advanced cancer is not uncommon. In collected autopsy studies of patients with disseminated cancer, involvement of the heart and pericardium with metastatic malignancy is seen in up to 21% of cases (49,95,96,97 and 98), with the highest incidence occurring in patients with leukemia (69%), melanoma (64%), and lymphoma (24%) (98). Because a large number of patients with malignant pericardial effusions are asymptomatic, autopsy studies tend to have a higher incidence than in clinical series (99). In terms of the actual clinical impact of symptomatic pericardial effusions, there were 7000 patients who underwent pericardiectomy for all causes in U.S. hospitals in 1993 (100). Generally, 25–50% of all patients requiring surgical pericardial drainage have proven malignant pericardial involvement (101,102 and 103). Because not all patients with a malignant pericardial effusion undergo a pericardiectomy, the total number of patients developing this complication of advanced cancer is much higher.

Etiology

Almost any tumor (except primary tumors of the brain) can metastasize to the pericardium and lead to an effusion (99). However, the most common tumors to involve the pericardium and heart are the same as with malignant pleural effusions: tumors of the lung and breast, lymphoma, and leukemia. These metastatic tumors account for almost 75% of all pericardial malignancies (104). When it metastasizes, melanoma frequently involves the heart, occurring in up to 50% of cases (104). Other malignancies that may spread to the pericardium to cause an effusion include gastrointestinal tumors and sarcomas. Primary tumors of the pericardium can cause effusions, but they are rare and include sarcomas, malignant teratomas, and mesotheliomas. Searching for the cause of a symptomatic pericardial effusion is critically important, because approximately 40% of patients with an underlying cancer have a nonmalignant cause of the effusion (105).

Pathophysiology

The pericardium, as it is commonly known, is actually the parietal pericardium. The visceral pericardium is a monocellular serosal layer constituting what is also known as the epicardium of the heart. Together, both pericardial layers constitute a serosal sac containing at any one time 15–50 ml of low-protein fluid. The pericardium is flexible but relatively inelastic. It probably functions to mechanically protect the heart from outside friction, provide a barrier from inflammation, maintain cardiac position against gravitational forces and acceleration, and support the thinner heart chambers such as the atria and the right ventricle (105).

Like the pleurae, the fluid inside the pericardial sac is normally in a balanced steady state of secretion by the serosal surface and reabsorption by the visceral (epicardium) and parietal pericardia. The increase in pericardial fluid that may lead to tamponade generally results from obstruction of the mediastinal lymphatic system, commonly by tumors, such as lung and breast cancers, that involve the mediastinal lymph nodes. Infiltration of the epicardium by tumor may block subepicardial venous flow, resulting in an outpouring of fluid into the pericardium. The parietal pericardium may also be infiltrated by tumor, resulting in increased fluid secretion. The result of blockage of pericardial fluid reabsorption, as well as often a net increase in secretion, may ultimately result in a symptomatic pericardial effusion (106,107). The role of VEGF or other growth factors modulating vascular permeability is unknown, with no reported series to date.

When fluid increases slowly, the pericardium will distend greatly, up to as much as 2 liters, before the pericardium becomes tense. However, when the fluid accumulates more rapidly, the pericardium fails to stretch, pericardial pressure rises, and hemodynamic compromise may occur with as little an accumulation as 200 ml (108). The critical effect of this increase in pericardial pressure is impaired diastolic filling of the right side of the heart. The condition termed *cardiac tamponade* develops when there is “hemodynamically significant cardiac compression due to accumulating pericardial contents that evoke and defeat compensatory mechanisms” (109). On the basis of Starling's law, impaired diastolic filling will result in a depressed stroke volume and cardiac output. A greater volume of pericardial fluid and pressure causes an increase in ventricular diastolic pressure, which further impairs venous return, leading to a declining cardiac output. The autonomic nervous system responds to this decreased stroke volume and initially compensates by a release of catecholamines, resulting in an increased heart rate and arterial and venous vasoconstriction. The kidneys also respond to the decreased cardiac output by increasing sodium and fluid retention, leading to increased intravascular volume and venous pressure. Eventually, these compensatory mechanisms fail as intrapericardial pressure rises (often abruptly), resulting in a further decline in cardiac output with hypotension and circulatory collapse (108).

Clinical Presentation

Symptoms

Nearly two-thirds of the patients with metastatic tumor involving the heart and pericardium will have no definite cardiovascular signs or symptoms (95), even when a careful history is taken. When the initial symptoms of a malignant pericardial effusion begin, they are often subtle and may be attributed to the underlying primary tumor. The actual development of symptoms depends on the rate at which the effusion accumulates, the actual effusion volume (and how close it is to causing maximal pericardial distention), and the underlying cardiac function, which itself may be impaired because of myocardial metastases or prior chemotherapy, as with doxorubicin (104,108). When the intrapericardial pressure increases sufficiently to impair diastolic ventricular filling, then symptoms begin appearing.

The most common and earliest symptom is dyspnea on exertion (93% of symptomatic patients), which may progress to dyspnea at rest as cardiac function is progressively compromised (95,104,109). Dyspnea is also the initial presenting symptom in patients with a malignant pleural effusion, a much more common complication of advanced cancer. A pleural effusion occasionally accompanies a malignant pericardial effusion, and this by itself may draw attention away from the actual pericardial problem and confound the diagnosis. A comparison of the presenting signs and symptoms of pericardial and pleural effusions is found in Table 28-8 (94,110). Other common symptoms include chest pain or heaviness (63%), cough (30–43%), and weakness (26%) (94). Less common symptoms include peripheral edema, low-grade fever, dizziness, nausea, diaphoresis, and peripheral venous constriction. The presence of peripheral edema often leads unsuspecting clinicians to give diuretics, which significantly worsen the underlying physiological problem. Cyanosis from decreased venous return and venous hypertension, and agitation and tachypnea from low cardiac output and hypoxia, are late manifestations of pericardial tamponade (104,109).

Frequency	Pericardial	Pleural
Common	Dyspnea (exertion)	Dyspnea (exertion)
	Dyspnea (rest)	Dyspnea (rest)
	Chest pain or heaviness	Orthopnea
		Cough
	Cough	Percussion dullness
	Jugular venous distention	Egophony
		Percussion dullness
	Hypotension	—
	Pulsus paradoxus	—
	Resting tachycardia	—
Uncommon	Cyanosis	Cyanosis
	Peripheral edema	Pleuritic chest pain
	Low-grade fever	Anorexia
	Distant heart sounds	—
	Peripheral vasoconstriction	—
	Narrowed pulse pressure	—
	Kussmaul's sign	—
	Low-voltage electrocardiogram (limb leads)	—
	Electrical alternans	—

TABLE 28-8. COMPARISON OF THE PRESENTING SIGNS AND SYMPTOMS OF MALIGNANT PLEURAL AND PERICARDIAL EFFUSIONS

Signs

The classic signs associated with cardiac tamponade were described in 1937 by Claude Beck and are often referred to as *Beck's triad*: quiet heart sounds, hypotension, and venous distention (111). These signs remain the most commonly seen, although the muffled heart sounds may be more difficult to appreciate clinically. Unfortunately, all of these clinical signs appear late in the course of the physiological deterioration. Therefore, waiting for them to develop before ordering diagnostic tests is inappropriate. Hypotension is found in 41–63% of patients, elevated venous pressure is seen in 50–63%, and resting tachycardia occurs in 68–89% (95). The venous pressure is almost always elevated in cardiac tamponade, although rarely it may be normal or low if the patient is hypovolemic. A central venous pressure greater than 15 mm Hg with hypotension is highly suggestive of tamponade.

The pathophysiologic effects of cardiac tamponade tend to exaggerate the normal fall in systolic blood pressure (usually less than 10 mm Hg) and stroke volume that occur with inspiration. The causes of this normal event are controversial but are thought to involve any or all of the following: (a) inspiratory pooling of blood in the lungs with decreased filling of the left side of the heart, (b) increased right ventricular filling with leftward movement of the interventricular septum to cause reduced left ventricular filling and increased afterload, (c) a fall in left ventricular stroke volume as a result of increased left ventricular transmural pressure, and (d) “reverse thoracic pump” mechanism that is due to an inspiratory decrease of intracavitary left ventricular pressure relative to atmospheric pressure (109). Cardiac tamponade exaggerates this normal physiology and was termed by Kussmaul in 1873 to be a *pulsus paradoxus*. This term is a misnomer, because it refers to the accentuation of a normal phenomenon, not a reversal of it. Clinically, a patient is considered to have a pulsus paradoxus if the inspiratory drop in the systolic blood pressure is greater than 10 mm Hg. Although strongly associated with tamponade, a pulsus paradoxus may also be detected in other conditions such as pulmonary embolism, chronic obstructive lung disease, obesity, failure of the right side of the heart, and tense ascites.

Other signs, less frequent, that may be present include a narrowed pulse pressure, a visible increase in venous pressure on inspiration (Kussmaul's sign), hepatomegaly, hepatojugular reflux, peripheral edema, cyanosis, pericardial friction rub, arrhythmias, cold clammy extremities, lowgrade fever, and ascites.

Diagnosis

Radiographic

In a patient with cancer with or without symptoms, a change in the size and contour of the heart with clear lung fields on a standard chest radiograph should alert the clinician to consider the diagnosis of a pericardial effusion. The cardiac silhouette may resemble the so-called “water-bottle heart” with bulging of the normal contours. Nevertheless, a normal-size heart shadow does not exclude the presence of a pericardial effusion or even a life-threatening tamponade. A coexisting pleural effusion may be present in up to 70% of patients with pericardial effusion (95).

Chest CT obtained for staging or followup in a cancer patient will reveal a pericardial effusion with more sensitivity than a standard chest radiograph (95). The chest CT scan may suggest a malignant pericardial process if the effusion has a high density, there is pericardial thickening, masses are contiguous with the pericardium, or there is an obliteration of the tissue planes between the mass and the heart. As a screening tool, however, chest CT has limited usefulness because of the blurring of the pericardial contents on the scan caused by continuous cardiac motion.

Another more invasive diagnostic procedure is catheterization of the right side of the heart, which can easily be done at the bedside in the intensive care unit. The passage of a flowdirected pulmonary artery catheter (Swan-Ganz catheter; Edward Lifesciences, Irvine, CA) is a common critical care procedure that can establish the presence of a cardiac tamponade. The findings from this procedure in true tamponade are depressed cardiac output and the equalization of diastolic pressures in all heart chambers (109). Specifically, the right atrial mean, the right ventricular diastolic, and the pulmonary capillary wedge pressures all tend to equalize in tamponade and can be readily measured with the pulmonary artery catheter. However, if malignant pericardial effusion is suspected, catheterization of the right side of the heart is rarely necessary, because echocardiography is sensitive enough to establish a reliable diagnosis of tamponade noninvasively, thereby allowing for prompt pericardial decompression.

Electrocardiography

The electrocardiogram often has changes associated with a pericardial effusion, including tachycardia, atrial and ventricular arrhythmias, low-voltage QRS, and diffuse nonspecific ST and T wave abnormalities. Electrical alternans is occasionally seen and consists of alternating large and small P wave and QRS complexes, caused by the increased rotary motion of the heart in the large fluid-filled pericardium. This interesting electrocardiographic abnormality generally resolves immediately with drainage of the effusion (96,109).

Echocardiography

The most sensitive and precise tool used to evaluate a peri-cardial effusion is echocardiography, usually in the two-dimensional mode (95). Any patient suspected of having an effusion deserves to have an echocardiogram. Not only is this examination rapid and noninvasive, it can be per-formed quickly at the patient's bedside even with the patient in a sitting position, and this instrument is then available immediately to aid in the performance of a diag-nostic or therapeutic pericardiocentesis. Echocardiography is extremely sensitive and may detect as little as 15 ml of fluid, as well as identifying myocardial masses and even loc-ulations of fluid.

Aside from its role in the diagnosis of a pericardial effu-sion, echocardiography is quite useful in assessing the hemodynamic consequences of the effusion. Cardiac tamponade is suggested by diastolic collapse of the right atrium or ventricle, inspiratory decrease in left ventricular dimen-sions, inspiratory increase in right ventricular dimensions, or failure of the inferior vena cava to collapse on inspiration (inferior vena cava plethora) (112,113). Prompt perfor-mance of an echocardiogram in a patient with a suspected effusion is quite important, since only 69% of patients with echocardiographic signs of tamponade are suspected of having a tamponade clinically prior to the study (114).

The most powerful predictor of the development of subsequent cardiac tamponade is the size of the effusion, because not all effusions will lead to hemodynamic compromise (115). Although the ready availability of echocardiography has allowed the earlier diagnosis of effusions in more patients, it also may have led to some overdiagnoses (116). Small effusions without symptoms are very rarely malignant and almost never require invasive evaluation or treatment. In addition, it is most uncommon for isolated pericardial disease to be the initial manifestation of new malignant disease (116).

Pericardial Fluid Examination

Percutaneous, ultrasound-guided pericardiocentesis can safely be performed in patients with larger effusions (>1 cm anterior clear space on echocardiogram). It will yield pericardial fluid for examination in approximately 90% of patients and will promptly and temporarily relieve tamponade (95,114). The fluid obtained should be sent to the lab for cytology and for determination of LDH and total protein levels. If the patient has symptoms suggesting an infectious or rheumatologic cause of the effusion, other tests, such as glucose, cell count, and culture, should be added. This is rarely needed in the patient with an obvious intrathoracic malignancy. In a malignant pericardial effusion, the result of cytology will be positive for malignant cells in 65–90% of cases (49,99,109,117,118). False-negative cytologic results are frequently seen with lymphoma and mesothelioma. However, the lack of malignant cells in the effusion fluid obviously does not exclude the possibility of neoplastic pericarditis, and it is often necessary to obtain pericardial tissue for histology if a malignant diagnosis is still suspected.

Bloody (“crank-case oil” appearance) or serosanguineous fluid is associated with neoplastic pericarditis, but it may also be seen with idiopathic causes. Malignant effusions are bloody or serosanguineous in 76% of cases and serous in the rest (119). This bloody fluid never clots because it is defibrinated by the motion of the heart inside the pericardium in addition to the intrinsic, local fibrinolytic activity of the serosal lining of the pericardium (106).

Differential Diagnosis

Because up to 40% of patients with a symptomatic pericardial effusion and an underlying cancer will have a benign cause of the effusion and perhaps require different treatment, it is important to find out the specific cause of the effusion (105). Of particular importance in the differential diagnosis is radiation-related pericardial effusion in patients who have received mediastinal radiation therapy (especially >4000 cGy) (121). From 7–30% of these patients may develop effusive or effusive-constrictive pericardial disease, usually within 24–36 months (occasionally within just a few weeks) of the radiotherapy (105,121). Purulent or tuberculous pericarditis is another possibility to consider, especially in the cancer patient who is debilitated and febrile. Drug-induced pericarditis from agents, such as procainamide or hydralazine, or even from cancer chemotherapy drugs, such as doxorubicin (pericarditis-myocarditis syndrome) (122) may occasionally occur. Idiopathic (viral), uremic, hypothyroid, cholesterol, postmyocardial infarction, or autoimmune pericarditis are other considerations in the differential diagnosis (99). Generally, the pericardial fluid analysis plus the patient's history will exclude most of the potential diagnoses and will pinpoint the actual cause of the effusion. In patients with cancer and evidence of a significant effusion of echocardiogram, we do not perform an intervening pericardiocentesis, but perform fluid analysis on the fluid removed at the time of treatment.

Prognosis

Although cancer patients with cardiac tamponade from a malignant pericardial effusion usually are severely ill at presentation, prompt relief of the tamponade will often allow them to return to a surprisingly good functional status for significant time intervals. The quality and quantity of life depends largely on the histology of the malignancy and its extent. After surgical drainage of the pericardial effusion, breast cancer patients have a mean survival of 8–18 months (102,116,118,123); lymphoma patients have a mean survival of 10 months (123). Lung cancer patients fare somewhat worse, with a mean 3–5-month survival (102,123). However, the extended survival of these advanced cancer patients with malignant pericardial effusions underscores the importance of tailoring treatment of this complication to provide maximal benefit with the least chance of reaccumulation of the effusion.

Treatment

The optimal therapy for this problem is controversial. The medical literature is filled with reports about various therapeutic options (Table 28-9) whose results vary as widely as the techniques. When these invasive techniques are compared, it is important to focus on the most recent reports, because the associated morbidity and mortality as well as the results generally improve with further experience. In the discussion that follows, each option in therapy will be discussed, but true comparative data among techniques are not currently available.

Pericardiocentesis with or without catheter drainage
Intrapericardial sclerosis with chemicals or radioisotopes
Chemotherapy
Radiotherapy
Subxiphoid pericardiectomy ("window")
Left anterior thoracotomy with pericardiectomy
Median sternotomy with pericardiectomy
Videothoracoscopic pericardiectomy
Pericardioperitoneal shunt
Percutaneous balloon pericardiotomy

TABLE 28-9. TREATMENT OPTIONS WITH MALIGNANT PERICARDIAL EFFUSIONS

Pericardiocentesis

The earliest described method of nonsurgical drainage of the pericardium, performed by Schuh in 1840, was pericardiocentesis, which he used to relieve a hemorrhagic effusion in 30 patients, of whom seven subsequently survived (124). As techniques have evolved and safety has improved, pericardiocentesis has remained the most common approach for diagnosis and therapy in patients with malignant pericardial effusions (119). It may be performed quickly under local anesthesia and is the initial procedure of choice in the emergency management of life-threatening tamponade (119).

Pericardiocentesis is best performed from the subxiphoid approach, with the needle inserted between the xiphoid and the left costal arch at a 45 degree angle directed toward the left shoulder. This is the easiest and safest approach because there is a smaller chance of damaging a coronary artery. The patient is placed in the semi-Fowler's position so that most of the effusion is in the most dependent portion of the pericardium inferiorly (125). In a true emergency, the needle can be advanced blindly or with electrocardiographic monitoring with the needle attached to a V lead. With continuous electrocardiographic monitoring, contact with the epicardium will be seen as an immediate ST segment elevation, often with premature ventricular contractions, warning the clinician to withdraw the needle. If bloody pericardial fluid is removed, it should not clot and generally has a hematocrit lower than that of intravascular blood. Whenever possible, a thoracic surgeon should be notified that the pericardiocentesis is being performed in case a complication occurs requiring immediate surgical drainage.

Adding echocardiographic guidance to the pericardiocentesis has increased the success rate in obtaining fluid for diagnosis and relieving symptoms to almost 97% and has decreased the complication rate (95,118). Major complications include coronary artery laceration, myocardial puncture, pneumothorax, trauma to abdominal organs (especially the liver), and even death. The complication rate in collected series of pericardiocentesis using echocardiographic guidance is 2.4% with no deaths (118). The hazards of the procedure may be minimized if it is performed only on patients with a significant anterior clear space greater than 1 cm, using echocardiographic guidance, correcting thrombocytopenia prior to the procedure, and avoiding obviously loculated or posterior effusions (95,118,119).

Pericardiocentesis by itself is considered only an initial temporizing procedure to obtain diagnostic fluid and relieve symptoms. It is particularly useful in stabilizing a patient's condition before surgical drainage is performed. However, pericardiocentesis is not considered to be definitive treatment, since most (39–56%) malignant effusions will recur even after single or repeated taps (95,118). Insertion of a small no. 7 or no. 8 French multihole pigtail catheter over a guidewire into the pericardial space can be easily accomplished at the time of initial tap, to allow intermittent drainage over several days. Still, a large number of patients treated in this manner will require more definitive surgical drainage for long-term control of the effusion (95).

One word of caution is highlighted by two recent reports of large-volume pericardiocenteses on patients in tamponade. Wolfe and Edelman noted transient, severe, symptomatic systolic dysfunction in two women, lasting 1–2 weeks after they had undergone pericardiocentesis (650ml bloody pericardial fluid removed from either patient) to relieve a tamponade for a malignant pericardial effusion from metastatic breast cancer (126). Both patients were treated symptomatically and recovered gradually. Braverman and Sundaresan (127) reported a similar picture in a 27-year-old woman with a pericardial tamponade from benign acute pericarditis who was noted to have global myocardial dysfunction after undergoing pericardiocentesis that removed 500 ml serous fluid. A subxiphoid pericardial window was subsequently made, with removal of 1000 ml more fluid. Dobutamine was used to treat her low-output syndrome, which resolved completely 3 weeks later. The cause of this phenomenon, which we have also seen, is not known, but it may relate to diminished coronary blood flow during the period of tamponade, leading to a degree of myocardial stunning that was eventually reversible.

Intrapericardial Sclerosis

The logical extension of pericardiocentesis with catheter drainage is injection of a sclerosing agent into the pericardium through the indwelling catheter to prevent a recurrence of the effusion, much like that practiced with malignant pleural effusions. Almost half of the pleural sclerosis agents listed in Table 28-5 have been used in various small series intrapericardially. Agents were chosen on the basis of their irritating qualities and/or their antitumor activity, but the mechanism of action of the successful agents is unknown.

Nitrogen mustard, thiotepa, and quinacrine were tried in the 1970s in small studies with fair results but with pain and substantial toxicity from bone marrow suppression, leading to abandonment of these agents (41). Intrapericardial tetracycline, the most widely used drug, has had a combined success rate of 85% in the two largest reports (128,129). Tetracycline was instilled in doses of 500 mg–1 g on several days in all patients (mean, 2.9 days), and the pericardial catheters remained in place for a mean 8.8 days in one of the studies (128). Although a fairly effective agent with the expected toxicities of fever (18.7%), pain (9.9%), arrhythmias (12.1%), and catheter plugging (4.4%), tetracycline had the distinct disadvantage of requiring a long hospitalization. Tetracycline is no longer available, and the analog now used, doxycycline, has had a 100% success reported in one small series of seven patients, but they too required multiple instillations (130). The most recent series using pericardial sclerosis as primary management was larger, involving 85 patients, and had a 73% success rate in controlling the effusion for over 30 days (131). This group used tetracycline early in the series and doxycycline later, but as in prior reports, multiple instillations of drug were also necessary for success.

Bleomycin has also been used in very small series (a total of 15 patients in five series) with fairly good results and minimal toxicity, although these small patient series are difficult to interpret (118). Other anecdotal reports of cisplatin, teniposide, and fluorouracil have also appeared, although such small series preclude drawing any conclusions about efficacy and safety.

Immunostimulators interleukin-2 (132) and OK-432 (133) have also been employed by intrapericardial infusion to control malignant effusions. The results from these small series suggest that in twothirds of patients, the effusion can be controlled. However, this novel approach appears to offer no advantage over other agents (118).

One primary concern about the advisability of intrapericardial sclerosis is whether there is an increased risk of pericardial constriction in patients so treated. Lee and associates reported their favorable experience with intrapericardial sclerosis in 20 patients using mitomycin C, and had a 70% success rate (134). Soon afterward,

however, the same group reported that in one of their initially successful cases, the patient developed constrictive pericarditis 6 months later. They noted that this complication may occur if the patient survives long enough after pericardial sclerotherapy (135). Despite this concern, late pericardial constriction has not been commonly reported.

Intrapericardial radioisotopes, including gold and chromic phosphate, have been used (95,118). They are only partially effective even in radiosensitive tumors, and the logistical problems associated with them have precluded their use. In a novel approach, radioactive iodine (^{131}I) has been tagged to a monoclonal antibody (HMFG2) with intrapericardial administration, and the preliminary excellent results in a small series of four patients suggest that this technique bears further investigation (136).

Radiotherapy

External beam radiotherapy has been advocated for a variety of tumors with cardiac and pericardial involvement (137). In collected series (118), most patients underwent initial pericardiocentesis followed by radiotherapy in the 1500–4000 cGy dose range, the threshold at which radiation pericarditis and myocarditis can appear (98,138,139). Approximately 67% of patients so treated will have a positive response, although the best results are found with lymphomas and leukemias (118). Pericardial inflammation is a complication of therapy and may lead to acute pericarditis or possibly late constriction. Generally, radiotherapy is recommended for patients with radiosensitive tumors without hemodynamic compromise, who have not previously received radiotherapy (95).

Surgical Approaches

Since pericardial tamponade is predominantly a mechanical problem related to compression of the heart by an effusion, it is not surprising that the earliest attempts to treat this problem involved a surgical approach to drainage, and surgery has remained the preferred technique, although it has been considerably refined. In 1649, Jean Riolan first suggested trephination of the sternum to decompress a pericardial effusion compressing the heart, although the technique was not used until several centuries later (140). In 1819, Romero performed the first successful surgical pericardiotomy (141). However, it was Napoleon's famous surgeon, Baron Dominique-Jean Larrey, who first used the subxiphoid approach to drain the pericardial cavity, considering this an easy operation with small risk. He believed, as we do today, that this most dependent portion of the pericardium was best, since the collection of fluid was more prominent and the heart was at the greatest distance away from the pericardium, with the least chance of a rhythm disturbance (142). Techniques have advanced during the intervening 150 years, although Larrey's approach is still favored.

The term *window* in reference to pericardial surgery was described first by Williams and Soutter in 1954 in their description of an anterior thoracotomy through which they created a small opening in the pericardium and held it open by suturing it to the lung (143). The term *subxiphoid pericardial window* was finally used by Fontanelle and associates in 1970, and that term has continued to the present (144).

Subxiphoid Pericardiectomy (“Window”)

The most popular approach to surgical treatment of a malignant pericardial effusion is the subxiphoid pericardiectomy, which offers the distinct advantages of very low mortality (1% or less), 1% major morbidity, 100% immediate efficacy in relieving tamponade, and a long-term recurrence rate of 3–7% (41,95,119,145). Diagnostic accuracy is also excellent and approaches 100%, since fluid and pericardial tissue are both removed and are sent for pathological evaluation. In critically reviewing surgical series, it is important to consider only reports of surgery performed in the last 10 years or so, in the era of the most modern anesthetic techniques, so that the assessment of results reflects current practice with its lower risks. The most recent report involved 82 patients with malignant pericardial effusion who underwent subxiphoid pericardiectomy (146). No postoperative deaths were attributable to the surgical procedure, and there was only a 2.4% recurrence rate in the long term requiring further intervention.

Subxiphoid pericardiectomy may be performed in the operating room in only 30–45 minutes on critically ill patients under local anesthesia. Often general endotracheal anesthesia is used if there is no significant hemodynamic compromise or if the pericardium has been decompressed by pericardiocentesis. With general anesthesia, exposure is improved and a larger portion of pericardium may be removed because there is greater muscle relaxation (145). In addition, general anesthesia is necessary if there is extreme obesity or a narrow costal angle, or if there has been a previous upper midline incision. In fact, in these circumstances it may be preferable to divert to a left anterior thoracotomy for the pericardiectomy.

For the subxiphoid approach, a short 4- to 6-cm midline incision is made, extending caudad from the xiphoid with entrance into the preperitoneal space after the linea alba has been opened. After fluid has been collected for cytology, the pericardium is explored with the finger to find tumor nodules and to break up loculations. Recurrence of the effusion is best prevented when a large 4 cm × 4 cm portion of pericardium is removed for pathological examination (95). Pericardial tubes can be then inserted anterior and posterior to the heart before the wound is closed. The tubes are left in place 2–3 days until the drainage is 50–100 ml/day. Commonly, patients are discharged home on the second or third postoperative day.

Occasionally, no obvious tumor nodules are seen on the pericardium when it is visualized directly through the wound. In this situation, the diagnostic yield may be improved with pericardioscopy using a rigid or flexible scope, which can be used to better inspect the rest of the pericardium to obtain directed biopsy specimens of suspected lesions (147). Three of 40 patients in the series of Millaire and associates had suspected malignancies confirmed by pericardioscopy alone at the time of surgery, that would have otherwise been missed (147).

Although the term *pericardial window* implies that the communication remains open to drain the pericardium, it is not clear that this is actually the mechanism of action. A subxiphoid pericardiectomy (“window”) drains into the preperitoneal space, and probably it seals fairly soon. Sugimoto and associates (148) examined this question in following up their series of 26 patients who had undergone a subxiphoid pericardial window procedure. They found by echocardiography that there was thickening of the pericardium/epicardium and obliteration of the pericardial space. Autopsies of four patients who eventually died of their cancer a mean of 120 days after the procedure confirmed the fusion of the visceral and parietal pericardia. These workers concluded that the mechanism allowing success with this procedure is not the maintenance of a “window” draining the effusion continuously, but rather an inflammatory reaction causing fusion of the pericardium to the epicardium, obliterating the former space. They emphasized the necessity of keeping the pericardial space decompressed by suction postoperatively until the fluid drainage is minimal (<50 ml/24 hours) to keep the two pericardial surfaces in opposition to allow fusion.

Left Anterior Thoracotomy and Pericardiectomy

The left anterior thoracotomy for pericardiectomy is quick to perform, has a low morbidity and mortality, and allows examination and biopsy of the contents of the left pleural cavity if desired (125). The procedure is performed through a 10-cm long submammary incision entering the chest through the fifth intercostal space just lateral to the sternum. The pericardium is removed from just anterior to the left phrenic nerve over to the right mediastinal pleural reflection.

Some studies suggest that the amount of pericardium remaining after surgical drainage of the pericardium is directly related to the frequency of development of postoperative complications and recurrent effusion (102). Nevertheless, in collected series of pericardiectomy by left anterior thoracotomy (118), the overall success rate was 83% (freedom from recurrent effusion) and the mortality. was 13%—not as favorable as the results with subxiphoid pericardiectomy. The other primary disadvantage of the left anterior thoracotomy is that it is major thoracotomy requiring general anesthesia (118), and it also may be technically difficult to perform because of adhesions in the occasional patient with a lung cancer in the left pleural cavity who has been treated with radiotherapy.

Currently, the left anterior thoracotomy for pericardiectomy is preferred for benign effusive pericarditis, as occurs with purulent pericarditis and viral pericarditis. Benign pericarditis has a propensity to late constriction if most of the pericardium is not removed initially when surgery is performed. Conversely, a subxiphoid pericardial window is generally not recommended for drainage of benign and perhaps some malignant pericardial effusive disease when the patient is expected to have a significant life span (102,118,119).

Median Sternotomy with Pericardiectomy

The median sternotomy is an even more extensive procedure and gives very wide exposure to most of the pericardium. This approach is preferred only for constrictive pericardial disease, which may occur in the cancer patient as the late result of radiation pericarditis, extensive tumor mass or cake, or possibly as the result of a late failure from a previous approach to pericardial drainage (125). Because of the risk of myocardial laceration and significant bleeding, most surgeons prefer to have cardiopulmonary bypass on standby when dealing with constrictive pericarditis.

One of the most important technical points in the performance of a pericardiectomy for constriction is to remove the pericardium over the left side of the heart first to prevent the acute pulmonary edema that may occur if the right side of the heart is decompressed first, which would allow increased blood flow to the constricted left ventricle (125). In addition, it is important to continue the pericardial resection down to include the cavae to release them; otherwise, the right-sided failure symptoms may persist postoperatively.

Thoracoscopic Pericardiectomy

The recent advent of videothoracoscopic surgery has allowed the surgeon to perform many previously open procedures using this minimally invasive approach (149). Pericardiectomy for effusive disease has proved to be technically feasible with videothoracoscopy, with a recent series of 28 patients by Liu and associates demonstrating 100% long-term success, no significant morbidity, and 0% mortality (150).

Videothoracoscopy has the disadvantages of requiring the lateral decubitus position, minimally increased operating time, and a double-lumen endotracheal tube, and the surgeon must have substantial videothoracoscopic experience to perform this procedure effectively and safely. However, this approach is ideal in the patient with simultaneous pulmonary or pleural pathology that needs evaluation and treatment (such as with a pleural abrasion or talc poudrage), a recurrent or loculated pericardial effusion, previous heart surgery or subxiphoid pacemaker insertion, or a previous substernal esophagogastrostomy (150). The videothoracoscopic pericardiectomy may also be performed from either the right side or the left side of the chest. Technically, a large area of pericardium may be removed, as much as 6 cm × 8 cm, including pericardium posterior to the phrenic nerve if needed for complete drainage (125).

Pericardioperitoneal Shunt

An additional alternative drainage method was reported by Wang and associates (151) in a small series of four patients. They used the Denver pleuroperitoneal shunt to drain the pericardium into the peritoneal cavity. They performed the procedure with the patients under local anesthesia; the mean hospital stay was 2.8 days in these shunt patients. Further results in larger groups of patients will be needed before any conclusions can be made about the efficacy and safety of this technique.

Percutaneous Balloon Pericardiotomy

Palacios and associates in 1991 reported a novel approach to drainage of pericardial effusions using a percutaneous balloon pericardiotomy (152). The pericardium is entered by a conventional subxiphoid pericardiocentesis. A guidewire is advanced into the pericardium, over which a Mansfield 20mm × 3 cm dilating balloon is passed to a point where it straddles the pericardium and is then inflated to create a pericardial window. Usually the pericardial fluid drains into the pleural cavity, as indicated by a new pleural effusion. A catheter is then left in the pericardium until the drainage is minimal.

In their first 50 cases (153), successful, long-term decompression of the effusion was accomplished in 92%, with the rest requiring surgery on an urgent or emergent basis. A new left pleural effusion requiring treatment occurred in 16% of patients, and 4% required a chest tube for a pneumothorax. Another 11% developed a fever, but no pericardial infection was found. The current experience by this group includes 88 patients with a success rate of 88% (154). Experience with this new technique thus far is limited to just a few investigative groups. However, the results look promising, especially in patients with recurrent effusions, and this technique bears close observation over the next few years.

Recommendations

A malignant pericardial effusion is a not uncommon complication of advanced cancers, particularly with cancer of the lung and breast and lymphoma/leukemia. The effusion can rapidly progress to tamponade and if unrecognized may lead to death. Prompt decompression of the effusion has been shown to markedly improve the quality and quantity of life. However, the optimal method of accomplishing this objective is not easily determined because of the difficulty in comparing the large number of nonrandomized series with heterogeneous patient populations employing various techniques and having varying criteria for successful clinical response. No treatment modality clearly emerges as the preferred technique. In addition, therapy to some extent must be individualized, depending on the tumor cell type and its sensitivity to chemotherapy or radiotherapy, the performance status of the host and expected length of survival, and whether the patient presents with pericardial tamponade. Our recommendations are as follows:

1. In a patient without hemodynamic compromise and a chemosensitive tumor, such as lymphoma, leukemia, testicular cancer, or small cell lung carcinoma, systemic chemotherapy should be given. If symptoms or tamponade appear, then a pericardiocentesis should be performed, possibly followed by subxiphoid pericardiectomy. If chemotherapy fails and the tumor is also radiosensitive, then radiotherapy should be considered as the next step.

2. Patients with a symptomatic, suspected, or proven malignant pericardial effusion, a reasonable life expectancy (3 months or more), and no tamponade should be considered for an elective subxiphoid pericardiectomy. If tamponade and hemodynamic compromise are present, a decompressing pericardiocentesis should be performed and a subxiphoid pericardiectomy should be performed the next day. If the institutional resources are such that surgical decompression is unavailable, a suitable approach would be intrapericardial sclerosis with bleomycin or doxycycline, although a higher failure rate should be expected.

3. Very poor candidates for surgery, on the basis of comorbid disease, such as severe chronic obstructive pulmonary disease, should be considered primarily for intrapericardial sclerosis. Patients with a very short life expectancy (less than 1 month) should also be considered for intrapericardial sclerosis.

4. In patients with a history of malignancy and who develop a pericardial effusion in which the diagnosis is uncertain, or when pericardial tissue is necessary for a histologic diagnosis, an operative intervention by the subxiphoid, videothoracoscopic, or left anterior thoracotomy approach is indicated.

5. Videothoracoscopic pericardiectomy is indicated in the setting of coexisting pleural disease requiring evaluation and treatment or when a subxiphoid pericardiectomy is technically not advisable.

6. Patients in whom chemotherapy, radiotherapy, or intrapericardial sclerosis has failed should be managed by surgical pericardiectomy.

In general, patients with pericardial involvement by their primary cancer have an incurable disease. Nevertheless, most patients with symptomatic effusions should be offered treatment, because they usually will respond rapidly and often quite remarkably to pericardial decompression and will have a meaningful period of palliation outside of the hospital at home.
